Older patients and those with significant comorbidities, continued bleeding, and hemodynamic instability are also at higher risk of poor outcomes and should be managed more aggressively and monitored in the intensive care setting. Prognostic scores such as the Glasgow-Blatchford score, Rockall scale, and AIMS65 score may help identify high-risk patients in need of more urgent evaluation and treatment.

Treat

The fourth step in the management of GIB is to confirm the location and etiology of bleeding and to deliver treatment both locally and systemically. The goal of this step is to achieve adequate hemostasis and minimize the risk of rebleeding. A comprehensive treatment plan for GIB may consist of up to six components that can be summarized by another simple mnemonic *CAMPER*: Coagulopathy, Acid suppression, Medical therapy, Preprocedural preparation, Endoscopy, and Rescue technique.

Coagulopathy

Coagulopathy should be addressed in any patient presenting with overt GIB. In general, pharmacologic anticoagulation and antiplatelets should be held, unless otherwise contraindicated due to another medical condition such as recent vascular stent placement, until hemostasis is achieved. In patients presenting with hemodynamically significant

GIB, reversal of warfarin using intravenous vitamin K as well as inactivated 4-factor prothrombin complex concentrate (PCC) should be considered. Fresh frozen plasma has fallen out of favor due to its higher risk of adverse reactions and volume overload but may be an option when PCC is not available. Patients on direct oral anticoagulants do not typically require reversal due to their shorter half-life, although the use of antifibrinolytic agents can be considered in those with significant comorbidities or worsening bleeding symptoms. Specific reversal agents for the direct oral anticoagulants are reserved for those at imminent risk of death from bleeding. Cirrhotic patients are not necessarily hypocoagulable despite the elevated INR due to impaired synthesis of both anticoagulants and procoagulants. Platelet transfusion should be considered in those with a platelet level less than 50,000/ μ L but has limited benefit in individuals continuing on antiplatelet agents. Desmopressin can be considered in patients with uremic platelet dysfunction or von Willebrand disease.

Acid Suppression

Acid suppression with an intravenous proton pump inhibitor (PPI) should be initiated on admission in patients with suspected UGIB. It primarily helps with clot stabilization and is associated with reduced rates of high-risk stigmata identified on endoscopy, the need for endoscopic therapy in patients with peptic ulcer bleeding, and the risk of ulcer rebleeding. The optimal dose of preprocedure PPI has not been determined, although intermittent PPI therapy was found to be comparable to continuous therapy in patients with endoscopically treated high-risk bleeding ulcers.

Medical Therapy

Medical therapy plays an important role in the management of GIB in cirrhotic patients. Prophylactic antibiotics, intravenous ceftriaxone or a quinolone, may be administered to any cirrhotic patients with GIB for 7 days to decrease the risk of bacterial infections and mortality. Vasoactive medications, such as octreotide, terlipressin, and vasopressin, should be initiated as soon as possible in any patients presenting with suspected variceal bleeding and continued for 3 days if the etiology is confirmed on endoscopy.

Preprocedural Preparation

Preprocedural preparation is essential to achieving adequate endoscopic hemostasis while minimizing procedure-related complications. Prokinetic agents, such as erythromycin or metoclopramide, should be considered in patients presenting with ongoing or recurrent hematemesis in order to clear the stomach of food and blood clots, which may obscure potential bleeding sources and increase the risk of aspiration. Similarly, adequate colon cleansing using a polyethylene glycol-based solution until the colon is clear of stool and blood clots is preferred prior to colonoscopy and associated with higher cecal intubation rate, improved diagnostic yield, and lower risk of perforation.

Endoscopy

Endoscopy serves a diagnostic and therapeutic role in the management of GIB after adequate resuscitation. Urgent upper endoscopy should be performed within 12 hours of hospitalization in any patients with suspected variceal bleeding, and early upper endoscopy within 24 hours of hospitalization is recommended in patients with nonvariceal overt UGIB. Patients with ulcers and stigmata of recent bleeding may need endoscopic therapy to reduce risk of rebleeding. Examples of endoscopic hemostatic techniques include epinephrine injection, contact thermal coagulation for visible vessels, as well as through-the-scope clip and over-the-scope clip as methods to achieve physical tamponade of a bleeding site. In cases of variceal bleeding, band ligation and

injection of sclerosing agents for esophageal varices and injection of cyanoacrylate and other tissue glue in gastric varices can be performed. Other techniques include argon plasma coagulation for superficial vascular lesions and hemostatic topical powders as temporizing measures. The optimal timing of colonoscopy for overt LGIB is less well defined. Urgent colonoscopy, defined variably as within 12 to 24 hours of hospitalization, may improve diagnostic yield but does not improve rebleeding risk, need for surgery, or length of stay compared to elective colonoscopy. In general, it is reasonable to prioritize patients with ongoing or recurrent overt LGIB for an inpatient colonoscopy whereas those with self-limiting bleed may be evaluated electively. Hemodynamically unstable patients with suspected LGIB should also undergo upper endoscopy to rule out a brisk UGIB. Presence of blood in terminal ileum may be indicative of a proximal or small bowel bleeding source. Video capsule endoscopy (VCE) is a valuable tool for diagnosing a small bowel bleeding source, especially when performed within 72 hours of index bleeding episode. Patients with occult GIB should undergo endoscopy and colonoscopy, followed by VCE if necessary, electively once they are medically optimized. Enteroscopy techniques such as push, balloon, or spiral enteroscopy can be used for diagnosis and treatment of small bowel pathology detected on capsule endoscopy. Computed tomography (CT) and magnetic resonance (MR) enterography techniques have largely replaced fluoroscopy and can be used to diagnose small bowel pathology when VCE is not available.

Rescue Technique

Rescue techniques are sometimes necessary, for both diagnostic and therapeutic purposes, in patients who fail endoscopic management or are unable to tolerate endoscopy. CT angiography or multidetector row CT is a reasonable first-line imaging test to facilitate localization of GIB in patients presenting with hemodynamically significant overt GIB. Angiography relies on active bleeding and may be falsely negative in cases of intermittent bleeding. Tagged red blood cell scintigraphy, although less readily available and more logistically cumbersome than CT angiography, is ideally suited for evaluation of intermittent, obscure GIB because of its higher sensitivity and the ability to perform

repeated scans after initial injection of tagged cells. Super-selective angiographic embolization can be successful in achieving immediate hemostasis in many cases of GIB, including large penetrating duodenal ulcers, small bowel tumor bleed, and colonic diverticular bleed. In cases of uncontrollable variceal bleeding, balloon tamponade or esophageal stenting can be used as a bridge to more definitive treatment such as transjugular intrahepatic portosystemic shunt (TIPS) or balloon-occluded retrograde transvenous obliteration (BRTO) for esophageal and gastric varices, respectively. Hemostatic spray consists of an inorganic powder that may be used endoscopically in cases of severe ulcer or cancer-related bleeding or other nonvariceal bleeding where directed therapy may not be possible. Ultimately, surgery may be necessary in a small proportion of patients with severe or recurrent bleeding, such as bleeding associated with tumors, perforated ulcers, recurrent ulcer bleeding or severe colitis that is refractory to endoscopic or interventional radiologic therapies.

Common Clinical Manifestations of Gastrointestinal Disease: Malabsorption

Brisas M. Flores, Sharmeel K. Wasan

DEFINITION AND EPIDEMIOLOGY

The main purpose of the gastrointestinal (GI) tract is to digest and absorb major nutrients (fats, carbohydrates, and proteins), essential micronutrients (vitamins and trace minerals), water, and electrolytes. Impaired absorption of these nutrients is defined as malabsorption. Under normal conditions, the digestion and absorption of nutrients requires both mechanical and enzymatic breakdown of food. Mechanical processes include chewing, gastric churning, and the to-and-fro mixing in the small intestine. Enzymatic hydrolysis is initiated by intraluminal processes requiring salivary, gastric, pancreatic, and biliary secretions and is completed at the intestinal brush border. The final products of digestion are then absorbed through the intestinal epithelial cells and transported into the portal circulation. The coordinated regulation of gastric emptying, normal intestinal progression, and the presence of adequate intestinal surface area are all important factors. The human gut microbiome, which comprises the communities of microorganisms that inhabit the GI tract, has been recognized to play an important role in nutrient utilization as well. From birth, interactions between the microbiota and the intestinal mucosa contribute to maturation of the host immune system. Disruptions to the homeostasis between the microbiota and the host immune system can lead to increased inflammation and decreased absorption.

Most dietary components can be absorbed anywhere along the length of the small intestine, but there are important exceptions in which absorption is limited to specific areas (e.g., vitamin B₁₂ and cholesterol are absorbed only in the terminal ileum). Diseases associated with diffuse mucosal involvement, such as celiac disease, can lead to impaired absorption of many nutrients, whereas diseases affecting only the terminal ileum can lead to decreased vitamin B₁₂ absorption. Bile acids are necessary for fat absorption; they undergo an enterohepatic circulation with release into bile and reabsorption from the terminal small intestine. Diseases interfering with this mechanism deplete the bile acid pool and can lead to fat malabsorption. Water and electrolytes are absorbed primarily by the colon. In addition, there is caloric salvage of much of the carbohydrate from indigestible fiber through bacterial enzymatic activity in the colon. The following sections discuss normal assimilation of the major nutrients and the approach to evaluation of patients with suspected malabsorption.

DIGESTION AND ABSORPTION OF FAT

Dietary fat is composed predominantly of triglycerides (≈95%) with long-chain fatty acids (16- and 18-carbon molecules). In animal fat, the constituent fatty acids are mostly saturated (e.g., palmitic acid, stearic acid), whereas those of vegetable origin are rich in unsaturated fatty acids (i.e., having one or more double bonds in the carbon chain, such as oleic and linoleic acids). Fats are insoluble in water (hydrophobic),

and digestion begins with a process of emulsification, wherein larger fat droplets are dispersed in the aqueous medium of the lumen. In the proximal small intestine, bile salts from liver and pancreatic enzymes are released into the intestinal lumen; there, they mix with and bind to the surface of these globules, where colipase activity results in the release of fatty acids and a monoglyceride. These are taken up as mixed micelles with bile salts, and these hydrophobic particles cross the unstirred water layer that overlies the epithelial brush border.

Within the cell, fatty acids are resynthesized into triglycerides, and, together with cholesterol and phospholipids, they are packaged into chylomicrons and very-low-density lipoproteins to be exported via lymphatic channels. Bile salts remain in the intestinal lumen, are recycled into new micelles, and are finally reabsorbed in the terminal ileum with 95% efficiency. Most dietary lipids are absorbed in the jejunum, together with the fat-soluble vitamins A, D, E, and K. It is recommended that dietary fat account for no more than 35% of calories because higher levels are associated with increased risk of cardiac disease, obesity, and some cancers. The recommended intake is 20% to 35% of daily dietary intake.

DIGESTION AND ABSORPTION OF CARBOHYDRATES

Most dietary carbohydrates consist of starch (a glucose polymer) and the disaccharides sucrose and lactose, but only monosaccharides are absorbed. Salivary and pancreatic amylases release oligosaccharides from starch. The final hydrolysis to glucose monomers occurs at the brush border and includes disaccharide hydrolysis by sucrase and lactase. Glucose and galactose are actively transported in conjunction with sodium, whereas fructose absorption occurs by facilitated diffusion. About one half of dietary energy is derived from carbohydrate, with a nutritional goal of 45% to 65% and an increased component of insoluble fiber (i.e., that which is indigestible by mammalian enzymes but variably broken down by colonic bacteria).

DIGESTION AND ABSORPTION OF PROTEINS

Dietary proteins are the major source for amino acids and the only source for the essential amino acids. Digestion starts in the stomach with pepsins secreted by the gastric mucosa, but most of the hydrolysis is accomplished by pancreatic enzymes in the proximal small bowel. The pancreas secretes the proteases trypsin, elastase, chymotrypsin, and carboxypeptidase as inactive proenzymes. Enterokinase (more properly, enteropeptidase) is secreted by the intestinal brush border; it splits trypsinogen to its active form, trypsin, which in turn converts the other proenzymes to their active forms. The products of luminal brush border peptidase digestion consist of amino acids and oligopeptides,

which are transported across the epithelial cell. The transfer of most amino acids is sodium dependent and takes place in the proximal small bowel. Dietary requirements for amino acid nitrogen are met with about 10% to 35% of calories from protein.

MECHANISMS OF MALABSORPTION

The term *maldigestion* refers to defective hydrolysis of nutrients, whereas *malabsorption* refers to impaired mucosal absorption. In clinical practice, however, *malabsorption* refers to all aspects of impaired nutrient assimilation. Malabsorption can involve multiple nutrients, or it can be more selective. Therefore, the clinical manifestations of malabsorption are highly variable. The complete process of absorption consists of a *luminal phase*, in which various nutrients are hydrolyzed and solubilized; a *mucosal phase*, in which further processing takes place at the brush border of the epithelial cell with subsequent transfer into the cell; and a *transport phase*, in which nutrients are moved from the epithelium to the portal venous or lymphatic circulation. Impairment in any of these phases can result in malabsorption (Table 33.1).

Luminal Phase

Digestion is accomplished for the most part by pancreatic enzymes, particularly lipase, colipase, and trypsin; the gastric digestive enzymes do not play a major role. As a consequence, chronic pancreatitis can result in malabsorption, particularly for fat and protein. Deficiency in bile salts also contributes to fat malabsorption and may result from cholestatic liver disorders (impaired secretion of bile), bacterial overgrowth (resulting in luminal bile salt deconjugation), or ileal disease or resection with loss of effective enterohepatic circulation of the bile acids. The major part of the luminal phase of digestion occurs in the duodenum and the proximal jejunum.

Mucosal Phase

Mucosal disease is a more common cause of malabsorption. It can result from diffuse small intestinal diseases such as celiac disease or

Crohn's disease, or from a decrease in surface area (e.g., after surgical resection for small bowel infarction). The net effect is a smaller effective mucosal surface and a relative loss of mucosal absorption. Selective defects in an otherwise normal intestine may result in specific entities such as lactase deficiency or abetalipoproteinemia.

Transport Phase

After absorption, nutrients leave the cells through venous or lymphatic channels. Consequently, malabsorption may be associated with mesenteric venous obstruction, lymphangiectasia, or lymphatic obstruction due to malignancy or infiltrative processes such as Whipple disease.

The absorptive process can be impaired at many stages. For example, patients with subtotal gastrectomy or bariatric surgery often experience malabsorption. There are resultant defects at all phases: impaired gastric churning, premature emptying, and impaired mixing (in the jejunum) of food with bile and pancreatic enzymes. The impaired mixing is a consequence of anatomic changes (gastrojejunostomy bypassing the duodenum) and reduced production of pancreatic enzymes (because cholecystokinin and secretin release is blunted when gastric contents bypass the duodenum). Moreover, stasis may lead to bacterial overgrowth in the afferent loop with changes in the bile acids needed for fat absorption. Another example of manifold mechanisms is diabetes mellitus, which may lead to delayed gastric emptying, abnormal intestinal motility, bacterial overgrowth, and pancreatic exocrine insufficiency.

CLINICAL PRESENTATION

The clinical manifestations of malabsorption are usually nonspecific, particularly in the early stages. A change in bowel movements, usually with diarrhea, and weight loss despite adequate food intake may occur in more severe cases. Usually, however, patients have relatively mild symptoms such as bloating and flatulence. Clinical manifestations related to a specific micronutrient deficiency can occur. For example, iron deficiency anemia may be the only manifestation of celiac disease

TABLE 33.1 Pathophysiologic Mechanisms in Malabsorption

Luminal Phase	Mucosal Phase	Transport Phase
Reduced nutrient availability	Extensive mucosal loss (resection or infarction)	Vascular conditions (vasculitis; atheroma)
Cofactor deficiency (pernicious anemia; gastric surgery)	Diffuse mucosal disease (celiac disease)	Lymphatic conditions (lymphangiectasia; irradiation; nodal tumor, cavitation, or infiltrations)
Nutrient consumption (bacterial overgrowth)	Crohn's disease; irradiation; infection; infiltrations; drugs: alcohol, colchicine, neomycin, iron salts	
Impaired fat solubilization	Brush border hydrolase deficiency (lactase deficiency)	
Reduced bile salt synthesis (hepatocellular disease)	Transport defects (Hartnup cystinuria; vitamin B ₁₂ and folate uptake)	
Impaired bile salt secretion (chronic cholestasis)	Epithelial processing (abetalipoproteinemia)	
Bile salt inactivation (bacterial overgrowth)		
Impaired cholecystokinin release (mucosal disease)		
Increased bile salt losses (terminal ileal disease or resection)		
Defective nutrient hydrolysis		
Lipase inactivation (Zollinger-Ellison syndrome)		
Enzyme deficiency (pancreatic insufficiency or cancer)		
Improper mixing or rapid transit (resection; bypass; hyperthyroidism)		

Modified from Riley SA, Marsh MN: Maldigestion and malabsorption. In Feldman M, Scharschmidt BF, Sleisenger MH, editors: Sleisenger and Fordtran's Gastrointestinal and Liver Disease: Pathophysiology/Diagnosis/Management, ed 6, Philadelphia, 1998, WB Saunders, pp 1501-1522.

in some patients. Muscle wasting and edema result from protein malabsorption. Nutritional anemia, caused by deficiencies of iron, folate, and vitamin B₁₂, contributes to fatigue. Bleeding tendency (e.g., ecchymosis) may be attributed to prolonged prothrombin time resulting from vitamin K deficiency related to fat malabsorption. Bulky, oily stools are the hallmark of steatorrhea resulting from fat malabsorption, whereas bloating (abdominal distention) and soft diarrheal movements occur as a result of carbohydrate malabsorption. Signs associated with malabsorption are presented in Table 33.2.

DIAGNOSIS

Malabsorption can be caused by a large number of disorders, some of the more common of which are listed in Table 33.2. The cause of malabsorption can often be determined by a very detailed patient history. However, because the clinical symptoms are varied, more specific

assays of albumin, cobalamin, iron, cholesterol, calcium, folic acid, and prothrombin time are useful to support the diagnosis of malabsorption. These tests are helpful in assessing the severity of malabsorption, but they are not specific for the differential diagnosis. Many tests are available in the work-up of malabsorption; those that have been most useful clinically are discussed in the following sections (Fig. 33.1).

Fecal Fat Analysis

If fat malabsorption is suspected, the simplest qualitative method for detecting fat in stool is microscopic examination with Sudan staining of a drop of stool. Sensitivity varies anywhere from 80% to 99%, but the test is quick and easy. The result correlates well with the quantitative measurement of fecal fat when moderate to severe steatorrhea is present. To quantify fat, stool is collected for three consecutive days while the patient is on a diet containing 60 g to 100 g of fat per day, and the specimen is analyzed for fat content. If the fecal fat amount is

TABLE 33.2 Signs Associated With Malabsorption Syndromes

Signs	Associated Syndromes
Gastrointestinal	
Mass	Crohn's disease, lymphoma, tuberculosis, glands
Distention	Intestinal obstruction, gas, ascites, pseudocyst (pancreatic), motility disorder
Steatorrheic stool	Mucosal disease, bacterial overgrowth, pancreatic insufficiency, infective or inflammatory, drug induced
Extraintestinal	
Skin	
Nonspecific	Pigmentation, thinning, inelasticity, reduced subcutaneous fat
Specific	Blisters (dermatitis herpetiformis), erythema nodosum (Crohn's disease), petechiae (vitamin K deficiency), edema (hypoproteinemia)
Hair	
Alopecia	Gluten sensitivity
Loss or thinning	Generalized inanition, hypothyroidism, gluten sensitivity
Eyes	
Conjunctivitis, episcleritis	Crohn's disease, Behçet's syndrome
Paleness	Severe anemia
Mouth	
Aphthous ulcers	Crohn's disease, gluten sensitivity, Behçet's syndrome
Glossitis	Deficiencies of vitamin B ₁₂ , iron, folate, niacin
Angular cheilosis	Deficiencies of vitamin B ₁₂ , iron, folate, B complex
Dental hypoplasia (pitting, dystrophy)	Gluten sensitivity
Hands	
Raynaud's phenomenon	Scleroderma
Finger clubbing	Crohn's disease, lymphoma
Koilonychia	Iron deficiency
Leukonychia	Inanition
Musculoskeletal	
Monoarthropathy and polyarthropathy	Crohn's disease, gluten sensitivity, Whipple disease, Behçet's syndrome
Back pain (osteomalacia, osteoporosis, sacroiliitis)	Crohn's disease, malnutrition, gluten sensitivity
Muscle weakness (low potassium, magnesium, vitamin D; generalized inanition)	Diffuse mucosal disease, bacterial overgrowth, lymphoma
Nervous System	
Peripheral neuropathy (weakness, paresthesias, numbness)	Vitamin B ₁₂ deficiency
Cerebral (seizures, dementia, intracerebral calcification, meningitis, pseudotumor, cranial nerve palsies)	Whipple disease, gluten sensitivity, diffuse lymphoma

From Riley SA, Marsh MN: Maldigestion and malabsorption. In Feldman M, Scharschmidt BF, Sleisenger MH, editors: Sleisenger and Fordtran's Gastrointestinal and Liver Disease: Pathophysiology/Diagnosis/Management, ed 6, Philadelphia, 1998, WB Saunders, pp 1501-1522.

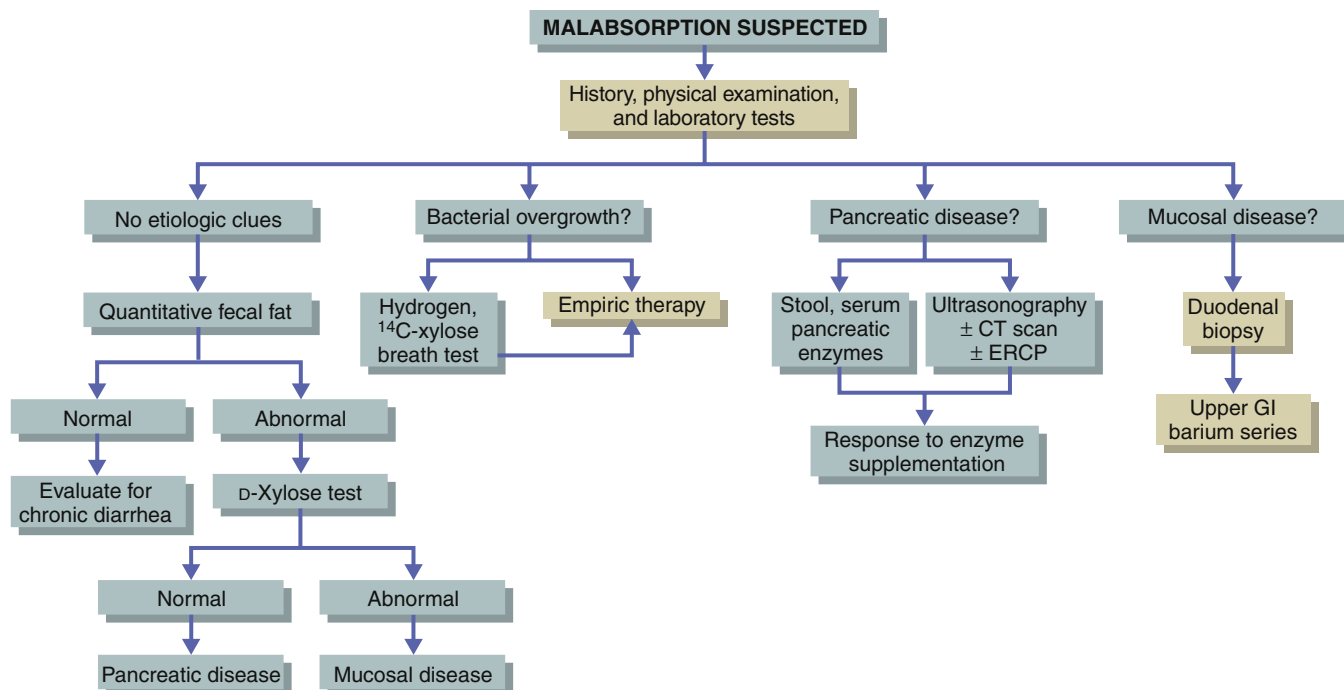

Fig. 33.1 Approach to the patient with suspected malabsorption. *CT*, Computed tomography; *ERCP*, endoscopic retrograde cholangiopancreatography; *GI*, gastrointestinal. (Modified from Riley SA, Marsh MN: Maldigestion and malabsorption. In Feldman M, Scharschmidt BF, Sleisenger MH, editors: Sleisenger and Fordtran's Gastrointestinal and Liver Disease: Pathophysiology/Diagnosis/Management, ed 6, Philadelphia, 1998, WB Saunders, pp 1501-1522.)

greater than 7 g per day, it is suggestive of fat malabsorption. Patients with steatorrhea (excess fat in the stool) often have results with greater than 20 g per day. Values ranging from 7 to 14 g per day are suggestive of fat malabsorption, but values should be interpreted judiciously as diarrheal illnesses can also produce these results. This test is cumbersome and nonspecific, but it offers an accurate quantification of fecal fat excretion provided fat consumption is appropriate. Near-infrared reflectance spectroscopy may produce similar results, but this is not often utilized in the United States.

Tests of Pancreatic Exocrine Function

Aspiration of duodenal contents for evaluation of bicarbonate and enzyme output after stimulation of the pancreas may be the best index of pancreatic exocrine function. However, the test is invasive, time-consuming, and performed only in a few specialized centers. The measurement of pancreatic enzymes (i.e., fecal elastase 1) in the stool is simple and provides helpful laboratory evidence for the diagnosis of moderate to severe pancreatic insufficiency. Pancreatic calcifications seen on abdominal films or computed tomography (CT) scans indicate the presence of chronic pancreatitis. Magnetic resonance cholangiopancreatography (MRCP) and endoscopic retrograde cholangiopancreatography (ERCP) can help outline abnormal duct anatomy and may supplement CT scanning for diagnostic purposes to evaluate the sequelae of chronic pancreatitis. However, normal findings on pancreatography do not exclude the presence of pancreatic exocrine insufficiency.

Small Intestinal Biopsy

Whereas the gross appearance of the mucosa during upper GI endoscopy can provide some clues regarding the presence of a disease causing malabsorption, biopsy of the small intestinal mucosa is a key diagnostic test for diseases that affect the cellular phase of absorption.

In some diseases, the histologic features are diagnostic; in others, the findings may be highly suggestive (Table 33.3). Several tissue samples should be taken from the duodenal bulb and from the distal duodenum to enhance the diagnostic accuracy.

Imaging Studies

In patients with malabsorption, barium studies of the small bowel are usually nonspecific. Occasionally, however, distinct anatomic changes are seen, such as in jejunal diverticulosis, lymphoma, Crohn's disease, strictures, or enteric fistulas. Also, there may be a distinctive barium pattern of thin-walled, dilated loops suggestive of celiac disease. CT and magnetic resonance enterography provide a more detailed imaging of the small intestine and are more sensitive in identifying abnormalities such as active bowel inflammation, mesenteric stranding and edema, strictures, fibrofatty proliferation of the mesentery, and fistula formation.

Wireless capsule endoscopy is a noninvasive method that permits direct visualization of the small bowel mucosa and can provide a more detailed evaluation of small bowel disease compared with radiographic studies. However, capsule endoscopy should be avoided in patients in whom a stricture is suspected because of the risk of retention. The detection of mucosal lesions by the capsule endoscopy can often be followed by deep enteroscopy (double-balloon endoscopy, single-balloon endoscopy, or spiral enteroscopy), allowing for tissue biopsy, tattoo placement before surgery, balloon dilatation, and foreign body retrieval.

Schilling Test

Vitamin B₁₂ is an essential micronutrient, and its absorption requires several steps. First, the ingested vitamin binds to salivary R-factor protein. In the stomach, gastric parietal cells secrete intrinsic factor, which mixes with the ingested meal. In the duodenum, pancreatic trypsin

TABLE 33.3 Utility of Small Bowel Biopsy Specimens in Malabsorption**Findings Often Diagnostic**

Whipple disease

 Tropical sprue
 Crohn's disease

Data from Trier JS: Diagnostic value of peroral biopsy of the proximal small intestine. *N Engl J Med* 285:1470, 1971.

hydrolyzes the R-protein, freeing the vitamin to bind with intrinsic factor. The vitamin B₁₂-intrinsic factor complex is then absorbed by specific receptors that are found only on enterocytes in the distal ileum. Malabsorption of vitamin B₁₂ can occur because of lack of intrinsic factor (e.g., pernicious anemia, gastric resection), pancreatic insufficiency, bacterial overgrowth, or ileal resection or mucosal disease (e.g., Crohn's disease).

The Schilling test quantifies vitamin B₁₂ absorption using radiolabeled vitamin B₁₂ as a marker. The test may be expanded to several stages to amplify its diagnostic spectrum. In stage 1, after the injection of 1000 µg of unlabeled vitamin B₁₂ to saturate hepatic storage, the patient ingests 0.5 µg of radiolabeled vitamin. Urine is then collected for the measurement of radioactivity; reduced radioactivity suggests B₁₂ malabsorption. The test is repeated (stage 2) with the addition of oral intrinsic factor to the ingested vitamin B₁₂. If urinary excretion of the radiolabel is corrected, pernicious anemia is diagnosed. If malabsorption is still present, the patient is given a short course of oral antibiotics (stage 3), and the test is repeated; correction of radiolabeled B₁₂ excretion establishes bacterial overgrowth. If the test result remains abnormal, oral pancreatic enzymes are given (stage 4) and the test is repeated; correction of the abnormality at this stage implies pancreatic deficiency. Finally, if all these interventions fail, ileal disease or absence of transcobalamin protein is determined by other diagnostic tests, including assessment for intrinsic factor antibodies or *Helicobacter pylori* infection. This long outline serves merely as an example of an algorithm of clinical analysis; the usual routine in clinical settings is to administer parenteral vitamin B₁₂ while the etiology is delineated by other modalities.

D-Xylose Test

The D-xylose test serves as an indicator of mucosal absorption in the proximal small bowel and is used to determine whether defects in the epithelium of the intestine are responsible for malabsorption. D-Xylose is a 5-carbon monosaccharide that is transported across the intestinal mucosa largely by passive diffusion. In this test, the subject ingests 25 g of D-xylose, and urine is collected for the next 5 hours. Healthy subjects excrete more than 4.5 g of D-xylose in 5 hours (or ≥20% of

the ingested load). Excretion of a lower amount of D-xylose suggests abnormal absorption. However, an abnormally low (false-positive) result may occur in the presence of impaired renal excretory function, gastroparesis, massive peripheral edema, ascites, aspirin, neomycin, indomethacin, and glipizide. Abnormal results can also be seen in the presence of bacterial overgrowth as a result of bacterial degradation of D-xylose in the lumen, but this "pseudomalabsorption" may be corrected after treatment with antibiotics serving as a therapeutic trial.

Breath Tests

Breath tests rely on bacterial degradation of luminal compounds, which releases metabolic byproduct gases (e.g., hydrogen, methane, carbon dioxide) that can be measured in the exhaled breath. In the case of disaccharidase deficiency, a specific disaccharide (e.g., lactose) that is orally ingested but not properly absorbed in the small intestine is delivered to the colon, where bacterial fermentation liberates metabolites; hydrogen gas is the marker assayed in the breath. In the presence of bacterial overgrowth of the small intestine, orally ingested glucose ferments in the proximal small bowel (instead of being absorbed), resulting in increased hydrogen in the breath; here, the timing of exhaled hydrogen aids in the diagnosis. The measurement of radioactive carbon dioxide in the breath after ingestion of a nutrient labeled with carbon 14 (¹⁴C) has been used to estimate the malabsorption of fat or bile acids and for measurement of bacterial overgrowth (¹⁴C-xylose).

Summary

The overlap of symptoms and the large number of diagnostic tests available for evaluation of malabsorption necessitate the use of a systematic approach and a rational algorithm (see Fig. 33.1). The most accurate test for fat malabsorption remains the 72-hour fecal fat analysis; however, the test is difficult to carry out in clinical practice. Surrogate screening for steatorrhea is done with the qualitative stool fat examination (Sudan stain) and measurement of serum carotene. If the stool fat content is normal, the patient may still have selective impairment of absorption of a specific carbohydrate. This latter condition should be suspected if the primary symptoms are cramps, flatulence, and diarrhea. The most common example of carbohydrate malabsorption is lactose intolerance; specific tests include the oral lactose tolerance test, but measurement of breath hydrogen is more sensitive and more specific.

More generally, an *osmotic gap in fecal water* suggests a dietary (rather than a secretory) cause of the diarrhea related to luminal short-chain fatty acids or carbohydrates. The osmotic gap is calculated by the following formula:

$$\text{Osmotic gap} = \text{Plasma osmolality} - [2 \times (\text{fecal } [\text{Na}^+] + \text{fecal } [\text{K}^+])]$$

The osmotic gap is not calculated by directly measuring stool osmolality, because it increases with time in the specimen container. In addition, luminal osmolality is equal to serum osmolality because the colon cannot establish a gradient against the serum concentration of solutes.

When fat malabsorption is demonstrated (>7 g/24 hours, or increased qualitative stool fat and decreased serum carotene), a D-xylose absorption-excretion test should be performed next. A normal D-xylose test result makes diffuse mucosal disease unlikely and suggests maldigestion, principally pancreatic enzyme or bile salt deficiency. Clues to chronic pancreatitis include a history of alcohol abuse or previous episodes of pancreatitis. Unusual causes of pancreatic malabsorption, such as cystic fibrosis, microlithiasis,

or drug toxicity, require specific testing and a detailed history. Serum enzyme tests and abdominal imaging (plain films or, with much greater sensitivity, abdominal CT scans) can be obtained next to identify pancreatic disease. If the urinary D-xylose excretion is abnormal, the breath hydrogen test may be used to diagnose bacterial overgrowth using glucose for the carbohydrate load. If no bacterial overgrowth is present, a mucosal biopsy should be performed (see Table 33.3). Imaging studies of the small bowel may be helpful on occasion.

If the cause of malabsorption remains unclear, other considerations should include parasitic infection, such as *Giardia lamblia*, or ascariasis involvement of the pancreatic duct (more common in undeveloped countries). These diagnoses require a careful stool examination for ova and parasites or fecal antigen studies.

TREATMENT

The specific treatment of malabsorption depends on identification of the underlying condition. Occasionally, therapeutic trials for treatable conditions should be instituted, such as a gluten-free diet for celiac disease, pancreatic enzyme replacement for pancreatic exocrine mal-function, metronidazole for *G. lamblia* infection, or broad-spectrum antibiotics for suspected bacterial overgrowth. Parenteral nutrition may have a role in maintaining adequate nutritional status. Treatment modalities are discussed in later chapters focusing on specific diseases. Two disorders, celiac disease and bacterial overgrowth, are discussed here as illustrative of the pathophysiology.

Celiac Disease

Celiac disease (also called celiac sprue, nontropical sprue, or gluten-sensitive enteropathy) is characterized by intestinal mucosal injury resulting from gluten-related immunologic damage in persons genetically predisposed to this condition. The prevalence is estimated at about 1% in Western countries and has notably been rising across the world over the past 20 years. There is about an 80% concordance rate in monozygotic twins and less than 20% concordance rate in dizygotic twins. The prevalence of the disease among relatives of patients with celiac disease is approximately 10%. There is a strong association of celiac disease with human leukocyte antigen (HLA) class II molecules, particularly HLA-DQ2 and HLA-DQ8. However, in Western countries about 40% of the population possess either HLA-DQ2 or DQ8, notably different than the estimated celiac disease prevalence of 1%.

The disease is induced by exposure to storage proteins found in grain plants such as wheat (which contains gliadin), barley, and rye and their products. Oats are implicated, not because of gliadin, but because of contamination with wheat during packaging and transportation. The exposure initiates a cellular immune response that results in mucosal damage, particularly in the proximal intestine. Results of investigations suggest that an enzyme, tissue transglutaminase, may be the autoantigen of celiac disease.

Clinical Presentation

Celiac disease can manifest with the classic constellation of symptoms and signs of a malabsorption syndrome. Not uncommonly, however, the manifestation is atypical, with nonspecific GI symptoms such as bloating, chronic diarrhea (with or without steatorrhea), flatulence, lactose intolerance, or deficiencies of a single micronutrient (e.g., iron deficiency anemia). Extraintestinal complaints such as depression, weakness, fatigue, arthralgias, osteoporosis, or osteomalacia may predominate. A number of diseases, including dermatitis herpetiformis, type 1 diabetes mellitus, autoimmune thyroid disease, and selective

immunoglobulin A (IgA) deficiency, are found in significant association with celiac disease.

Diagnosis

Celiac disease is a leading consideration in every patient with the malabsorption syndrome. It should be included as well in the differential of atypical manifestations, such as iron deficiency anemia, metabolic bone disease, neuropsychiatric symptoms, and intestinal lymphoma. Fiberoptic or capsule endoscopy may show the typical features of broad and flattened villi; with the former instrument, tissue can be sampled for histologic analysis. Intestinal biopsy is the most valuable test in establishing the diagnosis. The spectrum of pathologic changes ranges from normal villous architecture with an increase in mucosal lymphocytes and plasma cells (the infiltrative lesion) to partial blunting or total villous flattening. Although abnormal biopsy findings are not specific, they are highly suggestive, particularly because most other conditions that can mimic celiac disease (e.g., Crohn's disease, gastrinoma, lymphoma, tropical sprue, graft-versus-host disease, immune deficiency) may be distinguished clinically. A clinical response to a gluten-free diet establishes the diagnosis and precludes the need, in adults, to document healing by repeated biopsies. Serologic blood tests (antigliadin, antiendomysial, antireticulin, and tissue transglutaminase IgA antibodies) are helpful in screening of patients with atypical symptoms and asymptomatic relatives of patients with celiac disease. HLA genotyping has a high negative predictive value but low positive predictive value and is not routinely ordered.

Treatment

Strict, lifelong adherence to a gluten-free diet is the only treatment for celiac disease. Specific nutritional supplementation should be provided to correct deficiencies, particularly those of iron, vitamins, and calcium. A clinical response may be seen within a few weeks. Follow-up monitoring with serologic testing should be done after 3 to 6 months in the first year and then yearly thereafter in stable patients clinically responding to a gluten-free diet. Repeat biopsies should be considered for those who are seronegative or have persistent symptoms despite a gluten-free diet. The long-term prognosis is excellent for patients who adhere to the diet, although there may be a slight increase in the incidence of malignancies, particularly lymphoma.

Nonresponsive and Refractory Celiac Disease

Patients with ongoing symptoms more often than not are not truly adhering to a gluten-free diet. There may also be presence of an additional disease process, such as inflammatory bowel disease, microscopic colitis, lactose intolerance, pancreatic insufficiency, and ulcerative jejunitis.

Patients with persistent celiac disease activity despite adherence to a strict gluten-free diet for 12 months are deemed to have refractory celiac disease (RCD). Type 1 RCD is characterized by normal intraepithelial lymphocytes and a polyclonal T-cell receptor population. Type 2 RCD is described as having aberrant intraepithelial lymphocytes with monoclonal T-cell receptors. The overall prognosis for type 1 RCD is good, with a 5-year survival rate of 80%. Type 2 RCD, on the other hand, has a 5-year mortality rate of 50%. Type 2 RCD is strongly associated with ulcerative jejunitis and enteropathy-associated T-cell lymphoma (EATL). MR enterography, CT enterography, capsule endoscopy, and device-assisted enteroscopy may all be helpful in the diagnosis. PET CT is useful in diagnosing associated malignancy. Treatment options for type 2 RCD include azathioprine, steroids, methotrexate, cyclosporine, alemtuzumab, cladribine or fludarabine with or without autologous stem cell transplant.

Bacterial Overgrowth Syndrome

The proximal small bowel normally contains fewer than 10^4 bacteria per milliliter of fluid, with no anaerobic *Bacteroides* organisms and few coliforms. Overgrowth of luminal bacteria can result in diarrhea and malabsorption by a number of mechanisms, including (1) deconjugation of bile salts, which leads to impaired micelle formation and impaired uptake of fat; (2) patchy injury to the enterocytes (small intestinal epithelial cells); (3) direct competition for the use of nutrients (e.g., uptake of vitamin B₁₂ by gram-negative bacteria or the fish tapeworm *Diphyllobothrium latum*); and (4) stimulated secretion of water and electrolytes by products of bacterial metabolism, such as hydroxylated bile acids and short-chain (volatile) organic acids.

Conditions Associated With Bacterial Overgrowth

The most important factors maintaining the relative sterility of the upper gut are gastric acidity, peristalsis, and intestinal immunoglobulins (IgA). Conditions that impair these functions can result in bacterial overgrowth. Impaired peristalsis may be caused by motility disorders (e.g., scleroderma, amyloidosis, diabetes mellitus) or by anatomic changes (e.g., surgically created blind loops, obstruction, jejunal diverticulosis). Achlorhydria, pancreatic insufficiency, and hypogammaglobulinemia are also associated with bacterial overgrowth but uncommonly result in clinical steatorrhea. One should have particular suspicion for bacterial overgrowth in patients with chronic pancreatitis and associated diabetes mellitus, low zinc levels, and opiate use with ongoing weight loss or steatorrhea despite enzyme replacement therapy.

Diagnosis

Direct culture of jejunal aspirate is the most definitive diagnostic test, but it is invasive, uncomfortable, and costly. The ¹⁴C-xylose breath test is an accurate and sensitive laboratory test; measurement of breath hydrogen after an oral challenge with glucose is simpler but not as sensitive or as specific. Adding methane to the hydrogen breath test may capture up to 20% to 30% of the population who produce methane as the byproduct of carbohydrate fermentation. An empirical therapeutic trial with antibiotics is an acceptable alternative to diagnostic testing.

Treatment

When appropriate, specific therapy, such as surgery for intestinal obstruction, should be provided. More commonly, patients are treated with antibiotics, most appropriately those that are effective against aerobic and anaerobic enteric organisms. Rifaximin, amoxicillin-clavulanate, quinolone, metronidazole with a cephalosporin or trimethoprim-sulfamethoxazole are suitable agents. A single course of therapy for 7 to 10 days may be therapeutic for months. In other

patients, intermittent therapy (1 week of every 4) or even an extended period of continuous therapy may be effective, although data are limited.

MALABSORPTIVE THERAPY

Cardiovascular disease and other consequences of obesity have reached epidemic proportions in the United States, and one approach to this problem has been the deliberate induction of malabsorption (primarily of fats) to reduce a patient's lipid levels and body mass index. Medications used for this purpose include bile acid-binding resins, such as cholestyramine and colestipol, and the lipase inhibitors orlistat (Xenical) and ezetimibe (Zetia). Surgical treatment (bariatric operations) usually consists of gastric partition combined with some degree of small intestinal bypass, which induces significant weight loss by several proposed mechanisms, including malabsorption, improved nutrient deposition, and enhanced satiety. Recent data suggest that the malabsorption itself contributes less to overall weight loss from bariatric surgery than the latter two mechanisms and that it is fat malabsorption, rather than carbohydrate or protein malabsorption, that predominates. Please refer to Chapter 69 to review obesity in more detail.

Common Clinical Manifestations of Gastrointestinal Disease: Diarrhea

Ronan Farrell, Sean Fine

DEFINITION

Diarrhea can range from a mild self-limiting illness to a chronic debilitating disease. Although many definitions of diarrhea exist, the most clinically relevant definition is the passage of a greater number of stools of decreased form from a patient's baseline. The average number of bowel movements for a normal adult can range from three per day to three per week. Therefore, it remains crucial to establish through history a normal, baseline bowel habit prior to making the diagnosis. Once a diagnosis is made, diarrhea is initially classified into acute or chronic. Acute diarrhea has a duration of less than 4 weeks and is commonly infectious, whereas chronic diarrhea is diagnosed when symptoms have been ongoing for more than 4 weeks.

PATHOPHYSIOLOGY

Each day, as we consume water and food, the fluid ingested is added to the many secretions produced in our body, including salivary, pancreatic, and biliary secretions. Approximately 9 L of fluid eventually enters the small bowel, of which 90% is absorbed, leaving 1 L of fluid to pass into the colon. Ninety percent of this fluid is absorbed in the colon, leaving 100 mL to be excreted each day in feces. Any disease process in the gut that interferes with the absorption of water or the excretion of electrolytes can result in excess water in the gut lumen and diarrhea. The colon can overcome excess water excreted into its lumen by absorbing up to 4000 mL/24 hr, although 100 mL of excess water beyond this compensation is enough to cause diarrhea.

EVALUATION OF ACUTE DIARRHEA

The majority of acute diarrheal illnesses are infectious in nature. Acute infectious diarrhea can have an abrupt onset with clinical features including cramps, fevers, vomiting, bloody stools, and urgency. Outbreaks can be found in groups of people who travel or work closely together (daycare centers, nursing facilities, college dorms, hospital wards). For these reasons, it is important to take a detailed travel and exposure history from all patients who present with acute diarrhea. Most cases of infectious diarrhea are self-limiting, requiring only supportive treatment, and do not require further investigation. However, infants, elderly, immunosuppressed, and pregnant patients are at a greater risk for potential complications and may need closer attention to hydration status and electrolyte disturbances in a hospital setting. Other indicators of severe disease that may warrant a more robust clinical evaluation (Table 34.1) and treatment include diarrhea lasting longer than 72 hr, fever, bloody or mucoid stools, severe abdominal pain or signs of sepsis.

Acute Infectious Diarrhea

Clinically, acute infectious diarrhea can be classified into milder non-inflammatory diarrhea and the more severe inflammatory diarrhea (Table 34.2). Noninflammatory diarrhea is usually a mild illness but can still result in severe electrolyte disturbances. These microorganisms act by disrupting the absorptive or secretory mechanisms of the small bowel and do not typically invade the mucosa, thus fecal leukocytes are usually absent. Noninflammatory acute diarrhea is mostly caused by viral illness such as rotavirus and norovirus. These viral illnesses are passed easily from person to person and can occur in large outbreaks. Symptoms can last 2 to 3 days before fully resolving. Bacteria that act in a similar way include Enterotoxigenic *Escherichia coli* and *Vibrio cholera*. Enterotoxigenic *Escherichia coli* is a common cause of travelers' diarrhea than can last up to 7 days. *Vibrio cholera* is less common in industrialized nations and can present with extreme diarrhea and can cause large epidemics in countries with unclean drinking water or poor sanitation.

Noninflammatory acute diarrhea caused by bacteria that use preformed toxin to mediate small bowel mucosal disruption is commonly referred to as "food poisoning." These bacteria use preformed toxin to mediate mucosal disruption that leads to an abrupt onset of illness, almost within 6 hours of eating contaminated food. *Staphylococcus aureus* is typically found in stale dairy products or processed meats. *Clostridioides perfringens* forms a toxin that is heat-labile and therefore found in meats that have not been reheated or cooked properly, whereas *Bacillus cereus* is classically implicated in acute diarrheal illness after eating reheated rice.

Protozoal infections are a rare cause of noninflammatory acute diarrhea. *Giardia*, a protozoal infection, can present as an acute illness often with abdominal bloating but is more commonly associated with chronic diarrhea and found in hikers who drink stream water. *Cryptosporidia* is a waterborne and self-limiting diarrhea but can also cause chronic diarrhea in the immunocompromised. It is important to note that although the above infectious agents may be implicated, often no diagnosis is found in self-limiting noninflammatory diarrhea and extensive investigation can be avoided.

Inflammatory diarrhea is caused by microorganisms that invade or release toxins that disrupt the intestinal barrier. This leads to the presence of elevated numbers of fecal leukocytes. These acute diarrheal illnesses are usually less voluminous and associated with bloody diarrhea, high fevers, cramping, and tenesmus. Risk factors include food consumption and preparation of undercooked meats, vegetables, and dairy products. In the United States, *Salmonella* and *Campylobacter jejuni* are the two most commonly isolated bacterial agents. Both are associated with undercooked poultry and stale, unpasteurized dairy products. *Shigella* is an invasive bacteria that can result in grossly bloody diarrhea. Enteroinvasive and enterohemorrhagic *Escherichia*

coli, found in undercooked meats or raw produce, can also cause bloody diarrhea. *Yersinia enterocolitica* is associated with undercooked pork and may present as a “pseudo-appendicitis” from mesenteric adenitis. When acute diarrhea is the presenting symptom in pregnant women, *Listeria monocytogenes* found in unpasteurized dairy products should always be considered in the differential diagnosis. *Vibrio parahaemolyticus* is commonly found in brackish water or in coastal areas and in contaminated shellfish.

Although rare, and usually only in the immunosuppressed, cytomegalovirus can cause invasion and ulceration of the colon resulting in inflammatory diarrhea. *Entamoeba histolytica* is a parasite that can cause severe diarrhea. It is found mostly in tropical countries with poor sanitation and may also seed to liver and brain resulting in abscess formation.

Another rare form of infectious diarrhea is Whipple disease, caused by the actinomycete *Tropheryma whipplei*, which causes malabsorption that results in weight loss, diarrhea, joint pain, and cognitive problems. Tropical sprue also causes malabsorption and is found in tropical climates of the Caribbean, South America, and Asia. The causative organism has not been identified, but symptoms respond to antibiotic treatment and therefore are highly suspected to be infectious.

Clostridioides difficile infection (CDI) is a common cause of severe hospital-acquired diarrheal infection resulting in a pseudomembranous colitis. *Clostridioides difficile* can colonize the human GI tract but usually does not cause clinical symptoms unless the normal gut flora is altered, therefore allowing *C. difficile* to grow uncontrolled. CDI should be considered in all hospitalized patients that develop diarrhea

or have a history of antibiotic use. Other high-risk patients include the elderly, immunosuppressed patients, and patients with inflammatory bowel disease. CDI can result in large, voluminous, watery diarrhea, usually with significant leukocytosis, that can be a major cause of morbidity and mortality. Testing for CDI is commonly done using molecular tests for the toxins associated with CDI such as polymerase chain reaction and is highly sensitive but does not differentiate between colonization and infection. This can result in high false-positive testing; therefore, it is important to only send CDI testing in patients with symptoms of infectious diarrhea. This will increase the positive predictive value of the test.

Treatment

Volume depletion is the main consideration when evaluating a person with acute diarrhea. By evaluating the volume status of patients and their ability to maintain adequate oral intake, a decision can be made whether to treat with oral rehydration or if admission to hospital and intravenous fluids are needed. The objective of rehydration and electrolyte replacement is to prevent hypotension and electrolyte disturbances that can be a major cause of morbidity and mortality, especially in the elderly and very young. For most people with acute diarrhea, fluid replacement can be achieved with sports drinks and eating saltine crackers. Some people with more severe disease or the elderly and infants may require a more balanced commercially available oral rehydration solution. In patients with mild illness, who are afebrile and do not have bloody diarrhea, symptomatic relief agents such as loperamide or diphenoxylate can be used to reduce the volume of diarrhea. These antimotility drugs reduce gut motility, therefore allowing slower passage of water through the gut and allowing greater reabsorption of fluid. Another class of agents that can be used are antisecretory drugs such as bismuth subsalicylates.

The decision to treat with antibiotics is a common one faced by physicians who are evaluating patients with acute diarrhea. In the community, most diarrheal illnesses are viral and therefore empiric treatment with antibiotics is not recommended. In a returning traveler who is being evaluated for diarrhea, the severity of the illness will guide treatment. Mild travelers' diarrhea should not be treated with antibiotics. Antibiotics have been shown to be effective in reducing the duration of moderate to severe travelers' diarrhea by 1 to 3 days when compared to no treatment. Moderate to severe travelers' diarrhea

includes patients with fever, abdominal pain, bloody stool, and sepsis. The most common pathogen identified in travelers' diarrhea is enterotoxigenic *Escherichia coli*, followed by *Campylobacter jejuni*, *Shigella*, and *Salmonella*. Fluoroquinolones, such as ciprofloxacin, are the antibiotics of choice for most cases of travelers' diarrhea. Rifaximin also has been shown to be as effective as ciprofloxacin for noninvasive travelers' diarrhea. However, the resistance of *Campylobacter* to fluoroquinolones is increasing, and in such cases, treatment with a macrolide such as azithromycin should be used. Antibiotics should be avoided in enterohemorrhagic *Escherichia coli* because there may be an increased risk of hemolytic-uremic syndrome related to increased release of Shiga-like toxin.

The recommended treatment of initial CDI is with oral vancomycin or fidaxomicin for 10 days. Patients who have a repeat CDI should be treated with oral vancomycin therapy using a tapered and pulsed regimen. Finally, patients who have more than one recurrence of CDI should be considered for fecal microbiota transplant. Although numerous studies and meta-analyses have been performed on the benefits of probiotics in CDI, currently there is insufficient evidence to recommend their use for the primary prevention of CDI.

CHRONIC DIARRHEA

Chronic diarrhea can be defined as an increase in stool frequency, reduced consistency, and duration longer than 4 weeks. Patient symptoms may include loose stools, increased stool frequency, change of consistency or incontinence. These symptoms can be disabling, and patients will often describe a fear of leaving the house or avoiding long trips without immediate access to a toilet. Though acute diarrhea is commonly infectious in nature, the differential diagnosis of chronic diarrhea is vast and includes intestinal inflammation, colonic neoplasia, malabsorption due to small bowel mucosal disorders, maldigestion due to pancreatic insufficiency, motility disorders, and functional bowel disorders.

Evaluation of Chronic Diarrhea

A thorough history is essential in narrowing down the diagnosis in chronic diarrhea. History should focus on travel and exposures, stool characteristics, prior surgeries, current medications, and over-the-counter supplements. Infectious causes of chronic diarrhea are uncommon in the United States but should be considered in newly arrived immigrants, returned travelers, and people with exposure to farm animals or unclean drinking water. The characteristics of the patient's stool should be described because the presence of blood may suggest

malignancy or inflammatory bowel disease (IBD), oily or sticky stools may suggest malabsorption or maldigestion, and watery stools point to an osmotic or secretory process. Associated symptoms such as fevers, abdominal pain, bloating, and cramps should be noted, as should the relationship of defecation to meals and periods of fasting. Nocturnal symptoms and weight loss can strongly suggest an organic etiology. In patients who are of colon cancer screening age or have alarm features, endoscopic evaluation should be performed. Alarm features include microcytic anemia, bloody diarrhea, fevers, weight loss, nocturnal symptoms, or family history of IBD or colorectal cancer. It is helpful to classify chronic diarrhea into inflammatory, watery or fatty (Table 34.3).

Laboratory Testing

Routine laboratory testing can be used to provide clues to the etiology or severity of chronic diarrhea. A microcytic anemia may point towards chronic blood loss or iron malabsorption seen in an inflammatory process. Macrocytic anemia may point towards a vitamin B₁₂ deficiency that can be seen in IBD or in patients who have had small bowel or gastric resection.

Leukocytosis, elevated inflammatory markers such as C-reactive protein, and fecal calprotectin can be seen in inflammatory diarrhea. Serology testing for antitissue transglutaminase antibodies can be performed to rule out celiac disease. Finally, hormone-secreting tumors are rare and should only be tested for in highly selected patients.

Further Evaluation of Chronic Diarrhea

Due to clustering of symptoms, one of the most practical tasks facing a physician in evaluating chronic diarrhea is to try and make the distinction between functional and organic etiologies.

Irritable bowel syndrome (IBS) is common and can present with an array of symptoms that can include diarrhea, bloating, cramping, and abdominal pain associated with defecation. The Rome IV consensus, formed by a worldwide committee to set criteria for the diagnosis of functional gastrointestinal disorders, may help establish the diagnosis. The most recent criteria focuses on abdominal pain in relation to defecation, change in frequency or change in consistency of stool (Table 34.4). The majority of patients who present with classic symptoms of IBS do not need further diagnostic testing and the focus should be on treatment through diet or available medicines approved for IBS.

When a specific etiology is strongly suspected in the work-up of chronic diarrhea that has no confirmatory testing or testing may be invasive or expensive, an empirical trial of treatment may be pursued. Examples include patients with a history of small bowel resection or

cholecystectomy who may be empirically treated for bacterial overgrowth or started on a bile acid binder. In such patients who fail empiric treatment or in which the diagnosis remains broad and elusive, a colonoscopy with biopsies should be performed.

Chronic Inflammatory Diarrhea

Chronic inflammatory diarrhea typically presents with bloody diarrhea associated with abdominal pain. Any disease process that can disrupt or inflame the mucosa of the gut should be considered, including infections, inflammatory bowel disease, ischemia, neoplasm or radiation enteritis. Direct visualization with colonoscopy is the best next diagnostic step. Biopsies should be taken to characterize the inflammation. Ischemic colitis should be suspected in elderly patients with underlying vascular disease and a recent hypotensive episode. Characteristic findings on colonoscopy show rectal sparing that is not seen with ulcerative colitis and well-demarcated, segmental inflammation, usually in the watershed area of the splenic flexure. Inflammatory bowel disease, which includes both Crohn's disease or ulcerative colitis, is a more common cause of chronic inflammatory diarrhea. Crohn's disease can involve any part of the GI tract and the presentation may not include bloody diarrhea and can be more varied. Typical symptoms include abdominal pain, weight loss, and diarrhea. However, oral ulcers, fistulous openings or perianal disease in the setting of chronic inflammatory diarrhea are also strong indicators pointing towards Crohn's disease. During colonoscopy, the terminal ileum should be evaluated for ulcers and strictures, which would be consistent with Crohn's disease. In contrast, ulcerative colitis involves only the colon. Clinical presentation and severity are dependent on the location and extent of colonic involvement. When the rectum or rectosigmoid region is involved, patients can present with mild intermittent bloody diarrhea, rectal urgency, and tenesmus. Rarely, patients with isolated severe rectal inflammation may also present with constipation and an inability to pass stools. Pancolitis and left-sided colitis typically have more profound presentations with severe abdominal pain, fevers, anemia, and frequent bloody diarrhea.

Chronic Watery Diarrhea

Chronic watery diarrhea should be subdivided into secretory and osmotic types, based on fecal osmotic gap. The fecal osmotic gap is calculated as $290 \text{ mOsm/kg} - 2 \times (\text{stool Na} + \text{stool K})$. When the calculated fecal osmotic gap is greater than 100 mOsm/kg, it is consistent with osmotic diarrhea, while a gap of less than 50 mOsm/kg is suggestive of a secretory etiology of diarrhea such as infection, inflammation, or circulating secretagogues (Table 34.5).

Osmotic diarrhea may be caused by magnesium ingestion or malabsorption of carbohydrates. Both result in water retention in the lumen of the gut and therefore a high osmotic gap. High magnesium concentration in the stool is commonly seen in patients who use laxatives or high doses of antacids. For this reason, it is important to review medication lists. Lactose intolerance due to lactase deficiency or ingestion of other poorly absorbed sugars can also pull water into the lumen of the gut, resulting in diarrhea. As these malabsorbed carbohydrates

TABLE 34.5 Chronic Watery Diarrhea

	Osmotic	Secretory
Stool volume (L/day)	<1 L	>1 L
Effect on fasting	Reduced	Continued
Fecal osmotic gap	>100 mOsm/kg	<50 mOsm/kg
pH	Usually <5	Usually >6

ferment, the stool becomes more acidic. Therefore, a pH less than 7.0 can point to excess carbohydrates in the stool. Common dietary sugar substitutes that cause osmotic diarrhea include sorbitol and high-fructose corn syrup. For this reason, osmotic diarrhea should disappear with fasting.

Secretory diarrhea can result from any process that impairs or disrupts the absorption of salt and water in the gut. Often an overlap of secretory and inflammatory diarrhea may be seen.

Although rare in developed countries, infectious organisms can cause chronic diarrhea and should be ruled out, especially in returned travelers. Parasites such as *Cryptosporidium*, *Microsporidia*, *Cyclospora*, and *Giardia* can all cause chronic secretory diarrhea. Testing of stool for ova and parasites should be performed if there is a travel history or recent immigration from a high-risk area. *Giardia* testing using ELISA is recommended in all patients with chronic diarrhea.

More commonly, mucosal disease as seen in IBD or structural disease as seen in short bowel syndrome or neoplasm is the cause of chronic secretory diarrhea. Imaging with small bowel radiograph or computerized tomography (CT) should be used to assess for tumors, strictures, fistulas or inflammation. Further examination with colonoscopy should be performed for direct visualization and biopsies of the mucosa.

Microscopic colitis is characterized by chronic watery diarrhea and is commonly seen in women older than 60 years old, although men and women of any age can be affected. Typical symptoms include more than 10 watery stools/day that can be accompanied by abdominal cramping and even mild weight loss. Nocturnal symptoms are common. There are two subtypes of microcytic colitis, lymphocytic and collagenous. The cause of microscopic colitis is unknown but there is a strong association with other autoimmune diseases and certain medications such as proton pump inhibitors and nonsteroidal anti-inflammatory drugs. Direct visualization with colonoscopy typically shows no mucosal inflammation, so biopsies of the left and right colon are needed to make this histologic diagnosis. Budesonide is recommended as first-line treatment for microscopic colitis; however, this medication may be cost prohibitive, and alternative treatments include bismuth subsalicylate or aminosalicylates.

Patients who are post cholecystectomy or have ileal disease or resection may have bile acid malabsorption. This can result when excess bile acid is passed into the colon resulting in electrolyte absorption impairment. In such cases, a trial of bile acid-sequestering resins should be tried.

Peptide-secreting neuroendocrine tumors are rare and should only be investigated when the work-up has been unrevealing for chronic diarrhea. Plasma peptides such as gastrin and vasoactive intestinal peptide (VIP) can be used to help diagnose Zollinger-Ellison syndrome or VIPoma respectively. Elevated levels of gastrin can be seen in patients taking acid suppressing medications such as proton pump inhibitors; however, in Zollinger-Ellison syndrome, gastrin levels are often 10 times the upper limit of normal. CT, MRI, or endoscopic ultrasound of the liver and pancreas should be performed to identify tumors. Zollinger-Ellison syndrome can have characteristic multiple gastric

ulcers seen on endoscopy whereas VIPoma can have profound hypokalemia when electrolytes are checked.

Carcinoid syndrome is characterized by secretory diarrhea resulting from the release of excess serotonin from a neuroendocrine tumor. Serotonin syndrome should be suspected in patients with unexplained chronic diarrhea who have symptoms such as flushing of the skin, wheezing, and heart murmurs. Urine should be tested for elevated 5-HIAA.

Chronic Fatty Diarrhea

Chronic fatty diarrhea or steatorrhea can often be described as oily, floating, or sticky stool. Such characteristic stool often implies malabsorption or maldigestion from pancreatic or small bowel mucosal disease. In many cases the cause of fatty diarrhea may be obvious, such as a patient with chronic pancreatitis or severe biliary disease. In other cases, the etiology may not be so obvious and Sudan stain of fecal smear or fecal fat concentration can be obtained. A high concentration of fat in the stool greater than 9.5 g/100 g suggests maldigestion as seen in exocrine pancreatic insufficiency and lack of bile. A low concentration of fecal fat can be seen in mucosal disease that results in the malabsorption of fat and carbohydrates together (see below). CT or MRI of the pancreas, biliary system, and small bowel should be obtained to further assess structural disease and pancreatic disease.

Malabsorption of fat and carbohydrates can result in excess fluid being pulled into the lumen of the gut, therefore diluting the concentration of fecal fat. Such conditions include celiac disease, short bowel syndrome, and small intestine bacterial overgrowth (SIBO). Celiac disease is caused by gluten intolerance and is mainly seen in people of European descent. Presentation can vary from iron deficiency anemia and weight loss to mild abnormalities in liver function tests. Testing for antitissue transglutaminase antibodies with an IgA level can be used to screen for the disease. If suspicions remain high despite negative serologic testing, endoscopy with duodenal biopsies can be performed for definitive diagnosis. The treatment is complete gluten

avoidance. SIBO results when the small bowel is colonized by excessive microbes. Patients with motility disorders such as gastroparesis or structural disease such as blind intestinal loops are at risk. SIBO should be considered in such patients who complain of bloating, abdominal pain, and chronic diarrhea. Hydrogen breath testing can be used to confirm the diagnosis. Treatment with a course of antibiotics can be initiated following a positive test.

Maldigestion is seen in patients who have insufficient amounts of bile to break down fats, such as in primary biliary cholangitis or exocrine pancreatic insufficiency due to lack of pancreatic enzymes. In such cases, measuring stool chymotrypsin and stool elastase can be performed to confirm suspicions of this disorder. In other cases, imaging with MRI, CT or endoscopic ultrasound should be obtained to confirm pancreatic disease. Patients who are strongly suspected of having pancreatic insufficiency are best served with a trial of pancreatic enzymes and evaluating their response.

Endoscopic and Imaging Procedures

Andrew Canakis, Christopher S. Huang

INTRODUCTION

Since Mikulicz first used a prototype esophagoscope to visualize the lumen of the esophagus in 1880, physicians have been attempting to peer into every portion of the gastrointestinal (GI) tract in an attempt to understand disease and to restore their patients to health. This goal has become more achievable than ever, thanks to the wide variety of both invasive and noninvasive endoscopic and imaging procedures that are currently available. This chapter reviews the various endoscopic and radiographic procedures currently in use, including their indications and basic information regarding their performance.

GASTROINTESTINAL ENDOSCOPY

Gastrointestinal endoscopy is the primary modality for directly visualizing the GI tract, as well as obtaining tissue samples to establish definitive diagnoses. Moreover, a wide variety of therapeutic maneuvers can be performed endoscopically to deal with a host of disease processes, such as hemostasis for bleeding ulcers or varices, resection or ablation of neoplastic tissue, dilation or stenting of strictures, and removal of bile duct stones, to name just a few.

Over the years, endoscopes have evolved from early rigid designs with limited capabilities to more sophisticated flexible instruments with advanced imaging capabilities, specialized features for therapeutic maneuvers, and different designs to enable examination of specific areas of the GI tract and biliopancreatic systems. Endoscopes come in varying lengths and diameters ranging from 3.1 mm to 15 mm (Fig. 35.1) and consist of a control handle, insertion tube, and connector section that attaches to the light source and image processing units. The control handle comprises dials that deflect the scope tip in all directions, as well as buttons for suction, air/water insufflation, and image capture. The control handle also includes the entry port to the “working channel” that runs down the length of the insertion tube, through which a wide array of accessories such as biopsy forceps, snares, and balloon dilators can be passed. The tip of the insertion tube houses a charge-coupled device for color image generation, a light guide illumination system, and an objective lens, which may be oriented for forward viewing, side viewing, or oblique viewing, depending on the type of endoscope.

Technologic advances continue to improve the quality of endoscopic imaging, such as the recent introduction of high-definition instruments, magnification endoscopy (from baseline of 30 to 35× to up to 150×), and enhanced imaging technologies such as narrow band imaging (NBI) and multiband imaging.

GI endoscopy can be performed in dedicated endoscopy suites or at a patient’s bedside in emergency situations. After positioning the patient appropriately and providing sedation, if necessary, the lubricated endoscope is passed through the intended orifice and advanced

manually by the endoscopist. The angulations of the GI lumen are navigated by deflecting the endoscope tip and by applying torque to the instrument shaft (i.e., rotating the shaft along the long axis of the instrument). Endoscopy is generally safe, with complications that include bleeding (0.3% to 1% after colonoscopic polypectomy), perforation (0.05% in general, but 0.1% to 0.5% after polypectomy), and sedation-associated hypotension and hypoxia (1% to 5%). Death related to endoscopic procedures is exceedingly rare (0% to 0.01%).

Esophagogastroduodenoscopy

Esophagogastroduodenoscopy (EGD), often referred to as *upper endoscopy*, is performed with a *gastroscope* and allows the endoscopist to visualize the esophagus, stomach, and duodenum to its third and sometimes fourth portions (Fig. 35.2). Common indications for EGD include evaluation of upper GI symptoms (such as dyspepsia, heartburn, nausea, vomiting, dysphagia and odynophagia), screening for and surveillance of Barrett esophagus, screening for gastroesophageal varices, suspected upper GI bleeding (acute or chronic), and investigation of malabsorptive diarrhea (e.g., celiac sprue or protein-losing enteropathy). A partial list of the therapeutic interventions that can be performed during EGD include the treatment of esophageal varices; dilation of esophageal strictures, rings, and webs; removal or ablation of neoplastic tissue; hemostasis therapy for upper GI bleeding; and the placement of palliative stents for malignant obstruction of the esophagus, pylorus, or duodenum.

Enteroscopy

Examination of the small intestine beyond the ligament of Treitz is not feasible with a standard gastroscope. More recently, greater strides have been made to gain direct visualization of the 6 m or so of the small intestine. *Push* enteroscopy using a long (>200 cm) endoscope allows the endoscopist to both image and biopsy or cauterize lesions in the small intestine, but due to looping of the endoscope and tortuosity of the small intestine, advancing this instrument beyond the first 50 cm of jejunum can be difficult. Balloon-assisted enteroscopy is a newer technique that provides endoscopic access to most of the small bowel. Double balloon enteroscopy (DBE) was initially introduced in 2001 and has emerged as the primary modality for extensive examination of the small bowel. This method employs balloons, incorporated into overtubes or the endoscope itself, to permit pleating of the small bowel onto the endoscope. By inflating and deflating the balloons in sequence, the enteroscope can be advanced through extremely long stretches of small intestine. Combining an antegrade (through the mouth) and retrograde (through the anus) approach may potentially allow for complete examination of the entire small intestine. However, its use is limited to high volume tertiary centers due to its technical difficulties and long procedure times. As a result, single balloon

Fig. 35.1 Endoscopes used for upper GI endoscopy. Endoscopes of varying sizes are available for use in different situations. The uppermost endoscope (6-mm diameter) can be used for unsedated endoscopy. The middle endoscope (9-mm diameter) is used for standard diagnostic endoscopy. The lowermost endoscope (12-mm diameter) is used for therapeutic endoscopy, such as the placement of enteral stents. (Courtesy of Brian C. Jacobson.)

enteroscopy (SBE) was developed in 2007 as a means to shorten procedure times, though the chances of total enteroscopy are limited by its single balloon design. A meta-analysis comparing DBE and SBE found that both modalities had similar diagnostic/therapeutic yields, adverse events, and failure rates.

Spiral enteroscopy represents a different technique that utilizes rotational energy of a spiral overtube device that retracts the small bowel over the scope, allowing for deep enteroscopy. Recently, the novel use of a motorized spiral endoscope was developed as a means to improve scope maneuverability, decrease procedure times, and limit the cumbersome nature of balloon enteroscopy (which often requires two operators). Through the use of a foot-switch-operator motor, an overtube equipped with spiral-shaped fins can smoothly advance through the small bowel. Additionally, the system is equipped with high-definition imaging and a 3.2-mm channel that may offer versatile diagnostic and therapeutic modalities in the near future.

Intraoperative enteroscopy is the final means for obtaining visualization of the entire small bowel, although this is obviously the most invasive approach and is now uncommonly performed given the development of device-assisted enteroscopy procedures. In this procedure, a surgeon will make an incision in the patient's abdomen and then pleat the small bowel onto the enteroscope while the endoscopist visualizes the lumen. Once a lesion is identified, the surgeon may elect to proceed directly to a resection of the affected segment of small intestine if the lesion is not amenable to endoscopic treatment.

Video Capsule Endoscopy

The desire to obtain visualization of the GI lumen in the least invasive way has resulted in the development of video capsule endoscopy, the use of pill-sized wireless cameras that the patient swallows (E-Fig. 35.1 and Video 35.1). Currently, capsule endoscopes are available for the

evaluation of the esophagus, small intestine, and the colon. Capsule endoscopes are swallowed or deployed endoscopically and transmit images wirelessly to a data recorder as they travel through a patient's GI tract, without the need for sedation. At the end of the study, the data recorder allows for stored images to be uploaded into a computer for viewing while the capsule is ultimately passed in the patient's stool. The esophageal capsule is helpful in patients being screened for esophageal varices or individuals with suspected complications of acid reflux, such as reflux esophagitis or Barrett esophagus. The small bowel capsule has become the gold standard for visualizing the small intestine, most commonly for the purpose of investigating obscure GI bleeding (E-Figs. 35.2 and 35.3 and Videos 35.2 and 35.3) and suspected inflammatory bowel disease (E-Figs. 35.4 and 35.5). Colon capsule endoscopy (CCE) is typically used in patients with a prior colonoscopy failure or suspected lower GI bleeding and may even offer a role in monitoring disease activity in inflammatory bowel disease (IBD) patients. Recent technologic advancements in second-generation CCE now offers clinicians with high-resolution, nearly 360-degree views of the colon with adaptive frame rates that improve battery life and visualization during rapid motions. Additionally, its adjunctive software can estimate polyp size and provide flexible spectral imaging color enhancement to further differentiate neoplastic versus non-neoplastic lesions. Although rare, the main potential complication of capsule endoscopy is retention within the small bowel, usually at a site of pathology.

Sigmoidoscopy and Colonoscopy

Flexible sigmoidoscopy allows visualization of the rectum, sigmoid colon, and descending colon to the level of the splenic flexure. Enemas are given before the procedure to clear stool from the distal colon. Because sigmoidoscopy is generally a brief procedure and not particularly painful, sedation is typically not necessary, making it a convenient tool for colorectal cancer screening. Sigmoidoscopy may also be useful for evaluating symptoms such as chronic diarrhea and rectal bleeding suspected to be arising from the distal colon or rectum, as well as assessing response to therapy in patients with inflammatory bowel disease involving the rectosigmoid colon.

Colonoscopy allows direct visualization of the entire large bowel and the terminal ileum. Bowel cleansing for colonoscopy requires the ingestion of osmotically active solutions, such as polyethylene glycol, coupled with a clear liquid diet for 24 hours before the procedure. Colonoscopy can be more uncomfortable for the patient than sigmoidoscopy due to stretching and distension of the colon, so sedation and analgesia are typically provided. Colonoscopy has become widely performed as a first-line colorectal cancer screening test because of its ability to not only detect early cancers but also *prevent* colon cancer (through the removal of premalignant polyps). Other indications for colonoscopy include evaluation of chronic diarrhea, iron deficiency anemia, overt and occult GI blood loss, and assessing inflammatory bowel disease, including surveillance for dysplasia. Therapeutic interventions possible during colonoscopy include polypectomy, endoscopic mucosal resection of neoplastic lesions, thermal ablation of vascular ectasias, decompression of colonic dilation associated with pseudo-obstruction, stenting of malignant obstruction, and control of lower GI bleeding.

Endoscopic Retrograde Cholangiopancreatography

Endoscopic retrograde cholangiopancreatography (ERCP) is a combined endoscopic and radiographic procedure for imaging and intervening within the biliary and pancreatic ducts. A *duodenoscope* is a specially designed instrument for use during ERCP that includes an imaging lens oriented on the side of the endoscope's tip (as opposed to the front), allowing a direct view of the ampulla of Vater on the medial wall of the second

E-Fig. 35.1 Capsule endoscopy of the normal small intestine. The ingested small bowel capsule captures still images of the small intestinal mucosa that enable visualization of the normal villi and plicae circulares.

E-Fig. 35.3 Capsule endoscopy image of an ulcerated small intestinal tumor. The capsule passes near an ulcerated mass protruding into the small bowel lumen (see Video 35.3). The ulcerated lesion is seen originating from the bottom right-hand side of the lumen. Surgical pathology diagnosed this neoplasm as a carcinoid tumor.

E-Fig. 35.2 Capsule endoscopy image of an actively bleeding vascular ectasia. An area of active bleeding was identified on capsule endoscopy performed for unexplained gastrointestinal blood loss. It was later identified as vascular ectasia and ablated during push enteroscopy.

E-Fig. 35.4 Capsule endoscopy image of an ulceration and stricture of the small intestine consistent with Crohn's disease. This abnormal area exhibits evidence of mucosal narrowing consistent with a stricture (S) and an irregularly bordered ulceration (U) that appears to be circumferential. Crohn's disease was proven on biopsy. (Courtesy Daniel S. Mishkin, Boston, Mass.)

E-Fig. 35.5 Capsule endoscopy image of a deep ulceration (*U*) in the ileum, consistent with Crohn's disease. (Courtesy Daniel S. Mishkin, Boston, Mass.)

Fig. 35.2 (A) Endoscopic view of the distal esophagus. The distal esophagus contains an abrupt transition between its squamous-lined mucosa and the columnar-lined mucosa of the stomach. (B) Endoscopic view of Barrett esophagus, in which the squamous epithelium of the distal esophagus is replaced by columnar-lined epithelium. Evident in this view is a tongue of columnar-lined mucosa extending proximally into the esophagus. (C) Endoscopic view of a gastric ulcer. A yellow-based ulceration with a pigmented spot is visualized on the gastric wall at the transition between the corpus and the antrum. (Courtesy of M. Michael Wolfe.)

portion of the duodenum. An adjustable instrument *elevator* located at the tip of the duodenoscope helps the endoscopist guide a catheter and other accessories into the duct of interest. Contrast is then injected through the catheter, filling the duct, and fluoroscopic images are obtained (Fig. 35.3). Indications for ERCP include evaluation and treatment of bile duct obstruction due to benign or malignant causes (e.g., bile duct stones, strictures, and bile duct or pancreatic malignancies), cholangitis, postoperative or traumatic bile leaks and pancreatic duct leaks, and transpapillary drainage of pseudocysts. Therapeutic interventions possible during ERCP include sphincterotomy (an incision through the sphincter of Oddi using a catheter with an electrocautery cutting wire), removal of bile duct stones, and placement of biliary or pancreatic duct stents to alleviate signs and symptoms of obstruction or to promote healing of duct leaks. ERCP

carries a significant (5%) risk for complications, including pancreatitis, postsphincterotomy bleeding, and perforation. Therefore, ERCP should only be performed when therapeutic benefits are anticipated.

Choledochoscopy and *pancreatoscopy* are techniques in which an endoscope 3 mm or less in diameter is passed through the accessory channel of a duodenoscope and into the bile or pancreatic ducts. The use of this small endoscope permits direct visualization of ductal abnormalities, guides electrohydraulic lithotripsy of large stones, and allows for direct sampling of ductal lesions.

Endoscopic Ultrasound

Endoscopic ultrasound (EUS) or endosonography is performed with an endoscope containing an ultrasound transducer in its tip. Because

Fig. 35.3 Endoscopic retrograde cholangiopancreatography (ERCP). (A) Normal cholangiogram. Contrast injected into the biliary tree during ERCP demonstrates the intraductal anatomy of the common bile duct (CBD), right hepatic duct (RHD), left hepatic duct (LHD), and smaller intrahepatic biliary radicals. (B) Normal pancreatogram. Contrast injected into the pancreatic duct during ERCP defines the intraductal anatomy throughout the length of the pancreas. (Courtesy of Brian C. Jacobson.)

Fig. 35.4 Endoscopic ultrasound of the gastrointestinal wall. A 12-MHz ultrasound probe, passed through the accessory channel of an endoscope, demonstrates the normal layers of the rectal wall. The mucosa (*m*) appears as a superficial, hyperechoic (white) band and a deeper hypoechoic (black) band. The submucosa (*sm*) appears as the next hyperechoic layer. The muscularis propria (*mp*) appears hypoechoic, and the serosa (*s*) appears as the outermost, hyperechoic layer. (Courtesy of Brian C. Jacobson.)

this transducer can be placed within the GI lumen, high-resolution images of the bowel wall can be obtained, revealing distinct layers that correspond to the mucosa, submucosa, muscularis propria, and serosa (Fig. 35.4). This technique allows the endoscopist to stage tumor depths and determine the layer of origin of subepithelial masses. In

addition, EUS can image beyond the gastrointestinal tract wall, providing sonographic images of adjacent structures within the mediastinum and upper abdomen, including the pancreas, liver, gallbladder, mesenteric vessels, lymph nodes, and adrenal glands. High-frequency EUS catheter probes can be passed through the accessory channel of a duodenoscope and into the biliary and pancreatic ducts to provide sonographic images of small tumors and stones. They can likewise be used through a standard endoscope to evaluate diminutive subepithelial lesions and stage obstructing esophageal cancers. Fine-needle aspiration (FNA) as well as core biopsy can be performed under EUS guidance and is the preferred approach to obtaining a tissue diagnosis in many circumstances (e.g., pancreatic masses or cysts, subepithelial lesions of the GI tract, and intra-abdominal or paraesophageal lymphadenopathy). Technologic advancements such as elastography and contrast-enhanced harmonic EUS have further enhanced the diagnostic capability of EUS, particularly in terms of distinguishing malignancy from benign processes. Furthermore, EUS-guided vascular access provides a unique modality for portal vein sampling and portal pressure measurements. However, EUS is more than just a diagnostic modality, and the spectrum of EUS-guided therapies is rapidly expanding. Therapeutic maneuvers that can be performed via EUS guidance include transluminal drainage of pseudocysts and walled-off pancreatic necrosis, pancreatic cyst ablation, celiac axis neurolysis, fiducial (technical) placement into solid tumors to guide stereotactic radiotherapy, and achieving bile duct access or biliary drainage (when initial attempts at ERCP have failed or surgically altered anatomy precludes standard ERCP.)

“Second Space” and “Third Space” Endoscopy

Recent advancements in endoscopic techniques and equipment have led to the development of so-called “second-space” and “third-space” endoscopy procedures within the peritoneal cavity and intramural/submucosal tissue planes, respectively.

Fig. 35.5 Upright plain radiograph of the abdomen. Air in dilated loops of colon and air-fluid levels can be seen in this patient with a sigmoid volvulus. (Courtesy of Brian C. Jacobson.)

Natural orifice transluminal endoscopic surgery (NOTES) is an evolving, minimally invasive field that combines endoscopic and surgical approaches to access the peritoneal cavity. Through the use of an endoscope, a clinician can access a desired target or organ through a transgastric, transcolonic, transvaginal or transurethral approach. Examples of NOTES procedures include cholecystectomy, appendectomy, sleeve gastrectomy, hysterectomy, and hernia repair.

The success and promise of NOTES procedures has led to the development of “third space” endoscopic interventions within the intramural tissue planes of the gastrointestinal tract. Such procedures include full-thickness resection of subepithelial tumors of the GI tract, as well as peroral endoscopic myotomy (POEM) to treat achalasia and esophageal motility disorders. By utilizing submucosal endoscopy, the POEM procedure consists of four steps involving a mucosal incision, submucosal tunneling, subsequent myotomy, and finally mucosal closure through the placement of clips or sutures. POEM has become a very popular modality in treating achalasia, due to its long-term efficacy, lack of abdominal incisions, and rapid recovery.

The same principles and techniques of POEM have been used in the treatment of pyloric dysfunction in patients with gastroparesis in what is known as gastric POEM (G-POEM). Lately, there has been a growing body of evidence proposing that pyloric dysfunction may indeed be a significant contributor to the pathogenesis and symptomatic effects related to gastroparesis. In this context, the need for an alternative, more effective, and minimally invasive therapeutic modality that can target a subset of patients who exhibit pyloric dysfunction has emerged. G-POEM has shown promise, but further long-term and head-to-head studies are needed to see if this modality can emerge as first-line therapy.

NONENDOSCOPIC IMAGING PROCEDURES

Plain Abdominal Radiographs

Plain abdominal radiographs include upright, supine, and lateral decubitus films obtained with standard radiograph equipment and without the use of contrast agents. Plain films are most useful in the initial evaluation of abdominal pain or nausea and vomiting, particularly when

Fig. 35.6 Small bowel follow-through. Ingested barium defines the contours of the small and large bowel lumen. A long stricture (S) of the terminal ileum can be seen in this patient with Crohn’s disease. (Courtesy of Brian C. Jacobson.)

perforation or obstruction is suspected, and they may reveal evidence of a pneumoperitoneum, dilated bowel loops and air-fluid levels, excessive amounts of stool, or displacement of bowel loops. These findings are indicative of a perforation, obstruction or ileus, constipation or fecal impaction, and volvulus or organ enlargement, respectively (Fig. 35.5). Calcifications, such as those seen in chronic pancreatitis and gallstone disease, may also be visible on these radiographs.

Contrast Studies

Contrast agents such as barium or the water-soluble diatrizoate (e.g., Gastrografin) can be administered by mouth or rectum to detect mucosal abnormalities (ulcerations and masses), strictures, herniations, diverticula, and abnormal peristalsis. Contrast agents can be used alone (*single contrast*) or with the instillation of air or ingestion of gas-forming agents (*double contrast*). The former method is more useful for detecting obstructing lesions and motility disturbances, whereas the latter method aids in detecting more subtle findings such as small ulcerations or polyps.

A *video esophagogram* (also known as modified barium swallow) entails the filming of a patient’s oral cavity and pharynx during the ingestion of contrast materials of various thicknesses and textures. This imaging modality permits careful assessment of a patient’s ability to manipulate a food bolus, swallow effectively, and avoid aspiration events. A video esophagogram is indicated for evaluating patients with oropharyngeal dysphagia and recurrent aspiration pneumonia. A standard *barium esophagogram* (barium swallow) focuses attention on the esophagus during the ingestion of a bolus of contrast. This study can detect esophageal rings, webs, strictures, and motility problems that endoscopy might miss. A barium esophagogram may be useful for evaluating esophageal dysphagia, either as a complementary test to endoscopy, or when endoscopy is contraindicated.

An *upper GI series* includes serial radiographic images as an ingested contrast agent travels through the esophagus, stomach, and duodenum. This study can define gastric abnormalities, such as masses, ulcerations, and mucosal thickening. It is indicated in evaluating abdominal pain and suspected gastric outlet obstruction. If radiographic imaging continues as the contrast agent traverses the jejunum and ileum, the study is called a *small bowel follow-through* (Fig. 35.6). Indications for a small bowel follow-through include suspected small bowel obstruction or partial obstruction from any cause, suspected small bowel mucosal diseases such as Crohn’s disease, and obscure GI blood loss (although this has been

Fig. 35.7 Computed tomography enterography. A long segment of inflamed terminal ileum is demonstrated in this patient with Crohn's disease. (Courtesy of Christopher S. Huang.)

largely replaced by video capsule endoscopy). During this more involved procedure, a radiologist will obtain multiple films, including *spot films*, or close-up views of regions that appear abnormal. Fluoroscopy can be used to follow a contrast agent during the journey through the small bowel. Attention is paid not only to structural findings but also to the length of time required for contrast to reach and enter the colon. For more detailed small bowel images, *enteroclysis* can be performed. This method requires the infusion of concentrated contrast directly into the small bowel through a nasojejunal tube placed under fluoroscopic guidance. Because of its invasive nature, as well as the availability of better small bowel imaging techniques, enteroclysis is now rarely performed.

Single- and double-contrast barium enemas can detect colonic strictures, diverticula, polyps, and colonic ulcerations, and they can be therapeutic in reducing a sigmoid volvulus. Double-contrast barium enema may be used for colorectal cancer screening as a stand-alone test or in conjunction with flexible sigmoidoscopy, or it may be used to visualize the proximal colon when colonoscopy cannot be completed for various reasons. However, it is now infrequently used for these purposes given its relatively poor sensitivity, as well as availability of computed tomography colography ("virtual colonoscopy," discussed later). In general, the upper GI series and barium enema have been superseded by upper endoscopy and colonoscopy because the endoscopic procedures offer increased sensitivity for detecting mucosal abnormalities, the ability to obtain mucosal biopsies, and the potential for resection of identified lesions.

Transabdominal Ultrasound

Ultrasonography is often the first imaging study obtained in the evaluation of suspected biliary colic, jaundice, and abnormal liver tests. Its use of sound waves to create an image obviates the need for radiation exposure, and the addition of Doppler techniques permits the assessment of vascular flow. Ultrasound can detect parenchymal abnormalities, such as fatty liver or cirrhosis, focal masses or cysts, ascites, biliary ductal dilation, gallstones, and large vessel thromboses. It may detect thickening of the gut wall and areas of intussusception. Ultrasound is also used to guide needle placement for biopsies or fluid aspiration. Ultrasound cannot penetrate bone or air, preventing its use as a more general diagnostic tool for the GI tract.

Computed Tomography, Computed Tomography Enterography, and Computed Tomography Colography

Computed tomography (CT) uses computer-aided reconstruction of multiple radiographic images obtained in a circular or helical course around a patient's vertical axis. Internal organs are visualized based

on their inherent tissue densities compared with their surroundings. The GI lumen is usually opacified by having the patient drink an oral contrast agent. In addition, intravenous contrast agents can be administered to highlight regions with increased blood flow, thereby improving detection of pathologic lesions, such as tumors and areas of active inflammation. CT can detect parenchymal lesions, such as tumors, cysts, and abscesses, as well as define the size, shape, and characteristics of parenchymal organs, such as the liver and spleen. Vascular abnormalities, such as perigastric varices or large vessel thromboses, and intra-abdominal fluid, such as ascites, can also be seen with CT. The caliber and contour of the GI tract wall are demonstrated by CT, aiding in the diagnosis of inflammatory lesions, such as colitis, diverticulitis, and appendicitis. CT can also be used to guide needle biopsies of abdominal masses and to place electrodes into tumors for ablative therapies such as radiofrequency ablation. The use of CT to guide placement of drainage catheters has made possible the percutaneous treatment of intra-abdominal abscesses, pseudocysts, and pancreatic necrosis.

CT enteroclysis and *CT enterography* are two emerging techniques developed to provide better images of the small intestine. *CT enteroclysis* uses a nasojejunal tube to deliver contrast into the small intestine, whereas *CT enterography* uses an orally ingested low-density intraluminal contrast to distend the lumen and highlight the small intestinal mucosa (Fig. 35.7). With the advancement of this technology and its ability to reconstruct images in multiple planes, both luminal and extraluminal information can be obtained.

CT can also be used to obtain high-resolution images of the colon. *CT colonography*, or *virtual colonoscopy*, makes use of special image reconstruction software to create accurate visualization of the colonic lumen, provided that the patient has completed a bowel-cleansing regimen identical to that used for colonoscopy (although techniques that do not require such preparation are being developed). These CT images are 70% to 90% sensitive for detecting polyps or masses within the colon, helping to determine which patients need therapeutic colonoscopy. *CT colonography* is considered an acceptable option for colorectal cancer screening in average risk individuals but is primarily used to complete colonic visualization in the setting of an incomplete colonoscopy (due to technical reasons or obstructing pathology).

Magnetic Resonance Imaging and Magnetic Resonance Cholangiopancreatography

Similar to CT, magnetic resonance imaging (MRI) provides multiple cross-sectional images of the abdomen and pelvis. These images are created using powerful field magnets to orient small numbers of nuclei within the body in such a way as to produce a measurable magnetic moment. MRI therefore avoids radiation exposure but requires the patient to lie nearly motionless, and often within a small enclosed tube, for prolonged periods. MRI can visualize parenchymal lesions such as masses and cysts and may better characterize abnormalities seen on CT, such as hemangiomas, hepatic focal nodular hyperplasia, and fatty liver. MRI is also helpful in better characterizing perirectal abscesses and fistulas in Crohn's disease. Special rectal MRI probes or coils can provide detailed images of rectal cancer used for tumor staging, as well as evaluate the anal sphincters in patients with fecal incontinence.

MRI of the biliary and pancreatic ducts (*magnetic resonance cholangiopancreatography*, MRCP) is a noninvasive method that can detect ductal dilation, strictures, stones (Fig. 35.8), pancreatic parenchymal changes in chronic pancreatitis, and congenital ductal abnormalities, such as pancreas divisum. *Magnetic resonance angiography* is a magnetic resonance method for visualizing blood vessels and serves as an important noninvasive tool for evaluating patients with suspected mesenteric ischemia, vasculitis, and other vascular anomalies.

Fig. 35.8 Magnetic resonance cholangiopancreatography. Several stones are visualized within the common bile duct, appearing as hypointense filling defects on T2-weighted images. (Courtesy of Christopher S. Huang.)

Visceral Angiography

Angiography is an invasive technique whereby a catheter is introduced into a blood vessel, and intravascular contrast is injected during fluoroscopic imaging to visualize the vessel's lumen. Visceral angiography is used for evaluating mesenteric vessels in the setting of GI bleeding and suspected mesenteric ischemia. For GI bleeding, angiography is sensitive enough to detect 1 to 1.5 mL per minute of blood loss. Once the site of bleeding has been localized, the radiologist can infuse vasopressin (a vasoconstrictor) or embolize the vessel using tiny coils or gelatin sponges to ensure hemostasis. In the setting of mesenteric ischemia, angiography permits localization of a vascular stenosis or obstruction, followed by possible therapeutic interventions (e.g., balloon angioplasty, stent placement, infusion of vasodilators and thrombolytics). Other indications for angiography include the placement of transjugular intrahepatic portosystemic shunts (TIPS) in cirrhotic patients with intractable variceal bleeding or refractory ascites and for chemoembolization of liver tumors.

Radionuclide Imaging

Technetium-99m (^{99m}Tc) is currently the major radionuclide used in GI imaging. Its 6-hour half-life and ready availability make it ideal for clinical use. ^{99m}Tc is used to label various substances for use in several imaging techniques. ^{99m}Tc -sulfur colloid scanning and ^{99m}Tc -labeled red blood cell scanning are two distinct methods that can be used to detect active GI bleeding. The latter uses the patient's own blood cells to carry the radionuclide throughout the body. These methods can detect as little as 0.05 to 0.4 mL per minute of blood loss. However, localization of the site of bleeding is less accurate with these methods compared with angiography. ^{99m}Tc scans are often performed before angiography to document ongoing bleeding before subjecting a patient to the more invasive, less sensitive study. A ^{99m}Tc -labeled red blood cell scan can also be used to diagnose a hepatic hemangioma with an almost 100% positive predictive value.

Cholescintigraphy using ^{99m}Tc -iminodiacetic acid (IDA) analogs is the most commonly performed liver study in nuclear medicine. The radionuclide is taken up by the liver, is excreted into bile, and passes through the biliary tree into the gallbladder and duodenum. Failure to visualize the gallbladder during a hepatobiliary IDA scan may

indicate cholecystitis secondary to cystic duct obstruction by a gallstone. Meckel's diverticulum can be a source of abdominal pain and bleeding, but it can be difficult to visualize with standard endoscopic and radiographic imaging. The agent ^{99m}Tc -pertechnetate has a high affinity for gastric mucosa and is therefore used to demonstrate the presence of this congenital anomaly.

Gastric emptying studies are useful for the evaluation of patients with suspected gastroparesis. Patients are given a ^{99m}Tc -sulfur colloid-labeled standardized meal (consisting of liquid egg whites, toast, jam/jelly, and water) and are imaged at 0, 1, 2, and 4 hours after meal ingestion. Gastric retention of greater than 10% at 4 hours is highly sensitive and specific for delayed gastric emptying.

Radionuclide imaging studies are also useful for the detection, staging, and monitoring of certain neoplasms such as neuroendocrine tumors (NETs). Most well-differentiated NETs express somatostatin receptors and can therefore be detected with radiolabeled somatostatin analogues such as ^{111}In -pentetreotide and ^{68}Ga -DOTATATE.

PROSPECTUS FOR THE FUTURE

Through continued technologic advances, improvements in both endoscopic and radiologic image quality and resolution will also continue. In addition, the gastrointestinal lumen will no longer be regarded as a boundary to therapeutic endoscopy. Examples of expected innovations include the following:

- *The continued expansion of endoscopic procedures beyond the walls of the GI tract*, providing a less invasive approach to treatment of diseases traditionally managed surgically.
- “Second-space” and “third-space” endoscopy techniques are likely to be refined further, and bariatric endoscopy techniques are likely to become more widely performed.
- Further development of computer-aided diagnosis (or “artificial intelligence”) for colonoscopy with automated polyp detection and characterization.

Esophageal Disorders

Harlan Rich, Zilla Hussain, Neal D. Dharmadhikari

INTRODUCTION

The esophagus is a muscular tube that serves as conduit for the passage of solids and liquids into the stomach. It averages 23 to 25 cm in length and descends from the pharynx, at the lower border of the cricoid cartilage, to the stomach, at the cardiac orifice. Its descent is generally vertical and follows anterior to the vertebral column through the diaphragm and into the abdomen.

The esophagus is made up of four strata: mucosa, submucosa, muscularis externa, and adventitia. The stratified squamous nonkeratinized mucosa also contains the lamina propria and smooth muscle muscularis mucosae. Esophageal cardiac glands, in the lamina propria, produce mucous secretions that coat the lining of the esophagus. The submucosal layer contains esophageal glands, mucous and serous cells, and the Meissner, or submucosal, plexus. The muscularis externa is composed of an inner circular and outer longitudinal muscle layer. The upper third is mostly skeletal muscle innervated by the vagus nerve, while the lowest third is predominantly smooth muscle innervated by the enteric nervous system. The middle third is a mix of both skeletal and smooth muscle. The Auerbach, or myenteric, plexus is located between the inner circular and outer longitudinal layers. The outermost layer of the esophagus is the adventitia. A serosal layer covers the short segment of the abdominal esophagus across the diaphragm to the gastric cardia.

Sphincters are found at each end of the esophagus: the upper esophageal sphincter (UES) and the lower esophageal sphincter (LES). The UES is composed of three striated skeletal muscles: cricopharyngeus, thyropharyngeus, and cranial cervical esophagus. It maintains a degree of muscular activity at rest and relaxes during swallowing, vomiting, or belching. Opening of the UES occurs both via relaxation of these muscles and the pulling open of the sphincter via the superior and inferior hyoid and posterior pharyngeal muscles. The LES is a zone of circular, smooth muscle that maintains tonic contraction at rest and relaxes during swallowing, vomiting, and belching. The LES is supported by a functional external sphincter composed of the right crus of the diaphragm, which surrounds the esophagus as it enters the abdomen. Together, the LES and the functional external sphincter contribute to a high-pressure zone, preventing the regurgitation of gastric contents. Relaxation of the LES occurs when vagal efferent impulses activate myenteric neurons that release nonadrenergic, noncholinergic neurotransmitters, predominantly nitric oxide, and vasoactive intestinal polypeptide.

Swallowing requires the synchronization of voluntary and involuntary processes. Food mixes with saliva in the mouth and then is pushed back into the oral pharynx by the tongue. Once food enters the oral pharynx the glottis closes, protecting the airway. The bolus is then pushed to the esophagus where the UES is located. The UES

relaxes, allowing food to enter the esophagus and then immediately closes, preventing the regurgitation of food. The bolus spends 8 to 13 seconds in the esophagus. Primary peristaltic waves, activated by central sequential firing mechanisms in the striated esophagus, and a latency gradient through the smooth muscle esophagus activated by vagal impulses, allow the bolus to travel through the esophagus. The pressure created by these waves ranges from 40 to 180 mm Hg. The pressure varies by the bolus's location in the esophagus, consistency, volume, and temperature. The LES relaxes and peristaltic waves push the bolus into the stomach.

SYMPTOMS OF ESOPHAGEAL DISEASE

Heartburn and regurgitation are two of the most common symptoms of esophageal disease and are defining features of gastroesophageal reflux disease (GERD). Heartburn is described as a burning sensation in the chest but can also be described as chest pain. Regurgitation is the sensation of food or liquid moving up and down the esophagus or as a sour taste in the mouth.

Dysphagia describes difficulty swallowing and can be characterized by trouble initiating a swallow or a bolus of material feeling stuck in the neck or chest while swallowing. The etiology of dysphagia can be mechanical or functional in nature. Odynophagia is pain with swallowing. Globus sensation is the feeling of something "stuck" or "tightness" in the esophagus. This symptom may be unrelated to swallowing, separating it from dysphagia.

Chest pain can be a manifestation of esophageal disease, but cardiac disease should always be considered. Chest pain related to cardiac disease, or angina, can have characteristics similar to those associated with esophageal-related chest pain. A careful history and physical examination with appropriate diagnostic studies can help distinguish the etiology of chest pain.

DIAGNOSTIC STUDIES OF THE ESOPHAGUS

Radiology

Barium esophagography, a video fluoroscopic procedure, can be used to assess dysphagia and can diagnose structural abnormalities in the esophagus or altered motility. When performed with a speech therapist (a modified barium swallow), it can be used to study the swallowing mechanism in more detail. A timed barium esophagogram can be used to assess esophageal emptying.

Computed tomography (CT) and magnetic resonance imaging (MRI) can often be used to define anatomy further and assess disease outside the lumen and beyond the mucosa. Positron emission tomography (PET) can be used to evaluate the esophagus but is typically used to evaluate malignant pathology when there is concern for metastasis.

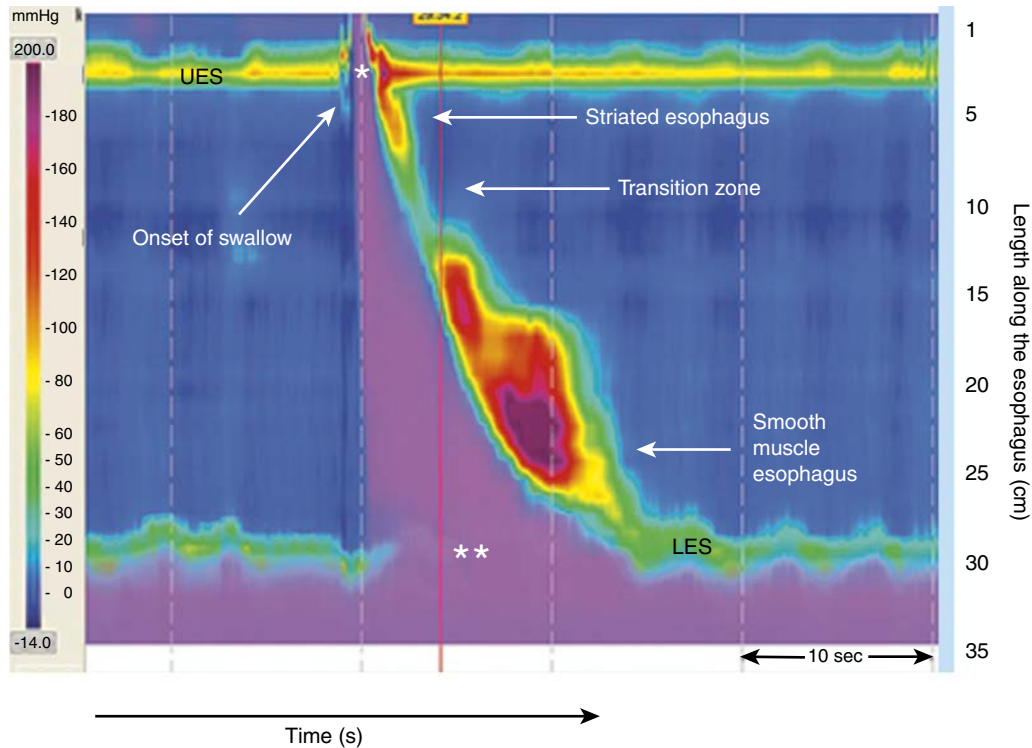

Fig. 36.1 High-resolution manometry (HRM) of normal esophageal peristalsis. HRM catheter consisting of 36 pressure sensors is inserted via the nares into the stomach to provide a complete physiologic pressure map of the hypopharynx, upper esophageal sphincter (UES), esophagus, lower esophageal sphincter (LES) and stomach. The Y-axis represents with sensor location; whereas the X-axis represents time. The color variation represents the different pressures along the length of the catheter at a given time and location. The resting UES and LES are shown as horizontal color bands. The relaxations of the UES (*) and LES (**) are shown as decreases in pressures (corresponding to approximately 20 mm Hg on color-pressure bar). The LES opens shortly after the UES relaxes with the onset of a wet swallow. Esophageal primary peristalsis is shown as a diagonal color band running from the UES to the LES. The onset of the swallow is seen on HRM as the high pressure contraction in the proximal, striated esophagus, followed by a lower pressure segment corresponding to the transition zone and a subsequent increase in pressure in the smooth muscle esophagus.

Endoscopy and Endoscopic Imaging

Esophagogastroduodenoscopy (EGD, upper endoscopy) allows for a direct visualization of the mucosal surface of the esophagus, stomach, and duodenum. An endoscope is a flexible fiberoptic tube with a camera that can be used for the diagnosis, screening, monitoring, and treatment of various pathologies. Endoscopes have additional channels through which a variety of endoscopic tools (i.e., forceps, dilators, injection needles, hemostatic tools) can be used to sample or treat the visualized area.

Endoscopic ultrasound (EUS) incorporates an ultrasound probe on the end of an endoscope. This ultrasound allows for imaging and biopsy across the wall of the esophagus and other nearby anatomical structures.

Manometry

Esophageal manometry is a physiologic evaluation of esophageal contractile function. High-resolution manometry is the diagnostic gold standard for the diagnosis of motility disorders. It utilizes a catheter lined with 20 to 36 pressure sensors at 1-cm intervals that is inserted via the nasal passage to the gastric body. The sensors record and compute the frequency and pressures of esophageal peristaltic waves and LES and UES function. The high-resolution manometry pressures are used to generate esophageal pressure topographies represented by color-coded, pressure-space-time plots. These objective metrics are applied to the Chicago Classification to diagnose esophageal motility disorders (Fig. 36.1).

Esophageal pH Monitoring

Esophageal wireless pH monitoring and catheter-based reflux testing are diagnostic tools used to study reflux disease. The wireless pH capsule is typically positioned 5 cm above the LES. The capsule measures the pH at the site for 24 to 48 hours in the ambulatory setting. The data are then reported as a percentage of the day the pH remains below 4. A combined impedance-pH probe measures acid and non-acid reflux as well as the direction of transit of a food or fluid bolus.

STRUCTURAL DISORDERS

Cricopharyngeal Bars

A cricopharyngeal bar is a radiographic finding consisting of a prominent posterior indentation of the esophagus at the level of the cricopharynx that is often asymptomatic but can contribute to dysphagia. The prominence is thought to be due to muscle spasm or impairment of muscle compliance at the UES. Cricopharyngeal bars can be managed via surgical and nonsurgical interventions. Nonsurgical options include dilation at the site or injection of botulinum toxin. Surgical management technique occurs via cricopharyngeal myotomy.

Diverticula

Diverticula of the esophagus are outpouchings contained within layers of the esophageal wall. True diverticula involve all layers to the esophageal wall, whereas false diverticula are limited to the submucosa and mucosa.

Fig. 36.2 Esophageal diverticula.

All diverticula are further categorized by their location. They are classified as proximal or pharyngoesophageal (Zenker’s and Killian-Jamieson) diverticula, mid-esophageal or traction or parabronchial diverticula,

and epiphrenic diverticula. The prevalence of Zenker’s diverticula (ZD) ranges from 0.01% to 0.11%, and the majority of patients are diagnosed in their sixth to eighth decades of life. The prevalence of the other types of

diverticula are unknown but are far less common than Zenker's diverticula (Fig. 36.2).

ZD forms in the Killian triangle, an area of sparse musculature bordered by the cricopharyngeus and thyropharyngeus muscles in the posterior pharyngeal wall. As a result of diminished compliance of the cricopharyngeus muscle and the UES, the hypopharynx is exposed to increased intra-bolus pressures while swallowing, causing the ZD to form. ZD are false diverticula. Parabronchial diverticula are likely associated with mediastinal fibrosis, which is often due to inflammation of the mediastinum caused by other pathology (i.e., fungal infections, tuberculosis). Traction on the esophageal wall causes these diverticula to form. Long-standing distal esophageal obstruction can lead to the formation of pulsion diverticula either through anatomic abnormalities or motility disorders. Diffuse esophageal spasm has been associated with parabronchial diverticula, whereas achalasia has been associated with epiphrenic diverticula. The latter two are true diverticula.

Patients with ZD often present with oropharyngeal dysphagia but can also suffer from complete esophageal obstruction. Classically, these patients will complain of dysphagia with regurgitation and halitosis. Parabronchial and epiphrenic diverticula are most often asymptomatic and diagnosed as incidental findings on imaging. The complications of these diverticula are typically related to their underlying disorders (i.e., motility disorders).

Diverticula are diagnosed using barium swallow, endoscopy, and computed tomography. Manometry can also be used to diagnose underlying motility issues that contribute to diverticula formation.

Symptomatic ZD should be treated. Smaller ZD can be treated with cricopharyngeal myotomy alone. Larger ZD may need additional interventions, including diverticulum suspension or diverticulectomy. Endoscopic cricopharyngeal myotomy is an alternative to surgical approaches. Parabronchial and epiphrenic diverticula are most successfully addressed by treating the underlying disorder (i.e., motility disorders or strictures). They can also involve extended myotomy and diverticulectomy.

Rings and Webs

Esophageal rings are areas of narrowing in the esophageal lumen. An "A" ring is a muscular ring found in the upper part of the phrenic ampulla at the area of highest pressure in the LES and is defined by smooth muscle hypertrophy with normal surface epithelium. A "B" (or Schatzki) ring is a mucosal ring at the squamocolumnar junction with squamous epithelium above the ring and columnar epithelium below. This ring can lead to luminal narrowing and dysphagia. Their etiology and pathophysiology are poorly understood.

Patients with Schatzki ring often complain of dysphagia to solid food that is chronic and intermittent. The diameter of the ring is inversely associated with the incidence and symptoms. A barium swallow with a full column technique is the best modality to diagnose Schatzki rings. An endoscope can visualize Schatzki rings but can miss rings with larger diameters.

The treatment of all esophageal rings is mechanical dilation. This can be performed with Savary dilators or radial expanding balloon dilators. There is a high rate of recurrence after treatment and a scant 11% of patients are symptom free after 3 years. However, repeated dilations can be performed without increasing the complication rate.

An esophageal web is a thin, membranous tissue covered with squamous epithelium that reduces the size of the esophageal lumen. The webs can be congenital or acquired. Congenital webs are rare. Acquired esophageal webs are associated with Plummer-Vinson syndrome (iron deficiency anemia, glossitis, koilonychia, and esophageal/pharyngeal carcinoma).

Patients with esophageal webs will present with dysphagia. The webs are diagnosed by barium swallow or endoscopy. Lifestyle

modifications are encouraged to reduced symptoms, but some patients must be treated with mechanical dilation similar to the treatment for Schatzki rings.

Malignancy

Esophageal cancer is the seventh most common cancer and the sixth leading cause of cancer-related mortality worldwide. The five-year survival rate after diagnosis is 15% to 20%. The incidence of esophageal cancer varies by region. In developed countries, the incidence of squamous cell cancer (SCC) has fallen and adenocarcinoma has become the leading type. However, SCC remains more prevalent worldwide. The major risk factors for developing SCC are alcohol and tobacco use. There are other carcinogens which, similar to alcohol and tobacco, are thought to lead to inflammation and dysplasia. Tobacco is a moderate risk factor for the adenocarcinoma. Obesity and body mass index remain the strongest risk factors for the development of esophageal adenocarcinoma. Obesity can predispose patients to GERD and Barrett esophagus, which also cause adenocarcinoma. The progression of gastrointestinal reflux disease to adenocarcinoma is described in a subsequent section (Fig. 36.3).

With esophageal cancer, patients often complain of progressive dysphagia and weight loss. Depending on the progression of symptoms, they may also present with anemia or other symptoms. The treatment of esophageal cancer depends on progression and staging but can involve chemotherapy, radiation, surgery, and/or palliative measures.

Hiatal Hernias

A hiatal hernia results in abdominal contents, such as the stomach, becoming displaced above the diaphragm. Hiatal hernias are subcategorized into four types: type I (sliding hiatal hernia), type II (paraesophageal hernia; the proximal stomach protrudes up through the diaphragm along the distal esophagus), type III (a combination of type I and type II), and type IV (herniation of other abdominal organs). Sliding hiatal hernias are the most common variety. Types II through IV are considered variations of paraesophageal hernias (Fig. 36.4).

Sliding hernias are a result of laxity in the phrenoesophageal membrane, a membrane that anchors the esophagus to the diaphragm. This results in a widening of the hiatal tunnel, allowing the gastric cardia to herniate into the thorax. Increasing age and obesity often contribute to the decreasing elasticity of the phrenoesophageal membrane. Paraesophageal hernias are caused by defects in this membrane.

Hernias may be diagnosed by plain film, barium swallow studies, cross-sectional imaging, and endoscopy. Asymptomatic hiatal hernias rarely need to be treated. If a type I hiatal hernia is associated with GERD, then medical or surgical treatment should be considered. The course of treatment would focus on treating the symptoms of GERD. Paraesophageal hernias (type II-IV) are prone to complications including volvulus, obstruction, incarceration, and perforation and should be treated expediently because continued enlargement will lead to worsening symptoms and complications.

GASTROESOPHAGEAL REFLUX DISEASE AND SEQUELAE

A consensus (the Montreal consensus, specifically) amongst a panel of world experts defined GERD as "a condition which develops when the reflux of stomach contents causes troublesome symptoms and/or complications." This definition includes symptomatic syndromes and syndromes with esophageal injury but does not include functional heartburn.

Fig. 36.3 Histologic progression of Barrett esophagus with no dysplasia (A) to low-grade (B) dysplasia, high-grade dysplasia (C), and esophageal adenocarcinoma (D).

Pathophysiology and Symptoms

The pathophysiology of GERD is determined by numerous factors including gastric acid–esophageal mucosa interaction, incompetence of the gastroesophageal junction, decrease in esophageal mucosal defenses, and altered sensory mechanisms that interpret the symptoms.

Numerous modalities can be used to help diagnose and manage GERD, but often history is enough to diagnose and begin treatment. The symptoms that are characteristic of GERD include heartburn and regurgitation. Chest pain can also be a presenting symptom but should be distinguished from cardiac chest pain. Patients can also present with less common, atypical symptoms such as dysphagia, dyspepsia, epigastric pain, bloating, nausea, and belching.

Diagnosis

The diagnosis of GERD is established using history of symptoms, objective testing (endoscopy and esophageal pH monitoring), and patient responsiveness to therapy. A proton pump inhibitor (PPI) trial is a method that may be used to diagnose GERD in patients with typical symptoms without concerning features that may include dysphagia, odynophagia, weight loss, anemia, nausea, or vomiting. A lack of response to PPIs does not exclude the diagnosis of GERD, and atypical symptoms are not as reliable at predicting response. Therefore, objective testing with endoscopy or esophageal pH monitoring should be considered in patients who do not respond to PPIs.

Endoscopy provides direct visualization of the esophageal lumen and evaluation of the esophageal mucosa in patients with suspected GERD. It can demonstrate objective findings suggestive of GERD such as erosive esophagitis, strictures, and Barrett esophagus. Not all symptomatic patients will have evidence of erosions or mucosal damage, which can limit the diagnostic specificity of endoscopy. Endoscopy allows for biopsy of the mucosa, which is helpful in screening for Barrett esophagus, but can also aid in establishing another diagnosis. Eosinophilic esophagitis may have a similar presentation and biopsy can be used to differentiate between GERD without erosions and eosinophilic esophagitis. Biopsy is not recommended to diagnose GERD in patients with heartburn and normal endoscopy.

Esophageal pH monitoring with or without impedance may objectively demonstrate the presence of abnormal esophageal acid exposure, non-acid reflux, reflux frequency, and symptoms associated with reflux.

Management

Lifestyle modifications are a part of the initial therapy for GERD. Patients are counseled on behaviors that may improve symptoms and recommendation of avoidance of foods that trigger symptoms. Weight loss is advised for overweight and obese patients. Weight gain, even in patients with normal BMI, can provoke new GERD symptoms. Other behavior modifications include tobacco cessation, raising the head of the bed, and avoiding recumbent position for at least 2 hours after a meal. The common foods that can trigger heartburn and regurgitation include coffee, alcohol, chocolate, fatty foods, citrus, and spicy foods. It is important that all lifestyle modifications be tailored to each patient's symptoms and disease course.

When lifestyle modifications fail, medical interventions should be attempted. Medications that can treat GERD include antacids, histamine-receptor antagonists (H₂ blockers), and PPIs. Patients often utilize over-the-counter antacids to provide symptom relief of GERD. These antacids work to neutralize gastric hydrochloric acid and inhibit pepsin. With the advent of H₂ blockers and PPIs, antacid use has declined, but a smaller cohort of patients will continue using them for heartburn. H₂ blockers reversibly bind to histamine H₂ receptors, preventing histamine released during a meal from binding to receptors on ECL and parietal cells. PPIs are superior to H₂ blockers because they essentially irreversibly block the hydrogen-potassium ATPase that secretes hydrochloric acid from the gastric parietal cells. They have been shown to contribute to esophageal healing and have decreased relapse rates when compared to H₂ blockers. In addition, PPIs have also been shown to be superior for heartburn relief.

Surgical options can be considered for GERD or esophagitis refractory to medical therapy, when patients suffer side effects of medical therapy, exhibit noncompliance, or need correction of a concomitant large hiatal hernia. The surgical options for treatment include laparoscopic fundoplication or bariatric surgery. Laparoscopic fundoplication involves “wrapping” the fundus of the stomach around the end of the esophagus to help repair and provide support to the LES. Bariatric surgery with gastric bypass in obese patients with GERD can also be used to treat GERD.

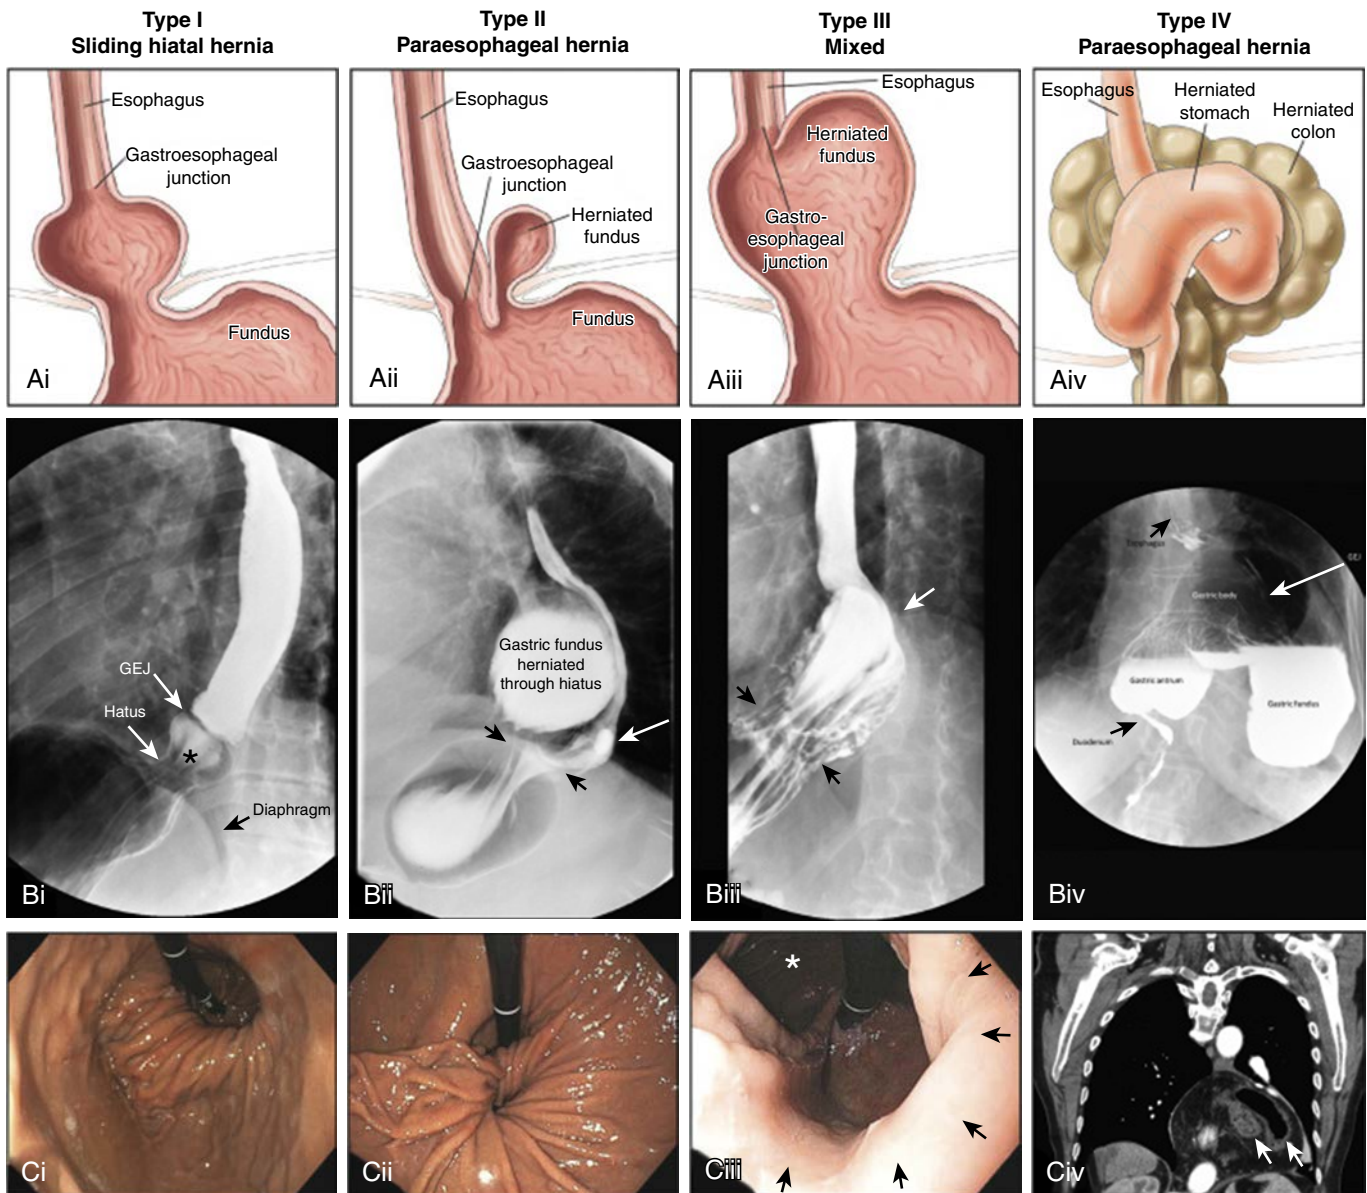

Fig. 36.4 Anatomic drawings (row A), barium contrast radiography (row B), and endoscopic (i-iii) and computed tomographic (iv) views (row C) of Type I or sliding hiatal hernia (column 1), Type II PEH (column 2), Type III PEH (column 3), and Type IV PEH (column 4). Pane Bi: *, sliding hiatal hernia. Pane Bii: True paraesophageal hernia adjacent to GEJ. Separation between GEJ and diaphragm noted, consistent with a small adjacent hiatal hernia. *White arrow*: Barium tablet present. *Black arrows*: Widened hiatus. Pane Biii: *White arrow*: Gastroesophageal junction. *Black arrows*: Widened diaphragmatic hiatus. Pane Biv: Herniated, intrathoracic stomach with herniation of duodenum. This stomach is flipped in an organoaxial rotation. Pane Ci: Sliding hiatal hernia. Pane Cii: Separate PEH present, herniated through laxity in phrenoesophageal membrane. Lax diaphragmatic hiatus also present. Pane Ciii: Image taken from the diaphragmatic hiatus (*black arrows*). Herniation of GEJ noted with large adjacent fundus/PEH (*white asterisk*). Pane Civ: Coronal computed tomography (CT) image of an intrathoracic stomach with herniated loops of colon (*white arrows*). GEJ, Gastroesophageal junction; PEH, paraesophageal hernia.

Extraesophageal Manifestations of GERD

GERD contributes to several extraesophageal manifestations including respiratory, laryngopharyngeal, and dental symptoms. Respiratory symptoms include pulmonary disease (asthma, idiopathic pulmonary fibrosis, bronchitis, etc.), cough, wheezing, and shortness of breath. Laryngeal symptoms present as hoarseness, throat pain, globus, choking, postnasal drip, laryngeal and tracheal stenosis, and laryngospasm. Dental erosions can also be a result of GERD.

Non-GERD causes of extraesophageal manifestations should be considered prior to associating the symptoms with GERD. Diagnostic tools are

unable to provide reliable evidence of causality between GERD and extraesophageal symptoms. In addition, PPIs have not shown a clear therapeutic benefit in the treatment of these symptoms. The diagnosis of GERD, as described previously, can help with the association, but the presence or absence of GERD cannot reliably establish it as cause of extraesophageal symptoms. Clinicians often rely on symptom association analysis to find a temporal association between reflux symptoms and other symptoms.

Acid suppression with a PPI is still used to treat extraesophageal symptoms when typical GERD symptoms are present. When typical GERD symptoms are not present, reflux monitoring is considered prior to

starting a PPI trial. Surgery is not generally considered in PPI nonresponders because the available data show no benefit in patients who have surgery.

Barrett Esophagus

Barrett esophagus (BE) is defined as the presence of at least 1 cm of metaplastic columnar epithelium in the tubular esophagus and can be described as either long-segment BE (>3 cm) or short-segment BE (<3 cm). It can further be described using the Prague classification system, which uses the circumferential extent of BE and the extent of the longest visualized segment.

BE can develop from long-standing GERD. The diagnosis of GERD is associated with a 10% to 15% risk of developing Barrett esophagus. The risk factors for developing BE are chronic GERD (>5 years), age greater than 50, male gender, tobacco use, central obesity, and Caucasian race. BE can progress to dysplasia and esophageal adenocarcinoma. The risk factors for progression include advancing age, central obesity, tobacco use, and lack of NSAID, PPI, or statin use. The majority (>90%) of patients diagnosed with BE do not die of esophageal adenocarcinoma. The risk of progression from BE to cancer is determined by the amount of dysplasia (nondysplastic is 0.2% to 0.5% risk per year, low-grade dysplasia is 0.7% risk per year, high-grade dysplasia is 7% per year).

Screening for BE should be considered in men with chronic GERD (>5 years) and/or weekly symptoms of reflux who have two additional risk factors: age greater than 50 years, Caucasian, central obesity, history of smoking, or first-degree relative with BE or adenocarcinoma. Although the progression of BE to adenocarcinoma is rare in females, they should still be screened based on the presence of the aforementioned risk factors. The endoscopist should take at least eight random biopsies to maximize yield on histology to look for intestinal metaplasia. The pathology from the biopsies is confirmed by two pathologists making the diagnosis. Alternative screening modalities include balloon cytology.

BE is treated with chemoprevention, endoscopic therapy, or surgery. All patients with BE should receive once-daily PPI for chemoprevention. Endoscopic treatment is not required in the absence of dysplasia. At initial diagnosis, if nodularity is observed in the suspected segment, the patient should undergo endoscopic mucosal resection as a diagnostic and therapeutic procedure. Endoscopic ablative therapy is used in patients with low-grade and high-grade dysplasia. Ablative techniques include radiofrequency ablation and the lesser used cryotherapy. Recurrence rates appear to be similar across different ablative modalities. Endoscopic ultrasound can also be used to evaluate the depth of invasion of nodules and adenocarcinoma, guiding definitive therapy. Antireflux surgery can be used in patients with poor control of reflux symptoms on PPI.

Endoscopic surveillance is continued to monitor for stability or progression of BE. The surveillance intervals are determined by the level of dysplasia from 3 to 5 years for patients without dysplasia, to as often as every 3 months for patients with high-grade dysplasia treated endoscopically. Surveillance endoscopy will collect four-quadrant biopsies at 2-cm intervals in patients without dysplasia and 1-cm interval in patients with prior dysplasia. Any visible abnormalities are also sampled. Virtual or chemical chromoendoscopy may enhance the yield of surveillance.

MOTILITY DISORDERS

Achalasia

Achalasia is a primary esophageal motor disorder defined as aperistalsis in the esophageal body and relaxation failure of the LES resulting in increased tone in the LES. The pathophysiology of achalasia is related to the loss of inhibitory innervation in the esophagus. Primary achalasia is caused by the failure of distal inhibitory neurons (ganglion cells) in the esophageal myenteric plexus. Denervation can also occur within the extraesophageal vagus nerve or dorsal motor nucleus of the vagus. Cholinergic innervation has also been found to remain intact and

Fig. 36.5 Barium contrast radiography demonstrating narrowing at the esophagogastric junction with a bird-beak appearance and a dilated distal esophagus with retained contrast and an air-fluid level.

could possibly contribute to the increase in LES pressure. The denervation is thought to be an autoimmune process with increasing evidence, suggesting that genetic susceptibility and latent human herpes simplex virus 1 may also play a role. This is considered primary achalasia and is idiopathic by definition.

Dysphagia to solids and liquids is the classic presentation, but patients may also suffer from regurgitation, heartburn, and chest pain. Initial work-up of achalasia includes a barium swallow and/or endoscopy. A barium swallow can show esophageal dilation with a bird-beak narrowing around the gastroesophageal junction (Fig. 36.5). An endoscopy allows observation of esophageal dilation, a high-pressure LES, and the possibility of retained food in the esophagus and helps to exclude causes of secondary achalasia. The “gold standard” for the diagnosis of achalasia is high-resolution esophageal manometry. Manometry can record aperistalsis in the distal esophagus and absent LES relaxation. High-resolution manometry has defined subsets of patients with achalasia, using the Chicago Classification, who have different responses to treatment and prognoses. Type I, or classic achalasia, shows aperistalsis, incomplete or absent LES relaxation, and high resting LES pressure. Type II shows panesophageal pressurization with swallows and type III shows spastic lumen obliterating contractions of the distal esophagus with 20% or more of swallows.

The goal of treating achalasia is to promote esophageal emptying and decrease LES pressure. The initial (and most effective) treatment options include pneumatic dilation or laparoscopic surgical (Heller) myotomy. Pneumatic dilation is an endoscopic approach used to treat achalasia, involving the use of balloons to dilate the LES, theoretically breaking the fibers within. The number and the degree of dilations are determined by progression of symptom relief. Surgical (Heller) myotomy can provide a permanent solution by cutting the LES, allowing for food and liquid to pass through freely. In patients who are poor candidates for definitive therapy, endoscopy can be used to inject botulinum toxin into the gastroesophageal junction, which inhibits acetylcholine release from nerves. Acetylcholine is responsible for increased LES tone, especially when there is denervation of the inhibitory nerves. Botulinum toxin will thereby reduce the tone of the LES. If botulinum toxin therapy fails, pharmacologic therapy with nitrates and calcium-channel blockers may be considered, but the effects do not provide long-term treatment. The

newest approach to treatment, POEM (Per Oral Endoscopic Myotomy), uses an endoscope to tunnel below the esophageal mucosa to perform a myotomy from within, without the need for surgical incisions.

Diffuse Esophageal Spasm

Diffuse esophageal spasm (DES) is defined by uncoordinated contractions in the esophagus. Esophageal manometry provides the most specific description of the spasms. Specifically, the Chicago Classification defines DES as 20% or greater premature contractions (<4.5 seconds) with normal LES relaxation. Patients often present with dysphagia and chest pain. Similar to achalasia, DES is likely related to a decrease in inhibitory innervation. This is often observed on barium swallow.

Pharmacologic therapy has been ineffective in reliably treating DES. Pneumatic dilation of the LES or the esophageal body may alleviate some of the symptoms, but botulinum toxin is used to a better effect.

VARIANT FORMS OF ESOPHAGITIS

Eosinophilic Esophagitis

Eosinophilic esophagitis (EoE) is (likely) an allergen-mediated eosinophilic-dominant inflammation of the esophageal mucosa and is diagnosed when esophageal biopsies in symptomatic patients show 15 or greater eosinophils per high-power microscopic field. When assessing for EoE, two to four esophageal biopsies should be taken from the proximal and distal esophagus. Endoscopy can visualize fixed esophageal rings in the lumen, which are characteristic, but not diagnostic, of EoE. These rings are often referred to as trachealization of the esophagus. Other features include white eosinophilic exudates, longitudinal furrows, edema, diffuse esophageal narrowing, strictures, and lacerations secondary to the endoscope.

When EoE is diagnosed, a PPI response should be tested. Following an 8-week PPI trial, a repeat endoscopy and biopsy should be performed. If symptoms and eosinophilia have resolved then PPI-responsive esophageal eosinophilia (PPI-REE) is diagnosed. PPI-REE may be associated with GERD. If symptoms and eosinophilia persist, then EoE is diagnosed.

The goal of treatment for EoE is improvement in symptoms and decrease in esophageal inflammation. The first-line pharmacologic therapy is 8 weeks of swallowed topical corticosteroids (fluticasone or budesonide). If symptoms do not improve or rapid improvement is needed, then systemic corticosteroids (i.e., prednisone) can be used. Conversely, a specific elimination diet can also be used as initial therapy prior to the administration of topical corticosteroids. When medical and dietary therapy fail, then esophageal dilation is considered in patients with strictures.

Pill-Induced Esophagitis

Pill-induced esophagitis results in direct esophageal mucosal injury due to a pill. Patients will complain of heartburn, chest pain, odynophagia, and dysphagia. Common medications that can cause this include: tetracycline, doxycycline, clindamycin, aspirin, nonsteroidal anti-inflammatory drugs (NSAIDs), bisphosphonates, potassium chloride, quinidine preparations, iron compounds, emepronium, alprenolol, and pinaverium.

Complications include stricture, esophageal hemorrhage, and perforation. Cessation of the offending agent is often enough to treat the condition with eventual mucosal healing.

ESOPHAGEAL INFECTIONS

Infections of the esophagus are rare in immunocompetent patients. Immunocompromised individuals are typically affected, including

patients on immunosuppressive medications, chemotherapy, and patients suffering from AIDS. In patients with AIDS, infectious esophagitis is more prevalent as the CD4 count declines, especially with counts below 100. The most common symptom of infectious esophagitis is odynophagia often associated with dysphagia, chest pain, and gastrointestinal bleeding. Coinfection is common and treatment is targeted by etiology. Maintenance suppressive therapy with antifungal or antiviral agents may need to be initiated in patients with AIDS.

The most common cause of infectious esophagitis is *Candida*. It typically presents with dysphagia and odynophagia, but oral thrush in patients has a high positive predictive value for esophageal candidiasis. On endoscopy, friable white patches overlying the mucosa are visualized and fungal hyphal forms are seen on histology. Patients are typically treated successfully with oral fluconazole whereas intravenous fluconazole or an echinocandin is used in patients unable to tolerate oral therapy.

Cytomegalovirus (CMV) esophagitis occurs in severely immunocompromised patients. These patients present almost identically to patients with candida esophagitis except without oropharyngeal thrush. Endoscopy reveals large (>10 cm), shallow ulcers in the middle to distal parts of the esophagus. The margins are distinct and the ulcers are often described as “punched-out.” Histopathologic examination of mucosal and submucosal biopsies from the ulcer edges and bases can accurately diagnose CMV esophagitis. Histology will reveal large endothelial cells or fibroblasts with large, dense inclusion bodies. CMV esophagitis is treated with intravenous ganciclovir, foscarnet (intravenous) or valganciclovir (intravenous or oral).

Another cause of infectious esophagitis is herpes simplex virus (HSV). HSV-1 is typically the offending strain, but HSV-2 can also be a cause. HSV esophagitis is often seen in immunosuppressed individuals but can affect healthy adults. The endoscopic appearance of HSV esophagitis is multiple, small, superficial ulcers in the distal esophagus. More advanced or aggressive infections can reveal large confluent ulcers, pseudomembranous or denuded epithelium. Viral cultures can grow HSV-1 and occasionally HSV-2. The quantitative polymerase chain reaction for HSV-1 has a high sensitivity when tested in biopsy samples. Histopathologic examination reveals large intranuclear Cowdry type-A inclusion bodies along with ballooning degeneration and multinucleated giant cells. HSV esophagitis is treated with acyclovir (oral or intravenous) or valacyclovir (oral).

ESOPHAGEAL TRAUMA AND EMERGENCIES

Perforation of the Esophagus

Perforation of the esophagus can be due to numerous etiologies. The most common cause is iatrogenic but can occur due to trauma, caustic injury, malignancy, or severe vomiting. Iatrogenic perforation is often related to instrumentation from endoscopy, nasogastric tube insertion, intubation, or dilation. Boerhaave syndrome describes the spontaneous rupture of the esophagus following severe vomiting.

The most common presenting symptom is pain, which can vary depending on location of the perforation. Patients may also present with symptoms of shock or systemic infection. A physical exam can reveal palpable crepitus in the neck or chest related to subcutaneous emphysema.

Esophageal perforation should be diagnosed and treated promptly. A chest radiograph can suggest perforation by revealing mediastinal air, pleural effusion, pneumothorax, and subdiaphragmatic air. The diagnosis can be confirmed with computed tomography, Gastrografin imaging or emergency endoscopy.

The treatment of esophageal perforation starts with adequate resuscitation and early antibiotics, if needed. The perforation can be

repaired surgically or by endoscope. Surgery is indicated in unstable patients or patients with abdominal esophageal perforations. An endoscope can be used to place stents or clips. Perforations can be treated conservatively as well with medical management. This includes no oral intake for at least 7 days, parenteral nutrition, empiric antibiotics (consider antifungals), and management of complications (i.e., drainage of abscesses).

Foreign Bodies and Food Impaction

Ingestion of foreign bodies can be accidental or intentional. Symptoms depends on the object's size, shape, consistency, and location, but some patients will remain asymptomatic. Food can also become lodged in the esophagus and present with similar symptoms to foreign bodies. Food impaction is normally the result of an underlying disease process including peptic stricture, Schatzki ring, EoE, or malignancy.

Foreign bodies and food can result in complete obstruction of the esophagus. Patients will present with inability to handle secretions and severe chest pain. If the obstruction does not resolve spontaneously, emergent endoscopy is often required to resolve the obstruction. Occasionally, glucagon can be administered intravenously when food impaction is suspected prior to endoscopic intervention. Glucagon relaxes the LES and esophageal smooth muscle allowing for spontaneous passage of the bolus.

Mallory-Weiss Tear

A Mallory-Weiss tear is a mucosal or submucosal tear near the gastroesophageal junction. It results from anything that may cause a rapid increase in intra-abdominal pressure and gastric herniation. It is most often described in the setting of retching or vomiting but can also occur as a result of increased strain or forceful coughing.

Patients present with hematemesis and/or melena. They will often report excessive retching or vomiting, but the tear can also occur without this history. Endoscopy is used to diagnose a tear and rule out other causes of an upper gastrointestinal bleed.

Supportive therapy involves treating the underlying disorder and reducing instances of vomiting and retching. A Mallory-Weiss tear can be massive but is rarely fatal. Endoscopic therapies for ongoing bleeding include use of epinephrine, which can be injected locally to reduce bleeding. Cauterization, clipping, and ligation can also be

used to control the site of bleeding. Patients with persistent bleeding may undergo angiographic intervention or, in rare instances, surgical intervention.

SYSTEMIC AND OTHER ILLNESSES

Scleroderma

Progressive systemic sclerosis can affect any part of the gastrointestinal tract, but more often involves the esophagus. The progressive loss of smooth muscle, collagen deposition, and fibrosis in the esophageal wall can cause reduced or absent peristalsis, GERD, and a patulous LES. Manometry is used to diagnose the esophageal disease, whereas endoscopy can be used to evaluate for complications.

Dermatologic Disorders

A wide variety of dermatologic disorders can affect the esophagus. These disorders include pemphigus vulgaris, bullous pemphigoid, erythema multiforme, Behçet's syndrome, lichen planus, dermatitis herpetiformis, and toxic epidermolysis necrosis/Stevens-Johnson syndrome. The treatment of the underlying disorder is most effective in treating the esophageal involvement and often involves glucocorticoids.

Diseases of the Stomach and Duodenum

Alma M. Guerrero Bready, Akwi W. Asombang, Steven F. Moss

INTRODUCTION

The process of digestion begins in the mouth, with mastication. The ingested food bolus is then propelled into the esophagus, passes through the lower esophageal sphincter (LES), and enters the stomach. The stomach can hold between 1.5 and 2 L of food, which allows for intermittent feeding. While in the stomach, food is further broken down through a series of chemical and mechanical reactions into smaller particles (chyme) that travel through the pyloric channel into the beginning of the small intestine, the duodenum. This chapter reviews the normal anatomy and physiology of the stomach and duodenum and discusses the most common disease processes affecting these two organs.

ANATOMY

Anatomy of the Stomach

The stomach is a hollow organ with a superior dome-like structure on the lateral aspect (the fundus) (Fig. 37.1). The outer edge along the dome and down to the end of the stomach is called the greater curvature. On the other side is the lesser curvature. The stomach is made up of four parts: the cardia, fundus, corpus, and the pylorus. The stomach is connected proximally to the distal esophagus by the LES, a circular smooth muscle structure under parasympathetic and sympathetic control. The LES acts as a valve to prevent gastric contents from traveling in a retrograde fashion into the esophagus, thus preventing gastroesophageal reflux. The most proximal region of the stomach is the cardia, which is the area between the LES and the fundus. Below the fundus is the gastric body (also known as the corpus), which has characteristic longitudinal folds or ridges (rugae). This gastric body is where food is mainly mixed and broken down. Below a prominent circular fold (the *angulus incisura*), is the antrum, which leads into the pyloric channel. The antrum holds food until it is ready to be released through the pylorus (a circular structure made up of smooth muscle) into the duodenum. A hiatal hernia occurs when part of the stomach is pushed upward through a weakness in the diaphragm into the chest.

The stomach is innervated and controlled by both the sympathetic nervous system, via the celiac plexus, and by the parasympathetic nervous system, which is supplied by the anterior and posterior trunks of the vagus nerve. The arterial supply for the stomach originates from the celiac trunk (Video 37.1).

Anatomy of the Duodenum

Immediately past the pylorus, the duodenum bends posteriorly to become a retroperitoneal structure and curves around the head of the pancreas in a C-shape and then re-emerges into the peritoneal

cavity to join the second portion of the small intestine, the jejunum (see Fig. 37.1). The duodenum can be divided into four parts: superior (first part, or bulb), descending (second part), horizontal (third part), and ascending (fourth part). Within the descending duodenum is the ampulla of Vater, where the biliary system and the pancreatic duct unite to drain their secretions into the duodenum via the major duodenal papilla.

Similar to the stomach and the rest of the digestive tract, the duodenum is innervated by both the parasympathetic and sympathetic nervous system. The blood supply to the first half of the duodenum is from projections of the celiac trunk and to the second half of the duodenum by the superior mesenteric artery. It is this transition point that demarcates the progression from foregut to midgut.

HISTOLOGY

Histology of the Stomach

The walls of the stomach and duodenum, like the rest of the digestive system, are composed of four layers: the mucosa, submucosa, muscularis externa, and serosa. In the stomach, the mucosa is formed by a layer of simple columnar epithelial cells that invaginate to create gastric pits. These extend into millions of gastric glands that secrete gastric acid and other products. The depth and function of the gastric pits and glands differ between the various regions of the stomach. Below the mucosa is the submucosa, which houses dense connective tissue and lymphocytes, plasma cells, arterioles, venules, lymphatics, and the submucosal plexus (Meissner plexus). Deeper to this layer is the muscularis externa, which provides the contractions needed for the stomach to churn chyme. This muscle layer contains the inner oblique, middle circular, and outer longitudinal smooth muscle layers. In addition, it contains the myenteric neural plexus (Auerbach plexus). The outermost layer of the stomach is a continuation of the visceral peritoneum called the serosa.

Histology of the Duodenum

The duodenal wall is also comprised of the mucosa, submucosa, muscularis externa, and serosa. However, in the case of the duodenum, the epithelial cells contain microvilli and are arranged such that the surface of the duodenum has projections of epithelial cells called villi that are flanked by intestinal glands, called crypts of Lieberkühn. Villi and microvilli serve to increase the absorptive surface of the duodenum. In addition to its primarily absorptive function, the submucosa of the duodenum contains Brunner glands, which secrete an acid-neutralizing solution that protects the rest of the digestive tract from the effects of the acidic gastric juices.

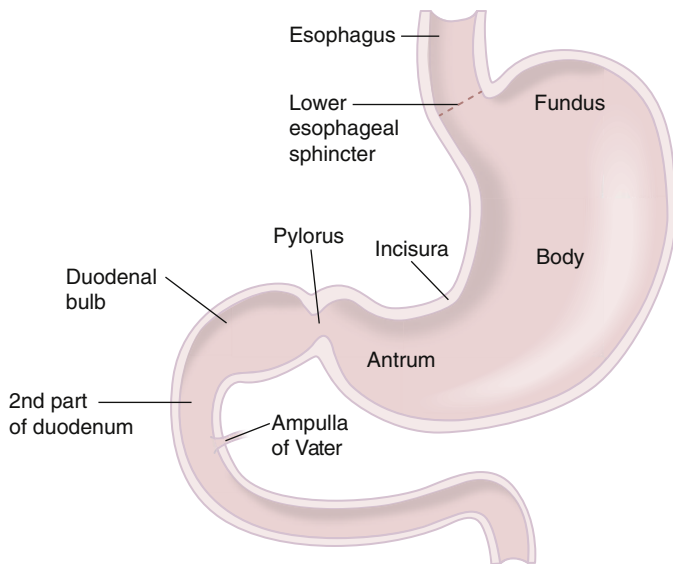

Fig. 37.1 Normal gastroduodenal anatomy.

GASTRODUODENAL SECRETIONS

Gastric secretions are responsible for breaking down food macromolecules into nutrients that can be absorbed in the gut. Gastric secretions are finely coordinated in a sophisticated system of feedback loops that ensure the balance between an acidic environment to break down food (created by parietal cells secreting hydrochloric acid) and a protective environment that defends the integrity of the gastric lumen. The latter is achieved by secretion of a bicarbonate-rich water/electrolyte/mucus solution from surface mucosal cells that buffers the gastric acid, to prevent autodigestion of the gastric epithelial cells and glands. Gastric secretions also function to protect the digestive tract from pathogenic microorganisms and aid in the absorption of calcium, iron, and vitamin B₁₂.

Parietal Cells

Acid Secretion

Gastric juice is primarily made up of hydrochloric acid (HCl), which is secreted by parietal cells at a concentration of 160 mmol/L. Parietal cells are mostly located in the gastric fundus and body, and they are stimulated to release HCl through three major pathways.

Histamine is released by specialized neuroendocrine cells called enterochromaffin-like (ECL) cells, and it is the major stimulant of H⁺ ion secretion. Histamine acts on H₂ receptors, to activate adenylate cyclase leading to increased level of intracellular cAMP. This results in activation of the proton pumps (H⁺, K⁺-ATPases), located on the apical surface of the cell, to promote the release of HCl into the gastric lumen (Fig. 37.2).

Acetylcholine (ACh), which is released from nerve endings following vagal stimulation, also promotes acid secretion by acting on the M₃ receptor on the basal aspect of parietal cells. This increases intracellular Ca²⁺, which also stimulates acid release into the stomach lumen via the apical proton pump (see Fig. 37.2).

Gastrin promotes acid release in two distinct ways (see Fig. 37.2). Gastrin is released from G cells in the antrum in response to food (especially protein) and also in response to the neural release of gastrin-related peptide, stimulated by gastric distension. Gastrin circulates in the bloodstream and may directly bind CCK₂/gastrin receptors in parietal cells, stimulating the release of H⁺. Of greater functional consequence during feeding, gastrin also stimulates acid secretion indirectly by binding similar CCK₂/gastrin receptors in ECL cells to

Fig. 37.2 Stimuli and mechanisms of gastric acid secretion by the parietal cell.

promote the release of histamine, which in turn acts on H₂ receptors on parietal cells, as previously mentioned.

Acid secretion is inhibited by somatostatin, which is released by D cells in the gastric antrum and fundus. D cells are stimulated to secrete somatostatin when there is a high concentration of H⁺ ions in the gastric lumen, and they are inhibited by ACh. Somatostatin inhibits acid secretion by decreasing cAMP levels in parietal cells and by inhibiting gastrin release from G cells (see Fig. 37.2).

Intrinsic Factor

In addition to being the key cell for acid secretion, parietal cells also secrete intrinsic factor, a glycoprotein that plays a critical role in vitamin B₁₂ absorption. Intrinsic factor is released from parietal cells under the same stimuli as H⁺ ions and binds vitamin B₁₂ in the alkaline environment of the duodenum. This binding ultimately enables vitamin B₁₂ absorption via specific receptors in the terminal ileum.

Chief Cells

Chief cells are zymogenic cells located deep in the gastric pits that secrete the pro-enzyme pepsinogen. Pepsinogen is converted into the active form, pepsin, under the acidic conditions created by gastric juices. Pepsin aids in digestion by breaking down proteins into peptides and amino acids, which, as mentioned above, aid in the release of gastrin as well as CCK.

Protective Factors

Gastroduodenal cells are at a high risk for damage given the very low pH of gastric juices, but these cells are well protected by several mechanisms that prevent autodigestion. The first line of defense is a mucosal barrier that consists of a thick, alkaline, aqueous mucus and HCO₃⁻-rich fluid that serves to lubricate the mucosa and neutralize acid at the epithelial level. This mucus is secreted in the stomach by mucus-producing cells located at the neck of gastric pits and in the

Fig. 37.3 Diverse pathologic and clinical consequences of *H. pylori*. Acid secretory status and ultimately clinical outcome are dependent upon the extent and degree of gastric inflammation in response to *H. pylori* infection. (From Amieva MR, El-Omar EM. Host-bacterial interactions in *Helicobacter pylori* infection. *Gastroenterology*. 2008;134:306-23.)

duodenum by mucus-producing goblet cells. Additionally, the lipid bilayer and tight junctions of the apical epithelial cell membranes serve to protect the mucosa from H^+ ions diffusing into the stomach wall, thus preserving mucosal integrity. A rich submucosal blood supply enables rapid drainage of H^+ ions from the mucosa and neutralizes H^+ ions intravascularly with HCO_3^- and proteins. Of note, prostaglandins promote blood flow, mucus secretion, and stimulation of HCO_3^- secretion, thus prostaglandins play an important role in gastric mucosal defense.

GASTRODUODENAL MOTILITY

The physiology of gastric motility and emptying can be understood via two major gastric geographic regions. As food enters the stomach, it increases gastric intraluminal pressure, causing the fundus and proximal body to relax reflexively (a process called accommodation) in order to allow space to store recently ingested food. The proximal stomach, however, also has characteristic tonic contractions, which aid in downstream gastric emptying.

Distally in the stomach, high-pressure peristaltic contractions by the lower gastric body and the antrum grind food and liquefy it into chyme. Once food particles reach a small enough size, they are propelled through the pylorus and into the duodenum.

Gastroduodenal motility is coordinated through intrinsic and extrinsic neural and hormonal signals. Neuronal control originates from the enteric nervous system and the sympathetic and parasympathetic nervous system via gastric mechanoreceptors, whereas certain hormones, such as gastrin and cholecystikinin, serve to relax the proximal stomach and create contractions in the distal stomach.

A series of negative feedback loops initiated by the presence of chyme within the duodenum inhibit further gastric emptying into the duodenum.

PEPTIC ULCER DISEASE

Definition and Epidemiology

A peptic ulcer is a defect or defects in the mucosal layer of the stomach or duodenum measuring at least 5 mm in diameter that penetrates into the muscularis mucosa. Lesions that are smaller than 5 mm or more superficial to the muscularis mucosa are classified as erosions. Men and women are at equal risk for developing peptic ulcer disease (PUD), and in the United States the lifetime risk of suffering from PUD is about 5% to 10%.

Gastric acid plays an important role in the digestion of food. PUD development is the result of an imbalance of gastric acid and other noxious substances in the gastric lumen relative to gastric protective functions. Some persons with PUD do secrete excessive amounts of gastric acid, particularly in duodenal ulcer disease, where depletion of antral somatostatin by *Helicobacter pylori* leads predictably to gastrin and acid hypersecretion (Fig. 37.3). However, most people with PUD have normal-to-low acid secretion, suggesting that a defect in mucosal defense is the major pathophysiologic culprit.

The two most common causes of PUD are *H. pylori* infection and the use of nonsteroidal anti-inflammatory drugs (NSAIDs). These two factors compromise mucosal defense mechanisms and predispose patients to peptic ulcers. They work synergistically to increase the risk of PUD when both factors are present. The risk of developing PUD increases with age, and, given that the prevalence of *H. pylori* has been decreasing in the general population and the use of NSAIDs has been increasing among older persons, the incidence of PUD has been decreasing in younger age groups (who tend to have low rates of NSAID use and *H. pylori* infection), and increasing in persons 65 years of age and older.

Other factors also modulate the risk of developing PUD. For example, smoking impairs ulcer healing, increases the risk of recurrence, and is associated with a higher PUD-related mortality. Similarly, there

is an association between PUD development and concomitant use of high-dose corticosteroids with NSAIDs, though there is no evidence that corticosteroids alone cause PUD.

Less common causes of PUD include hypersecretory states such as Zollinger-Ellison syndrome, Crohn's disease, vascular insufficiency, viral infection, radiation therapy, and cancer therapy. Development of PUD may also be influenced by other factors such as stress, personality type, alcohol consumption, occupation, and diet, though these play a relatively minor role compared with the effects of *H. pylori* infection and NSAID usage.

Additionally, certain chronic diseases are positively correlated with PUD. These include chronic obstructive pulmonary disease, systemic mastocytosis, cirrhosis, and uremia.

Given that PUD is a complex disease resulting from diverse pathophysiologic processes, this chapter focuses on the different etiologic agents and mechanisms individually, after considering the shared clinical features.

Clinical Presentation

The clinical presentation of PUD varies depending on the location and severity of the ulcer. Uncomplicated PUD typically presents as sharp, burning, nonradiating epigastric abdominal pain. In duodenal ulcers the pain tends to occur 2 to 3 hours after the ingestion of food or at night, when the stomach is empty. The opposite is often true of gastric ulcers. Patients with duodenal ulcers tend to present with weight gain because the ingestion of food relieves symptoms, whereas patients with gastric ulcers tend to be food averse and are more likely to present with weight loss. Older patients (>60 years) may report no pain at all at the time of presentation and may instead present with nonspecific complaints, such as confusion, restlessness, abdominal distention, and falls. In pregnant patients, symptoms are often fairly mild and might even improve as the pregnancy progresses. They may also present as abnormal patterns of nausea and vomiting of pregnancy, such as nocturnal vomiting or worsening of vomiting in the third trimester. Most patients with PUD present after several weeks or months of symptoms, unless there is a complication that necessitates urgent medical care.

Diagnosis

The diagnosis of PUD requires clinical suspicion in patients with the appropriate clinical presentations. Physical exam may determine focal epigastric tenderness.

Contrast imaging with a barium upper GI series used to be the primary method of diagnosis but is now supplanted by the widespread availability of upper gastrointestinal endoscopy, now considered the "gold standard" for diagnosis because it permits direct visualization of the ulcer or ulcers.

In addition to providing a diagnosis of PUD, endoscopy also enables tissue sampling by biopsy to evaluate for malignancy and *H. pylori* infection. Furthermore, endoscopy can be therapeutic, providing curative hemostasis in patients with acute life-threatening GI bleeding secondary to PUD.

Causes of Peptic Ulcer Disease

There are several conditions associated with the development of ulcer disease; these may be present in isolation or coexist with each other. Identifying specific causes is important to prevent recurrences.

Helicobacter pylori

H. pylori is a flagellated gram-negative bacillus that colonizes the gastric epithelium of half of the world's population. This bacterium is responsible for over 80% of duodenal ulcers and at least half of all cases of gastric ulcers. However, only a fraction of patients with *H. pylori* infection

Fig. 37.4 (A) Gastric biopsy (hematoxylin and eosin stain) showing gastric mucosa with intense inflammatory infiltrate including clusters of neutrophils infiltrating gastric pit and surface epithelium and lymphocytes and plasma cells in the lamina propria. At high power (B) *H. pylori* organisms can be seen faintly (arrows) adjacent to surface epithelial cells. (Courtesy of Murray Resnick, MD, PhD, Adjunct Professor of Pathology and Laboratory Medicine, Warren Alpert Medical School, Providence, RI.)

develop PUD. *H. pylori* infection is also a strong risk factor for PUD and malignancy (adenocarcinoma and mucosa-associated lymphoid tissue [MALT] lymphoma), as well as a cause of iron deficiency anemia and immune thrombocytopenic purpura (ITP). Infection is transmitted via the fecal-oral route and typically occurs during childhood. *H. pylori* infection tends to persist throughout the lifetime of the host if left untreated, despite a strong gastric inflammatory response and both cell-mediated and humoral immune system recognition.

Rates of *H. pylori* infection differ globally, with highest prevalence in the developing world. In the United States, infection rates are 10% to 15% in persons under 12 years old and 50% to 60% in persons older than 60 years. There is increased prevalence in persons with lower socioeconomic status, increased household crowding and, in the United States, higher prevalence in immigrants from the developing world.

H. pylori has several unique characteristics enabling gastric colonization. *H. pylori* can survive in gastric acid by producing urease, which catalyzes the conversion of urea (which is present in gastric juice) into ammonia, thus neutralizing *H. pylori*'s microenvironment. *H. pylori*'s flagella allow the organism to move fluidly through the stomach's viscous mucous layer toward gastric epithelial cells, where *H. pylori* uses a series of adhesins and receptors to attach and chronically infect its host. At the gastric epithelium, *H. pylori* induces an inflammatory response consisting of neutrophils, leukocytes, plasma cells, and macrophages. Neutrophilic infiltration of the gastric epithelium causing chronic gastritis is a hallmark of *H. pylori* infection, easily recognizable in gastric biopsies (Fig. 37.4).

Determinants of pathogenicity include the location of infection within the stomach, *H. pylori* genomic heterogeneity, and differences in host response. For example, infections that are most predominant in the antrum are more strongly associated with duodenal ulcers and increased acidity due to depletion of antral somatostatin-producing cells leading to uninhibited gastrin secretion. In contrast, *H. pylori* colonization of the corpus is correlated with gastric ulcers, gastric adenomas, and decreased acid production due to inflammation-mediated inhibition of parietal cell secretion and subsequent parietal cell

loss resulting in atrophic gastritis (see Fig. 37.3). This latter pattern of gastric inflammation is most common in persons residing in Southeast Asia, South America, and certain regions of Central, Eastern, and Southern Europe.

Additionally, *H. pylori*'s ability to produce lipopolysaccharide, leukocyte-activating factors, specific adhesins and vacuolating toxins, and a type IV bacterial secretory system contribute to its virulence. Strains with more of these pathogenic factors have been associated with more severe disease states. The most important of those pathogenic markers is cytotoxin-associated gene (*cagA*), a marker of the presence of the type IV secretory system, which is associated with acute gastritis, peptic ulcers, and gastric cancer. This multigene *H. pylori* system serves as a "molecular syringe" functioning to insert certain *H. pylori* proteins directly into host epithelial cells to activate pro-inflammatory and pro-oncogenic signaling pathways.

Diagnosis of *H. pylori*

In persons with clinical manifestations of *H. pylori*, eradication of the infection leads to improved outcomes. Because eradication of *H. pylori* from asymptomatic patients has not yet been shown to significantly prevent disease, *H. pylori* diagnostic testing is generally reserved for those patients with certain *H. pylori*-associated diseases or conditions such as PUD, uninvestigated dyspepsia without alarm symptoms, unexplained iron deficiency anemia, idiopathic thrombocytopenic purpura, early gastric cancer, and low-grade MALT lymphoma. It is remarkable that 80% of patients with low-grade MALT lymphoma and *H. pylori* infection will be cured by *H. pylori* eradication.

There are two categories of diagnostic tests for *H. pylori*: invasive and noninvasive. Noninvasive tests include urea breath test and stool antigen test, and the invasive tests are performed on endoscopic biopsies by histology, rapid urease test, and culture. The sensitivity of these tests, however, is decreased by proton pump inhibitors (PPIs), antibiotics, and bismuth compounds. Blood tests for the presence of *H. pylori* antibodies are relatively inaccurate and no longer recommended. They are particularly poor at monitoring the outcome of treatment because they may remain positive months to years after successful eradication.

For the urea breath test, patients must stop taking PPIs 2 weeks prior to the test. They ingest urea in which the carbon atoms are labeled with either radioactive carbon-14 or nonradioactive carbon-13. If present, *H. pylori* hydrolyzes the urea into ammonia. The presence of a labeled carbon atom in exhaled CO₂ indicates active *H. pylori* infection, and with a 95% specificity and sensitivity, it is the best choice for test of cure.

The stool antigen test detects fecal antigens by immunoassay. Proton pump inhibitors must be stopped 2 weeks prior to the test, but it is a good test for both detection and eradication, though their sensitivity and specificity are slightly lower than the urea breath test.

Invasive tests all require endoscopic biopsies. The *H. pylori* can be visualized histologically (especially if immunohistochemistry or other special stains are used) and the presence of chronic active gastritis, a hallmark of *H. pylori* infection, noted. Additionally, the biopsy can be tested with a rapid urease test, which detects pH changes in the urea-rich test matrix when the *H. pylori* derived urease converts urea to ammonia. Biopsies may also be used to culture *H. pylori*; however, this is a relatively costly and time-consuming process that is currently rarely used. The major advantage of this method is that it allows testing for antibiotic resistance of individual strains. This is an increasingly important focus of research and likely to be important in clinical practice, too, due to the emergence of multiply antibiotic-resistant *H. pylori*.

Given the increasing incidence of antibiotic resistance in *H. pylori*, a test of cure 4 weeks after the end of treatment and 2 weeks after

cessation of PPI treatment with a stool antigen or breath tests is recommended to confirm eradication of *H. pylori*.

Treatment of *H. pylori*

Treatment consists of combination therapy with antibiotics and acid inhibitors to guarantee adequate antibiotic coverage and to ensure penetration of the antibiotics into the gastric mucosa (Fig. 37.5). Additionally, the duration of therapy must be long enough to ensure eradication.

The increasing rates of antibiotic resistance, especially to clarithromycin and levofloxacin, make it imperative that providers ask patients about any prior macrolide antibiotic exposures, because prior exposure is associated with likely resistance. They have also spurred efforts to measure local antibiotic resistance rates.

The treatment options are bismuth quadruple therapy, which consists of a PPI, bismuth, tetracycline, and metronidazole for 14 days, and clarithromycin triple therapy, which consists of a PPI, clarithromycin, and amoxicillin or metronidazole for 14 days. Given the increasing rates of clarithromycin resistance, however, clarithromycin triple therapy is falling out of favor and should only be used in regions where it is known that *H. pylori* clarithromycin resistance rates are less than 15% and in patients with no history of macrolide exposure. Otherwise, bismuth quadruple therapy is the current therapy of choice with an expected cure rate of 80% to 90%.

If a patient fails initial treatment, then second-line therapy for that patient should avoid any antibiotics that were previously taken by the patient. If the patient failed first-line bismuth quadruple therapy, salvage therapy should contain either clarithromycin or levofloxacin depending on local antimicrobial resistance patterns and the patient's prior antibiotic exposures. If the patient failed clarithromycin triple therapy, bismuth quadruple therapy should be tried next. Other "salvage" options in cases of recurrent failure include regimens containing rifabutin and dual regimens of high-dose amoxicillin and high-dose PPIs.

H. pylori infection treatment is complete only after eradication has been confirmed with a test of cure, as outlined above.

NSAID-Induced PUD

NSAIDs are a class of drugs that are very useful in the treatment of pain, arthritis, and inflammatory diseases; however, their use can be limited by their side effect profile. Upper GI side effects are dose dependent and include PUD and GI bleeds. Side effects are also more common in patients with certain risk factors, such as age older than 65 years, past history of PUD, heart disease, and concomitant therapy with antiplatelet agents, corticosteroids, and anticoagulants. There is synergism between *H. pylori* infection and chronic NSAID use in terms of PUD risk.

NSAID-induced PUD accounts for approximately 100,000 hospital admissions annually, and about 25% of persons on chronic NSAID therapy will develop PUD. Chronic NSAID users who have the above-mentioned risk factors have a 9% risk of having a serious adverse event, while those who do not have risk factors only have a 0.4% risk. Thus, before starting a patient on chronic NSAIDs, it is important to evaluate their risk factors and consider alternative therapies, if appropriate.

Mechanism of Injury

Half of people taking NSAIDs will develop NSAID-induced gastropathy consisting of superficial mucosal hemorrhages and erosions. These asymptomatic erosions are usually found incidentally during upper endoscopies performed for other reasons and are mainly concentrated in the gastric antrum. Most cases of NSAID gastropathy will not progress to PUD.

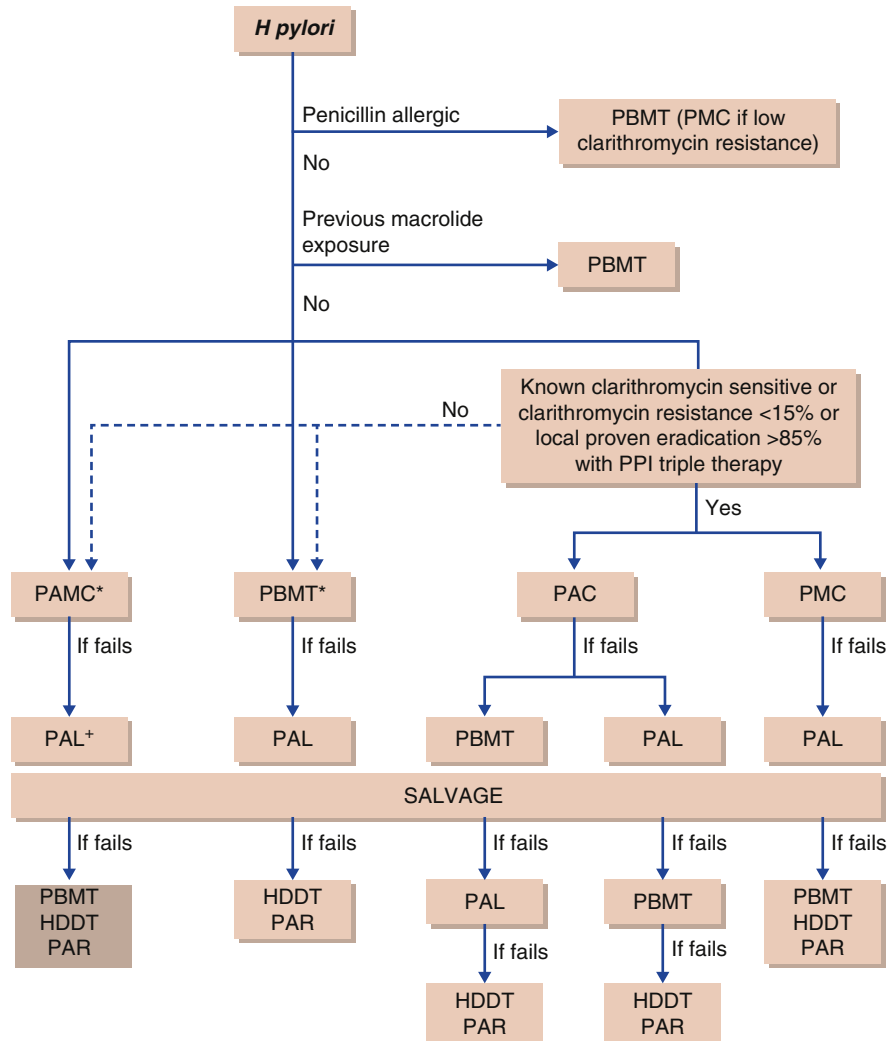

Fig. 37.5 *H. pylori* eradication therapy algorithm. PAC, Clarithromycin-based PPI triple therapy with amoxicillin; PAL, levofloxacin-based therapy; PAMC, concomitant non-bismuth quadruple therapy; PAR, rifabutin containing therapy; PBMT, PPI/bismuth/metronidazole/tetracycline quadruple therapy; PMC, clarithromycin-based PPI triple therapy with metronidazole; HDDT, high-dose dual therapy. (From Fallone CA, Moss SF, Malfertheiner P. Reconciliation of recent *Helicobacter pylori* treatment guidelines in a time of increasing resistance to antibiotics. *Gastroenterology* 2019;157:44-53.)

Once ingested and exposed to gastric acid, NSAIDs become weak acids and are able to cross the lipid bilayer membranes of gastric epithelial cells. There, they lose a hydrogen atom and become trapped intracellularly, disrupting normal cell function. This leads to decreased cellular integrity and increased cellular permeability leaving gastric epithelial cells vulnerable to topical injury, hemorrhages, erosions, and cell death.

Additionally, NSAIDs also inhibit the arachidonic acid pathway, which is crucial for the synthesis of prostaglandins (PGs) that protect gastric epithelial cells, and for mucosal integrity. The synthesis of PGs is catalyzed by cyclooxygenases (COX). The COX-1 isoform is constitutively expressed in the GI tract independent of external factors. In contrast, COX-2 is largely inducible, promoting PG synthesis under the influence of inflammatory mediators that are present in pro-inflammatory states. PGs play a very important role in gastric mucosal protection by increasing mucus and bicarbonate production, increasing blood flow to the gastric mucosa, and promoting epithelial cell repair and turnover after injury. Inhibition of PG synthesis by NSAIDs leaves epithelial cells vulnerable to unopposed injury from gastric acid and pepsin. Aspirin exposes patients to PUD in a similar way. It acetylates COX-1, thus irreversibly inhibiting it.

The more common NSAIDs, such as ibuprofen, naproxen, diclofenac, and aspirin, are nonselective COX inhibitors. Selective COX-2 inhibitors, such as celecoxib and valdecoxib, were developed with the aim of reducing gastric toxicity by primarily acting at sites of inflammation, thus leaving COX-1 function intact. Though the COX-2 inhibitors have fewer GI side effects, they have been associated with increased cardiovascular events such as myocardial infarctions and strokes. The COX-2 inhibitors that are still on the market now carry a black box warning.

Prevention and Therapy of NSAID-Induced PUD

Prevention and treatment of NSAID-induced PUD can be divided into three categories: primary prevention, treatment, and secondary prevention.

Prior to prescribing chronic NSAIDs, providers should assess a patient's risk for NSAID-induced adverse side effects, such as history of ulcers and GI bleeding, age older than 65 years, concomitant *H. pylori* infection, and co-prescription with antiplatelet agents, steroids, and anticoagulants.

Those patients with risk factors for developing NSAID-induced PUD should receive co-therapy with a gastroprotective agent. Currently there are several treatment options, including H₂ receptor antagonists (H₂RAs), synthetic prostaglandins, and PPIs. PPIs remain the co-treatment of choice because they are most efficacious in this regard and generally very well tolerated.

H₂RAs work by blocking histamine 2 receptors in parietal cells, thus decreasing acid production. However, in clinical trials their effects on NSAID ulcer prevention have been very limited.

Prostaglandins such as misoprostol work similarly to endogenous prostaglandins in the protection of the stomach and duodenal lining. Unfortunately, prostaglandins are poorly tolerated due to their side effect profile, which includes diarrhea and abdominal pain.

PPIs inhibit the H⁺/K⁺-ATPase in parietal cells, hence reducing acid secretion into the gastric lumen. Prescription of PPIs together with NSAIDs significantly reduces GI-related NSAID complications with a 10% to 15% absolute risk reduction in ulcer formation and ulcer-related bleeding in high-risk patients taking nonselective NSAIDs. It must be noted, though, that recent studies have shown that selective COX-2 inhibitors plus a PPI provide better GI protection compared to a nonselective NSAID plus PPI.

With the widespread overuse of chronic PPIs in recent years (principally for GERD and dyspepsia), several likely adverse side effects of PPIs have come to light. These include increased risk of micronutrient deficiencies such as hypomagnesemia, iron and vitamin B₁₂ deficiency, and GI-related infections, such as *Clostridioides difficile* infection (CDI) and small intestinal bacterial overgrowth (SIBO). Additionally, PPI use has been associated with increased incidence of osteoporosis and bone fractures and acute interstitial nephritis. More controversially, associations of chronic PPI usage with chronic kidney disease, cerebrovascular disease, upper GI cancers, and dementia have been reported in some studies, though almost entirely from observational cohorts. Better controlled prospective studies are needed to clarify any causal link between PPIs and these side effects. However, given these potential side effects, patients should be evaluated individually for PPI co-prescription with NSAIDs, and the lowest effective doses should be used when prescribing long-term in primary prophylaxis.

H. pylori infection in the setting of chronic NSAID has been shown to increase the risk of PUD, more specifically for duodenal ulceration. The risk for developing ulcers in *H. pylori* positive patients starting chronic NSAID therapy is higher during the first few months after starting therapy. Therefore, *H. pylori* testing, and treatment is recommended prior to starting chronic NSAID use.

Treatment of NSAID-related ulcers is more straightforward. First and foremost, the offending NSAID or aspirin should be discontinued if medically possible in order to allow endogenous protective prostaglandins to be formed. Subsequently, acid secretion should be suppressed with standard doses of PPIs (or H₂RAs or misoprostol). In patients who require NSAID therapy but have a history of PUD, risk factors should be assessed, and COX-2 inhibitors should be used preferentially, along with co-therapy with a PPI if there are no cardiovascular contraindications to COX-2 inhibitor therapy.

Patients with cardiovascular risk factors for whom aspirin is required for secondary prevention of myocardial infarction cannot stop aspirin therapy. In this case, cardiovascular protection outweighs the benefit of aspirin cessation for PUD treatment. These patients must be tested for *H. pylori*, if they have not been previously tested, and they should be treated if they test positive. Additionally, these patients must remain on PUD prophylaxis with either a PPI or misoprostol.

Zollinger-Ellison Syndrome

PUD generally occurs in patients with normal or near normal rates of acid secretion. However, a rare cause of PUD is the Zollinger-Ellison

syndrome (ZES), in which PUD is the direct result of severe acid hypersecretion due to gastrin-producing G-cell tumors, called gastrinomas. These tumors are generally located in the pancreas or the duodenum, and patients with ZES typically present with recurrent, multiple, refractory ulcers as well as PUD-related complications, esophagitis, and diarrhea. Individuals with ZES generally do not have concomitant *H. pylori* infection or use NSAIDs therapy. This condition will be discussed in further detail later in the chapter.

Stress-Induced Ulcers

Critically ill ICU patients are at increased risk of developing stress ulcers that lead to increased risk of clinically significant GI bleeding. The risk is higher in burn victims, those with significant injury, cranial trauma, shock, and mechanical ventilation. Endoscopically, stress-related mucosal damage is found in 60% to 100% of patients recently admitted to the ICU. Stress ulcers are typically multiple and shallow. They usually present with hematemesis or melena in the ICU patient.

ICU patients are predisposed to stress ulcers due to decreased splanchnic vascular perfusion and impaired microcirculation due to hypovolemia, shock, and low cardiac output leading to gut ischemia and injury. Additionally, they are often subject to pro-inflammatory states, associated with decreased innate mucosal defenses.

Prevention of stress ulcers with acid suppression through prophylactic treatment with PPIs or H₂RAs has been common practice for the past four decades. Recently, the side effect profile of these agents has been evaluated against the risk of stress ulcer bleeds. Serious side effects of PPIs and H₂RAs in the ICU setting include increased rate of nosocomial infections, such as ventilator-associated pneumonia and CDI. Consequently, stress ulcer prophylaxis should be reserved only for those patients at high risk for life-threatening GI bleeding such as patients with a history of GI bleeding within the past 12 months, greater than 48 hours of mechanical ventilation, spinal or traumatic brain injuries, and patients with coagulopathies.

Idiopathic Ulcers

Ulcers that appear to arise spontaneously with no known cause are called idiopathic ulcers. Idiopathic PUD (IPUD) prevalence varies by geographic location and has a prevalence of about 15% in developed countries as compared to around 80% in developing countries. With the advent of increased *H. pylori* treatment, the incidence of non-*H. pylori* idiopathic ulcers has increased dramatically, mainly in Asian countries. Idiopathic ulcers, similar to *H. pylori* ulcers, have a slightly higher likelihood of being located in the duodenum.

Diagnosis of idiopathic ulcers requires exclusion of all known causes of PUD such as missed *H. pylori* infection, surreptitious use of ulcerogenic medications, certain systemic diseases such as Crohn's disease, eosinophilic gastroenteritis, vasculitis, ZES, and other infections besides *H. pylori* that may lead to ulcers such as cytomegalovirus (CMV), herpes simplex virus (HSV), tuberculosis (TB), and syphilis.

IPUD carries an increased risk of ulcer recurrence when compared with other etiologies. One study concluded that recurrence rates for *H. pylori*-positive, NSAID-induced, and IPUD-related ulcers were 4.1%, 11.7%, and 23.2%, respectively.

Treatment consists of PPI administration for 4 to 8 weeks, or longer in the case of complicated disease. After PPI administration, it is important to monitor patients clinically. If there is recurrence, maintenance therapy is reasonable.

General PUD Treatment

As highlighted above, the single most important treatment option for PUD is to tailor therapy based on ulcer etiology. Generally, ulcers will heal with antisecretory treatment with a PPI. Uncomplicated duodenal

ulcers, specifically those associated with *H. pylori* infection, will heal with 14 days of PPI treatment, which is part of *H. pylori* treatment itself. Complicated ulcers, however, necessitate a longer treatment of 8 to 12 weeks. NSAID-induced ulcers should be treated for a minimum of 8 weeks if the NSAID is stopped. Idiopathic ulcers must be evaluated as previously mentioned. Patients with ZES will need treatment as outlined later.

Maintenance Treatment

In addition to detailed evaluation of the etiology of ulceration for each individual patient and treatment according to the root cause of PUD (i.e., *H. pylori* infection, NSAIDs, ZES), some patients will require maintenance therapy to prevent ulcer recurrence.

After eliminating risk factors for PUD, patients with the following high-risk characteristics may benefit from antisecretory therapy with a PPI: (1) giant ulcer (>2 cm) and age older than 50 or multiple comorbidities, (2) *H. pylori*-negative ulcer disease, (3) non-NSAID disease, (4) refractory peptic ulcers defined as ulcers that do not heal after 12 weeks of PPI treatment, (5) *H. pylori* eradication failure, (6) recurrent peptic ulcer, (7) continued NSAID use. Maintenance therapy regimens include either an H2RA or a PPI at the lowest possible therapeutic dose. The risks of chronic PPIs versus the likelihood of developing PUD should be reviewed periodically.

Special Considerations

Patients that require dual antiplatelet therapy, specifically aspirin and clopidogrel, for treatment after cardiac catheterization, unstable angina, NSTEMI or stroke tend to be co-treated with PPIs to reduce GI side effects. Both PPIs and clopidogrel are metabolized by CYP2C19, leading to concerns that PPIs may decrease the efficacy of clopidogrel and lead to catastrophic events. This risk, however, has been assessed by various systematic reviews and, although the research obviously shows that PPIs decrease the risk of GI events, it has not demonstrated a clear adverse effect on patients on clopidogrel.

Additionally, new anticoagulants, such as dabigatran, rivaroxaban, apixaban, and edoxaban, are becoming more commonly used in patients who need long-term anticoagulation. Though research on these drugs and GI bleeding as it relates specifically to PUD is lacking, these drugs are linked to increased risk of GI bleeding overall and likely lead to increased bleeding in patients with PUD.

Surgery

The efficacy of nonsurgical ulcer treatment has increased dramatically with the discovery of *H. pylori* eradication treatment and antisecretory therapy. As a result, surgery is rarely used to treat PUD. It is an important therapeutic option, however, for patients with complications, such as gastric outlet obstruction, bleeding and perforation.

Complications of PUD

The most common complications of PUD include bleeding, perforation, and obstruction, with bleeding being the most common and obstruction being the least common.

Bleeding

GI bleeding accounts for half a million hospitalizations per year and about \$5 billion in annual costs in the United States. Upper GI bleeds (UGIBs) make up half of those hospitalizations and carry a significant mortality rate of up to 7.4%. Peptic ulcers are the most frequent cause of UGIBs, making up about a third of all cases.

Bleeding ulcers present with the classic symptoms of an UGIB and vary depending on the severity of the bleed. In chronically bleeding UGIB, patients present with occult blood in the stool and possibly

iron deficiency anemia. When the bleed is acute, patients will have coffee-ground emesis and melena (black and tarry stool); however, a patient with a brisk UGIB may present with hematemesis and, possibly, hemochezia with hypotension. Treatment of bleeding ulcers includes fluid resuscitation, blood transfusions when hemoglobin levels fall below 7 g/dL or below 8 g/dL in patients with existing cardiovascular disease or who are symptomatic, intravenous PPI therapy (which should be switched to oral therapy as soon as the patient tolerates oral medications), and an esophagogastroduodenoscopy (EGD) within 24 hours of admission. If the patient has high-risk clinical features, such as hemodynamic instability or hematemesis, EGD should be performed within 12 hours of admission. Endoscopic intervention is dictated by the features of the bleeding ulcer. Typically, endoscopic interventions, such as injections, sclerotherapy, or clips, are employed if there is active bleeding from the ulcer, or if there is a clot adherent to the ulcer. In active bleeding, combination therapy such as injected epinephrine followed by the application of clips produces improved outcomes over a single modality. Hospital discharge is dependent on the patient's clinical status, but it is typically after 3 days of hospitalization for patients with high-risk bleeds.

Perforation

Perforation of a peptic ulcer accounts for 2% to 10% of ulcer complications. Perforation happens when an ulcer penetrates the full thickness of the stomach or duodenal wall. It should be suspected if a patient develops sudden, severe abdominal pain. On physical examination, the patient will have exquisite abdominal pain and tenderness, guarding, and, potentially, signs of peritonitis such as rebound tenderness. Upright chest and abdominal radiographs will show free peritoneal air under the diaphragm; however, if they do not, and the clinical suspicion for perforation is high, the next most useful imaging modality, if the perforation happened within the previous 6 hours, is ultrasound. After 6 hours have elapsed, CT may provide diagnostic value.

Patients with an abdominal perforation need to be treated for hemodynamic instability and receive antibiotics targeting enteric bacteria. Additionally, they should undergo an emergent surgical evaluation. Risks of surgery must be weighed against the individual patient's risk of perforation-related mortality. However, nonoperative management is appropriate only for a small number of patients, and the most effective treatment remains surgical repair of the perforation.

Gastric Outlet Obstruction

Though much less common than UGIB and perforation, gastric outlet obstruction (GOO) is a serious complication of a peptic ulcer located at the pylorus. Though PUD historically accounted for the majority of cases of obstruction, the incidence of GOO in PUD has declined as treatment for PUD has steadily improved. Currently, the leading cause of GOO is malignancy, therefore malignancy must be ruled out by endoscopy in all cases.

The precise etiology of GOO is unknown; however, it is more prevalent in patients with duodenal or pyloric ulceration. Causes of GOO secondary to PUD are likely multifactorial, from inflammatory-related causes such as spasm, edema, and pyloric dysmotility in the acute setting to more chronic causes such as scarring and fibrosis as the ulcer heals.

Patients with GOO present with early satiety, nausea, bloating, vomiting, and weight loss. On physical exam, patients will have stigmata of dehydration, abdominal distention, and a succussion splash. At presentation, patients should undergo gastric decompression to clear the gastric contents, and electrolyte abnormalities must be evaluated and treated along with IV rehydration.

Radiographic imaging will demonstrate an enlarged gastric bubble and dilated proximal duodenum on abdominal radiographs. Computed tomography of the abdomen will generally show gastric distention and retained chyme in the gastric cavity with an associated fluid level (Fig. 37.6).

Ultimately, patients must undergo EGD for diagnostic and possible therapeutic purposes (Fig. 37.7). Endoscopic biopsies must be obtained from the site of obstruction to evaluate for malignancy and from the antrum and body to determine if there is underlying *H. pylori* infection. If PUD is suspected, antisecretory IV treatment with a PPI must be initiated to promote healing of the ulcer and alleviation of the obstruction. Oral alimentation must be introduced slowly, as tolerated by the patient. Patients with refractory obstruction who fail conservative treatment may be treated endoscopically with balloon dilation, endoscopic stent placement, or even surgery. Additionally, patients should receive treatment for *H. pylori* and other causes of PUD, if indicated.

Fig. 37.6 Transverse view of an abdominal CT demonstrating a gastric outlet obstruction with significant narrowing at the distal stomach (arrow). This has caused gastric distention with retained fluid in the stomach and a visible fluid level. (From Mönkemüller, et al. *Gastrointestinal Endoscopy* 2012;75:463-465.)

ZOLLINGER-ELLISON SYNDROME

Definition and Epidemiology

ZES is a rare condition that results from ectopic gastrin secretion due to a neuroendocrine tumor, called a *gastrinoma*. This leads to elevated levels of basal acid secretion in the stomach. Symptoms such as multiple or *H. pylori*-negative duodenal ulcers, recurrent ulcers, refractory ulcers, esophagitis, and unexplained diarrhea should raise clinical suspicion of ZES. Gastrinomas are primarily located in the duodenum (60% to 80%) or pancreas (10% to 14%) in an area known as the “gastrinoma triangle.” They are also rarely found in other areas such as the stomach, liver, bile duct, and ovary. ZES tends to present in patients between 45 and 50 years old, and there is a slight male predominance with an estimated male to female ratio of 2:1 to 3:2. The diagnosis is often delayed due to low clinical suspicion.

Although the majority of ZES cases develop sporadically, 10% to 54% of ZES cases are found in patients with multiple endocrine neoplasia type 1 (MEN1). Multiple endocrine neoplasia type 1 is an autosomal dominant genetic disorder, usually of the *menin* gene located on chromosome 11q13. In addition to gastrinomas, patients with MEN1 also have increased incidence of parathyroid hyperplasia, pancreatic endocrine tumors, pituitary adenomas, and adrenal adenomas. Therefore, patients diagnosed with ZES must be screened for MEN1.

Pathophysiology of ZES

The main pathologic characteristic of ZES is excessively elevated levels of circulating gastrin, secreted autonomously from gastrinomas. Unlike physiologic gastrin production, gastrin release from gastrinomas is not subject to regular inhibitory feedback loops. This unregulated acid secretion causes excessive acid secretion that eventually leads to peptic ulceration in 90% of people with ZES. Exaggerated gastrin levels also act as trophic factors for ECL and parietal cells resulting in hypertrophic gastric rugae that are visible on endoscopy.

Clinical Presentation

In addition to an elevated risk of PUD, as detailed above, a third of patients may present with unexplained diarrhea, which can sometimes lead to electrolyte imbalances such as hypokalemia, steatorrhea, and weight loss. Diarrhea may be the sole clinical manifestation in about 20% of patients. Diarrhea occurs when the high acid load reaches the small intestine causing direct enterocyte damage, inactivation of pancreatic lipase, and precipitation of bile acids, which interferes with micelle formation.

Fig. 37.7 Endoscopic appearance of gastric outlet obstruction due to a pyloric channel stricture. (A) Pyloric channel stricture. (B) Endoscopic view of balloon dilation of the pyloric stricture. (C) Post-procedure view of the pylorus after successful balloon dilation. (From Kochhar et al. *Gastrointestinal Endoscopy* 2018;8:899-908.)

Other manifestations of ZES include esophageal syndromes from gastric acid hypersecretion, such as dysphagia, esophagitis, esophageal ulceration, strictures, or even perforation. In fact, reflux esophagitis may occur in up to 40% of patients with ZES.

Diagnosis

As in the diagnosis of other rare diseases, the most important factor in diagnosing ZES is having a high index of suspicion for ZES in patients that present with classic symptoms, as detailed above. These classic symptoms, however, may be hard to discern in the age of ubiquitous PPI use because these antisecretory agents may mask ZES symptoms. Diagnosis of ZES requires the presence of hypergastrinemia and hyperchlorhydria.

Initially, patients with suspected ZES should be evaluated by obtaining a fasting gastrin level and obtaining a gastric pH. A low gastric pH in conjunction with high gastrin levels is characteristic because, in achlorhydric states, gastrin will be appropriately elevated but so will pH. Because PPIs also affect the gastric pH, PPIs must be discontinued for at least 1 week prior to testing. PPI discontinuation in patients with ZES incurs serious risks and should be done only after careful evaluation of the risks and benefits of PPI withdrawal for diagnostic purposes under the supervision of experienced practitioners. Some case reports have described serious health complications of ZES that developed just 48 hours after PPI withdrawal.

Gastrin levels greater than ten times the upper limit of normal (ULN) with a gastric pH less than 2 establishes the diagnosis of ZES. However, most patients with ZES will have equivocal gastrin levels. A secretin stimulation test can help make the diagnosis in this case.

The secretin stimulation test takes advantage of the paradoxical increase in gastrin secretion after the administration of secretin in patients with gastrinomas. Similar to gastrin and gastrin pH levels, the secretin test must be obtained while the patient is not under antisecretory therapy. Gastrin levels are obtained before and after the administration of 2 U/kg of secretin. The test is positive if gastrin levels increase at least 120 pg/mL with secretin administration.

After the diagnosis of ZES is made, all patients must be screened for MEN1 by measuring calcium, parathyroid hormone (PTH), and MEN1 germline mutation testing. In addition, first-degree relatives of patients with MEN1 also must be screened. Because a majority of gastrinomas are malignant, it is critical to attempt to localize the gastrinoma with the purpose of tumor resection.

A useful imaging modality for localizing gastrinomas is a somatostatin-receptor scintigraphy (SRS) scan combined with CT scan, but other modalities such as CT, MRI, and ultrasonography may also be used. In experienced hands, upper endoscopy with endoscopic ultrasound (EUS) has similar sensitivity to SRS (74% and 75% respectively) and can be helpful in determining the location of the gastrinoma.

Treatment of ZES

After ruling out other causes of hypergastrinemia (such as pernicious anemia or PPI-induced hypergastrinemia, in which the high gastrin occurs secondary to low acid secretion), the most important treatment goal for ZES is reduction and normalization of acid secretion, which can be achieved through PPI therapy. To control acid secretion in ZES, PPIs typically need to be taken at elevated doses, sometimes double the standard dose or higher. PPI treatment must be titrated to achieve a basal acid output (BAO) that is less than 10 mmol/hour the hour preceding the next scheduled dose. When patients are unable to take oral medications, IV PPI therapy must be administered to control acid secretion. In extreme cases, vagotomy may be performed to decrease acid secretion.

Surgery can sometimes uncover a hitherto unrecognized primary tumor. Additionally, it allows for evaluation of tumor grade and stage and removes the source of the ectopic gastrin production. Regardless, surgery significantly improves survival rates in patients with ZES. Gastrinomas tend to metastasize via a hematogenous route primarily to the lymph nodes, followed by the liver. Up to 50% of patients will have liver metastases at presentation.

GASTRITIS

Gastritis is a general term that is used to describe inflammation in the gastric mucosa. Gastric inflammation can be caused by a variety of conditions, most commonly *H. pylori* infection and NSAID gastritis (more strictly in the latter case termed *gastropathy*, because inflammation is rather mild). Gastritis can be acute or chronic and may be secondary to other infectious causes, autoimmune disorders, drugs, and ischemia. Every effort should be made to identify the cause of gastritis, though many times a specific diagnosis may not be identifiable.

Atrophic gastritis is a histopathologic entity of glandular loss that results from chronic inflammation. It can be divided into two major types: multifocal (secondary to environmental factors, *H. pylori*, specific diets) or corpus predominant (autoimmune) gastritis. This section will focus on the corpus predominant subtype, autoimmune metaplastic atrophic gastritis (AMAG).

AMAG is a chronic inflammatory gastritis caused by autoantibodies against intrinsic factor and the parietal cells in the fundus and body. It has a prevalence of 2% with a female to male ratio of 3:1, and it is more common in persons with other autoimmune diseases, specifically diabetes mellitus and autoimmune thyroid disease. AMAG increases the risk of intestinal-type gastric adenocarcinoma and gastric carcinoid tumors. Patients typically present with nonspecific GI symptoms and are generally diagnosed relatively late in their disease, once they have hematologic manifestations, such as macrocytic anemia due to vitamin B₁₂ deficiency (pernicious anemia). Due to the inability to absorb vitamin B₁₂, these patients may present with concomitant neurologic and psychiatric symptoms, though this happens in less than 10% of cases. On biopsy, patients will have gastric body mucosal atrophy as well as ECL hyperplasia in the setting of hypochlorhydria (and resultant hypergastrinemia). Treatment consists of vitamin B₁₂ supplementation and surveillance for associated diseases.

Infectious gastritis may be caused by infections other than *H. pylori*, such as CMV, *Mycobacterium avium-intracellulare*, enterococcal infections, HSV, as well as parasitic and fungal infections. Treatment for infectious gastritis involves treatment of the specific microbe causing damage to the gastric mucosa.

Eosinophilic gastritis (EG) is a part of a continuum of eosinophil-associated gastrointestinal disorders (EGIDs). It is associated with systemic eosinophilia in about 75% of patients with EGID. In EG, there is an eosinophilic infiltration, which rarely includes all layers of the gastric wall. There is mucosal involvement in 60% of cases, muscular involvement in 30% of cases, and subserosal involvement in 10% of cases. Diagnosis is difficult, given the varying locations of infiltration, and the nonspecific appearance of the stomach on EGD. Eosinophilic gastritis may be a cause of GOO. Treatment includes systemic steroids; however, there has been some success treating patients with elemental diets free of allergenic foods.

Ménétrier's disease is a very rare condition associated with hypertrophy of the gastric mucosa primarily in the body of the stomach. Histologically, there is proliferation of the gastric glands with cystic dilation of the basilar portion. The etiology of the disease is unknown, and the diagnosis is difficult to make. Diagnosis generally necessitates

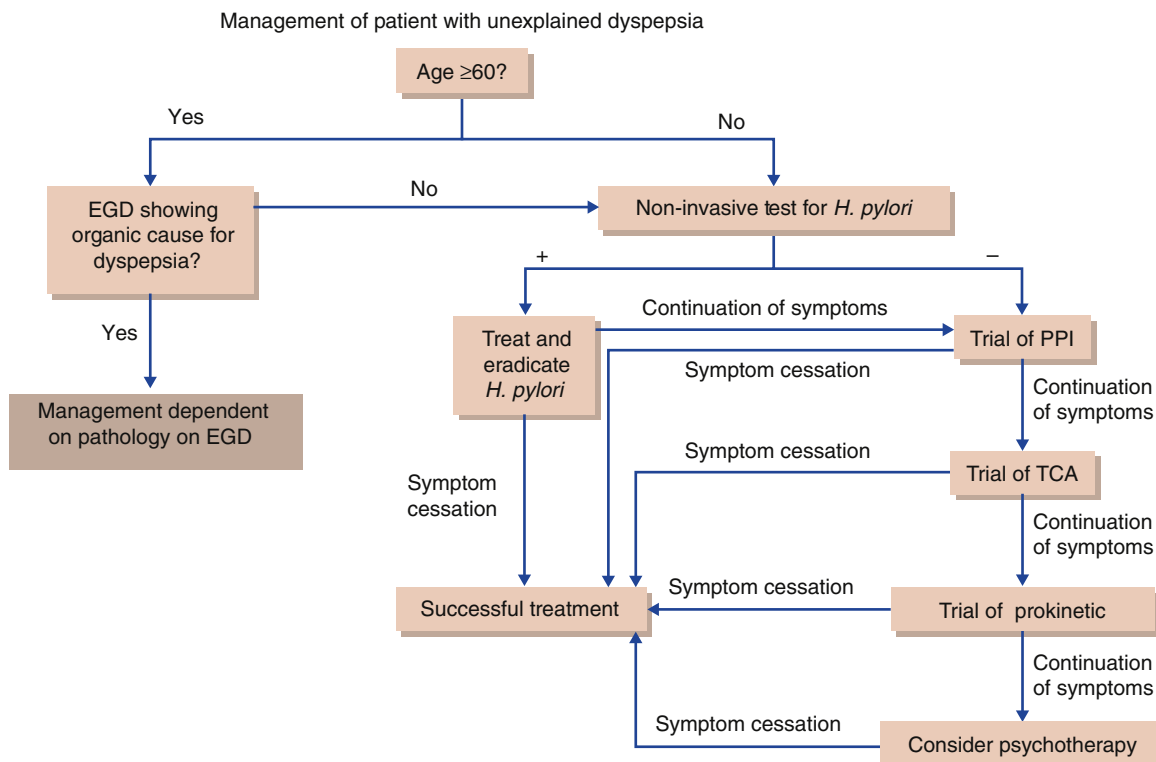

Fig. 37.8 Guideline for management of patients with dyspepsia. EGD, Esophagogastroduodenoscopy; TCA, tricyclic antidepressant. (Adapted from Moayyedi PM, Lacy BE, Andrews CN, Enns RA, Howden CW, Vakili N. ACG and CAG Clinical Guideline: Management of Dyspepsia. *Am J Gastroenterol.* 2017;112:988-1013.)

evaluation of the gross appearance of the gastric mucosa during endoscopy along with the characteristic constellation of symptoms. Clinically, there is associated nausea, vomiting, anemia, hypochlorhydria, and peripheral edema secondary to hypoalbuminemia.

Lymphocytic gastritis is another rare disorder characterized by mucous and gastric epithelium infiltration by T cells. It is associated with celiac disease, *H. pylori* gastritis, collagenous colitis, and Ménétrier's disease.

FUNCTIONAL (NONULCER) DYSPEPSIA

When a patient presents with a constellation of symptoms similar to that of PUD or gastritis without evidence of ulceration on EGD, they are said to have *nonulcer dyspepsia (NUD)*. Nonulcer dyspepsia is a diagnosis of exclusion. The etiology of NUD is not well understood; however, patients with NUD may have impaired gastric mucosal integrity, dysmotility, dysregulation of the gut-brain axis, or sensory dysfunction. Psychosocial factors and psychiatric disorders such as depression and anxiety, however, are very strongly associated with NUD. NUD affects 10% to 30% of the world's population.

Specific diagnostic criteria include bothersome postprandial fullness, early satiety, epigastric pain, or epigastric burning, in addition to a lack of evidence of an organic or structural explanation of the symptoms on EGD, imaging, or laboratory studies. Patients older than 60 years of age should have an EGD to evaluate for possible malignancy. Depending on individual clinical symptoms, some patients may benefit from motility studies to evaluate for dysmotility and gastroparesis (Fig. 37.8).

Unfortunately, treatment for NUD is limited and therapeutic modalities have not been well studied. Some (about 1 in 10) dyspeptic patients with NUD who test positive for *H. pylori* may respond to *H.*

pylori eradication even if they do not have evidence of PUD on endoscopy. Antisecretory therapy with a PPI or H₂RA is recommended for *H. pylori*-negative patients and those that have been successfully treated for *H. pylori* who continue to have symptoms. Tricyclic antidepressants are recommended for patients that continue to be symptomatic despite *H. pylori* eradication and antisecretory therapy. Further treatment options include prokinetics, such as cisapride and domperidone, though these are not available in the United States. Patients who do not respond to therapy and have ongoing, bothersome symptoms may benefit from psychological therapies, the most common being cognitive behavioral therapy.

CYCLIC VOMITING SYNDROME

Cyclic vomiting syndrome (CVS) is an idiopathic condition that presents both in children and adults with the mean age of presentation of 37 years in the adult population. The etiology of CVS is largely unknown, but it has been observed to be triggered in patients with chronic cannabis use, migraine headaches, and by certain foods (which typically also trigger migraine headaches). Characteristically, patients present with bouts of vomiting lasting hours to days with absence of vomiting between episodes. Adult patients will commonly report alleviation of symptoms while taking hot showers or baths.

Diagnosing CVS is difficult, and many years may elapse before a clear diagnosis is made. Clinicians may often misdiagnose patients with recurrent infectious gastroenteritis or other self-limiting causes of vomiting. Specific criteria for diagnosis include (1) stereotypical bouts of acute vomiting lasting less than 1 week, (2) three or more episodes in the prior year and two in the past 6 months, occurring at least 1 week apart, (3) absence of vomiting between episodes. The diagnosis of CVS must be made only after excluding other possible diagnoses.

In the acute setting, therapy is supported with IV fluids, antiemetics, and slow reintroduction of food as tolerated by the patient. Antiemetics taken prior to the attack during the prodromal period may prevent or reduce the longevity of symptoms. Maintenance therapy consists of avoidance of triggers and, if appropriate, psychosocial treatment. When a patient presents with CVS in the setting of cannabis use, cannabis use must be stopped.

RAPID GASTRIC EMPTYING

Rapid gastric emptying, also known as *dumping syndrome*, is a debilitating condition manifesting in postprandial gastrointestinal and vasomotor symptoms that occur following esophageal, gastric, or bariatric surgery. It is due to premature delivery of food into the small intestine. Postsurgical rapid gastric emptying occurs in 25% to 50% of cases with 5% to 10% of patients experiencing debilitating symptoms; however, this diagnosis is also correlated with diabetes mellitus, and idiopathic cases have also been reported. Rapid gastric emptying can be divided into two categories, early and late dumping syndrome, of which the early variation is most common. It is defined as less than 30% retention of gastric contents within 1 hour of solid meal ingestion.

In early rapid gastric emptying, hyperosmolar food is delivered to the small intestine triggering the release of vasoactive substances such as neurostatin, vasoactive intestinal peptide (VIP), and glucose modulators such as incretins, insulin, and glucagon. This results in gastrointestinal symptoms such as early satiety, pain, diarrhea, nausea, cramps, and bloating, vasomotor symptoms such as hypotension, and sympathetic nervous system response such as facial flushing, palpitations, and diaphoresis within 30 minutes of meal ingestion.

The symptoms of late gastric emptying are a result of hyperinsulinemia and subsequent reactive hypoglycemia. Hyperinsulinemia occurs secondary to an increased release of incretins in response to undigested carbohydrates in the small intestine. Symptoms, including diaphoresis, tremulousness, decreased concentration, and altered levels of consciousness, occur 1 to 3 hours postprandially. Early and late gastric emptying may be present in isolation, but they frequently coexist.

Diagnosis of rapid gastric emptying primarily relies on a high clinical suspicion in patients with typical clinical symptoms of rapid gastric emptying. Other diagnostic modalities include oral glucose tolerance test and radionuclide scintigraphy.

First-line treatment includes lifestyle modifications to reduce the amount of food taken per meal, eating at more frequent intervals, and separating solid from liquid food ingestion. Additionally, it can be helpful to lie down after meals and decrease carbohydrate and lactose ingestion. Early consultation with a dietitian is important to ensure that an adequate nutritional status is maintained. When lifestyle modification methods fail to alleviate symptoms, pharmacologic options include acarbose, guar gum, or symptomatic treatment with loperamide, tincture of opium, and other methods of pain control. Octreotide, which inhibits the secretion of vasoactive agents, may also be helpful.

GASTROPARESIS

Gastroparesis occurs when there is delayed gastric emptying into the small intestine, causing a characteristic constellation of symptoms. It is most commonly seen in diabetics, postsurgical patients, and those on chronic scheduled opioid therapy. A third of cases are idiopathic, and women are more likely than men to develop this disorder. Up to 30% to 50% of patients with type 1 diabetes have delayed gastric emptying, as do 15% to 30% of patients with type 2 diabetes.

Diabetic gastroparesis is better understood than idiopathic gastroparesis. The etiology of diabetic gastroparesis is similar to that of diabetic neuropathy with possible denervation of the vagus nerve causing a delay in gastric emptying. Additionally, patients with diabetes-related gastroparesis have been found to have decreased numbers of interstitial cells of Cajal (ICCs), the pacemaker cells of the GI tract, as well as decreased levels of nitric oxide release from enteric neural cells. Although patients with idiopathic gastroparesis also have decreased numbers of ICCs, the cause of idiopathic gastroparesis is less well understood, though enterovirus infections have been implicated.

Clinically, patients experience early satiety, abdominal distension, nausea, vomiting, anorexia, and malnutrition. Though all patients with gastroparesis experience nausea, patients with diabetes tend to have more severe and more frequent episodes of vomiting when compared to those with idiopathic gastroparesis. Patients with idiopathic gastroparesis are more likely to have severe postprandial fullness and early satiety.

Some patients with idiopathic gastroparesis are misdiagnosed as having nonulcer dyspepsia, therefore a high index of suspicion is key to the diagnosis. After gastric outlet obstruction has been ruled out, the timing of gastric emptying may be evaluated with gastric emptying scintigraphy, breath testing, or a wireless motility capsule. It is very important that patients refrain from taking prokinetic or gastroparetic agents prior to these studies.

Treatment takes a stepwise approach beginning with dietary modifications (small, spaced out meals), improving glucose control in diabetic patients, and adding prokinetic agents. More invasive procedures such as gastric pacemakers may be tried in severe cases.

GASTRIC VOLVULUS

Gastric volvulus is a rare condition that affects both adult and pediatric patients, where the stomach rotates at least 180 degrees along its transverse or longitudinal axis causing gastric inlet or outlet obstruction. In extreme cases, gastric volvulus may cause strangulation, necrosis, and perforation; therefore it is considered a surgical emergency. The mortality rate for acute gastric volvulus ranges between 15% to 20%, whereas it is 0% to 13% for chronic cases. Rotation of the stomach is generally caused by paraesophageal hernias, structural abnormalities (such as neoplasms), adhesions, and gastric ligamentous laxity (Fig. 37.9).

Clinically, presentation varies depending on acuity and degree of obstruction. Borchartd triad of acute abdominal pain, severe retching without vomiting, and inability to place a gastric tube is present in 70% of cases with acute gastric volvulus. If the volvulus is severe enough to cause strangulation and necrosis, hematemesis may be seen. Patients with chronic gastric volvulus may present with vague symptoms such as abdominal pain, dysphagia, and bloating. These may be misdiagnosed as other upper GI disorders.

Given the rarity and nonspecific presentation of gastric volvulus, diagnosis is often done while investigating other causes for the patient's symptoms. Evidence of gastric outlet obstruction with an interruption, such as two pockets of air-fluid levels, is seen on radiographs. Additionally, given the correlation with esophageal hernias, these can also be seen on radiographs and should increase index of suspicion for gastric volvulus. These patients typically have subsequent abdominal CT scans that show abnormal location of the antrum and evidence of GOO.

Treatment can be divided into three categories: conservative, endoscopic, or surgical. In the acute setting, patients must be treated and

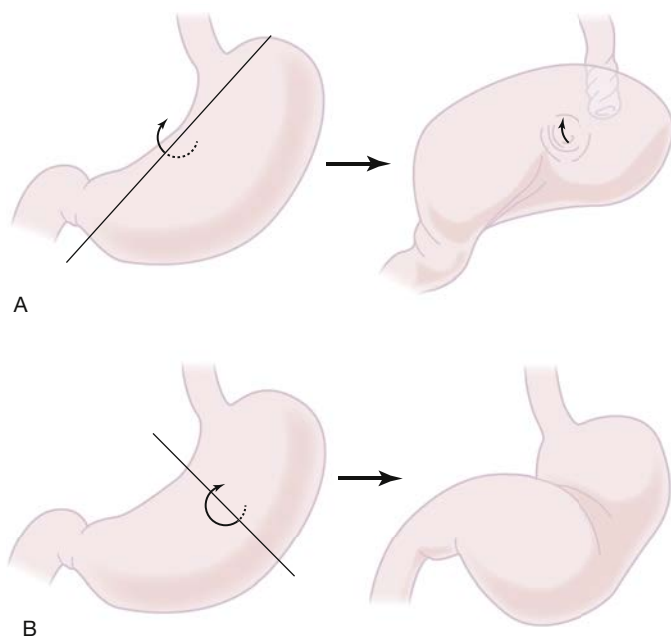

Fig. 37.9 The two major types of gastric volvulus. (A) Organoaxial volvulus, in which there is anterior rotation about the cardiopyloric axis, resulting in an upside-down stomach with the greater curve on top and the lesser curve on the bottom. Obstruction may occur at the gastroesophageal junction and the pyloroantral area. (B) Mesenteroaxial volvulus, in which there is anterior rotation about an axis perpendicular to the cardiopyloric axis. The greater curve remains on the bottom. (From Tsang, Tat-Kin et al. Endoscopic reduction of gastric volvulus: The alpha-loop maneuver *Gastrointestinal Endoscopy* 1995; 42: 244-248.)

stabilized. Conservative therapy consists of placing a gastric tube and laying patients in the prone position. It is generally reserved for stable patients with viable stomach tissue at the time of presentation. An endoscopic approach affords therapeutic and diagnostic value because it can assess the condition of the gastric mucosa and may sometimes lead to resolution of the volvulus with insufflation. Critically ill patients with evidence of tissue compromise generally must undergo surgery to relieve the volvulus and resect damaged tissue. Surgery also repairs gastric perforations and hiatal hernias. Patients generally undergo a gastropexy (fixation of the stomach to the anterior abdominal wall) to prevent future episodes.

Inflammatory Bowel Disease

Talha A. Malik, Michael F. Picco, Francis A. Farraye

INTRODUCTION

Inflammatory bowel disease (IBD) comprises two chronic disorders: ulcerative colitis (UC) and Crohn's disease. The diagnosis of IBD is based on review of clinical, endoscopic, radiologic, and histologic data. Although the cause of these two diseases has yet to be defined, new and emerging targeted anti-inflammatory treatments hold great promise in helping to reduce morbidity and improve the quality of life of individuals with IBD.

UC is characterized by chronic inflammatory changes that involve the colonic mucosa in a continuous superficial fashion, typically starting in the rectum and extending proximally. Depending on the extent of the disease, UC can be divided into proctitis (rectum only), proctosigmoiditis (rectum and sigmoid), left-sided colitis (extending to the splenic flexure), and pancolitis (inflammation extends proximal to the splenic flexure). This classification is significant for both prognosis and therapy. Unlike UC, Crohn's disease can involve any segment of the gastrointestinal tract from the mouth to the anus, often in a discontinuous fashion. It is characterized by transmural chronic inflammation, which results in complications such as abscesses, fistulas, and strictures.

Historical Perspective

Ulcerative colitis was first described in ancient Greece by Hippocrates as a condition characterized by chronic diarrhea and bloody stools. In 1859, Samuel Wilks, a British physician, described "ulcerative colitis" as a discrete disease entity.

In 1913, the British physician Kennedy Dalziel first described patients with transmural inflammation of the small and large intestines. Subsequently, in 1932, Dr. Burrill Crohn, Dr. Leon Ginzburg, and Dr. Gordon Oppenheimer published papers describing a condition that caused inflammation of the terminal ileum and which they called regional or terminal ileitis. This disease entity later began to be referred as Crohn's disease.

The first breakthrough that established IBD as the major intestinal autoimmune disease occurred in the 1950s when it was demonstrated that symptoms in patients with both UC and Crohn's disease responded to corticosteroids. In the 1980s, traditional immune modulators, mainly thiopurines, were used as first-line steroid sparing agents. In 1997, Targan and colleagues published findings from the "Crohn's Disease cA2 Study" that looked at the efficacy of infliximab, a biologic antibody against tumor necrosis factor (TNF) cA2 in the induction of remission in luminal Crohn's. This began the era of biologics. During the first decade of the 21st century, biologics given intravenously or as subcutaneous injections emerged as the most effective therapeutic agents used to induce and maintain remission in moderate to severe UC and Crohn's disease. Since then, new oral agents are now available and effective in the treatment of patients with IBD.

EPIDEMIOLOGY

There is variation in the incidence and prevalence of UC and Crohn's disease across the globe based on geographic region, particular environment, immigration trends, and ethnic group. In the past, UC was generally considered to be slightly more common. However, this trend has changed with the rising incidence of Crohn's disease. It is estimated that there are more than 2 million people with IBD in North America. The annual incidence in North America of both UC and Crohn's disease is estimated to be between 0 to 20 per 100,000 persons. The estimates for prevalence of UC and Crohn's disease in North America are 35 to 250 per 100,000 and 25 to 300 per 100,000, respectively. The incidence and prevalence of IBD reflect the interplay of complex genetic and environmental factors that contribute to these disorders. For example, both diseases are more common in northern climates and among white individuals, particularly among populations of European descent living in North America, South Africa, and Australia. Although incidence rates of IBD are lowest among Hispanic and Asian populations, IBD can occur in any ethnic or racial group from anywhere in the world. The cause of IBD remains unknown, but it is believed to result from a combination of genetic, immunologic, infectious, and environmental factors. In addition, research points toward a relationship between the human microbiome and dysfunction of the immune system in patients with IBD.

UC and Crohn's disease can occur at any age, but the peak age of onset for UC is between 30 and 40 years of age and for Crohn's disease it is between 20 and 30 years. There is another peak, especially for UC, between 60 and 70 years of age based on studies in several European cohorts. The incidence and prevalence of UC and Crohn's disease appear to be similar in North American men and women.

RISK FACTORS AND PATHOPHYSIOLOGY

IBD is likely a result of an uncontrolled immune-mediated inflammatory response in genetically predisposed individuals to an environmental trigger that interacts with the intestinal flora and primarily affects the alimentary tract.

Approximately 5% to 20% of patients with IBD have a first-degree relative with the disease, and first-degree relatives of IBD patients have about a 10- to 15-fold increased risk for developing IBD, predominantly with the same disease as the proband. A positive family history is more frequently observed in patients with Crohn's disease compared with UC, suggesting that genetic factors are more important in the etiology of Crohn's disease. The lifetime risk of developing IBD in first-degree relatives has been estimated at 5% in Crohn's disease and about 2% in UC among non-Ashkenazi Jewish populations and 8% and 5% within Ashkenazi Jewish populations, respectively.

Through genome-wide association studies (GWAS), over 200 genetic loci have been identified as being associated with IBD. However, there is little diagnostic utility in clinical practice of these genetic variants due to their overall low incidence in IBD populations. With increasingly diverse populations being studied, this may change. Examples of single nucleotide polymorphisms (SNPs) associated with Crohn's include sequences in the *NOD2*, *IL23-receptor* and the *ATG16L1* genes. It is thought that *NOD2* variants may predict more complicated disease, mainly in European patients with stricturing ileal and penetrating disease. *IL-12* variants may be associated with risk for early surgery.

Additionally, other genes associated with IBD that have been identified through GWAS include *IRGM*, *LRRK*, *FUT2*, *CARD9*, *TNFSF15*, *FCG2RA*, *NKX2-3*, *PTPN2*, *ZNF365*, *ECM1*, *STAT3*, and *IL10R* among others. As mentioned, these variants have little diagnostic or therapeutic utility in clinical practice at this time due to lack of replication of associations noted in small studies.

Profound alterations in mucosal immunology have been demonstrated in patients with IBD. In the normal immunologic state of the intestine, activated lymphoid tissue is abundant within the mucosal compartment. This state has been described as controlled or physiologic inflammation, and it likely develops in response to constant encounters with antigenic substances (derived from host microbial flora or dietary and environmental sources) that have crossed the epithelial barrier from the luminal environment. Indeed, one of the main functions of the intestinal immune system is to discriminate noxious or harmful substances and organisms from nonharmful ones. As a result, a large and well-maintained network of many different mucosal immune cells exists, including cells involved in reducing immune responses (regulatory cells) and those involved in activating immune responses. In IBD, this homeostatic balance, or immune tolerance, is dysregulated, resulting in overactivation of the immune system.

In the past, it was thought that inflammation in Crohn's was predominantly mediated by T_H1 cells and in UC it was primarily mediated by T_H2 cells; there is now considerable evidence that each of their pathogenesises is more complex and nuanced, whereby both types of T helper cells appear to play a role. Furthermore, there is recent evidence that T_H17 cells produce pro-inflammatory cytokines that facilitate inflammation in IBD, the most notable of which appear to be *IL-6* and *IL-17*. Moreover, *IL-23R* is expressed in high numbers on T_H17 cells and has been postulated to play a key role in propagation of inflammation in both UC and Crohn's disease.

Overall, the immune mechanisms mediating inflammation in IBD are complex and work through significant interactions with environmental triggers, the genome, and the gut microbiome to produce active disease necessitating the need for a personalized approach to management.

As alluded to, environmental factors also are believed to play a role in the pathogenesis of IBD because the disease is more common in industrialized countries. Moreover, the frequency has increased in countries as they become more industrialized. It has been postulated that poor sanitation, food contamination, and crowded living conditions are associated with helminthic infection, which leads to regulatory T-cell conditioning and stimulation of *IL-10* and transforming growth factor- β production by mononuclear cells, thereby preventing intestinal inflammation.

The only environmental factor clearly associated with IBD is tobacco smoking. Tobacco seems to be protective against UC, with an older age of onset in former smokers. Among UC patients, smoking cessation may cause an exacerbation. Moreover, studies have shown that tobacco smokers with UC may have a milder disease course, require less immune suppression, and have a reduced need for surgery.

Conversely, Crohn's disease is associated with a more aggressive disease course. Tobacco consumption is associated with a 2-fold increase in the risk of development of Crohn's disease and an earlier age of onset. Passive smoking may also increase the risk. Smoking leads to more frequent exacerbations of Crohn's disease, an increased need for immunosuppression and surgery, as well as a higher risk of post-resection recurrence. Not all studies demonstrate these associations, suggesting a gene-environment interaction of tobacco and IBD with the divergent effects on UC and Crohn's disease not well understood.

Diet may also play a role. There is observational evidence that patients with Crohn's disease consumed a much higher quantity of refined sugars represented by sugar, candy, and sweetened foods like cakes and cookies prior to their diagnosis. Subsequently, it was suggested that high sugar intake itself could also interact with intestinal flora and produce pro-inflammatory intestinal agents. In addition to increased intake of refined sugars, newly diagnosed patients with IBD consumed less dietary fiber, raw fruit, and vegetables when compared to healthy controls. A systematic review of past epidemiologic surveys and case control studies performed in Japanese patients suggested an association between increased consumption of animal meat in addition to carbohydrates as potential risk for development of Crohn's disease. The researchers hypothesized that Western dietary patterns may be responsible for the increased occurrence of IBD in Japan.

Study of the relationship between obesity and IBD is especially important because of credible molecular evidence that links adipose tissue physiology to intestinal inflammation. However, it is still not entirely clear whether this link translates into a causal or clinically meaningful association between obesity and Crohn's disease.

Recently, there has been interest in understanding the association between cannabis and IBD. There are no credible epidemiologic data suggesting that cannabis plays a role in the development of IBD or its management. However, studies are ongoing.

Medications suggested to be potential risk factors for the development of IBD include, most importantly, nonsteroidal anti-inflammatory drugs (NSAIDs). NSAIDs have also been implicated in exacerbating existing disease. Other medications potentially linked to development of IBD include oral contraceptives, hormone replacement therapy, and antibiotics, but evidence for these is not as strong as with NSAIDs.

Mycobacterium avium subspecies *paratuberculosis* has been linked to Crohn's disease but this association has not been confirmed. Similarly, associations between *Salmonella*, *Campylobacter*, and measles virus have been reported to increase the risk of IBD, but not proven.

Poor hygiene (lack of sanitation), especially early in life, may protect against the development of IBD. Other potential associations include stress, anxiety, depression, disruptive sleep pattern, and sedentary lifestyle. Although provocative, these associations have not been confirmed in well-designed prospective studies.

CLINICAL PRESENTATION

Intestinal Manifestations

Ulcerative Colitis

UC is characterized by chronic inflammation of the mucosal surface that involves the rectum and extends proximally through the colon in a continuous manner. The extent and severity of colonic inflammation determine prognosis and presentation (insidious vs. acute onset). Most patients initially exhibit diarrhea, abdominal pain, urgency to defecate, rectal bleeding, and the passage of mucus per rectum. At presentation, approximately 40% to 50% of patients have proctitis or proctosigmoiditis, 30% to 40% have left-sided colitis (disease extending to the splenic flexure), and the remaining 20% to 25% have pancolitis. Though data

are variable, depending on the cohort, it has been observed that up to 50% of patients diagnosed with proctitis or proctosigmoiditis will progress to more extensive disease by 25 years of follow-up.

The typical clinical course of UC is one of chronic intermittent exacerbations followed by periods of remission. A disease flare may be suggested by the development of diarrhea, hematochezia, and abdominal pain, with dehydration, fever, and tachycardia suggesting more severe disease. Elevated fecal calprotectin, erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP) level may also indicate a flare. Anemia commonly occurs and is caused by chronic blood loss from the involved colonic mucosa as well as bone marrow suppression from the systemic inflammatory process. Perforation can occur in patients with severe or fulminant colitis, especially those taking corticosteroids, and in the setting of toxic megacolon. Toxic megacolon is characterized by gross dilation of the large bowel associated with fever, abdominal pain, dehydration, tachycardia, and bloody diarrhea.

Crohn's Disease

The clinical presentation of Crohn's disease depends on the section of gastrointestinal tract involved and the type of inflammation. Crohn's disease can involve any portion of the gastrointestinal tract; the most common site is ileocecal/ileocolonic (40% of patients), followed by isolated small bowel disease mostly affecting the terminal ileum (30%), and isolated colonic involvement (25%). The remaining sites of Crohn's disease are rarely (5%) affected in isolation and include the esophagus, stomach, and duodenum.

Symptoms in Crohn's disease often include right lower quadrant abdominal pain, fever, weight loss, diarrhea, and sometimes a palpable inflammatory mass on physical exam. Hematochezia may be present with colonic involvement but is less common than in UC. The symptoms can often be present for months or years before a diagnosis is made, and in children, growth retardation may be the sole presenting sign. In contrast to UC, the inflammation in Crohn's disease is transmural and can result in deep ulcerations and the formation of fistulous tracts. Fistulas may form between different segments of bowel (e.g., enteroenteric, enterocolonic) or between bowel and skin (enterocutaneous), bowel and bladder (enterovesicular), or rectum and vagina (rectovaginal). Over time, as many as 30% to 40% of patients will develop perianal involvement with fissures, fistulas or abscesses.

Chronic inflammation can cause fibrosis and stricture formation, which in turn may result in partial or complete intestinal obstruction with the patient complaining of abdominal pain, distention, nausea, and vomiting. Strictures can also lead to stasis with subsequent small intestinal bacterial overgrowth. Small bowel disease may lead to vitamin D deficiency. Extensive ileal mucosal disease may lead to malabsorption of vitamin B₁₂ (resulting in a megaloblastic anemia and neurologic side effects if not corrected) and malabsorption of bile salts (resulting in diarrhea induced by unabsorbed bile salts and potential fat-soluble vitamin deficiency). Depletion of the bile salt pool can lead to the formation of gallstones. Weight loss may result from generalized malabsorption caused by loss of absorptive surfaces. Chronic fat malabsorption leads to luminal binding of free fatty acids to calcium; this allows oxalate, which normally is poorly absorbed because it complexes to calcium in the gut lumen, to be absorbed in the colon. The increase in oxalate absorption increases the risk for urinary calcium oxalate stone formation. Patients with an ileostomy or chronic volume loss from diarrhea are also at increased risk for uric acid stones.

Extraintestinal Manifestations

Although both UC and Crohn's disease primarily involve the bowel, they are also associated with inflammatory manifestations in other organ systems. This reflects the systemic nature of these disorders

TABLE 38.1 Extraintestinal Manifestations of Inflammatory Bowel Disease

Hypercoagulable state
Autoimmune hemolytic anemia
Amyloidosis

(Table 38.1). Extraintestinal manifestations can occur in parallel or independently of disease activity and they can become more difficult to treat than the bowel disease itself.

The most common extraintestinal manifestation is arthritis, which is seen in about 9% to 50% of patients and is divided into two major types: axial and peripheral. Axial arthropathy consists of sacroiliitis or ankylosing spondylitis and does *not* parallel activity of bowel disease. Ankylosing spondylitis occurs in 5% to 10% of IBD patients and manifests with low back pain and stiffness that is usually worse during the night, in the morning, or after inactivity. Sacroiliitis alone (without ankylosing spondylitis) is common in IBD (up to 20% of patients) but in many cases is asymptomatic. Peripheral arthropathy is divided into type 1 and type 2. Type 1 peripheral arthropathy affects peripheral large joints. It is an asymmetric, seronegative, oligoarticular, nondeforming arthritis that may involve the knees, hips, wrists, elbows, and ankles. This peripheral arthropathy usually parallels disease activity. Peripheral arthropathy type 2 involves typically metacarpal phalangeal (MCP) joints, is typically symmetrical, and does *not* parallel disease activity.

Liver complications of IBD include both parenchymal and biliary tract diseases. Parenchymal diseases include fatty liver, pericholangitis, and chronic active hepatitis. Pericholangitis, also known as small-duct sclerosing cholangitis, is the most common of these diseases. It usually is asymptomatic, identified only by abnormalities in alkaline phosphatase and γ -glutamyl transpeptidase (GGT) on laboratory tests and histologically by portal tract inflammation and bile ductule degeneration. Small-duct sclerosing cholangitis may progress to cirrhosis.

Biliary tract disease includes an increased incidence of gallstones and primary sclerosing cholangitis (PSC). PSC is a chronic cholestatic liver disease marked by fibrosis of the intrahepatic and extrahepatic bile ducts. It occurs in 1% to 4% of patients with UC and less often in those with Crohn's disease. Overall, about 70% of patients with PSC have UC. Fibrosis leads to strictures of the bile ducts, which in turn may lead to recurrent cholangitis (with fever, right upper quadrant pain, and jaundice) and progression to cirrhosis. In addition, about 10% of patients develop cholangiocarcinoma. Medical or surgical

TABLE 38.2 Differentiating Features of UC and Crohn's Disease

	Ulcerative Colitis	Crohn's Disease
Site of involvement	Involves colon only Rectum almost always involved	Any area of the gastrointestinal tract Rectum usually spared
Pattern of involvement	Continuous	Skip lesions
Diarrhea	Bloody	Usually nonbloody
Severe abdominal pain	Rare	Frequent
Perianal disease	No	In 30% of patients
Fistula	No	Yes
Endoscopic findings	Erythematous and friable Superficial ulceration	Aphthoid and deep ulcers Cobblestoning
Radiologic findings	Tubular appearance resulting from loss of haustral folds	String sign of terminal ileum RLQ mass, fistulas, abscesses
Histologic features	Mucosal involvement only Crypt abscesses	Transmural Crypt abscesses, granulomas (about 30%)
Smoking	Protective	Worsens course
Serology	pANCA more common	ASCA more common

ASCA, Anti-*Saccharomyces cerevisiae* antibodies; pANCA, perinuclear antineutrophil cytoplasmic antibody; RLQ, right lower quadrant.

therapy for IBD does not modify the course of PSC and most patients progress to cirrhosis and may require liver transplantation.

The two classic dermatologic manifestations that can be associated with IBD are pyoderma gangrenosum and erythema nodosum. Pyoderma gangrenosum occurs in about 5% of patients and is characterized by a discrete ulcer with a necrotic base, usually on the legs. The ulcer may spread and become large and deep, destroying soft tissues. Pyoderma is unrelated to disease activity. Treatment is usually with systemic or intralesional steroids, or both. Other treatment options include dapsone, cyclosporine, and anti-TNF agents. Erythema nodosum occurs in 10% of IBD patients, usually with peripheral arthropathy, and produces raised, tender nodules, usually over the anterior surface of the legs. Erythema nodosum responds to treatment for the underlying bowel disease. A less common dermatologic manifestation of IBD is Sweet syndrome or acute febrile neutrophilic dermatosis. This condition is characterized by the sudden onset of fever, leukocytosis, and tender, erythematous, well-demarcated papules and plaques that show dense neutrophilic infiltrates on histologic examination.

Ocular manifestations of IBD include uveitis and episcleritis. They occur in 1% to 5% of patients. Uveitis (or iritis) is an inflammatory condition of the anterior chamber that produces blurred vision, photophobia, headache, and conjunctival injection that may not parallel disease activity. Local therapy includes corticosteroids and atropine. Episcleritis is typically associated with disease activity. It produces burning eyes and scleral injection without vision deficits and is treated with topical corticosteroids.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnosis of IBD is based on a constellation of clinical features and endoscopic, radiographic, and histologic findings. Laboratory tests are not specific and usually demonstrate inflammation (leukocytosis) and anemia when the disease is active. Perinuclear antineutrophil cytoplasmic antibody (pANCA) is positive in up to 70% of patients with UC but is uncommon in patients with Crohn's disease, whereas anti-*Saccharomyces cerevisiae* antibodies (ASCA) are common (up to 60%) in Crohn's disease but not typically found in UC (Table 38.2). Additional markers, mainly for Crohn's disease, have improved the sensitivity and specificity of serologic testing, including antibodies to OmpC (*Escherichia coli* outer membrane porin C) and antibodies to bacterial flagellins CBir1, FlaX, and A4-Fla2. Due to lack of sensitivity

Fig. 38.1 Endoscopic image of ulcerative colitis demonstrates diffuse inflammation characterized by erythema, edema, friability, and hemorrhage.

and specificity, laboratory testing is of limited value and should not be used to make a diagnosis of IBD.

Colonoscopy findings in patients with UC are nonspecific, typically revealing granular mucosa, decreased vascular markings, exudate, and superficial ulcerations (Fig. 38.1) typically beginning in the rectum. In more severe cases, the mucosa is friable, with deeper ulcerations. Patients with long-standing severe disease can develop pseudopolyps, which represent islands of normal tissue in regions of previous ulceration. In Crohn's disease (Fig. 38.2), endoscopic examination may show aphthoid erosions, deep linear or stellate ulcers, edema, erythema, exudate, and friability with intervening areas of normal mucosa (skip lesions). However, a diagnosis of indeterminate colitis is made in 10% to 15% of patients because of an overlap of findings. For example, colonic Crohn's disease may produce superficial continuous rectal involvement similar to that seen in UC. Similarly, chronic UC

Fig. 38.2 Endoscopic image of Crohn's disease demonstrates linear ulcers in areas of otherwise normal mucosa.

can infrequently result in inflammation of the terminal ileum, called backwash ileitis, usually when severe disease of the cecum or ascending colon is present. In many patients with indeterminate colitis, repeated examination is necessary, or complications may develop that help identify the disease form.

Several types of radiologic studies can be used to diagnose IBD. In Crohn's disease, the most sensitive radiographic test to diagnose small bowel disease is CT or MR enterography. On traditional small bowel radiography, segments of edematous bowel appear thickened next to uninvolved mucosa, a characteristic pattern referred to as *cobblestoning*. Tight, long strictures in the small bowel can be identified and are called a *string sign*. Cross-sectional imaging with computed tomographic (CT) enterography and magnetic resonance enterography (MRE) has replaced traditional small bowel radiography. Cross-sectional imaging can identify bowel wall thickening with surrounding inflammation, as well as intra-abdominal abscesses and fistulas (Figs. 38.3 and 38.4). A characteristic finding on cross-sectional imaging in Crohn's disease is infiltration of the mesentery with fat, commonly known as *creeping fat*.

Video capsule endoscopy allows for direct visualization of the small bowel mucosa where erosions or ulcerations of the small bowel may be found (Fig. 38.5). Patients with known or suspected strictures should be evaluated for risk of capsule retention before undergoing capsule endoscopy.

Mucosal biopsies in IBD reveal acute and chronic inflammation with infiltration by plasma cells, neutrophils, lymphocytes, and eosinophils; focal ulcerations; crypt architectural distortion; and crypt abscesses (Figs. 38.6 and 38.7). The presence of chronic inflammation distinguishes IBD from other types of acute self-limited colitis like enteric infection. In Crohn's disease, the inflammation is transmural and more commonly focal. Granulomas are found in 25% to 30% of histologic specimens in Crohn's disease. The presence of granulomas is not required but can assist in making the diagnosis of Crohn's disease in the right clinical setting (Fig. 38.8). Granulomas are not diagnostic because they can be found in many other diseases, such as Behçet's disease, tuberculosis, *Yersinia* infection, gastrointestinal and hepatic sarcoidosis, and lymphoma.

Fig. 38.3 Computed tomographic enterography shows inflammatory stricture (arrow) and small bowel wall thickening in a patient with Crohn's disease.

Fig. 38.5 Video capsule endoscopic image shows ulcerated stenosis in a patient with Crohn's disease (arrows).

Fig. 38.6 Normal colonic mucosa (hematoxylin and eosin stain).

The differential diagnosis of IBD includes infectious colitis, ischemic colitis, radiation enteritis, enterocolitis induced by nonsteroidal anti-inflammatory drugs, diverticulitis, appendicitis, gastrointestinal malignancies, and irritable bowel syndrome. In patients with acute onset of bloody diarrhea, infectious causes that must be excluded with stool testing include *Salmonella enteritidis*, *Shigella* species, *Campylobacter jejuni*, *Escherichia coli* O157, and *Clostridioides difficile*. *Clostridioides difficile* is more common among patients with IBD. Among the infectious causes, *Yersinia enterocolitica* can mimic Crohn's disease because the pathogen causes ileitis, mesenteric adenitis, fever, diarrhea, and right lower quadrant abdominal pain. *Mycobacterium tuberculosis*

Fig. 38.7 Mucosal biopsy specimen demonstrates crypt branching and a crypt abscess characteristic of ulcerative colitis (hematoxylin and eosin stain).

Fig. 38.8 Colonic biopsy specimen demonstrates a chronic inflammatory infiltrate with a granuloma in a patient with Crohn's colitis (hematoxylin and eosin stain).

infection, strongyloidiasis, and amebiasis must be excluded in high-risk populations, because these infections can mimic IBD, and treatment with corticosteroids can lead to disseminated infection and death.

TREATMENT

Treatment of IBD follows a systematic, standardized, and evidence-based approach. It relies on first identifying the type of IBD, then categorizing severity of disease, and then identifying a management goal, which now encourages a “treat to target” approach and focuses on endoscopic improvement and healing. Next, a therapeutic agent is selected incorporating data from well-designed clinical studies and also patient tolerability and overall safety, convenience, and preference. Furthermore, the treatment of IBD includes a focus on employing more aggressive and effective “top down” strategies by using biologic and newer oral agents earlier in the course in selected patients with moderate to severe disease. Maximizing the efficacy of current therapies now includes achieving therapeutic levels of these drugs when possible in the attempt to achieve endoscopic healing rapidly and thus improve long-term outcomes.

TABLE 38.3 Treatment Options

Disease Severity	Ulcerative Colitis	Crohn's Disease
Mild	Oral and topical 5-ASA compounds Budesonide MMX	Budesonide EC Elemental diet
Moderate	Oral and topical 5-ASA compounds Oral steroids or budesonide MMX Azathioprine, 6-MP Infliximab, adalimumab, golimumab Vedolizumab Tofacitinib Ustekinumab	Oral steroids or budesonide EC Azathioprine, 6-MP Methotrexate Infliximab, adalimumab, certolizumab pegol Vedolizumab Ustekinumab
Severe	Intravenous steroids Cyclosporine Infliximab, adalimumab, golimumab Vedolizumab Tofacitinib Ustekinumab Surgery	Intravenous steroids Methotrexate Infliximab, adalimumab, certolizumab vedolizumab Ustekinumab Surgery

5-ASA, 5-Aminosalicylic acid; 6-MP, 6-mercaptopurine.

Patients with mild or moderate disease can be managed as outpatients. Patients with severe or fulminant disease—with abdominal pain, fever, tachycardia, anemia, and leukocytosis—require hospital admission and multidisciplinary team management. Because IBD is a chronic recurrent illness, treatment is centered on controlling the acute attack with induction of remission, followed by maintenance of remission. Treatment options for UC and Crohn's disease are summarized in Table 38.3.

In brief, treatment agents for IBD broadly include nontargeted immune suppressants such as corticosteroids, topical anti-inflammatories including 5-aminosalicylic acid (mesalamine) and related agents, antibiotics, and traditional immunomodulators including thiopurine analogs (azathioprine, 6-MP) that inhibit replication of inflammatory cells by inducing cell death or apoptosis and methotrexate, which inhibits replication of inflammatory cells by inhibiting cell division or mitosis.

Newer approved biologic and oral agents work variably by targeting effector pro-inflammatory cytokines such as TNF- α and IL-12/23, targeting immune cell function such as the JAK-STAT enzyme pathway or inhibiting cell trafficking such as the α -4/ β 7 adhesion inhibition.

5-Aminosalicylic Acid (Mesalamine)

The 5-aminosalicylates are given either orally or topically (suppository/enema) or as a combined regimen. They are safe and effective for treatment (i.e., induction of remission) of mild to moderate UC and for maintenance of remission. The efficacy of the 5-aminosalicylic acid (5-ASA) agents in induction or maintenance of remission in Crohn's disease has not been demonstrated. This class of anti-inflammatory medications includes sulfasalazine (Azulfidine) at a dose of 4 to 6 g/day in divided doses. This drug consists of 5-ASA linked to a sulfapyridine moiety; the 5-ASA is released after bacterial lysis of the azo bond in the distal small bowel and colon. Side effects, including headache, nausea, and skin reactions, require discontinuation of sulfasalazine in about 30% of patients. Reversible oligospermia may occur with sulfasalazine.

Rare serious side effects include pleuropericarditis, pancreatitis, agranulocytosis, interstitial nephritis, and hemolytic anemia may occur with sulfasalazine and 5-ASA. Patients who take sulfasalazine need folic acid supplementation.

Derivatives of oral 5-ASA compounds include mesalamine (Pentasa, 4 g/day in divided doses; Delzicol, 2.4 g/day in divided doses; Asacol HD, 2.4 to 4.8 g/day in divided doses; Lialda, 2.4 to 4.8 g once daily; Apriso, 1.5 g once a day), olsalazine (Dipentum, 1 to 2 g/day in divided doses), and balsalazide (Colazal, 6.75 g/day in divided doses; Giazio 3.3 g/day in divided doses). Topical forms of mesalamine (Canasa suppositories, 1000 mg once daily; Rowasa enemas, 4 g once nightly) are commonly used because of a more favorable side effect profile.

Corticosteroids

Corticosteroids may be used topically, orally, or intravenously. They are effective for controlling active inflammatory disease but not for maintaining remission and should act as a bridge to maintenance therapy. They are not indicated for maintenance therapy. They are indicated for moderate or severe disease in patients with UC for whom treatment with 5-ASA has failed. The most commonly used agents are parenteral methylprednisolone for severe/fulminant disease requiring hospitalization at doses of 45 to 60 mg intravenously daily and for outpatients, oral prednisone, started in doses between 40 and 60 mg/day. Patients typically improve rapidly, and the medication is usually tapered down slowly (i.e., by 5 to 10 mg/week) until discontinuation. Patients who do not improve after 1 week of oral treatment and those with more severe disease are best treated in the hospital with intravenous corticosteroids.

Controlled trials have shown that budesonide EC (Entocort EC) is more effective than placebo or oral 5-ASA and has similar efficacy to prednisolone for the induction of remission in Crohn's disease of the terminal ileum (level of evidence I, A). Entocort EC (9 mg given once daily as three 3-mg pills) undergoes extensive first-pass hepatic metabolism and is approved for inducing and maintaining remission of ileal and ileocolonic Crohn's disease (level of evidence III, A) with decreased corticosteroid side effects. Budesonide MMX (Uceris 9 mg given once daily) has an extended release that targets the colon and is approved for the treatment of mild to moderate UC but should not be used as maintenance therapy. Corticosteroids have numerous side effects with long-term use.

Traditional Immunomodulators

The traditional immunomodulators used in IBD include azathioprine (Imuran) and its active metabolite, 6-mercaptopurine (6-MP) (Purinethol), as well as methotrexate and cyclosporine. Metabolism of azathioprine and 6-mercaptopurine is based on the enzyme thiopurine methyl transferase (TPMT). TPMT should be measured in each patient before starting therapy to determine starting dose to minimize toxicity and maximize efficacy. Hematologic monitoring for drug toxicity on therapy is essential. Azathioprine and 6-MP are effective therapies for maintaining remission in both Crohn's disease and UC and are used primarily as corticosteroid-sparing agents. They have a slow onset of action (weeks to months) and consequently are not used to induce remission. Side effects include pancreatitis, nausea, abnormal liver enzymes, bone marrow suppression, opportunistic infections, and an increased risk of lymphoma and nonmelanoma skin cancer.

Methotrexate can be used for induction (25 mg subcutaneously once weekly) and maintenance of remission (15 to 25 mg subcutaneously once weekly) in active Crohn's disease; the side effect profile includes bone marrow suppression, mucositis, interstitial pneumonitis, and with long-term use, cirrhosis. Folic acid should be given with methotrexate to reduce the risk of mucositis. Methotrexate has been

studied as a primary treatment for UC and was not found to be effective. Intravenous cyclosporine (2 mg/kg/day given over 24 hours) is used as a rescue medicine and, in severe UC refractory to intravenous steroids, as a *bridge* treatment to one of the above immunomodulators or biologic agents. Given the potential for both short-term and long-term side effects, as well as the need for close follow-up, patients needing these medications are best managed by gastroenterologists.

Previously used as primary therapy for IBD, azathioprine/6-mercaptopurine and methotrexate are now more commonly used in combination with newer more effective biologic therapies, especially anti-TNF agents.

Biologic Agents

Biologics are a class of medications that target specific aspects of the immune system. The first such agent to be used in IBD was infliximab (Remicade), a chimeric monoclonal antibody to TNF- α , which has been shown to be effective in the treatment of both moderate to severe Crohn's disease, including fistulizing disease, and UC (level of evidence I, A). Anti-TNF agents that are administered subcutaneously include adalimumab (Humira) and golimumab (Simponi), which are fully human monoclonal antibodies, and certolizumab pegol (Cimzia), which is a humanized anti-TNF antibody Fab fragment. Adalimumab, certolizumab pegol, and infliximab are indicated for the treatment of patients with moderate to severe Crohn's disease. Adalimumab, infliximab, and golimumab are approved to treat moderate to severe UC. These agents can be associated with adverse reactions including infusion reactions (infliximab), delayed-type hypersensitivity reaction, and with development of anti-drug antibodies resulting in reduced effectiveness.

Natalizumab (Tysabri), a humanized anti- α_4 -integrin antibody, blocks inflammatory cell migration and adhesion and is approved for the treatment of moderate to severe Crohn's disease in patients who have had an inadequate response to, or are unable to tolerate, conventional Crohn's disease therapies including inhibitors of TNF- α . Due to its link with progressive multifocal leukoencephalopathy (PML) and approval of a more gut selective agent, vedolizumab, it is now rarely used. Vedolizumab (Entyvio), a humanized monoclonal antibody to $\alpha_4\beta_7$ integrin, is approved for the treatment and maintenance of both Crohn's and UC.

Ustekinumab, a monoclonal antibody against the P40 subunit of IL-12 and IL-23, is approved for the induction and maintenance of remission in moderate to severe Crohn's and UC.

Tofacitinib, an oral small molecule that inhibits Janus kinase (JAK) enzymes, is approved for treatment of moderate to severe UC in patients intolerant of or who have not responded to anti-TNFs. Because of the potent effects these biological drugs and oral agents have on the immune system, careful patient selection and monitoring for complications are necessary. Reactivation of latent tuberculosis and other serious infections have been reported with the anti-TNF agents. Other rare but serious complications include non-Hodgkin's lymphoma, exacerbation of congestive heart failure, abnormal complete blood count (CBC) and liver function test results, venous thrombosis, and demyelinating disease. Natalizumab is associated with rare cases of progressive multifocal leukoencephalopathy caused by the human JC virus.

Future biologic agents with alternative mechanisms of action are being developed. These include several selective IL-23 inhibitors such as risankizumab, mirikizumab, guselkumab, and brazikumab. These biologics selectively target the P19 subunit of the interleukin-23 (IL-23) cytokine, thus being more selective than ustekinumab (Stelara), which inhibits the P40 components of both IL-12 and IL-23. A theoretical advantage of IL-23 selectivity is thought to be reduced potential

side effects related to targeting of IL-12, including risk of carcinogenesis suggested in some animal studies.

Additional JAK inhibitors (filgotinib, upadacitinib) are being examined for their role in treatment of IBD. Etrolizumab, a beta7 inhibitor, and ontamalimab, a MadCAM-1 ligand inhibitor, are inhibitors of cell trafficking that are in clinical trials. Ozanimod (RPC1063), an oral agent that acts as a selective agonist and modulator of sphingosine phosphate receptor subtypes 1 and 5, thus inhibiting lymphocyte trafficking to sites of inflammation, is also being tested for its efficacy in UC and Crohn's disease.

The availability of these biologic agents has changed the approach to the management of IBD. The emphasis now has shifted from treating symptoms alone and maintaining clinical remission to treating to a target of endoscopic remission. Endoscopic remission or mucosal healing (as it is typically referred to) is defined as the absence of mucosal ulceration or erosion. The finding of ulceration in the lining of the bowel is associated with higher likelihood of disease flare in asymptomatic patients. Achieving endoscopic remission has been associated with better long-term patient outcomes including longer sustained clinical remissions, lower rates of hospitalization and, in some studies, lower rates of surgery. In this paradigm, after a therapy has been started, an asymptomatic patient will undergo an evaluation 6 to 9 months later to look for evidence of endoscopic remission or ongoing intestinal inflammation. If persistent or significant disease is present, then treatment is typically optimized or changed to try to achieve endoscopic remission. This treat to target approach continues to undergo further study.

Other Agents

Other agents for the treatment of IBD include antibiotics, probiotics, antidiarrheal agents, bile salt resin binders, and nutritional support.

Although used widely in the past for luminal Crohn's, antibiotics are now less commonly employed in routine treatment of patients with luminal Crohn's disease. Current use of antibiotics in active Crohn's is largely limited to treatment of pyogenic complications and in perianal disease. Metronidazole may prevent postoperative recurrence in some patients with luminal Crohn's but adverse effects typically limit its usefulness. There is some evidence for the efficacy of a novel enteric form of rifaximin in mild to moderately active luminal Crohn's disease. The role of antibiotics in UC is unclear, and further studies are required. However, intravenous antibiotics may be used in the initial treatment of severe, toxic, or fulminant colitis when infection is a concern. Antibiotics are useful to treat bacterial overgrowth that can be associated with Crohn's disease.

Probiotics are viable nonpathogenic organisms considered to be food products that after ingestion may prevent or treat intestinal diseases and have been explored in the treatment of IBD. There is some evidence for their efficacy in pouchitis (see later) and UC but no clear benefit in Crohn's disease has been noted thus far. Additional studies are ongoing.

Antidiarrheal agents and bile salt resin binders have no effect on IBD inflammation but can be used as adjuncts for management of diarrhea in patients with IBD, but antidiarrheal agents should be used cautiously during exacerbations of colitis because they may precipitate toxic megacolon. The main role of antidiarrheal medications involves controlling diarrhea in patients who have undergone previous resections. Patients with Crohn's disease who have had less than 100 cm of terminal ileum removed can develop a bile salt malabsorptive state, during which bile salts enter the colon and cause a secretory diarrhea. Bile salt resin binders such as cholestyramine are an effective treatment in these cases. When patients have undergone one or more extensive resections amounting to more than 100 cm of ileum, the bile salt

pool is depleted and fat malabsorption develops. These patients may require a low-fat diet supplemented with medium-chain triglycerides and anti-diarrheal agents, but bile salt resin binders should not be used.

Nutritional support is an important adjunctive aspect in the management of IBD. However, the role of nutrition as a primary treatment has been limited to patients with small bowel Crohn's disease, especially in children. These patients may achieve and maintain remission with total parenteral nutrition or elemental diets after prolonged periods (at least 4 weeks) and potentially avoid the need for corticosteroids. Many patients with Crohn's disease or UC experience weight loss during exacerbations of their illness and need caloric supplements. Vitamins and minerals can be given orally as a multivitamin with folic acid. Vitamin B₁₂ should be supplemented parenterally in patients who have extensive ileal disease or an ileal resection. Patients taking corticosteroids require supplemental calcium and vitamin D, and individuals with extensive small bowel involvement can also develop malabsorption of fat-soluble vitamins (A, D, E, and K), iron, and, rarely, trace minerals. A low-fiber diet may be necessary in patients with active disease or strictures. There is some observational evidence to suggest effectiveness of the specific carbohydrate diet (SCD) in patients with IBD but it is very restrictive in nature; therefore, it is not being widely recommended until further research becomes available.

More studies on diet as a treatment for IBD are needed. Complementary and alternative medicines are used frequently by patients with IBD and it is important that treating clinicians ask about their use.

Surgical Management

Surgical intervention is indicated for patients with complications such as obstruction, perforation, fibrotic stricture, massive gastrointestinal hemorrhage, or toxic megacolon or who are not responsive to medical treatment. The other main indication for surgical treatment is the presence of dysplasia or cancer. For patients with UC, regardless of the extent of disease, the entire colon must be removed. Historically, the initial operation for UC was a total proctocolectomy and Brooke ileostomy, but ileal pouch–anal anastomosis has become the procedure of choice in most patients. In this operation, the colon is removed and the small bowel is constructed into a reservoir (ileal pouch) that is anastomosed to the anus or a short segment of the rectum, allowing defecation through the anus. Complications include the development of inflammation of the rectum (cuffitis) or pouch (pouchitis), fecal incontinence, reduced fertility, and need for reoperation. Surgery is not curative in Crohn's disease. Many surgical procedures in patients with Crohn's disease are performed to manage complications of the disease, including segmental resection, stricturoplasty, fistulectomy, and abscess drainage.

PROGNOSIS

Approximately two thirds of patients with UC have at least one relapse in the 10 years after their diagnosis. About 20% to 30% of patients with extensive UC will require colectomy within their lifetime. Only 5% of individuals with proctitis undergo colectomy by 10 years after diagnosis. In contrast, more than 60% of Crohn's patients require surgery within the 10 years after their diagnosis although these data are based on patients treated in the pre-biologic era. The rate of recurrence in Crohn's disease is high, with 70% of patients having an endoscopic recurrence within 1 year after surgery and 50% having a symptomatic recurrence within 4 years. Predictors of a severe course in Crohn's disease include stricturing or penetrating disease and perianal disease.

The risk for colon cancer is increased in patients with UC, and its magnitude is related to the extent and duration of disease. The colon cancer risk is increased 10- to 20-fold after 8 to 10 years of disease in

pancolitis, and after 15 to 20 years in left-sided colitis. The cumulative incidence of colorectal cancer is 2.5% after 20 years and 7.6% after 30 years of disease. Proctitis is not associated with an increased risk of colorectal cancer. In colonic Crohn's disease, the risk of colorectal cancer is equivalent to that in patients with UC of similar extent and duration. Patients with isolated small bowel Crohn's disease are not at increased risk for colorectal cancer. The rates of small bowel carcinoma and lymphoma are increased in patients with Crohn's disease but the absolute risk is very low.

Surveillance for dysplasia and colon cancer among patients with UC and Crohn's disease colitis should be performed by colonoscopy 8 to 10 years after the onset of symptoms. Surveillance examinations are performed every 1 to 3 years. Proctitis does not require endoscopic surveillance, but colonoscopy should be performed 8 years after diagnosis to look for evidence of proximal spread of the disease. Patients with IBD and PSC appear to have a particularly increased risk for colon cancer, and yearly surveillance is recommended after the initial diagnosis of PSC. UC associated with PSC may have minimal or no symptoms, so all patients with PSC should undergo colonoscopy with biopsy to look for evidence of UC. The classic approach for UC surveillance has been to take a minimum of 33 "random" mucosal biopsy samples during the colonoscopic examination, in addition to targeted samples of visible lesions. The use of chromoendoscopy (spraying of the colon surface with indigo carmine or methylene blue dye during colonoscopy) increases the detection of dysplastic lesions in patients with UC and has replaced the performance of random biopsies in some societal guidelines. Polypoid dysplasia entirely removed by polypectomy in the colon can be managed with continued surveillance colonoscopy. Colectomy is indicated in patients with unresectable dysplasia or evidence of colorectal cancer.

As understanding of the etiologic and pathophysiologic aspects of IBD increases, major advances in diagnosis and treatment are anticipated. These will be based on better use of molecular, genetic, and serologic tests to differentiate among the subtypes of disease; earlier and more targeted use of biologic agents to manage inflammation; and improvements in the detection and prevention of colorectal cancer in those at risk.

Diseases of the Pancreas

David R. Lichtenstein, Pushpak Taunk

ACUTE PANCREATITIS

Definition and Epidemiology

Acute pancreatitis is an acute inflammatory process of the pancreas that may also involve peripancreatic tissues and remote organ systems. It is one of the leading causes of hospitalization for patients with gastrointestinal disorders in the United States, with more than 275,000 admissions annually. This translates into an overall incidence of 5 to 30 cases per 100,000 people in the general population. The aggregate cost of acute pancreatitis is more than \$2.6 billion per year and the overall case fatality is roughly 5%. Approximately 80% of patients admitted with acute pancreatitis have mild, self-limited disease.

Pathology

The pancreas is located in the retroperitoneum and has exocrine and endocrine functions (Fig. 39.1) derived from the pancreatic acinus and the pancreatic islet, respectively. As an exocrine gland, the pancreas participates in normal digestion and nutrient absorption. The enzymes secreted by the pancreas digest starch (i.e., amylase), fats (i.e., lipase), and protein (i.e., trypsin and other proteolytic enzymes). Within acinar cells, proteolytic digestive enzymes are synthesized and packaged separately in the Golgi region into condensing vacuoles and transported in an inactive form referred to as zymogens to the apical portions of the cell. When stimulated, they are discharged into the central ductule of the acinus by exocytosis.

Normal physiology involves secretion of inactive enzymes into the duodenum, where they are converted to an active form by enterokinase, a brush border enzyme secreted by small bowel enterocytes. Trypsinogen conversion to active trypsin is the trigger enzyme that subsequently converts the other zymogens to active enzymes (E-Fig 39.1).

The pathogenesis of acute pancreatitis remains incompletely understood. Based on experimental models, the initiating event appears to involve intra-acinar activation of trypsin from trypsinogen, resulting in acute intracellular injury, pancreatic autodigestion, and the potential for profound systemic complications after activated enzymes are leaked into the bloodstream. The acinar cell injury results in a systemic inflammatory response that involves multiple cytokines, including platelet activating factor, tumor necrosis factor- α (TNF- α), and various interleukins. Initiating events may include obstruction of the pancreatic duct (e.g., gallstones, pancreatic tumor), overdistention of the pancreatic duct (e.g., from endoscopic retrograde cholangiopancreatography [ERCP]), reflux of biliary or duodenal juices into the pancreatic duct, changes in permeability of the pancreatic duct, ischemia of the organ, and toxin-induced cholinergic hyperstimulation (Fig. 39.2).

During the initial hospitalization for acute pancreatitis, reasonable attempts to determine the cause are appropriate, particularly those that

may affect acute management. The cause of acute pancreatitis is readily identified in 70% to 90% of patients after an initial evaluation consisting of the history, physical examination, focused laboratory testing, and routine radiologic studies. Gallstones account for 45%, alcohol for 35%, miscellaneous causes for 10%, and idiopathic causes for 10% to 20% of acute pancreatitis cases (Table 39.1).

Gallstone Pancreatitis

Among patients with gallstones, the incidence of acute pancreatitis is about 0.17% per year. Gallstones increase the relative risk of pancreatitis 25- to 35-fold. Gallstone pancreatitis is more common in women than men. It is theorized that gallstone passage causes transient obstruction of the pancreatic duct, precipitating acute pancreatitis. Acute gallstone pancreatitis should be suspected when associated with a transient elevation in liver-associated enzymes, particularly alanine aminotransferase (ALT) levels greater than 150 IU/L. Most stones pass spontaneously from the ampulla and do not require intervention (discussed later).

Alcoholic Pancreatitis

Acute alcoholic pancreatitis is the second most common cause of pancreatitis in the United States. Approximately 10% of individuals with an alcohol use disorder develop attacks of pancreatitis that are indistinguishable from other forms of acute pancreatitis. Prolonged alcohol use (four to five drinks daily over a period of more than 5 years) is required for alcohol-associated pancreatitis. The type of alcohol does not affect risk, and binge drinking in the absence of long-term, heavy alcohol use infrequently precipitates acute pancreatitis. Alcoholics with acute pancreatitis most commonly have underlying chronic disease. However, some have true acute alcoholic pancreatitis because not all patients progress to chronic pancreatitis, even with continued alcohol use. The mechanism of pancreatic injury, the genetic and environmental factors that influence its development in alcoholics, and the reason only a small proportion of alcoholics develop pancreatitis are unclear (see "Chronic Pancreatitis").

Hypertriglyceridemia

Hypertriglyceridemia is the third most identifiable cause of pancreatitis, and serum triglyceride levels greater than 1000 mg/dL may precipitate attacks of acute pancreatitis. Patients may have lactescent (milky) serum owing to increased concentrations of chylomicrons. Both primary and secondary disorders of lipoprotein metabolism are associated with hypertriglyceridemic pancreatitis. Although the exact pathogenesis of hypertriglyceridemic pancreatitis is unclear, the release of free fatty acids by lipase may damage pancreatic acinar cells or capillary endothelium. The main treatment modalities for initial management of hypertriglyceridemia are apheresis with therapeutic plasma

E-Fig. 39.1 Mechanism of proenzyme activation in the intestinal lumen. (Modified from Solomon TE: Exocrine pancreas: pancreatitis. In the Undergraduate teaching project in gastroenterology and liver disease, unit 24, Bethesda, Md., 1984, American Gastroenterological Association.)

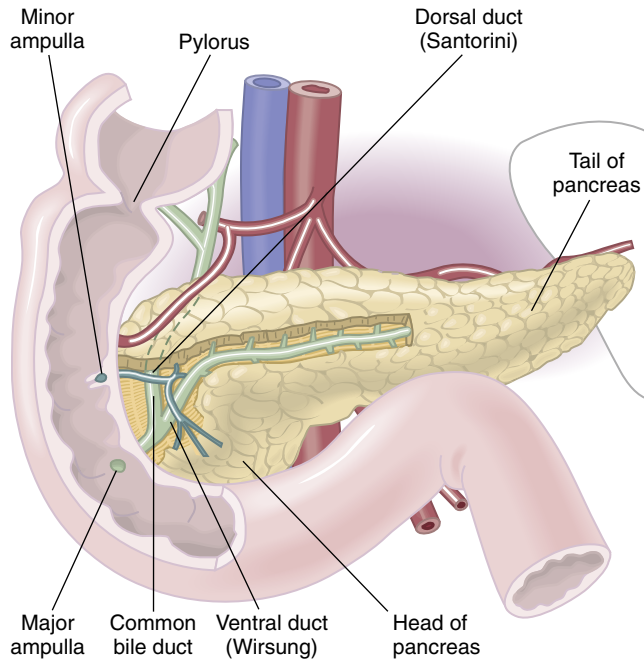

Fig. 39.1 Normal anatomy of the pancreas.

exchange and insulin. Lowering serum triglyceride levels to less than 200 mg/dL can prevent pancreatitis and is typically done with a combination of diet and medications.

Drug-Related Pancreatitis

Drugs appear to cause fewer than 5% of all cases of acute pancreatitis, although hundreds of medications have been implicated. The drugs most strongly associated with acute pancreatitis are azathioprine, 6-mercaptopurine, didanosine, valproic acid, angiotensin-converting-enzyme inhibitors, eluxadoline, and mesalamine. Though there are several potential pathogenic mechanisms of drug-induced pancreatitis, the most common is a hypersensitivity reaction. This tends to occur 4 to 8 weeks after starting the drug and is not dose related. On re-challenge with the drug, pancreatitis recurs within hours to days. The second mechanism is the presumed accumulation of a toxic metabolite that may cause pancreatitis, typically after several months of use. Pancreatitis caused by drugs is usually mild and self-limited.

Heredity

Hereditary causes of pancreatitis include mutations in the genes encoding cationic trypsinogen (*PRSS1*), pancreatic secretory trypsin inhibitor (serine protease inhibitor Kazal type 1 [*SPINK1*]), cystic fibrosis transmembrane conductance regulator (*CFTR*), chymotrypsin

Fig. 39.2 The pathophysiology of acute pancreatitis is not fully understood, but as the schematic shows, a cascade of events seems likely, beginning with the release of toxic substances into the parenchyma and ending with shock and death. Damage to the ductal epithelium or acinar cell injury may result from bile reflux, increased intraductal pressure, alcohol, or trauma. (Modified from Grendell JH: The pancreas. In Smith LH Jr, Thier SO, editors: Pathophysiology: the biological principles of disease, ed 2, Philadelphia, 1985, WB Saunders, p 1228.)

TABLE 39.1 Causes of Acute Pancreatitis**Obstruction**

Gallstones
 Tumors: ampullary or pancreatic tumors
 Parasites: *Ascaris* or *Clonorchis* species
 Developmental anomalies: pancreas divisum, choledochocoele, annular pancreas
 Periapillary duodenal diverticula
 Hypertensive sphincter of Oddi
 Afferent duodenal loop obstruction

Toxins

Ethyl alcohol
 Methyl alcohol
 Scorpion venom: excessive cholinergic stimulation causes salivation, sweating, dyspnea, and cardiac arrhythmias; seen mostly in the West Indies
 Organophosphorus insecticides

Drugs

Definite associations (documented with rechallenges): azathioprine or 6-mercaptopurine, valproic acid, estrogens, tetracycline, metronidazole, nitrofurantoin, pentamidine, furosemide, sulfonamides, methyl dopa, cytarabine, cimetidine, ranitidine, sulindac, dideoxycytidine
 Probable associations: thiazides, ethacrynic acid, phenformin, procainamide, chlorthalidone, L-asparaginase

Metabolic Disorders

Hypertriglyceridemia, hypercalcemia, end-stage renal disease

Trauma

Accidental: blunt trauma to the abdomen (e.g., car accident, bicycle)
 Iatrogenic: postoperative, endoscopic retrograde cholangiopancreatography

Infectious Diseases

Parasitic: ascariasis, clonorchiasis
 Viral: mumps, rubella, hepatitis A, hepatitis B, hepatitis C, coxsackievirus B, echovirus, adenovirus, cytomegalovirus, varicella virus, Epstein-Barr virus, human immunodeficiency virus
 Bacterial: mycoplasma, *Campylobacter jejuni*, tuberculosis, *Legionella* species, leptospirosis

Vascular Disorders

Ischemia: hypoperfusion (e.g., postcardiac surgery) or atherosclerotic emboli
 Vasculitis: systemic lupus erythematosus, polyarteritis nodosa, malignant hypertension

Idiopathic Disorders

Accounts for 10–30% of patients with pancreatitis
 Up to 60% have occult gallstone disease (e.g., biliary microlithiasis, gallbladder sludge)
 Less common causes: sphincter of Oddi dysfunction, mutations in the cystic fibrosis transmembrane regulator

Miscellaneous Disorders

Penetrating peptic ulcer
 Crohn's disease of the duodenum
 Pregnancy-associated disorders
 Pediatric associations: Reye's syndrome, cystic fibrosis
 Autoimmune pancreatitis

C (i.e., caldecrin) (*CTRC*), the calcium-sensing receptor (*CASR*), and claudin-2. Aside from acute pancreatitis, mutations in these genes may increase the risk of development of diabetes and pancreatic cancer.

The role of genetic testing in idiopathic acute pancreatitis is controversial. Diagnosis of these genetic disorders contributes little to direct management because specific therapy is unavailable. Similarly, inadvertent disclosure of the results of genetic testing protects patients' health care insurance but may impact other financial decisions such as disability and life insurance. However, identification of an underlying genetic cause may obviate the need for further testing, allow more informed family planning, and enable better surveillance for complications, including pancreatic

cancer. The decision to pursue genetic testing is one that should be made only with the advice and involvement of an experienced counselor.

Neoplasia

Primary pancreatic ductal adenocarcinoma, ampullary tumors, metastasis to the pancreas, and intraductal papillary mucinous neoplasms are uncommon causes of acute pancreatitis. The mechanism of pancreatitis is presumably secondary to obstruction of the pancreatic duct. These causes should be considered for patients older than 40 years. Pancreatitis has been reported in up to 10% of patients with pancreatic cancer (see [Chapter 58](#)).

E-Fig. 39.2 Endoscopic retrograde cholangiopancreatography shows the pancreatic ductal system in pancreas divisum. The upper duct (i.e., dorsal pancreas) was visualized by injecting contrast into the duct of Santorini. The lower duct (i.e., ventral pancreas) was highlighted by injecting the duct of Wirsung.

Smoking

Smoking was once thought to be a risk factor due to its synergism with alcohol. However, studies have suggested that cigarette smoking is an independent risk factor for acute and chronic pancreatitis by mechanisms that are unclear.

Autoimmune Pancreatitis

Autoimmune pancreatitis (AIP) is a benign disease representing two distinct but overlapping immune-mediated inflammatory conditions of the pancreas referred to as type 1 and type 2 AIP. Type 1 is the classic and more common form of AIP. It is characterized histologically by a periductal lymphoplasmacytic infiltrate, storiform fibrosis, obliterative phlebitis, and abundant immunoglobulin G4 (IgG4) immunostaining (>10 IgG4-positive cells per high-power field).

The most common manifestation of AIP is obstructive jaundice, which closely mimics pancreatic cancer with focal enlargement of the pancreatic head. AIP can also manifest as acute pancreatitis in up to 15% to 30% of individuals, and about 5% of patients evaluated for acute or chronic pancreatitis have AIP. AIP has a peak incidence in the sixth or seventh decades of life and tends to affect men twice as often as women. Serum IgG4 levels are elevated to more than two times the upper limit of normal in most patients. Computed tomography (CT) typically demonstrates diffuse enlargement of the pancreas with delayed (rim) enhancement and a diffusely irregular, attenuated main pancreatic duct. More than 60% of individuals have clinical and histologic involvement of other organs, including the biliary tree, retroperitoneum, lacrimal and salivary glands, lymph nodes, periorbital tissues, kidneys, thyroid, lungs, meninges, aorta, breast, prostate, pericardium, and skin. Although a majority of patients initially respond to glucocorticoids, a significant portion of patients relapse once glucocorticoids are discontinued. Immunomodulator drugs have been used in those that fail steroids, relapse or cannot be weaned off steroids.

A less common form of AIP (type 2 AIP) has a similar clinical and radiographic presentation in the pancreas, but in contrast to type 1 disease, it requires histologic confirmation of an idiopathic duct centric pancreatitis lesion. Other hallmarks of type 1 disease are absent such that IgG4 levels are normal and other organs are not involved. Type 2 AIP is similarly steroid responsive but unlike type 1 disease, relapse is uncommon.

Pancreas Divisum

At approximately 4 weeks' gestation, the dorsal pancreas forms as an evagination from the duodenum, and shortly thereafter, the ventral pancreas forms from the hepatic diverticulum (E-Fig. 39.2). At approximately the eighth intrauterine week of life, the ventral pancreas rotates posterior to the duodenum and comes to rest posterior and inferior to the head portion of the dorsal pancreas with associated fusion of the main ducts. If fusion is incomplete, the duct of Wirsung drains only the ventral pancreas through the major ampulla, and the duct of Santorini drains the bulk of the pancreas (i.e., dorsal pancreas) through the relatively small accessory (minor) ampulla. This anomaly, called *pancreas divisum*, occurs in 5% to 10% of the general population and is associated with acute and chronic pancreatitis.

Theories suggest that pancreatitis results from relative outflow obstruction of the main dorsal duct through the small accessory ampulla. Endoscopic papillotomy, stent placement across the minor papilla, and surgical sphincteroplasty are therapeutic maneuvers that may reduce the incidence of recurrent pancreatitis by increasing drainage through the accessory papilla. While there are studies that appear to show an association between pancreas divisum and pancreatitis, there is controversy as to whether pancreas divisum is truly a cause of acute recurrent pancreatitis.

Clinical Presentation

The hallmark of acute pancreatitis is persistent abdominal pain. In atypical cases, patients may have unexplained organ failure or postoperative ileus. The onset of pain is typically sudden, severe, and worse when supine. Pain is usually located in the upper abdomen and may radiate to the back, chest, and flanks. Nausea and vomiting are common. Physical examination usually reveals severe upper abdominal tenderness that is sometimes associated with guarding.

Pancreatic enzymes, vasoactive substances (e.g., kinins), and other toxic substances (e.g., elastase, phospholipase A₂) are liberated by the inflamed pancreas and extravasate along fascial planes in the retroperitoneal space, lesser sac, and peritoneal cavity. These materials cause chemical irritation and contribute to the development of ileus, chemical peritonitis, third-space losses of protein-rich fluid, hypovolemia, and hypotension. The toxic molecules may reach the systemic circulation by lymphatic and venous pathways and contribute to subcutaneous fat necrosis and end-organ damage, including shock, renal failure, and respiratory insufficiency (i.e., atelectasis, effusions, and acute respiratory distress syndrome [ARDS]). Grey Turner sign (i.e., ecchymosis of the flank) or Cullen sign (i.e., ecchymosis in the periumbilical region) may be associated with hemorrhagic pancreatitis.

Metabolic problems, which are common in severe disease, include hypocalcemia, hyperglycemia, and acidosis. Hypocalcemia is most commonly caused by concomitant hypoalbuminemia. Other mechanisms include complexing of calcium to released free fatty acids, protease-induced degradation of circulating parathyroid hormone (PTH), and failure of PTH to release calcium from bone.

Acute pancreatitis is associated with a variety of local and vascular complications, including local spread of inflammation to contiguous organs. The most common include peripancreatic fluid collections, pseudocyst formation, obstruction of the duodenum or bile duct, and exocrine or endocrine insufficiency. Less common complications include pancreatic fistula formation, vascular thrombosis (i.e., splenic, portal and superior mesenteric veins), colonic necrosis, and development of an arterial pseudoaneurysm. Trypsin can activate plasminogen to plasmin and induce clot lysis. However, trypsin also can activate prothrombin and thrombin and produce thrombosis leading to disseminated intravascular coagulation.

Acute peripancreatic fluid collections are pools of peripancreatic fluid confined by normal peripancreatic fascial planes without a definable wall encapsulating the collection. These fluid collections occur during the first 4 weeks after interstitial pancreatitis. When a localized acute peripancreatic fluid collection persists beyond 4 weeks, it is likely to develop into a pancreatic pseudocyst.

Pancreatic pseudocysts (E-Fig. 39.3) are encapsulated fluid collections with well-defined inflammatory walls and are usually located outside the pancreas with minimal or no necrosis. They occur a minimum of 4 weeks after the onset of acute pancreatitis. Although most pseudocysts remain asymptomatic, presenting symptoms may include abdominal pain, early satiety, nausea, and vomiting due to compression of the stomach or gastric outlet. Rapidly enlarging pseudocysts may rupture, hemorrhage, obstruct the extrahepatic biliary tree, erode into surrounding structures, and become infected.

The term *acute necrotic collection* describes a nonorganized accumulation of heterogeneous fluid and necrotic material in the setting of necrotizing pancreatitis. The necrosis may involve the pancreatic parenchyma or peripancreatic tissue, or both. Walled-off pancreatic necrosis is a mature, encapsulated collection of pancreatic or peripancreatic necrosis that usually occurs more than 4 weeks after the onset of necrotizing pancreatitis.

Abdominal compartment syndrome is diagnosed when the intra-abdominal pressure exceeds 20 mm Hg and there are signs of new

respiratory, renal, or vascular organ failure. Intra-abdominal hypertension typically occurs early and is the result of pancreatic inflammation and fluid third spacing. Abdominal compartment syndrome is associated with mortality rates ranging up to 50% to 75% in various reports. Suggested treatment includes analgesics, sedation, nasogastric tube decompression, and fluid restriction. If these measures do not result in improvement, percutaneous catheter decompression followed if unsuccessful by a surgical laparotomy is recommended. The ability of this approach to improve outcomes is the focus of ongoing research.

Diagnosis and Differential Diagnosis

The diagnosis of acute pancreatitis is based on a combination of clinical, biochemical, and radiologic factors. A diagnosis of acute pancreatitis requires two of the following three features: abdominal pain characteristic of acute pancreatitis; serum amylase or lipase levels, or both, at least three times the upper limit of normal; and characteristic findings of acute pancreatitis on imaging.

Elevated serum amylase levels may occur in a wide variety of other conditions, including bowel perforation, intestinal obstruction or ischemia, acute appendicitis, cholecystitis, tubo-ovarian disease, and renal failure. Serum amylase levels may be normal in patients with hypertriglyceridemia or alcohol-induced acute pancreatitis. Serum lipase is preferred because it is more sensitive and specific than serum amylase for the diagnosis of acute pancreatitis. The serum lipase level remains normal in some nonpancreatic conditions associated with an elevated serum amylase level, including macroamylasemia (i.e., formation of large molecular complexes between amylase and abnormal immunoglobulins), salivary gland disorders, and tubo-ovarian disease, but it may similarly rise in appendicitis, renal disease, and cholecystitis. The serum lipase concentration is more sensitive than that of amylase because it remains elevated longer and may be diagnostic even for patients seeking medical attention several days after symptom onset. Repeated measurements of serum pancreatic enzymes have little value in assessing clinical progress, and the magnitude of serum amylase or lipase elevation does not correlate with the severity of pancreatitis.

Contrast-enhanced computed tomography (CECT) or magnetic resonance imaging (MRI) of the pancreas should be used for patients whose diagnosis is unclear or who fail to improve within the first 48 to 72 hours after hospital admission. Imaging findings supporting acute pancreatitis include pancreatic enlargement, peripancreatic inflammatory changes, and extrapancreatic fluid collections. Imaging does not exclude the diagnosis of acute pancreatitis because the pancreas appears normal in 15% to 30% of those with mild disease. CECT is also useful for assessing disease severity based on the presence and extent of complications such as pancreatic necrosis and acute peripancreatic fluid collections. Pancreatic imaging should be performed after adequate fluid resuscitation to minimize the risk of contrast-induced nephrotoxicity.

MRI is preferred for patients with a contrast allergy and renal insufficiency because T2-weighted images without gadolinium contrast can similarly diagnose pancreatic necrosis. Early imaging (within 72 hours of symptom onset) can underestimate the existence and extent of pancreatic necrosis. Gallstone pancreatitis should be suspected in patients with transient elevation in liver function test results, particularly a serum ALT level elevated more than 3-fold. Transabdominal ultrasonography should be performed in all patients with acute pancreatitis when considering a diagnosis of gallstone pancreatitis.

Prognosis

The distinction between interstitial and necrotizing acute pancreatitis has important prognostic implications (Fig. 39.3). *Interstitial pancreatitis* is characterized by an intact microcirculation and uniform

enhancement of the gland on CECT. *Necrotizing pancreatitis* is characterized by disruption of the pancreatic microcirculation so that large areas (>3 cm or >30%) of pancreatic parenchyma do not enhance on CECT. Approximately 20% to 30% of patients with acute pancreatitis have necrotizing pancreatitis.

The finding of pancreatic necrosis predicts a more severe course, particularly infection in the necrotic pancreatic tissue, also called *infected necrosis*. Infection is a strong determinant of the severity of illness and accounts for a large percentage of the deaths from acute pancreatitis. Infected necrosis develops in 30% to 50% of patients with acute necrotizing pancreatitis but not in those with interstitial disease. Infected necrosis should be suspected in patients with persistent systemic inflammatory response syndrome (SIRS) or organ dysfunction. The diagnosis can be made if extraluminal gas is seen on CECT. More commonly, CT-guided needle aspiration is obtained for Gram stain and culture of necrotic material, or antibiotics are given empirically based on clinical suspicion after appropriate cultures are obtained. Antibiotics that penetrate pancreatic tissue, including cephalosporins, carbapenems, quinolones, and metronidazole, are used for treatment of infected necrosis.

Risk assessment should be performed for all patients to stratify the severity of illness. The current classification includes mild, moderate, and severe forms. Mild acute pancreatitis, the most common form, is characterized by the absence of organ failure and pancreatic necrosis. Mild pancreatitis usually does not require pancreatic imaging, and patients recover within several days with restoration of normal pancreatic function and gland architecture. Patients with mild acute pancreatitis account for 80% of all attacks and less than 5% of the overall mortality rate.

Moderately severe pancreatitis is characterized by local complications and/or transient organ failure over a time period of less than 48 hours. Local complications include pancreatic necrosis (with or without infection) and acute peripancreatic fluid collections or pancreatic pseudocysts. Death from moderately severe pancreatitis is much less common than in cases of severe pancreatitis.

Severe acute pancreatitis is defined by persistent organ failure extending for more than 48 hours. Severe acute pancreatitis occurs in 15% to 20% of patients. Most individuals with persistent organ failure have underlying necrotizing disease. The respiratory, cardiovascular, and renal systems are most commonly affected. Early deaths (within the first week) are most often the result of multiple organ failure caused by the release of inflammatory mediators and cytokines. Late deaths are more likely to result from local or systemic infection. The risks of infection and death correlate with disease severity and pancreatic necrosis. The overall mortality approaches 30% among patients with persistent organ failure.

Despite the importance of recognizing severe disease, most patients are initially admitted to the hospital without necrosis or organ failure, and methods to predict individuals more likely to progress to severe disease during the initial several days of hospitalization have been defined. A combination of clinical assessment, scoring systems, serum markers, and CECT scanning provides the most useful prognostic information (Table 39.2). Regardless of the prognostic factor chosen, there are significant limitations in predicting disease severity.

Clinical predictors of a poor outcome include severe comorbid illnesses, older age (≥ 60 years), obesity, and long-term, heavy alcohol use. Laboratory findings associated with increased mortality include blood urea nitrogen elevation (>20 mg/dL) on admission or a rise during the first 24 hours of admission, hemoconcentration from third spacing of fluids reflected by an elevated hematocrit of 44 or greater on admission, and serum markers reflecting a robust systemic inflammatory response, such as a C-reactive protein level greater than

E-Fig. 39.3 Computed tomography scan shows a large pancreatic pseudocyst.

Fig. 39.3 Contrast-enhanced computed tomography demonstrates interstitial pancreatitis (A) and necrotizing pancreatitis (B).

TABLE 39.2 Predictors of Severe Pancreatitis

Criteria	Prognostic Indicators
Signs ^a	Heart rate: >90 beats/min Temperature: >38° C or <36° C White blood cell count: >12,000 or <4,000 cells/μL or >10% bands Respiratory rate >20 breaths/min or PaCO ₂ <32 mm Hg
Patient characteristics	Comorbid illnesses Age >55 yr Obesity (BMI >30 kg/m ²)
Laboratory values	BUN level of 20 mg/dL or higher and any rise in BUN during the first 24 hr of admission associated with increased mortality Serum creatinine >1.8 mg/dL within first 24 hr Hemoconcentration with Hct ≥44 on admission or failure of Hct to decrease in first 24 to 48 hr with volume resuscitation predicts severe pancreatitis Serum marker reflecting a systemic inflammatory response, CRP >150 mg/dL
Imaging findings	Pleural effusion Pancreatic necrosis Acute extrapancreatic fluid collections
Scoring systems	
Ranson's criteria	Eleven prognostic indicators, including five available on admission (age >55 yr, WBC >16,000/mm ³ , glucose >200 mg/dL, LDH >350 IU/L, AST >250 U/L) and six measured at the end of the first 48 hr (Hct decreased >10, BUN >5 mg/dL, P _O ₂ <60 mm Hg, base deficit >4 mEq/L, serum calcium <8 mg/dL, estimated fluid sequestration >6 L); mortality rate of 10–20% for three to five signs and >50% for six or more signs
Acute Physiologic and Chronic Health Evaluation (APACHE II) system	Calculated by assigning points based on age, heart rate, temperature, respiratory rate, mean arterial pressure, PaO ₂ , pH, potassium, sodium, creatinine, Hct, WBC, GCS, and previous health status
Bedside Index for Severity of Acute Pancreatitis (BISAP)	Five variables available in initial 24 hr: BUN >25 mg/dL, impaired mental status (GCS score <15), finding of SIRS, age >60 yr, and pleural effusion on imaging. Each variable adds 1 point to the total score, and scores of 3, 4, and 5 correspond to mortality rates of 5.3%, 12.7%, and 22.5%, respectively.

AST, Aspartate aminotransferase; BMI, body mass index; BUN, blood urea nitrogen; CRP, C-reactive protein; GCS, Glasgow Coma Scale; Hct, hematocrit; LDH, lactate dehydrogenase; SIRS, systemic inflammatory response syndrome; WBC, white blood cells.

^aSIRS predisposes to multiple organ dysfunction and pancreatic necrosis. SIRS is defined by two or more of these criteria persisting for more than 48 hours.

150 mg/dL (sensitivity of 80%, specificity of 76%, positive predictive value of 67%, and negative predictive value of 86%). Imaging studies predicting a severe outcome include a pleural effusion seen on chest radiography within the first 24 hours or pancreatic imaging identifying necrosis. Unfortunately, CT evidence of severe acute pancreatitis lags

behind clinical findings, and an early CT study can underestimate the severity of the disorder.

Severe pancreatitis is predicted by organ dysfunction, including shock (systolic blood pressure <90 mm Hg), respiratory failure (PaO₂ ≤60 mm Hg), and acute renal injury (creatinine >2.0 mg/L after

rehydration). SIRS predisposes to multiple organ dysfunction and pancreatic necrosis.

Well-established scoring systems include Ranson's criteria, Acute Physiologic and Chronic Health Evaluation II (APACHE II), APACHE combined with scoring for obesity (APACHE-O), the Glasgow Scoring System, and Bedside Index for Severity of Acute Pancreatitis (BISAP). With increasing scores, the likelihood of a complicated, prolonged, and fatal outcome increases. Unfortunately, because these scoring systems have a high false-positive rate (i.e., in many patients with high score, severe pancreatitis does not develop), they are not universally used. During the first 48 to 72 hours, a rising hematocrit or BUN, persistent SIRS after fluid resuscitation or the presence of pancreatic or peripancreatic necrosis on cross-sectional imaging constitute evidence of evolving severe pancreatitis.

Treatment

Early steps in the management of patients with acute pancreatitis can decrease severity, morbidity, and mortality (Fig. 39.4). Prevention of complications depends largely on monitoring, vigorous hydration, and early recognition of pancreatic necrosis and choledocholithiasis. Patients with multiorgan dysfunction and those with predicted development of severe disease are at greatest risk for adverse outcomes and should be treated when possible in a care unit with intensive monitoring capability and multidisciplinary input.

Supportive Care

Patients with acute pancreatitis are treated supportively with aggressive intravenous hydration, parenteral analgesics, and bowel rest. Supplemental oxygen is recommended initially for all patients. Nasogastric tube suction is indicated for symptomatic relief in patients with nausea, vomiting, and ileus. No specific treatments are effective in limiting systemic complications. Agents that put the pancreas to rest (e.g., somatostatin, calcitonin, glucagon, H₂-receptor antagonists) and enzyme inhibitors (e.g., aprotinin, gabexate mesylate) have not been shown to lower disease-related morbidity and mortality.

Antibiotics

Antibiotic therapy is no longer recommended for patients with sterile necrosis due to the lack of proven benefit. For patients with suspected infected necrosis, appropriate antibiotics are initiated before the confirmatory diagnosis, with the initial choice taking into consideration the likely pathogenic organisms and the ability of the antimicrobials to penetrate into necrotic pancreatic tissues. After culture results are available, the antibiotics can be tailored appropriately.

Fluid Management

Vigorous fluid resuscitation is important for maintaining the microcirculation and perfusion of the pancreas during the early phase of acute pancreatitis. Early aggressive intravenous hydration during the first 12 to 24 hours after the onset of symptoms translates into a potential benefit of reduced pancreatic necrosis and organ failure. Vigorous fluid therapy is of little value after 24 hours. Crystalloid, the preferred intravenous fluid, is administered at an initial rate of 250 to 500 mL/hour or 5 to 10 mL/kg/hr with a preceding bolus infusion for individuals with severe volume depletion. Lactated Ringer's solution may be the preferred crystalloid replacement because in one comparative study, it reduced the incidence of inflammatory markers by more than 80% compared with normal saline infusion. Goal-directed fluid therapy is recommended for patients with acute pancreatitis. Goal-directed therapy is defined as titration of intravenous fluids every few hours to specific clinical and biochemical targets of perfusion (e.g., heart rate, blood pressure, urine output, BUN, and hematocrit). Caution must be

used for the elderly and those with underlying cardiovascular or renal impairment.

Analgesia

Despite the theoretical concern that narcotic analgesia may result in sphincter of Oddi spasm and worsening pancreatitis, there is no evidence to support withholding narcotics from patients with acute pancreatitis. The physician should consider liberal use of patient-controlled analgesia, although this approach has not been compared prospectively with on-demand analgesia. There is no evidence to indicate superiority of a specific opiate. Patients administered repeated doses of narcotic analgesics should have oxygen saturation monitored due to risks of unrecognized hypoxia.

Nutritional Care

Patients with mild acute pancreatitis can begin oral feeding within 24 hours of admission without waiting for resolution of pain or normalization of serum pancreatic enzyme levels. Early introduction of a low-fat solid diet is as safe as the traditional approach of progressive advancement from a clear liquid diet and is associated with a shorter length of hospital stay.

For patients with predicted severe pancreatitis or small bowel ileus, early introduction of oral intake may not be tolerated due to postprandial abdominal pain, nausea, and vomiting. These individuals can have nutrition introduced as nasoenteric or nasogastric feeding. Enteral feeding is preferable to total parenteral nutrition (TPN) because it is less expensive than TPN and is associated with a reduction in systemic infection, need for surgical intervention, organ failure, and mortality. Enteral feeding is usually well tolerated, even by patients with an ileus. Nasogastric feeding offers a safe alternative to nasojejunal feeding because it appears to be equally safe and effective. Parenteral nutrition should be reserved for patients who cannot achieve sufficient caloric intake through the enteral route or those in whom enteral access cannot be maintained.

Management of Recurrence and Necrosis

Gallstone pancreatitis. The risk of gallstone pancreatitis (see also Chapter 45) recurrence is as high as 50% to 75% within 6 months of the initial episode, and cholecystectomy before discharge is recommended for patients with mild attacks of pancreatitis. Cholecystectomy performed during the initial admission for patients with suspected biliary pancreatitis is associated with substantial reductions in mortality and gallstone-related complications, readmission for recurrent pancreatitis, and pancreaticobiliary complications. Cholecystectomy is often delayed in patients with severe pancreatitis to allow for better exposure of the ductal anatomy at the time of surgery. Urgent ERCP (Video 39.1) with identification and clearance of bile duct stones is recommended for patients with documented choledocholithiasis on imaging, cholangitis or strong evidence of ongoing biliary obstruction, as suggested by imaging and laboratory data. Biliary sphincterotomy leaving the gallbladder in situ is considered an effective alternative for those who are not candidates for cholecystectomy.

Acute fluid collections and pseudocysts. Acute peripancreatic fluid collections do not require any specific therapy, other than supportive therapy that is standard for acute pancreatitis. Most remain sterile and are reabsorbed spontaneously during the first several weeks after the onset of acute pancreatitis. When a localized acute peripancreatic fluid collection persists beyond 4 weeks, it is likely to develop into a pancreatic pseudocyst. While patients with asymptomatic pseudocysts should be followed, for those who are symptomatic, pseudocyst drainage should be considered. Indications for pseudocyst drainage include suspicion of infection or progressive

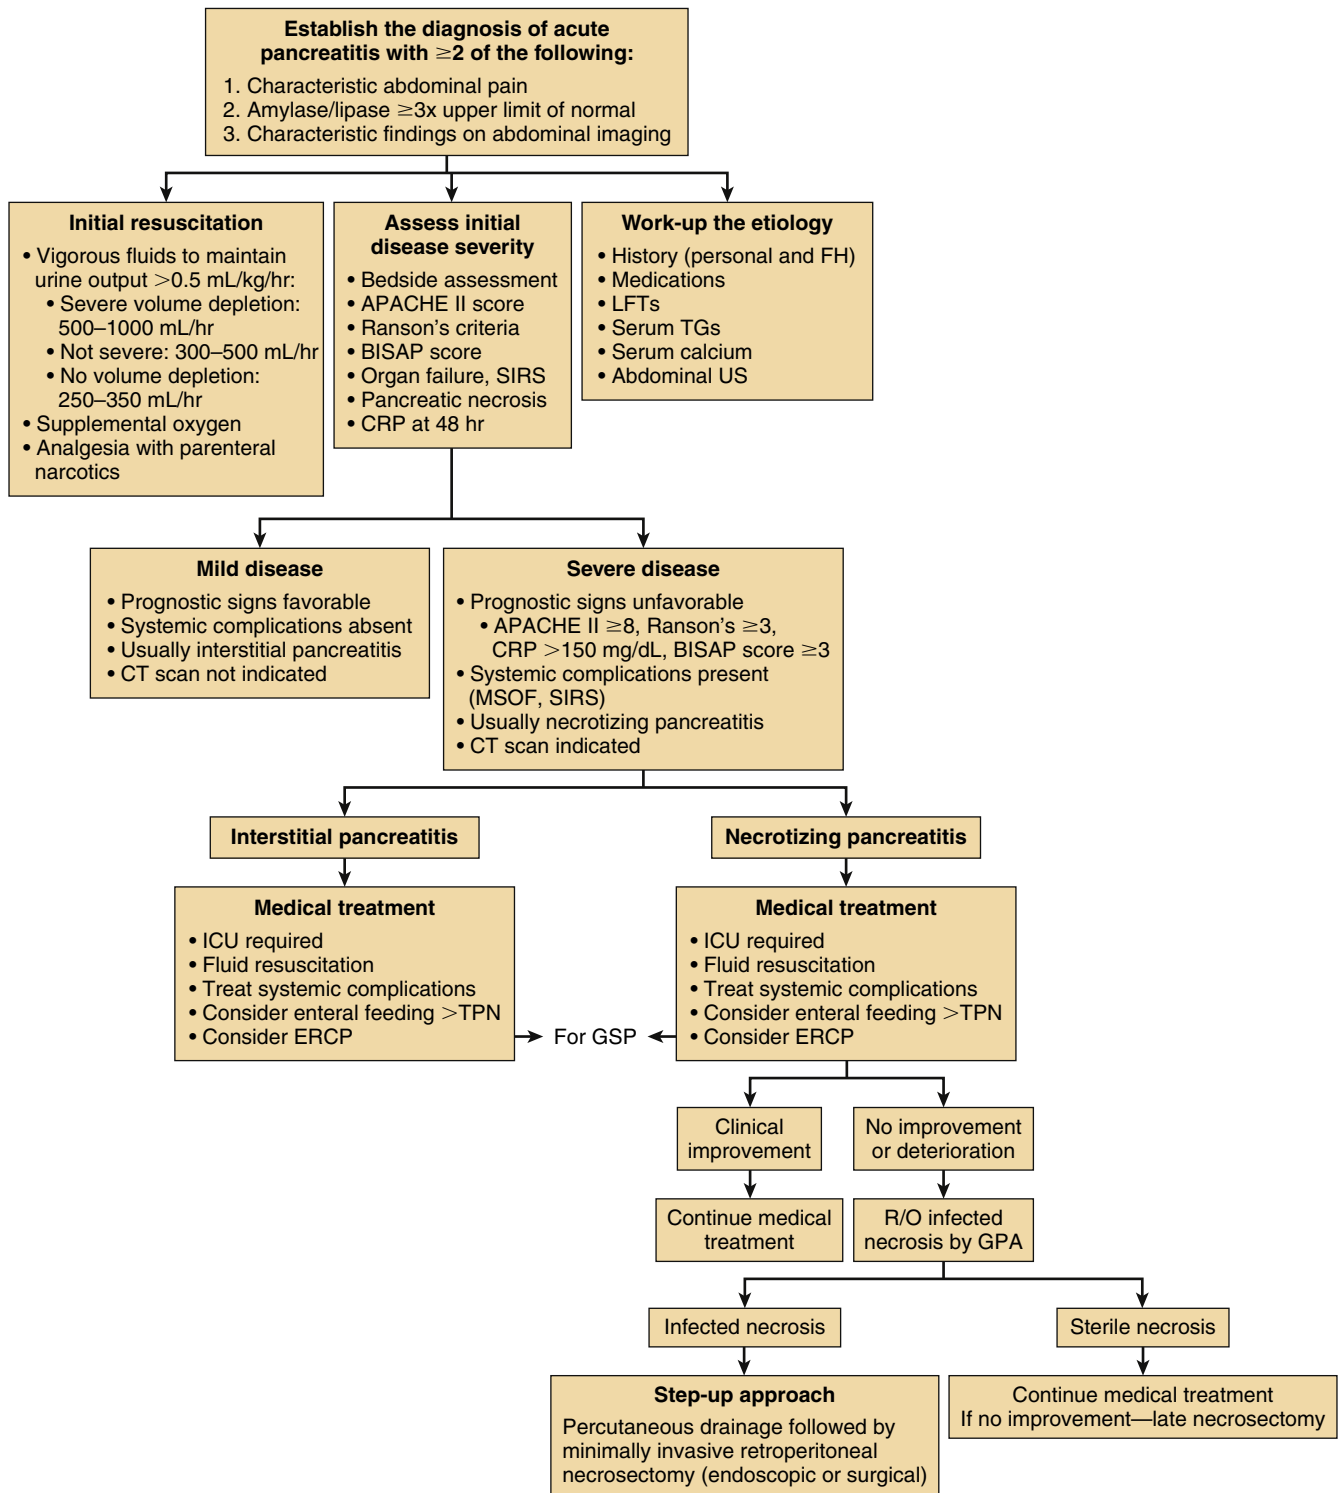

Fig. 39.4 Management algorithm for acute pancreatitis. Some of the guidelines, such as the diagnostic utility of the C-reactive protein (CRP) level, require further validation. Antibiotic use, including the type and duration of treatment, continues to be examined, and these suggested approaches will likely be modified by the findings of future studies. *APACHE II*, Acute Physiologic and Chronic Health Evaluation II; *BISAP*, Bedside Index for Severity of Acute Pancreatitis; *CT*, computed tomography; *ERCP*, endoscopic retrograde cholangiopancreatography; *FH*, family history; *GPA*, CT-guided percutaneous aspiration; *GSP*, gallstone pancreatitis; *ICU*, intensive care unit; *LFTs*, liver function tests; *MSOF*, multiple system organ failure; *R/O*, rule out; *SIRS*, systemic inflammatory response syndrome; *TGs*, triglycerides; *TPN*, total parenteral nutrition; *US*, ultrasound.

enlargement with associated symptoms including biliary obstruction, abdominal pain, early satiety, and nausea and vomiting due to stomach compression or gastric outlet obstruction. In symptomatic patients, if the pseudocyst is mature and encapsulated, treatment can involve endoscopic, surgical, or percutaneous drainage. Based on available expertise, endoscopic ultrasound (EUS) guided drainage is preferred with cystogastrostomy or cystoduodenostomy.

Sterile pancreatic and extrapancreatic necrosis. Sterile pancreatic necrosis usually is treated with supportive medical care during the first several weeks, even in patients with multiple organ failure. After the acute pancreatic inflammatory process has subsided and coalesced into an encapsulated structure (e.g., walled-off pancreatic necrosis), débridement may be required for intractable abdominal pain, vomiting caused by extrinsic compression of stomach or duodenum, biliary obstruction, failure to thrive or persistent systemic toxicity. Débridement is delayed for at least 4 to 6 weeks after the onset of pancreatitis and can be performed by a combination of endoscopic, radiologic, and surgical techniques. Asymptomatic pancreatic necrosis does not warrant intervention, regardless of the extent and location.

Infected pancreatic and extrapancreatic necrosis. The development of infection in the necrotic collection is the main indication for therapy. The development of fever leukocytosis and increasing abdominal pain suggests infection of the necrotic tissue. A CT scan may reveal evidence of air bubbles in the necrotic cavity.

Infected pancreatic necrosis is best treated with drainage or débridement, or both. Routine CT-guided fine-needle aspiration to diagnose infected necrosis is not recommended given that clinical and imaging signs are accurate in the majority of patients. In addition, there is a high false-negative rate of the samples. Thus, débridement warrants consideration when infected necrosis is suspected, even if infection is not documented. The consensus is that the best outcomes are achieved when invasive interventions are delayed for a minimum of 4 weeks after the onset of disease to allow liquefaction of necrotic tissues and a fibrous rim to form around the necrosis (i.e., walled-off pancreatic necrosis). This delay makes drainage and débridement easier and reduces the risk of complications or death. Patients with infected necrosis are initially treated with broad-spectrum antibiotics and medical support to allow encapsulation of the necrotic collections, which may facilitate intervention and reduce complications of bleeding and perforation. When there is dramatic clinical deterioration, patients are not stable and delay is not feasible, and early intervention with a percutaneous drain is required.

Traditional management of infected pancreatic necrosis has been open surgical necrosectomy with closed irrigation by indwelling catheters, necrosectomy with closed drainage without irrigation, or necrosectomy and open packing. The open surgical approaches are associated with a high morbidity (34% to 95%) and mortality (11% to 39%) rates. A more conservative step-up approach using percutaneous catheter drainage as the initial treatment has gained favor, and a delay in invasive treatment is now standard. The step-up approach consists of antibiotic administration, percutaneous drainage as needed, and after a delay of several weeks, minimally invasive débridement, if required. This approach is superior to traditional open necrosectomy with respect to the risk of major complications or death. If the percutaneous approach fails, it is followed by a less invasive, video-assisted retroperitoneal débridement (VARD) or endoscopic transluminal drainage with or without necrosectomy, provided expertise is available.

CHRONIC PANCREATITIS

Definition and Epidemiology

Chronic pancreatitis is characterized by inflammation, fibrosis, and irreversible loss of acinar (exocrine) and islet (endocrine) cell function.

TABLE 39.3 Causes of Chronic Pancreatitis (TIGAR-O)

Toxic-Metabolic

Alcohol
Tobacco
Hypercalcemia
Hypertriglyceridemia
Chronic renal failure

Idiopathic

Early onset
Late onset
Tropical

Genetic

Autosomal dominant-cationic trypsinogen (PRSS1)
Autosomal recessive-CFTR, SPINK1, chymotrypsin C

Autoimmune

Isolated (types 1 and 2)
Syndromic (Sjögren's, inflammatory bowel disease, primary biliary cholangitis)

Recurrent Acute Pancreatitis

Postnecrotic severe acute pancreatitis
Post-irradiation
Ischemic vascular

Obstructive

Benign-pancreas divisum, sphincter of Oddi dysfunction, post-traumatic pancreatic duct stricture
Neoplastic-pancreatic ductal adenocarcinoma, IPMN, ampullary tumor

CFTR, Cystic fibrosis transmembrane conductance regulator; *IPMN*, intraductal papillary mucinous neoplasia; *PRSS1*, serine protease 1; *SPINK1*, serine peptidase inhibitor Kazal type 1.

This disorder contrasts with acute pancreatitis, which is usually non-progressive. The two conditions may overlap because recurrent attacks of acute pancreatitis may lead to chronic pancreatitis, and individuals with chronic pancreatitis may experience exacerbations of acute pancreatitis. The annual incidence of chronic pancreatitis ranges from 5 to 12 cases per 100,000 people, and the prevalence is about 50 cases per 100,000 people.

Pathology

Chronic pancreatitis can be classified using a system termed "TIGAR-O," which refers to toxic-metabolic, idiopathic, genetic, autoimmune, recurrent and severe acute pancreatitis, and obstructive (Table 39.3). The most common cause of chronic pancreatitis is chronic alcoholism, accounting for 45% to 65% of cases. Alcohol can cause episodes of acute pancreatitis, but at the time of the initial attack, structural and functional abnormalities often indicate underlying chronic pancreatitis. Because most alcohol users do not develop pancreatitis, the presumption is that unidentified genetic, dietary, or environmental influences must coexist with alcohol use. Smoking is a causal, dose-dependent risk factor for chronic pancreatitis. The effect of smoking is synergistic with alcohol consumption and contributes profoundly to the development and progression of the disease.

Twenty percent of US patients with chronic pancreatitis have no immediately demonstrable cause. Gallstone pancreatitis, the major cause of acute pancreatitis, rarely leads to chronic pancreatitis. Calcific

pancreatitis is a major cause of chronic pancreatitis in South India and other parts of the tropics. Autoimmune pancreatitis, genetic mutations (*CFTR*, *SPINK1*, *PRSSI*, *CTRC*, *CASR*), obstruction (e.g., tumors, sphincter of Oddi dysfunction, pancreas divisum), hypertriglyceridemia, and hypercalcemia are potential causes of cases initially labeled idiopathic.

Clinical Presentation

Most patients with chronic pancreatitis experience episodic or continuous pain. Occasionally, patients exhibit exocrine or endocrine insufficiency in the absence of pain. Other patients are asymptomatic and are found to have chronic pancreatitis incidentally on imaging.

The pain of chronic pancreatitis is typically epigastric, often radiates to the back, is occasionally associated with nausea and vomiting, and may be partially relieved by sitting upright or leaning forward. The pain is often worse 15 to 30 minutes after eating. Early in the course of chronic pancreatitis, the pain may occur in discrete attacks; as the condition progresses, the pain tends to become continuous.

The pain of chronic pancreatitis is poorly understood. Possible causes include inflammation of the pancreas, increased intrapancreatic pressure, neural inflammation, and extrapancreatic causes, such as stenosis of the common bile duct and duodenum.

Glucose intolerance occurs with some frequency in chronic pancreatitis, but overt diabetes mellitus usually manifests late in the course of disease. Diabetes in patients with chronic pancreatitis is different from typical type 1 diabetes in that the pancreatic alpha cells, which produce glucagon, are also affected, increasing the risk of hypoglycemia.

Clinically significant endocrine or exocrine insufficiency (i.e., protein and fat deficiencies) does not occur until more than 90% of pancreatic function is lost. Steatorrhea usually occurs before protein deficiencies because lipolytic activity decreases faster than proteolysis. Mild pancreatic exocrine insufficiency (PEI) may take the form of abdominal bloating or malabsorption of fat-soluble vitamins (A, D, E, K) and vitamin B₁₂, although clinically symptomatic vitamin deficiency is uncommon. Because reduced vitamin D absorption can result in osteoporosis, osteopenia, and fractures, periodic assessment of vitamin D levels and bone densitometry are recommended. More severe PEI may lead to overt malabsorption and weight loss.

Diagnosis and Differential Diagnosis

Because direct biopsy of the pancreas has considerable risk, the diagnosis of chronic pancreatitis is typically based on indirect tests of pancreatic structure and function. Marked structural changes usually correlate with severe functional impairment. In early chronic pancreatitis, however, mild abnormalities of pancreatic function can precede the morphologic changes seen on imaging. Studies of pancreatic structure may remain normal even with advanced deterioration of pancreatic function.

Laboratory evaluations of serum pancreatic enzymes, such as amylase and lipase, are frequently normal in the setting of well-established chronic pancreatitis, even during painful exacerbations. Serum pancreatic enzymes neither confirm nor exclude the diagnosis.

Tests of Function

Function tests assess pancreatic secretory reserve of ductal function or acinar function by measuring secretion of bicarbonate ions (HCO_3^-) or digestive enzymes, respectively. Direct tests (e.g., secretin stimulation) involve stimulation of the pancreas through the administration of hormonal secretagogues. Indirect tests measure the consequences of pancreatic insufficiency, and although more widely available, the results usually are not abnormal until enzyme output has declined by more than 90%. Thus they are insensitive to early pancreatic insufficiency.

Clinicians have preferentially relied on noninvasive methods to circumvent the challenges associated with direct pancreatic function tests. Clinically available indirect tests of pancreatic function include analyses of fecal fat, fecal elastase, and serum trypsin.

The secretin stimulation test takes advantage of the normal response of pancreatic ductular cells to secrete HCO_3^- in response to physiologic and exogenously administered secretin. The observation that HCO_3^- production is impaired early in the course of chronic pancreatitis led to the use of this test to diagnose early-stage disease (sensitivity of 95%). The test involves oral placement of a double-lumen gastroduodenal catheter for aspiration and quantitative measurement of pancreatic enzyme and HCO_3^- production before and after stimulation with intravenous secretin. This test is primarily performed for patients with suspected chronic pancreatitis who have chronic abdominal pain but negative or equivocal results of imaging studies. Peak pancreatic fluid HCO_3^- concentrations of less than 80 mEq/L represent pancreatic insufficiency. The secretin stimulation test has been infrequently used in clinical practice because the study is labor intensive and is associated with discomfort. Endoscopic collection methods have simplified pancreatic fluid collection and made the test more suitable for clinical use.

The 72-hour fecal fat determination is sometimes used for detection of steatorrhea (fecal fat >7 g/24 hours), but the test is not specific for pancreatic exocrine insufficiency. The test also lacks sensitivity because steatorrhea occurs only in advanced chronic pancreatitis. Because the quantitative fecal fat test is inconvenient, unpleasant for patients, and prone to laboratory error, a qualitative assay is used preferentially in clinical practice to assess for malabsorption.

Determination of fecal elastase is the most commonly used noninvasive indirect test for the diagnosis of pancreatic exocrine insufficiency. Elastase, a protease synthesized by pancreatic acinar cells, is useful for evaluating insufficiency because it is stable in stool, unaffected by pancreatic enzyme replacement, and correlates well with stimulated pancreatic function test results. Moderate to severe exocrine insufficiency is based on fecal elastase values of less than 200 $\mu\text{g/g}$ of stool. False-positive results can be seen with diarrheal illnesses, due to a dilutional effect.

Tests of Structure

Imaging findings with CT scan, ultrasound, and MRI may show changes of chronic pancreatitis include ductal abnormalities (e.g., dilation, stones, irregular beaded walls, and side branch ectasia), parenchymal abnormalities (e.g., calcification, inhomogeneity, atrophy), gland contour changes, and pseudocysts (E-Fig 39.4). Imaging studies are often normal or inconclusive in the early stages of disease (see E-Fig. 39.4). CT imaging and MRI are also helpful in identifying complications of chronic pancreatitis including pseudocysts, portosplenic venous thrombosis, arterial pseudoaneurysms, and pancreatic duct fistulas.

CT scanning is often considered the preferred initial test for diagnosis of chronic pancreatitis. Magnetic resonance cholangiopancreatography is a noninvasive diagnostic imaging modality that provides visualization of the pancreatic parenchyma similar to CT scanning but with improved duct imaging resulting in a greater sensitivity for diagnosis of chronic pancreatitis. MRI pancreatic duct images are similar to those obtained by ERCP but without the risk of precipitating acute pancreatitis. Stimulation of the pancreas using IV secretin enhances main and side branch pancreatic duct visualization, which may improve the diagnostic accuracy for chronic pancreatitis. ERCP provides reliable structural information about the pancreatic ductular system including ductal dilation, strictures, abnormal side branches, communicating pseudocysts, and ductal stones and fistulas. ERCP is highly effective for visualizing these ductal and duct-related findings,

E-Fig. 39.4 Computed tomography scan shows calcifications and small pseudocysts in the pancreas that are consistent with a diagnosis of chronic pancreatitis.

with a sensitivity for the diagnosis of chronic pancreatitis of 71% to 93% and a specificity of 89% to 100%. The major limitation of ERCP is the development of procedure-related acute pancreatitis in up to 5% of patients. Thus, ERCP should not be used for diagnostic purposes but instead be reserved for patients with established chronic pancreatitis when endoscopic therapy is recommended (discussed later).

Endoscopic ultrasound (EUS) as a diagnostic imaging study for chronic pancreatitis relies on quantitative and qualitative parenchymal tissue and ductal findings. EUS appears to be equally or more sensitive than other tests of structure and function. An international consensus panel proposed the Rosemont criteria for diagnosing chronic pancreatitis. Major criteria include hyperechoic foci with shadowing that indicates pancreatic duct calculi and parenchymal lobularity with honeycombing. Minor criteria include cysts, a dilated main duct (≥ 3.5 mm in diameter), irregular pancreatic duct contour, dilated side branches (≥ 1 mm in diameter), hyperechoic duct wall, parenchymal strands, nonshadowing hyperechoic foci, and lobularity with noncontiguous lobules. In the absence of any of these criteria, chronic pancreatitis is unlikely, whereas with detection of four or more criteria, the disease is likely, even when other imaging and pancreatic function tests may still be normal.

Treatment

Malabsorption

Treatment of PEI is best achieved with pancreatic enzyme replacement therapy (PERT). Most commercial preparations consist of pancreatin, which is the shock-frozen powdered extract of porcine pancreas containing lipase, amylase, trypsin, and chymotrypsin.

In order to treat malabsorption due to PEI, it is necessary to provide approximately 10 percent of the normal pancreatic enzyme output. This translates into approximately 30,000 international units (IU) or the equivalent 90,000 United States Pharmacopeia units (USP) of lipase per meal. For most patients, the recommended dose depends on the size and nature of the meal (i.e., fat content), residual pancreatic function, and therapeutic goals (i.e., elimination of steatorrhea, reduction in the abdominal symptoms of maldigestion, or improvement in nutrition). Due to residual pancreatic lipase secretion and physiologic gastric lipase secretion, it is appropriate to begin therapy with 40,000 to 50,000 USP of lipase with each meal and one half of that amount with snacks. Administration of acid-stable, encapsulated microspheres or microtablets filled with pancreatic enzymes has greatly increased the efficacy of enzyme supplementation. Enzyme preparations should be taken with meals. If more than one capsule/tablet per meal must be taken, it may be beneficial to take one part of the dose at the beginning and the rest during the meal.

Other factors may accentuate steatorrhea, including concomitant small bowel bacterial overgrowth, which can occur in up to 25% of patients with chronic pancreatitis. Bacterial overgrowth may be caused by hypomotility due to pancreatic inflammation or chronic use of narcotic analgesics.

Pain

The greatest challenge in treating chronic pancreatitis is controlling abdominal pain. Pain may improve over time, but the course is not predictable and improvement may take years. Therapy targets the mechanisms responsible for pancreatic pain, including pancreatic hyperstimulation, ischemia, obstruction of ducts, inflammation, and neuropathic hyperalgesia. Pain can develop in the early stages of chronic pancreatitis before morphologic changes can be demonstrated on imaging studies. Patients with chronic pancreatitis are at increased risk for pancreatic cancer, which may cause a change in the pain pattern, and extrapancreatic causes of pain must always be considered.

Pain management should proceed in a stepwise fashion and begin with lifestyle modifications such as alcohol and tobacco abstinence, a low-fat diet, and pancreatic enzyme supplementation, followed by a sequentially more aggressive and invasive approach for symptomatic failures, although it should be recognized that placebo alone is effective for up to 30% of patients. Several approaches can be considered for chronic pain relief.

1. Tobacco and alcohol abstinence. Abstention may decrease the frequency of painful attacks and reduce the likelihood of pancreatic function deterioration and development of pancreatic cancer.
2. Analgesics. Most patients with chronic pain require analgesics. Nonopioid analgesics such as acetaminophen and nonsteroidal anti-inflammatory drugs are used as initial treatment. If possible, the use of opioids should be avoided due to the risk of abuse, tolerance, and addiction. When deemed necessary, weak opioids (e.g., tramadol or codeine) are initially prescribed before escalation to stronger opioids (e.g., morphine, oxycodone, fentanyl) for poorly controlled pain. The risk of dependence to opioids is not known in this setting; however, patients with previous addictive behaviors such as substance use with alcohol or tobacco are at greater risk for analgesic dependence and addiction. Safe opioid prescribing practices are necessary with close monitoring of patients' symptoms and adherence to a well-defined plan that includes a patient agreement, regular follow-up, urine drug testing, and query of the state's online prescription monitoring program.
3. Secretion suppression. Oral pancreatic enzyme replacement, somatostatin analogue, and enteral nutrition are proposed treatments to blunt pain by reducing pancreatic secretion. These therapies are of unproven benefit and not routinely recommended as adjuncts to pain therapy. When PERT is initiated for pain management, the non-enteric-coated pancrelipases (i.e., pancreatic enzyme preparations) are preferred because the enteric-coated preparations theoretically release their enzymes further down the intestine, away from the stimulatory cholecystokinin (CCK) enterocytes.
4. Neural transmission modification. Gabapentinoids, including pregabalin, have been used effectively to treat neuropathic pain disorders, including diabetic neuropathy and neuropathic pain of central origin. Based on the finding that pancreatic pain is accompanied by similar alterations of central pain processing, studies suggest a benefit with pregabalin as an adjuvant treatment to decrease pain associated with chronic pancreatitis. Similarly, tricyclic antidepressants, selective serotonin reuptake inhibitors, and serotonin-norepinephrine reuptake inhibitors can be administered on a trial basis.
5. Neuroablative techniques such as celiac plexus blockade can be performed by injection of a local anesthetic and a steroid into the region of the celiac ganglia. This can be accomplished through endoscopic (i.e., EUS) or percutaneous radiologic guidance. The results are disappointing with a pain reduction in a minority of individuals (15% to 50%) that is not durable with pain reduction or relief of up to 1 to 6 months.
6. Antioxidants. Oxidative stress can cause direct pancreatic acinar cell damage through several pathways. Supplementation with antioxidants, such as selenium, vitamins C and E, and methionine, may relieve pain and reduce oxidative stress. In a randomized trial, the reduction in the number of painful days per month was higher for the patients who received antioxidants compared with those who received placebo (7.4 vs. 3.2 days). Patients who received antioxidants also were more likely to become pain free (32% vs. 13%).
7. Endoscopic decompression. Endoscopic decompression of the pancreatic duct is an option for obstruction caused by strictures, stones, or sphincter of Oddi dysfunction. Endoscopic therapies include pancreatic sphincterotomy, stricture dilation, stone

removal with intracorporeal or extracorporeal shock wave lithotripsy, and temporary plastic stent placement. Complete or partial pain relief is reported for approximately 50% to 80% of carefully selected patients during follow-up extending as long as 3 to 4 years.

8. Surgery. Surgical pancreatic ductal drainage, usually with lateral pancreaticojejunostomy (i.e., Puestow procedure), can be offered to those with a dilated (>6 mm in diameter) main pancreatic duct. Pain reduction is reported by approximately 80% of patients. This procedure is safe and has an operative mortality rate of less than 5%; however, only 35% to 60% of patients are free of pain at the 5-year follow-up. Individuals with nonobstructed, nondilated pancreatic ductal systems with disease predominating in the pancreatic head may be offered resection of the focally diseased portion of the gland with a pancreaticoduodenectomy or a duodenum-preserving pancreatic head resection also referred to as a Frey or Beger procedure. Highly selected patients with diffuse pancreatic parenchymal disease refractory to other forms of therapy may benefit from a total pancreatectomy with islet cell auto-transplantation.

Management of Complications

The complications of chronic pancreatitis include pseudocysts, pancreatic fistulas, biliary obstruction, pancreatic cancer, small bowel bacterial overgrowth, and isolated gastric varices due to splenic vein thrombosis.

Pancreatic fistulas. Pancreatic fistulas occur as a result of duct disruption resulting in localized fluid collections, ascites, or pleural effusions. Treatment consists of bowel rest, endoscopic pancreatic duct stenting, and administration of a somatostatin analogue. Surgical intervention may be needed if this conservative approach is unsuccessful.

Vascular complications. The splenic vein courses along the posterior surface of the pancreas, where it can be affected by inflammation from pancreatitis or malignancy that leads to thrombosis. Splenic vein thrombosis can result in isolated fundal gastric varices. Splenectomy is usually curative for patients who develop bleeding from gastric varices.

Pseudoaneurysm formation is a complication of acute and chronic pancreatitis. Affected vessels, including the hepatic, splenic, pancreaticoduodenal, and gastroduodenal arteries, lie close to the pancreas. CT or MR imaging shows the pseudoaneurysm as a cystically dilated vascular structure in or adjacent to the pancreas. EUS with Doppler imaging can show blood flow within the pseudoaneurysm. Mesenteric angiography permits confirmation of the diagnosis and provides a means of therapy because selective embolization of the pseudoaneurysm can be accomplished during the procedure. Surgery for bleeding pseudoaneurysms is difficult and associated with high morbidity and mortality rates.

Biliary and duodenal obstruction. Symptomatic obstruction of the bile duct or duodenum, or both, develops in a few patients with chronic pancreatitis. Postprandial pain and early satiety are characteristic of duodenal obstruction, whereas pain and cholestasis (sometimes with resultant cholangitis) suggest a bile duct stricture. These complications most commonly result from inflammation or fibrosis in the head of the pancreas or an adjacent pseudocyst.

Endoscopic stenting may be attempted for bile duct strictures, but they are often refractory and typically require prolonged treatment. Endoscopic failures can be treated with surgical biliary decompression. The importance of decompression is underscored by the observation that it can reverse secondary biliary fibrosis associated with bile duct obstruction.

CARCINOMA OF THE PANCREAS

Definition and Epidemiology

Pancreatic ductal adenocarcinoma (PDAC) is the fourth leading cause of cancer-related death in the United States, with approximately 45,000 new cases diagnosed annually (see also Chapter 58). The peak incidence of PDAC occurs in the seventh decade of life. There is a modest male-to-female predominance (relative risk of 1.4:1), and blacks have a 30% to 40% higher incidence of PDAC than white individuals in the United States.

Many environmental factors have been implicated as increasing the risk for pancreatic cancer. Cigarette smoking is the most consistent factor, with the increased risk attributed to the aromatic amines found in cigarette smoke. Other risk factors include obesity, lack of physical activity, and diabetes mellitus. Studies evaluating the relationship between diet and pancreatic cancer are inconclusive. A Western diet (i.e., high intake of fat and meat, particularly smoked or processed meats) has been linked to the development of pancreatic cancer in many studies. Chronic pancreatitis also increases the risk of PDAC (relative risk as high as 13-fold), particularly in those individuals with hereditary pancreatitis and tropical pancreatitis. Epidemiologic studies have failed to find a consistent association between alcohol or coffee consumption and the development of pancreatic cancer.

Up to 10% of patients with pancreatic cancer have a family history of the disease, but most cannot be identified with a known genetic disorder. Recognized genetic disorders that predispose to pancreatic cancer include hereditary pancreatitis (*PRSS1* gene), hereditary nonpolyposis colorectal cancer, familial adenomatous polyposis, hereditary breast and ovarian cancers (*PALB2* and *BRCA2* genes), Peutz-Jeghers syndrome (*STK11* gene), familial atypical mole melanoma syndrome (*CDKN2A* gene), ataxia telangiectasia (*ATM* gene), and the Von Hippel-Lindau syndrome (*VHL* gene). Screening to detect precancerous lesions or early cancers should be considered for individuals with a cumulative predicted risk of PDAC greater than 5% or relative risk (RR) of 5 or greater (having ≥ 2 relatives with PDAC including ≥ 1 a first degree, or having a germline mutation of a predisposing gene and ≥ 2 relatives with PDAC or ≥ 1 a first degree, or Peutz-Jeghers syndrome even in the absence of a family history) and eligible for a possible pancreatic resection after discussion of the risks and benefits of such screening. Although imaging surveillance of high-risk family cohorts is practiced at some centers of expertise, there is no consensus about the optimal methods or frequency of pancreatic cancer screening. Screening with EUS and/or MRI can be considered but has not been shown to improve survival rates.

Pathology

More than 95% of malignant neoplasms of the pancreas arise from the exocrine pancreas. The term *pancreatic cancer* usually refers to ductal adenocarcinoma of the pancreas, representing 85% to 90% of all pancreatic neoplasms. *Exocrine pancreatic neoplasm* is a more inclusive term that includes neoplastic pancreatic ductal and acinar cells and their stem cells (e.g., pancreatoblastoma). Other, less common exocrine cancers include adenosquamous carcinomas, squamous cell carcinomas, signet ring cell carcinomas, and undifferentiated carcinomas. Neoplasms arising from the endocrine pancreas (i.e., islet cell or neuroendocrine tumors) comprise no more than 5% of pancreatic neoplasms.

Pancreatic cancers are composed of several distinct elements, including pancreatic cancer cells, tumor stroma, and stem cells. The precursor lesion of pancreatic cancer is pancreatic intraepithelial neoplasia, which progresses from mild dysplasia (PanIN grade 1) to more severe dysplasia (PanIN grades 2 and 3) and eventually to invasive carcinoma.

TABLE 39.4 Definitions of Pancreatic Ductal Adenocarcinoma Treatment Categories

Resectable	No evidence of tumor spread outside the pancreas No involvement of the superior mesenteric artery (SMA), celiac, or common hepatic artery (CHA) No invasion of the superior mesenteric vein (SMV) or portal vein (PV)
Metastatic	Evidence of spread to other organs (typically liver, lung, or peritoneum)
Borderline resectable	Tumor abutment (<50% of vessel circumference) of celiac, SMA or CHA Involvement but patent SMV or PV or short-segment occlusion with option for reconstruction
Locally advanced	Arterial encasement (>180 degrees or 50% of vessel circumference) of SMA, celiac or CHA SMV/PV occlusion without ability to surgically reconstruct

Clinical Presentation

The clinical manifestations of pancreatic carcinoma may be nonspecific and are often insidious. The clinical presentation is dependent to a great extent on tumor location and stage. PDAC localized to the head of the pancreas (70% to 80%) are more frequently symptomatic than those located in the body or tail (20% to 30%). Most PDAC has reached an advanced stage by the time of diagnosis. Common presenting signs and symptoms of pancreatic cancer include jaundice, weight loss, and abdominal pain. The pain is usually constant, with radiation to the back. Because most cancers begin in the pancreatic head, patients may exhibit obstructive jaundice or a large, palpable gallbladder (i.e., Courvoisier's sign).

Painless jaundice is the most common manifestation in patients with a potentially resectable and curable lesion. Anorexia, nausea, and vomiting may also occur, along with emotional disturbances such as depression. Less common manifestations include superficial thrombophlebitis (i.e., Trousseau sign), acute pancreatitis, diabetes mellitus, ascites, paraneoplastic syndromes (e.g., Cushing's syndrome), hypercalcemia, gastrointestinal bleeding, splenic vein thrombosis, and a palpable abdominal mass.

Diagnosis and Staging

The goal of imaging in the evaluation of suspected pancreatic carcinoma is to establish the diagnosis with a high degree of certainty and to determine resectability in patients who are otherwise candidates for operative resection. The diagnosis of pancreatic cancer is frequently suggested by a pancreatic mass seen on imaging studies. Evidence of a dilated pancreatic duct, hepatic metastases, invasion of vessels, or a dilated common bile duct in the setting of biliary obstruction may also be found. The imaging appearance may be impossible to distinguish from benign causes of pancreatic masses such as focal pancreatitis or autoimmune pancreatitis. Pancreas protocol triple phase (i.e., arterial, late arterial, and venous phases) cross-sectional multidetector CT scanning is the best initial study to diagnose and stage pancreatic cancer by identifying a mass lesion and assessing for liver metastasis or vascular invasion. CT is reported to have a sensitivity of 90% to 97% for identifying PDAC, although it is less sensitive for diagnosing small (<2 cm) lesions, with a sensitivity of 65% to 75%. CT is not sensitive for detecting nodal metastases. MRI is an alternative imaging modality that has similar accuracy to CT scanning for the diagnosis and staging of PDAC. EUS is superior to CT and MRI for detecting small lesions of the pancreas and should be performed when there is strong suspicion of PDAC despite the absence of a mass lesion by other imaging modalities. EUS-guided fine-needle aspiration (sensitivity of 85% to 90% and specificity approaching 100%) is recommended when histologic confirmation will alter management such as confirming malignancy in unresectable disease prior to initiating palliative care, confirming

a potentially resectable tumor prior to neoadjuvant therapy, and for a suspected mass not visible on cross-sectional imaging.

The imaging techniques are highly accurate for recognizing unresectable disease, but they are somewhat limited for identifying resectable disease because occult metastases (<1 cm in diameter) may be on the surface of the liver or peritoneum. Staging laparoscopy may reduce morbidity and cost from open surgical tumor resection; it should be considered for patients with the highest likelihood of occult metastatic disease (i.e., those with tumors of the body or tail of the pancreas) who appear to have potentially resectable disease by CT (one half of whom have occult peritoneal metastases), those with large (>3 cm) primary tumors, those for whom imaging suggests occult metastatic disease, and those with a very high initial CA 19-9 level (>1000 units/mL).

The use of tumor markers to diagnose carcinoma of the pancreas has yielded disappointing results. The tumor marker CA 19-9 has a sensitivity of 70% to 80% and a specificity of 85% to 95% for diagnosing selected patients already exhibiting signs and symptoms that suggest pancreatic cancer. However, for early-stage cancers, CA 19-9 has limited sensitivity. Use of CA 19-9 requires the Lewis blood group antigen, which is absent in 5% to 10% of the population. The greatest utility for CA 19-9 is to identify occult metastasis in patients with seemingly resectable tumors, for monitoring patients after apparently curative surgery, and for following those receiving chemotherapy for advanced disease. Rising CA 19-9 levels suggest recurrent disease even in the absence of radiographically detectable lesions.

Treatment

Dividing patients with PDAC into resectable, borderline resectable, locally advanced, and metastatic categories is clinically useful (Table 39.4).

Resectable Disease

Unfortunately, only 10% to 20% of carcinomas in the head of the pancreas and rare cancers of the body and tail are resectable for cure. Current criteria for resectability include the absence of distant metastases and the absence of tumor involvement of major arteries (superior mesenteric, celiac, and common hepatic). Venous involvement requires vascular patency and criteria for resectability will depend on the surgeon's experience and ability to perform vascular reconstruction.

Universal preoperative ERCP for patients with biliary obstruction is not recommended due to lack of proven benefit and the potential to increase adverse events. Selective use of ERCP with biliary stent placement is recommended for those patients with biliary obstruction and a clinical presentation of either cholangitis, intractable pruritus, marked hyperbilirubinemia, or when surgery is delayed for neoadjuvant therapy. Technical success of ERCP is achieved in over 90% of such patients with an acceptable complication rate of under 5%. At the

time of stent placement, ERCP tissue sampling techniques can confirm a diagnosis of pancreatic malignancy (sensitivity of 30% to 60% and specificity 100%).

The standard operation for pancreatic cancer of the head or uncinate process is the Whipple procedure (i.e., pancreaticoduodenectomy). Whipple resection consists of removal of the pancreatic head, distal common bile duct, gallbladder, duodenum, proximal jejunum, gastric antrum, and regional lymph nodes. Reconstruction requires pancreaticojejunostomy, hepaticojejunostomy, and gastrojejunostomy. The pylorus-preserving version of the Whipple procedure leaves the stomach intact. The surgical mortality rate for this procedure is approximately 3% when performed by experienced pancreatic surgeons. Adjuvant therapy is indicated in all patients following resection of PDAC, irrespective of the pTNM stage, as it improves progression-free and overall survival rates.

Locally Advanced and Borderline Resectable

The term *borderline resectable* is reserved for patients with focal tumor abutment of the visceral arteries (celiac, superior mesenteric artery [SMA], or common hepatic), defined as contact of the tumor with less than one half circumference of the vessel wall, or short-segment occlusion of the superior mesenteric vein (SMV) or SMV–portal vein confluence. The latter is considered a relative rather than absolute contraindication to curative resection as some surgeons are performing resection with vascular reconstruction for selected individuals under these circumstances. Also, for tumors of the tail of the pancreas, encasement of the splenic vein does not necessarily obviate resectability. Locally advanced disease refers to individuals with unresectable cancer due to arterial encasement ($>180^\circ$ or $>50\%$ vessel circumference) of SMA, celiac or common hepatic arteries or SMV/PV occlusion without an option for reconstruction.

The use of preoperative neoadjuvant chemoradiation therapy in an effort to convert patients with unresectable borderline or locally advanced disease to a resectable status has increased the overall resection rate, but no difference in survival has been demonstrated.

Metastatic or Unresectable Disease

Although practice varies across institutions, most surgeons consider a pancreatic cancer to be categorically unresectable if there is extra-pancreatic involvement, including extensive peripancreatic lymphatic extension, nodal involvement beyond the peripancreatic tissues, or distant metastases (e.g., liver, peritoneum, omentum, extra-abdominal sites). Other indications of unresectability include vascular encasement (i.e., tumor contact with more than one-half of the vessel's circumference), or direct involvement of the superior mesenteric artery, aorta, celiac artery, or hepatic artery, as defined by the absence of a fat plane between the tumor and these structures on CT imaging.

Patients with metastatic or inoperable pancreatic cancer should be offered treatment with multidisciplinary input based on goals of care, patient preferences, performance status (PS) and social support systems. If protocol enrollment is not available or is declined, conventional systemic chemotherapy should be offered because it provides benefit improving disease-related symptoms and overall survival.

- Patients under age 75 years with an ECOG PS 0 to 1 and bilirubin less than 1.5 mg/dL should be offered FOLFIRINOX or gemcitabine plus nab-paclitaxel;
- Patients with an ECOG PS 2 and bilirubin less than 1.5 ULN should be offered gemcitabine plus nab-paclitaxel or gemcitabine;
- Patients with an ECOG PS 0 to 2 and bilirubin 1.5 ULN or greater or comorbidities should be offered gemcitabine; and

- Patients with an ECOG PS 3 to 4 should be offered best supportive care.

For patients with inoperable cancers and poor performance status, palliative interventions to alleviate jaundice, pain, and intestinal obstruction often become the focus of therapy. When advanced disease is observed operatively, the surgeon must determine whether to perform additional palliative surgery. Biliary bypass is indicated in patients with obstructive jaundice. Duodenal bypass is indicated when features suggest impending gastric outlet obstruction. Alternative palliative endoscopic approaches are available for patients not undergoing exploratory surgery.

Prognosis

Carcinoma of the pancreas accounts for approximately 5% of cancer deaths in the United States. The overall prognosis is poor because less than 20% of patients are alive beyond the first year after diagnosis, and only 7% survive to the fifth year. Although 15% to 20% of patients have resectable disease at initial diagnosis, most have locally advanced or metastatic cancer. Median survival is 8 to 12 months for patients with locally advanced unresectable disease and 3 to 6 months for those with metastases at diagnosis.

A Whipple resection for pancreatic head cancers is the only chance for cure; however, the median survival after surgery is 15 to 20 months. Five-year survival after margin negative (R0) pancreaticoduodenectomy is approximately 25% to 30% following node-negative resection and 10% for node-positive disease. The overall 5-year survival rate is 10% to 25%, and up to 50% of those who survive 5 years ultimately die of recurrent cancer. Poor prognostic factors include a high tumor grade, a large tumor, high levels of CA 19-9 before and after surgery, tumor-positive surgical margins, and lymph node metastases.

For a deeper discussion of these topics, please see Chapter 135, “Pancreatitis,” and Chapter 185, “Pancreatic Cancer,” in *Goldman-Cecil Medicine*, 26th Edition.

Laboratory Tests in Liver Diseases

Michael B. Fallon, Ester Little

INTRODUCTION

The liver is a large and complex organ, involved in major metabolic, secretory, and nutritional functions. It plays a central role in glucose homeostasis, synthesis and secretion of bile, and synthesis of lipoproteins and plasma proteins, including clotting factors and vitamin storage (vitamins B₁₂, A, D, E, and K). It is also the site of biotransformation, detoxification, and excretion of a multitude of endogenous and exogenous compounds.

Given the diversity of the liver roles, the clinical manifestation of liver diseases is varied and can be quite subtle. The first step in evaluating a patient with liver disease is the clinical history, and signs of liver disease can also be seen on physical exam (e.g., jaundice, dark urine, light colored stools, gastrointestinal bleeding, spider angiomas, palmar erythema, hepatomegaly, splenomegaly, ascites, and asterixis). The history and physical findings guide the initial set of laboratory tests ordered.

LIVER CHEMISTRY TESTS

The most widely used tests to evaluate the liver are aspartate and alanine aminotransferases (AST and ALT), alkaline phosphatase (ALP), gamma glutamyl transpeptidase (GGT), bilirubin, albumin, and prothrombin time. They are commonly referred to as “liver function tests.” However, this is misleading because (1) they do not accurately reflect the function of the liver, (2) abnormal levels can indicate diseases affecting other organs, and (3) they may be normal in patients with advanced liver disease. A better terminology is liver chemistry tests. These tests reflect patterns of abnormalities seen in liver and biliary cell injury.

Patterns of Abnormalities in Liver Chemistry Tests

There are primarily three patterns of abnormalities in liver chemistry tests: one that reflects damage of the hepatocytes or hepatocellular damage (AST and ALT), one that reflects cholestasis and damage of the biliary cells (ALP and GGT), and one when patients have isolated elevation in bilirubin.

The tests are interpreted based on limits of normality and may vary between different laboratories. However, for ALT, it is now recognized that the limit of normality should be the same for all, and many professional societies have included the following levels in their guidelines: normal ALT ranges from 29 to 33 units/L in adult men and 19 to 25 units/L in adult women. [Table 40.1](#) depicts the most common liver chemistry tests and the disease processes associated with each set of tests.

Hepatocellular Damage

ALT and AST are intracellular enzymes that catalyze the transfer of the α -amino group of aspartate or alanine to the α -keto group of

ketoglutaric acid, resulting in formation of pyruvate or oxaloacetic acid, respectively. Vitamin B₆ is required to carry out this reaction. In the presence of cell injury or death, AST and ALT are released into circulation. ALT is found predominantly in hepatocytes and is more specific, whereas AST is also found in the heart, lungs, kidney, pancreas, brain, and skeletal muscle.

In most hepatocellular disorders (i.e., viral hepatitis, autoimmune hepatitis, hemochromatosis, Wilson’s disease and some drug-induced liver injury) ALT is higher than or equal to AST. However, in alcoholic liver disease this ratio is reversed. A ratio greater than 2 is seen in 70% and greater than 3 in 96% of the patients with known alcoholic liver disease. Chronic and heavy alcohol consumption leads to vitamin B deficiency. The effect of vitamin B₆ deficiency is more prominent on ALT than AST activity, causing the increase in AST/ALT ratio. Not uncommonly, the AST is also higher than ALT in patients with nonalcoholic fatty liver disease (NAFLD), mimicking alcoholic liver disease.

The magnitude of elevation in aminotransferases also helps identify the possible cause of liver damage. Marked elevation, above 15 times the upper limit of normality (ULN), is seen in acute viral hepatitis, acetaminophen toxicity, hypoxic hepatopathy (shock, ischemia, hypoxemia) or acute bile duct obstruction. More modest elevations, usually 10 to 15 times the ULN, are seen in alcoholic hepatitis, autoimmune hepatitis, Wilson’s disease, Budd-Chiari, and malignant infiltration of the liver (usually from breast cancer, small cell lung cancer, lymphoma, melanoma). In patients with chronic viral hepatitis, ALT and AST levels are rarely above 10 times the ULN, except during exacerbations of chronic hepatitis B. Elevations less than four times the ULN are more commonly seen in nonalcoholic fatty liver disease, hemochromatosis, α 1-antitrypsin deficiency, celiac disease, and thyroid disease. Once the liver damage has progressed to cirrhosis, the elevation in aminotransferases is mild and can be normal. Conversely, ALT and AST can be massively elevated in diseases not related to the liver, such as rhabdomyolysis and heat stroke. In addition to acetaminophen, multiple medications can cause elevation in the aminotransferases at different levels of magnitude, including diclofenac, fluoxetine, isoniazid, ketoconazole, lisinopril, phenytoin, rifampin, ritonavir, and statins.

The rate at which the AST and ALT levels decrease as the patient improves can also help in identifying the cause. More rapid decline suggests ischemia or resolution of an acute biliary obstruction.

Cholestasis

The tests that indicate cholestasis and biliary cell damage are ALP and GGT. Serum ALP comprises a group of isoenzymes derived from the liver, intestine, bone, and placenta. The liver isoenzyme (ALP-1) is present in the mucosal cells lining the bile ducts and increases in response to bile duct damage from inflammation or obstruction. In these circumstances,

TABLE 40.1 Liver Chemistry Tests

Liver Chemistry Test	What It Reflects	Associated Diseases
Aspartate aminotransferase and alanine aminotransferase	Hepatocellular damage	Viral hepatitis, autoimmune hepatitis (AIH), alcoholic hepatitis, hemochromatosis, ischemic hepatitis, Budd-Chiari syndrome, α 1-antitrypsin deficiency, Wilson's disease, and drugs
Alkaline phosphatase and γ -glutamyl transpeptidase	Cholestasis, biliary cell damage, and infiltrative processes	Primary biliary cholangitis (PBC), primary sclerosing cholangitis (PSC), familial cholestatic syndromes, AIDS cholangiopathy, cholestasis of pregnancy, biliary obstruction by stones or cancer, drugs, sarcoidosis, amyloidosis, and malignancy infiltration
Isolated bilirubin elevation	Increased production and impaired uptake, conjugation or excretion of bilirubin	Hemolysis, Gilbert, Crigler-Najjar, Dubin-Johnson, and Rotor syndromes
Decreased albumin and prolonged prothrombin time	Impaired synthetic liver function	Liver failure, severe acute hepatitis, and advanced liver disease with cirrhosis

GGT and 5'-nucleotidase (5'-NT) are simultaneously released. Thus, an elevation of ALP without elevation of GGT and 5'-NT indicates a non-hepatic cause. Fractionation of the different ALP isoenzymes by electrophoresis can be useful in determining alternative sources.

ALP does not differentiate intrahepatic from extrahepatic cholestasis. Examples of disorders that cause *intrahepatic cholestasis* are primary biliary cholangitis (PBC), primary sclerosing cholangitis (PSC), infections (AIDS cholangiopathy), familial cholestatic syndromes, cholestasis of pregnancy, total parenteral nutrition, ischemic cholangiopathy, liver allograft rejection, congestive hepatopathy (liver congestion secondary to right-sided heart failure), some medications (amiodarone, anabolic steroids, amoxicillin clavulanate, carbamazepine, estrogens, naproxen, phenytoin, rifampin), and infiltrative diseases (sarcoidosis, amyloidosis, malignant infiltration of the liver). Causes of *extrahepatic cholestasis* include bile duct stones or tumors, diverticulum of the ampulla of Vater, chronic pancreatitis, and pancreatic cancer.

ALP is frequently below normal range in patients with Wilson's disease, particularly those presenting with acute liver failure, in whom bilirubin is disproportionately elevated compared to alkaline phosphatase.

GGT is very nonspecific, and in addition to liver diseases it can be elevated in pancreatic diseases, myocardial infarction, renal failure, alcoholism, chronic obstructive pulmonary disease, and from several medications. As noted above, 5'-NT would not be elevated in these conditions.

Isolated Bilirubin Elevation

Patients with both hepatocellular diseases and cholestasis frequently also have bilirubin elevation secondary to leakage of bilirubin into the serum. However, some patients have elevated bilirubin with normal ALT, AST, ALP and GGT, which is termed *isolated bilirubin elevation*. In such cases, the first step is to fractionate the bilirubin to determine if it is caused by an elevation in the unconjugated (indirect) or conjugated (direct) bilirubin. An increase in *unconjugated bilirubin* results from overproduction (hemolysis), impaired uptake (Gilbert's disease) or impaired conjugation (Crigler-Najjar syndrome). An increase in *conjugated bilirubin* is due to decreased excretion in the bile ducts (Dubin-Johnson and Rotor syndromes) or leakage of the pigment from hepatocytes into serum.

More detailed discussion on cholestasis and isolated elevation of bilirubin can be found in [Chapter 41](#).

LIVER SYNTHETIC FUNCTION

Albumin

From 300 g to 500 g of albumin is distributed in body fluids, and the adult liver synthesizes 15 g of albumin per day. Serum albumin concentration reflects the rate of synthesis, degradation, and volume of distribution. The synthesis of albumin is influenced by several factors including nutritional status, serum oncotic pressure, hormones, and cytokines.

The half-life of albumin in serum is 14 to 20 days. Low albumin is seen in prolonged liver dysfunction or acute liver impairment, and a decrease in albumin concentration reflects a reduction in albumin synthesis.

Hypoalbuminemia does not always reflect liver synthetic dysfunction. Several other conditions may decrease albumin, including malnutrition, nephrotic syndrome, protein losing enteropathy, and systemic inflammation.

Coagulation Factors and Prothrombin Time

The liver is the major site for the synthesis of 11 coagulation factors, including factors I, II, V, VII, IX, X, XII, and XIII. Deficiency in clotting factors occurs in more severe or more advanced stages of liver diseases. These factors can be measured individually or indirectly by determining the prothrombin time (PT).

The PT is dependent on factors II, V, VII and X, all of which are synthesized in the liver. Prolonged PT is not specific to liver diseases and can be seen in several congenital or acquired disorders. When these conditions are excluded, a prolonged PT is usually secondary to deficiency of vitamin K (inadequate dietary intake, prolonged obstructive jaundice, intestinal malabsorption or prolonged broad spectrum antibiotic use) or by poor utilization of vitamin K because of advanced liver disease. The administration of a single parenteral dose of vitamin K normalizes the PT in cases of vitamin K deficiency.

The magnitude of the prolongation of PT reflects the severity of the liver disease; however, PT does not correlate with the coagulation status or the risk of bleeding in patients with cirrhosis. In fact, in patients with cirrhosis there is also a decrease in synthesis of anti-hemostatic factors, and some patients become relatively hypercoagulable and have an increased risk of clot formation, despite having prolonged PT. This is an important and frequently misunderstood concept.

Gamma Globulins

Elevation of individual gamma globulins can be suggestive of specific liver diseases. Some examples include elevation of immunoglobulin G (IgG) in patients with autoimmune hepatitis, elevation of immunoglobulin M (IgM) in PBC, and elevation of immunoglobulin A (IgA) in patients with alcoholic cirrhosis. IgG4-related disease is an autoimmune phenomenon in which increased IgG4 levels cause dysfunction in multiple organs, including bile ducts (IgG4-related cholangiopathy).

Specific Markers of Liver Diseases

Specific laboratory tests are required for the diagnosis of some liver diseases.

- **α 1-Antitrypsin (α 1AT):** it can be quantified and, if decreased, the A1AT phenotype can be determined
- **Autoimmune hepatitis:** antinuclear antibody (ANA), anti-smooth muscle antibody (ASMA), anti-liver/kidney microsomal antibody type 1 (anti-LKM1)

- **Primary biliary cholangitis:** antimitochondrial antibody (AMA)
- **Hemochromatosis:** iron panel (serum iron, total iron binding capacity, transferrin saturation and ferritin) and HFE gene mutations
- **Wilson's disease:** serum ceruloplasmin and urinary copper levels
- **Viruses:** different viruses (e.g., hepatitis A, B, C, D, E, Epstein-Barr virus, cytomegalovirus, and herpes virus) that cause hepatitis are detected using polymerase chain reaction.

Biomarkers of Liver Fibrosis

Liver biopsy is the “gold standard” for evaluation of liver histopathology. Although the complications are few, it is an invasive test and the need for less invasive means to evaluate fibrosis led to several studies in search of surrogate markers for hepatic fibrosis. Many such tests combine clinical and serum markers and have been validated in specific populations, particularly chronic hepatitis C and nonalcoholic fatty liver disease. Caution is needed when using the results in other patient populations. In addition, serum markers are not liver specific and concurrent sites of inflammation may contribute to deranged serum levels.

These tests are used to differentiate patients with more significant stages of fibrosis and cirrhosis (stages 3 and 4), from those with minimal or no fibrosis (stages 0 and 1). The stages are based on the METAVIR score and range from 0 to 4, where stage 4 corresponds to cirrhosis.

Examples of such tests include the following:

- **APRI Score** is based on the AST and platelet count (AST elevation/platelet count) \times 100. It has been mostly studied in patients with HCV, HCV and HIV co-infection, alcoholic liver disease, and NAFLD.
- **FibroSure or FibroTest** uses the measurement of α 2-macroglobulin, α 2-globulin, γ -globulin, apolipoprotein A1, GGT, and total bilirubin. It also utilizes the patient's age and sex. The results classify the patients as having mild fibrosis, indeterminate fibrosis or significant fibrosis. It has been better studied in patients with HCV and has a better specificity than sensitivity.
- **HepaScore** utilizes the combination of bilirubin, GGT, hyaluronic acid, α 2-macroglobulin, age, and sex. Its performance is similar to the FibroTest.

- **FIB 4 index** combines platelet count, ALT, AST, and age. Better studied in HCV and NAFLD.
- **NAFLD fibrosis score** considers the patient's age, body mass index, blood glucose, aminotransferases, platelet count, and albumin. Other panel tests have included products of collagen synthesis or degradation, enzymes involved in matrix biosynthesis or degradation, extracellular matrix glycoproteins, and proteoglycans/glycosaminoglycans.

The routine use of these panels in clinical practice is not clearly established and some suggest their use in combination with image modalities.

Image tests applying mechanical waves and measuring their propagation speed through liver tissue using ultrasound and MRI have become more readily available. They have been studied in a broader spectrum of liver diseases and have better sensitivity and specificity than the serologic tests. Nevertheless, at this point none of these tests fully substitute for liver biopsy.

Jaundice

Mohanad T. Al-Qaisi, Mashal Batheja, Michael B. Fallon

INTRODUCTION

Jaundice is the condition of yellowish pigmentation of the skin, the conjunctival membranes over the sclera, and other mucous membranes that is caused by elevated serum bilirubin levels (hyperbilirubinemia). The term jaundice is derived from *jaune*, the French word for “yellow,” and the condition is also known as *icterus* (Greek for “yellow”). Normal serum bilirubin levels range from 0.5 to 1.0 mg/dL, and plasma bilirubin concentrations typically must exceed 2.5 mg/dL before jaundice becomes evident clinically.

Although jaundice is commonly due to liver and biliary tract disease, it has many causes, so it is not surprising that the diagnosis and management of jaundice have challenged clinicians for centuries. In most cases, jaundice or hyperbilirubinemia per se is not a pathologic condition but rather a sign of one or more illnesses originating from or affecting the liver and blood. However, there is one notable exception: In newborns, high bilirubin levels can lead to pathologic cerebral changes. In this condition, which is known as *kernicterus* (*kern* is the German word for “nucleus”), persistent elevation of unconjugated bilirubin leads to its deposition in the cerebral basal ganglia (or nuclei). This process can be prevented and treated and therefore merits special recognition to prevent damage to the developing brain.

BILIRUBIN METABOLISM

Hyperbilirubinemia can be classified based on the three phases of hepatic bilirubin metabolism: uptake, conjugation, and excretion into the bile (the rate-limiting step). In addition, jaundice can be classified into prehepatic, hepatic, and posthepatic causes (Table 41.1). Although the approaches are complementary, the latter classification may be more useful for the practicing clinician.

The main source of bilirubin is the hemoglobin released from senescent red blood cells, and the liver serves as its primary site of metabolism and excretion. Abnormalities at any step in bilirubin production, metabolism, or excretion can lead to an increase in the serum bilirubin and clinical jaundice. Under normal conditions, human red blood cells have a lifespan of about 120 days. As they age, erythrocytes are broken down and removed from the circulation by phagocytes. Most bilirubin (80%) is derived from the breakdown of hemoglobin released from these cells; the remainder is derived from ineffective erythropoiesis in the bone marrow and from catabolism of myoglobin and hepatic hemoproteins such as the cytochrome P-450 isoenzymes. The normal rate of bilirubin production is approximately 4 mg/kg body weight per day (E-Fig. 41.1).

As erythrocytes are destroyed within the reticuloendothelial system, free hemoglobin is ingested by macrophages and then split into heme and globin moieties. The heme ring is cleaved by the enzyme

microsomal heme oxygenase to form biliverdin (*verde* = “green”), which is then converted to the tetrapyrrole pigment bilirubin by the cytosolic enzyme biliverdin reductase. This unconjugated (or “indirect”) bilirubin is released into the plasma, where it is tightly bound to albumin. Because unconjugated bilirubin is insoluble in water, it cannot be excreted in urine or bile. However, it is permeable across lipid-rich environments and therefore can traverse the blood-brain barrier and the placenta.

The unconjugated bilirubin-albumin complex is transported to the liver. Once in the space of Disse, this complex dissociates; unconjugated bilirubin is transported across the basolateral plasma membrane of liver cells and attaches to intracellular binding proteins (ligands). It is then conjugated with glucuronic acid by the enzyme uridine diphosphate glucuronyl transferase (UDP-GT) to form bilirubin monoglucuronide and diglucuronide, making the molecule water soluble. This conjugated (or “direct”) bilirubin is excreted into bile via active transport across the canalicular membrane by means of a multi-specific canalicular transport protein. In healthy persons, most bilirubin circulates in its unconjugated form with less than 5% of circulating bilirubin appearing in its conjugated form. If biliary excretion of conjugated bilirubin is impaired, it can exit the basolateral membrane and reenter the circulation, causing an increase in plasma levels. Because conjugated bilirubin is water soluble and less tightly bound to albumin than its unconjugated form, it is readily filtered by the glomerulus and appears in the urine, giving it a dark color (choloria). Once in bile, bilirubin enters the intestine, where bacteria convert it to colorless tetrapyrroles (urobilinogens) that are excreted in feces. Up to 20% of urobilinogen is reabsorbed and undergoes enterohepatic circulation or excretion in urine.

LABORATORY MEASUREMENT OF BILIRUBIN

The *van den Bergh reaction*, which is the most commonly used test for detecting bilirubin in biologic fluids, combines bilirubin with diazotized sulfanilic acid to form a colored compound. The direct-reacting fraction is roughly equivalent to conjugated bilirubin and the indirect-reacting fraction (total minus direct fraction) to unconjugated bilirubin. This characteristic provides a means for classifying jaundice into two categories: unconjugated hyperbilirubinemia and conjugated hyperbilirubinemia.

UNCONJUGATED HYPERBILIRUBINEMIA

Mechanisms that cause unconjugated hyperbilirubinemia include overproduction, impaired hepatic uptake, and decreased conjugation

TABLE 41.1 Classification of Jaundice and Representative Causes**Prehepatic Causes**

Predominantly unconjugated hyperbilirubinemia
 Hemolysis (e.g., sickle cell disease, autoimmune hemolytic anemia, mechanical cardiac valve with accelerated red cell destruction)
 Microbe-induced hemolysis (malaria, leptospirosis)
 Ineffective erythropoiesis (e.g., megaloblastic anemias)
 Hematoma resolution

Hepatic Causes

Unconjugated hyperbilirubinemia
 Decreased hepatic uptake
 Therapeutic drugs that interfere with bilirubin uptake (e.g., rifampin, metformin, methimazole, propylthiouracil, clopidogrel, sulfamethoxazole/trimethoprim)
 Herbal medicines (e.g., *Teucrium viscidum*, kava-kava, chaparral, greater celandine)
 Hyperthyroidism
 Diminished uptake and decreased cytosolic binding proteins (e.g., newborn or premature infants)
 Shunting of blood away from the liver (portal hypertension or surgical shunt)
 Decreased conjugation due to limited glucuronyl transferase activity
 Gilbert syndrome
 Crigler-Najjar syndrome types I and II
 Neonatal jaundice
 Breast-milk jaundice
 Drug-induced inhibition (e.g., chloramphenicol)
 Predominantly conjugated hyperbilirubinemia
 Impaired hepatic excretion
 Familial cholestasis (Dubin-Johnson syndrome, Rotor syndrome, benign recurrent cholestasis, cholestasis of pregnancy)
 Hepatocellular injury from infiltrative disorders, hemochromatosis, α_1 -antitrypsin deficiency, lymphoma, sarcoidosis, extensive metastases)
 Liver cirrhosis
 Hepatitis
 Drug-induced cholestasis (chlorpromazine, erythromycin estolate, isoniazid, halothane, and many others)
 Primary biliary cirrhosis
 Congestive heart failure
 Sepsis

Posthepatic Causes

Extrahepatic biliary obstruction
 Common bile duct obstruction from gallstones
 Benign and malignant tumors of the pancreas
 Tumors of bile ducts (cholangiocarcinoma) and ampulla of Vater
 Biliary strictures (postsurgical, gallstone-related, primary sclerosing cholangitis)
 Congenital disorders (biliary atresia, cystic fibrosis)
 Infectious cholangiopathy
 Chronic pancreatitis (fibrosis of the head of the pancreas)

of bilirubin. These disorders are not usually associated with significant hepatic disease.

Etiology of Hyperbilirubinemia

There are many potential causes of hyperbilirubinemia, and the major categories are summarized in Table 41.1. It is helpful to consider them mechanistically as conditions affecting the balance of bilirubin production, liver metabolism, and excretion. The classic cause of bilirubin overproduction is hemolysis, whereas the most common cause of impaired bilirubin uptake and metabolism is cirrhosis or other liver disease (viral hepatitis, drugs, hepatotoxins or ischemia). Bile duct obstruction due to cancer (classically cholangiocarcinoma or pancreatic head cancer), stones, or strictures is the most common cause of obstructive jaundice. Because multiple mechanisms are often involved in an individual patient, the evaluation of jaundice can be complex.

Prehepatic Jaundice

Prehepatic jaundice is associated with excessive bilirubin production (Fig. 41.1), which most often results from hemolysis (intravascular or extravascular), resolution of large hematomas, or mechanical injury to red cells, as in disseminated intravascular coagulation (see Chapter 48). Certain genetic diseases can lead to increased red cell lysis and therefore hemolytic jaundice. Sickle cell anemia is the classic cause, but others include glucose 6-phosphate dehydrogenase deficiency and hereditary spherocytosis. Infectious diseases also can cause hemolysis, either directly (e.g., malaria) or indirectly (e.g., autoimmune injury). Jaundice resulting from hemolysis is characteristically mild in degree, and serum bilirubin levels rarely exceed 5 mg/dL in the absence of coexisting hepatic disease. Ineffective erythropoiesis, which may be significantly increased in megaloblastic anemia, also leads to mild jaundice.

E-Fig. 41.1 Bilirubin production, metabolism, and excretion. See text for details. *UDP*, Uridine diphosphate; *UDPGA*, uridine diphosphate glucuronic acid.

Fig. 41.1 Hemolytic anemia associated with lymphoma. (A) Blood smear shows the destroyed red blood cells. (B) Lymphoma.

Fig. 41.2 Ultrasound image shows a cirrhotic liver with atrophy, irregular contours, and ascites.

Hemolysis should be considered in the evaluation of unconjugated hyperbilirubinemia and evaluated by examination of the peripheral blood smear (and, in some cases, the bone marrow smear and biopsy) as well as measurements of the reticulocyte count, haptoglobin, lactate dehydrogenase (LDH), erythrocyte fragility, and Coombs testing as indicated.

Hepatic or Hepatocellular Jaundice

Typically, considerable reserve exists within the liver, so jaundice of hepatocellular origin can be indicative of significant injury or dysfunction. The differential diagnosis is broad because the liver is susceptible to many different forms of injury (Fig. 41.2). The most common categories are viral hepatitis, exposure to toxins (e.g., alcohol, carbon tetrachloride, amanita, and increasingly herbs and supplements), medications (INH, antibiotics), autoimmune disorders (e.g., autoimmune hepatitis, primary biliary cholangitis [PBC], primary sclerosing cholangitis [PSC]), and liver tumors (primary or metastatic). Impaired hepatic uptake of bilirubin can be a cause of unconjugated hyperbilirubinemia. When present, it is typically caused by competition for bilirubin uptake by drugs such as rifampin. Removal of the competing agent usually leads to resolution of the jaundice.

Impaired Conjugation

Another common cause of unconjugated hyperbilirubinemia is Gilbert syndrome, a benign disorder that affects up to 7% of the population. This represents a normal variant that is not associated with intrinsic

liver disease. Rather, it typically manifests during the second or third decade of life as mild unconjugated hyperbilirubinemia that is exacerbated by fasting or physical stress. Most of those affected have a total bilirubin level of less than 3 mg/dL, mostly of the unconjugated (indirect) fraction. The underlying genetic variant responsible is a homozygous abnormality in the TATAA element of the promoter region of the UDP-GT gene that results in lower enzymatic levels. The diagnosis is strongly suggested by unconjugated hyperbilirubinemia in the setting of normal hepatic enzyme levels, no known liver disease, and no evidence of hemolysis. Liver biopsy usually is not indicated, and therapy is not warranted. However, the bilirubin level does decrease significantly with phenobarbital administration. It is important to be aware of this common cause of unconjugated hyperbilirubinemia so that the patient can be reassured and more costly or invasive tests can be avoided. Although Gilbert syndrome has generally been thought to have a benign course, sometimes people with this condition might be at an increased risk of developing gallstones. On the other hand, patients with Gilbert syndrome might be at a lower risk to develop cardiovascular disease, because unconjugated bilirubin has antioxidant properties that may offer some protective effect and mitigate progression of atherosclerosis.

Crigler-Najjar syndrome is another cause of unconjugated hyperbilirubinemia in which the bilirubin levels may be much higher due to a genetically determined decrease or absence of UDP-GT activity. Conjugation may also be impaired by mild, acquired defects of UDP-GT induced by drugs such as chloramphenicol.

NEONATAL JAUNDICE

About 50% of term and 80% of preterm babies develop jaundice, which usually appears 2 to 4 days after birth and resolves spontaneously after 1 to 2 weeks. Most jaundice in newborn infants occurs for two main reasons. First, the enzymatic and transport pathways responsible for bilirubin metabolism are relatively immature and are unable to conjugate bilirubin as efficiently or as quickly as in adults. Second, bilirubin production is increased. Of those two mechanisms, the major defect is in bilirubin conjugation, which may cause mild to moderate unconjugated hyperbilirubinemia between the second and fifth days of life lasting until day 8 in normal births or about day 14 in premature births. This neonatal jaundice is usually harmless, and no specific therapy is required other than close observation.

More severe pathologic unconjugated hyperbilirubinemia can occur in neonates and usually is caused by a combination of hemolysis secondary to blood group incompatibility and defective conjugation. This neonatal jaundice is a serious condition that requires immediate

attention because severe hyperbilirubinemia can lead to permanent neurologic damage (kernicterus). Phototherapy provided by conventional lighting or a fiberoptic light is the treatment of choice; it reduces neonatal jaundice (as assessed by serum bilirubin levels) compared with no treatment. Low-threshold compared with high-threshold phototherapy reduces neurodevelopmental impairment and hearing loss and reduces serum bilirubin on day 5 in infants with extremely low birth weight. However, it increases the duration of phototherapy, and it has no effect on mortality or on the rate of exchange transfusion. Close phototherapy, compared with distant light-source phototherapy, reduces the duration of phototherapy in infants with hyperbilirubinemia. If jaundice does not improve with phototherapy, other causes of neonatal jaundice should be assessed.

CONJUGATED HYPERBILIRUBINEMIA

Conjugated hyperbilirubinemia is associated with impaired formation or excretion of *all components* of bile, a situation termed *cholestasis*. The two major mechanisms of conjugated hyperbilirubinemia are defective excretion of bilirubin from hepatocytes into bile (intrahepatic cholestasis) and mechanical obstruction to the flow of bile through the bile ducts.

Impaired Hepatic Excretion (Intrahepatic Cholestasis)

Intrahepatic cholestasis can result from a wide range of conditions, including those that impair canalicular transport (e.g., certain drugs, circulating inflammatory cytokines during sepsis) and those that cause destruction of the small intrahepatic bile ducts. PBC, for example, is a chronic, progressive liver disease that occurs primarily in women and is characterized by the indolent destruction and subsequent disappearance over time of small lobular bile ducts. The gradual decrease in the number of bile ducts leads to progressive cholestasis, portal inflammation, fibrosis, and eventually cirrhosis. A similar loss of intrahepatic ducts can occur as a result of chronic rejection after liver transplantation.

Drug-induced cholestasis is increasingly common, and immune-mediated or idiosyncratic mechanisms can be the underlying cause. In some cases, there is associated hepatitis with significant cell injury (this can lead to hepatocellular damage and elevations in alanine aminotransferase [ALT] and aspartate aminotransferase [AST]). Representative drugs include, but are not limited to, nitrofurantoin, oral contraceptives, anabolic steroids, erythromycin, cimetidine, gold salts, chlorpromazine, prochlorperazine, imipramine, sulindac, tolbutamide, ampicillin, and other penicillin-based antibiotics. Given the broad access to drugs in Western societies and the unpredictable nature of the adverse liver effects, a high index of suspicion for drug-induced cholestasis is required. Drug-induced liver injury is generally considered a diagnosis of exclusion, after a thorough evaluation has ruled out other viral, autoimmune, and metabolic etiologies.

Intrahepatic cholestasis of pregnancy (ICP), also known as idiopathic jaundice of pregnancy, is a cholestatic disorder that is characterized by pruritus in the absence of a skin rash and elevation of aminotransferases (often up to 100 IU/L), alkaline phosphatase, 5-nucleotidase, and total and direct bilirubin concentrations. Total levels of bilirubin rarely exceed 6 mg/dL. The levels of γ -glutamyl transpeptidase are normal or only modestly elevated. ICP occurs in the second or third trimester of pregnancy and usually resolves spontaneously within 2 to 3 weeks after delivery. The diagnosis is suggested by the combination of pruritus and abnormal liver function tests with exclusion of other causes such as gallstones or intrinsic liver disease. ICP is associated with a higher risk for adverse perinatal outcome, including preterm birth, meconium passage, and fetal death.

The cause of ICP is not fully defined, but genetic, hormonal, and environmental factors are all likely to be involved. There is a high incidence of ICP in Chile and some other areas, and studies of potential genetic contributors are underway. Because adverse outcomes appear to occur predominantly after 37 weeks gestation, management by an experienced obstetrics team and consideration of early delivery are warranted. Ursodeoxycholic acid may be effective in ameliorating maternal pruritus and improving liver function test results; however, no medication has yet been shown to reduce the risk to the fetus.

The hemophagocytic syndrome, also known as hemophagocytic lymphohistiocytosis (HLH), is an uncommon hyperinflammatory disorder caused by severe hypercytokinemia. It manifests as fever, splenomegaly, and jaundice, with hemophagocytosis in the bone marrow and other tissues pathologically. Primary or familial HLH, also called familial erythrophagocytic lymphohistiocytosis, is a heterogeneous autosomal recessive disorder that has been found to be more prevalent with parental consanguinity. Secondary HLH is associated with malignancy, immunodeficiency, and infection, especially viral infection. In HLH, there is an inherent defect of natural killer cells and cytotoxic T cells, so they are unable to cope effectively with the infectious agent or antigen. Liver biopsies in HLH reveal sinusoidal dilation with hemophagocytic histiocytosis.

Postoperative jaundice typically occurs 1 to 10 days after surgery and has an incidence of approximately 15% after heart surgery and 1% after elective abdominal surgery. It is multifactorial in origin, with increased bilirubin load from bleeding and blood transfusions as well as impaired bilirubin conjugation and secretion caused by inflammatory cytokines. It typically resolves fully over time.

In hepatocellular disease, all three steps of hepatic bilirubin metabolism are impaired. Excretion, the rate-limiting step, is usually most affected, leading to predominantly conjugated hyperbilirubinemia.

Jaundice can be profound in acute hepatitis (see [Chapter 42](#)) without adverse prognostic implications. In chronic liver disease, however, persistent jaundice usually implies irreversible decrease in hepatic function and a poor prognosis.

Posthepatic Jaundice

Posthepatic jaundice, also called obstructive jaundice, results from a complete or partial obstruction of intrahepatic or extrahepatic bile ducts ([Fig. 41.3](#) and [E-Fig. 41.2](#)). The most common causes are gallstones in the common bile duct and tumors of the pancreatic head. Not infrequently, the first sign of pancreatic cancer is jaundice. Other causes include strictures of the common bile duct resulting from prior surgery or passage of gallstones. Primary sclerosing cholangitis should be considered in the setting of jaundice and biliary strictures that may be seen on imaging studies (magnetic resonance cholangiopancreatography [MRCP] or endoscopic retrograde pancreatography [ERCP]). Less common causes include congenital biliary atresia, pancreatitis, pancreatic pseudocysts, and parasites such as liver flukes (e.g., *Clonorchis sinensis*, *Dicrocoelium dendriticum*, *Opisthorchis viverrini*).

Mirizzi syndrome is an uncommon cause of posthepatic jaundice observed in 0.7% to 1.4% of patients after cholecystectomy. This syndrome is caused by extrinsic compression from an impacted stone in the cystic duct that impinges on and obstructs the common bile duct (see [Table 41.1](#)). Portal hypertensive biliopathy (or vascular biliopathy) is characterized by anatomic and functional abnormalities of the intrahepatic, extrahepatic, and pancreatic ducts in patients with portal hypertension associated with extrahepatic portal vein obstruction or, less frequently, cirrhosis. These morphologic changes, consisting of dilatation and stenosis of the biliary tree, are caused by extensive venous collaterals that develop in an attempt to decompress the portal

Fig. 41.3 Hepatocellular carcinoma compressing the bile ducts. (A) Sagittal view of computed abdominal tomography scan. (B) Endoscopic retrograde cholangiopancreatography demonstrates multiple strictures of the bile ducts.

venous blockage. The condition is usually asymptomatic until it has progressed to a more advanced stage such as biliary cirrhosis.

Immunoglobulin G4 (IgG4)-related sclerosing disease has recently been recognized as a distinct disease entity that can affect the bile ducts, gallbladder, pancreas, and other sites. Most cases of IgG4-related pancreatobiliary disease are associated with elevated serum IgG4 levels, extensive IgG4-positive plasma cells, and infiltration of lymphocytes into various organs, which leads to fibrosis. Several established systems are used to diagnose IgG4 disease; they rely on a combination of imaging findings of the pancreas, bile duct, and other organs; serologic findings; pancreatic histologic findings; and response to corticosteroid therapy.

CLINICAL APPROACH TO THE EVALUATION OF JAUNDICE

The differential diagnosis of jaundice is broad, thus a thorough history and physical examination along with judicious use of laboratory and imaging studies are necessary to define its underlying etiology. Jaundice appears as yellowing of the skin and sclera. Other conditions may mimic this presentation (e.g., carotenemia, Addison's disease, quinine ingestion), but scleral and mucosal discolorations are absent in these conditions. In hypercarotenemia, for example, the yellowish-orange coloration typically involves only the palms of the hands and soles of the feet.

An elevated serum bilirubin level, usually higher than 3 mg/dL, confirms the clinical impression of jaundice. The most important initial step is to define whether the jaundice is predominantly caused by an elevation of unconjugated or conjugated bilirubin. If jaundice is primarily the result of unconjugated bilirubin, evaluation for hemolysis and other conditions with shortened red blood cell survival is required. In patients with elevated conjugated bilirubin, the clinical challenge lies in determining whether biliary obstruction or impaired hepatic excretion is responsible (see [Chapter 40](#)).

In cholestatic jaundice caused by biliary obstruction, the alkaline phosphatase level is typically increased to more than three times normal, whereas serum transaminases are usually elevated less than 5-fold to 10-fold ([E-Fig. 41.3](#); see [Chapter 40](#)). Patients with cholestasis may

also develop pruritus and malabsorption of fat and fat-soluble vitamins (vitamins A, D, E, and K). More specific causes of biliary obstruction are suggested by recurrent abdominal pain and nausea (gallstones) or epigastric pain radiating to the back with weight loss and gallbladder distention (carcinoma of the pancreatic head). In complete biliary obstruction, conjugated hyperbilirubinemia is prominent and usually peaks at about 30 mg/dL in the absence of renal failure. Eosinophilia may accompany drug-induced jaundice. Inquiring about the use of drugs known to cause cholestasis, serologic testing for antimitochondrial antibody in suspected PBC, and ERCP or MRCP to evaluate PSC may be helpful.

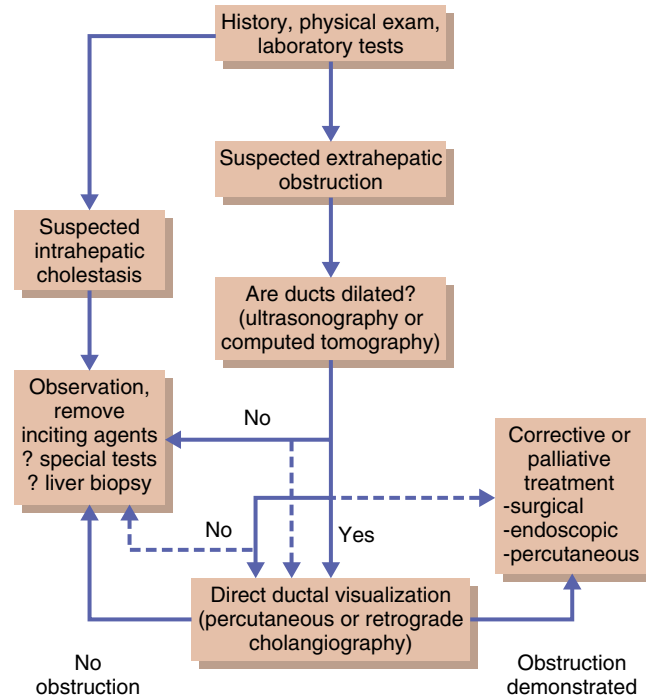

In jaundice produced by hepatocellular disease (see [Chapters 40 and 42](#)), serum transaminases are characteristically elevated more than 10-fold and alkaline phosphatase levels are less than three times normal. Evidence of hepatocellular damage is commonly associated and includes a prolonged prothrombin time, hypoalbuminemia, and clinical features of hepatic dysfunction (palmar erythema, spider angiomas, gynecomastia, and ascites). A careful evaluation includes inquiry about the use of drugs known to cause hepatocellular injury, alcohol, risk factors for viral hepatitis, and preexisting liver disease. More selected laboratory studies, such as serologic testing for hepatitis, are usually required (see [Chapter 42](#)).

A diagnostic approach to jaundice is outlined in [E-Fig. 41.3](#). If extrahepatic obstruction is suspected, noninvasive studies such as ultrasound or computed tomography should be used to determine whether bile ducts are dilated. If dilated ducts are found on noninvasive imaging, then direct cholangiography (either endoscopic or radiologic) provides the most reliable approach to management and potential treatment of cholestatic jaundice. If intrahepatic cholestasis is suggested clinically and extrahepatic obstruction is excluded by noninvasive means or by direct cholangiography, then the emphasis is placed on further laboratory testing to define the specific cause. Liver biopsy is sometimes required to define a specific histologic diagnosis, rule out other causes of disease, and assess the degree of injury and fibrosis.

For a deeper discussion on this topic, please see [Chapter 138](#), “Approach to the Patient with Jaundice or Abnormal Liver Tests,” in *Goldman-Cecil Medicine*, 26th Edition.

Acute and Chronic Hepatitis

Nayan M. Patel, Jen Jung Pan, Michael B. Fallon

INTRODUCTION

The term *hepatitis* denotes inflammation of the liver. It is applied to a broad category of clinicopathologic conditions that result from the damage produced by viral, toxic, metabolic, pharmacologic, or immune-mediated injury to the liver.

ACUTE HEPATITIS

Acute hepatitis implies a recent-onset inflammatory condition lasting less than 6 months. It can culminate either in complete resolution of the liver damage with return to normal function and structure or rapid progression of the acute injury toward extensive necrosis and a fatal outcome. Depending on the etiology, some may also progress to develop a chronic hepatitis. The most common causes of acute hepatitis are viral hepatitis (hepatitis A through E) and nonviral causes such as drug-induced liver injury, alcohol, toxins, autoimmune hepatitis, and Wilson's disease.

Acute Viral Hepatitis

Five hepatotropic viruses cause classic acute viral hepatitis (Table 42.1), but other viruses, including cytomegalovirus, herpesviruses, and Epstein-Barr virus can also cause liver injury. All of the hepatotropic viruses are ribonucleic acid (RNA) viruses except hepatitis B virus (HBV), which has a deoxyribonucleic acid (DNA) genome.

Hepatitis A virus (HAV) is a nonenveloped, single-stranded RNA virus classified in the Picornaviridae family and in the *Hepatovirus* genus. It is stable at moderate temperature and low pH, allowing the virus to survive in the environment and be transmitted by the fecal-oral route. The course is generally self-limited and does not lead to chronic infection.

Hepatitis E virus (HEV) belongs to the genus *Hepevirus* in the Hepeviridae family and has four genotypes. HEV1 and HEV2 are restricted to human beings and are transmitted via contaminated water in developing countries. HEV1 occurs mainly in Asia, whereas HEV2 occurs in Africa and Mexico. HEV3 and HEV4 infect human beings, pigs, and other mammalian species and are responsible for sporadic cases of autochthonous hepatitis E in both developing and developed countries. HEV3 has a worldwide distribution. HEV4 mostly occurs in Southeast Asia. While typically self-limited, acute liver failure and hepatic decompensation can occur in patients who are pregnant, malnourished, or have preexisting liver disease. Additionally, patients with solid organ transplants can develop a chronic HEV infection.

HBV is a small DNA virus that belongs to the Hepadnaviridae family. Approximately 250 million persons are carriers of HBV worldwide; of these, 75% reside in Asia and the Western Pacific. Both acute and chronic HBV infection can occur. Chronic hepatitis B infection is a major cause of hepatocellular carcinoma worldwide and can occur without cirrhosis because of integration of HBV DNA into hepatocytes.

Hepatitis C virus (HCV) is a single-stranded positive-sense RNA virus that belongs to the Flaviviridae family and has been classified as the sole member of the genus *Hepacivirus*. Approximately 74 million people are infected with HCV worldwide and 2.4 million in the United States. HBV has eight genotypes (labeled A through H), and HCV has six genotypes (1 through 6). Both HBV and HCV viruses are transmitted parenterally. HBV is present in virtually all body fluids and excreta of carriers. Transmission occurs most commonly through blood and blood products, contaminated needles, and sexual contact. Historically, HCV was the main cause of post-transfusion hepatitis before 1992. It is currently the most common cause of hepatitis among intravenous drug users. The Centers for Disease Control and Prevention now recommends one-time screening of persons born between 1945 and 1965 for hepatitis C because of the high prevalence of the disease in this birth cohort.

Hepatitis D virus (HDV) is classified in a separate genus of the Deltaviridae family. It is a small, defective RNA virus that can propagate only in an individual who has coexistent HBV infection, either after simultaneous transmission of the two viruses or via superinfection of an established HBV carrier. HDV has at least eight genotypes, four of which (genotypes 5 through 8) seem to be of exclusively African origin. Of the 250 million chronic carriers of HBV worldwide, more than 15 million have serologic evidence of exposure to HDV. Like HBV, HDV is transmitted via the parenteral route through exposure to infected blood or body fluids. Because there is evidence for sexual transmission, people with high-risk sexual activity are at increased risk for infection.

Clinical and Laboratory Manifestations

Acute viral hepatitis typically involves an asymptomatic incubation period from exposure to the first appearance of symptoms. This can be weeks to months depending on the type of viral hepatitis. Next a prodromal phase lasting several days that is characterized by constitutional and gastrointestinal symptoms including malaise, fatigue, anorexia, nausea, vomiting, myalgia, and headache occurs. A mild fever may be present (Fig. 42.1). Clinical manifestations of hepatitis A depend on the age of the host: fewer than 30% of infected young children showed symptomatic hepatitis, whereas about 80% of infected adults had severe acute hepatitis with remarkably elevated serum aminotransferases (Fig. 42.2). Arthritis and urticaria resembling serum sickness, attributed to immune complex deposition, are present in 5% to 10% of cases of acute hepatitis B and C. Taste and smell alterations may also occur. Jaundice soon appears, with bilirubinuria and acholic (pale) stools, which are often accompanied by an improvement in the patient's sense of well-being. The liver is usually tender and enlarged; splenomegaly is found in about one fifth of patients. Notably, many patients with acute viral hepatitis are asymptomatic or have symptoms without jaundice (anicteric hepatitis). In such instances, medical attention often is not sought.

TABLE 42.1 Characteristics of Acute Viral Hepatitis

	Hepatitis A	Hepatitis B	Hepatitis C	Hepatitis D	Hepatitis E
Causative agent	27–28 nm RNA virus Nonenveloped	42 nm DNA virus Enveloped	55–65 nm RNA virus Enveloped	36–43 nm RNA virus Enveloped	27–34 nm RNA virus Nonenveloped
Transmission	Fecal-oral	Blood-borne, sexual, percutaneous, perinatal	Similar to HBV; vertical and sexual route uncommon	Similar to HBV	Similar to HAV; transfusion; vertical transmission
Incubation period (days)	15–50	30–180	14–180	Similar to HBV	15–60
Onset	Acute	Acute, insidious	Insidious	Acute, insidious	Acute, insidious
Fulminant disease (%)	0.01–0.5	1	<0.1	5–20	1–2
Chronic hepatitis	No	Yes	Yes	Yes/No	Yes/No
Treatment	Supportive	Nucleos(t)ide analogues; IFN- α	DAA \pm ribavirin	IFN- α	Supportive; ribavirin
Prophylaxis	Hygiene; immune globulin, vaccine	Similar to HAV	Hygiene	Hygiene, HBV vaccine	Hygiene, vaccine

DAA, Direct-acting antiviral; HAV, hepatitis A virus; HBV, hepatitis B virus; IFN- α , interferon- α .

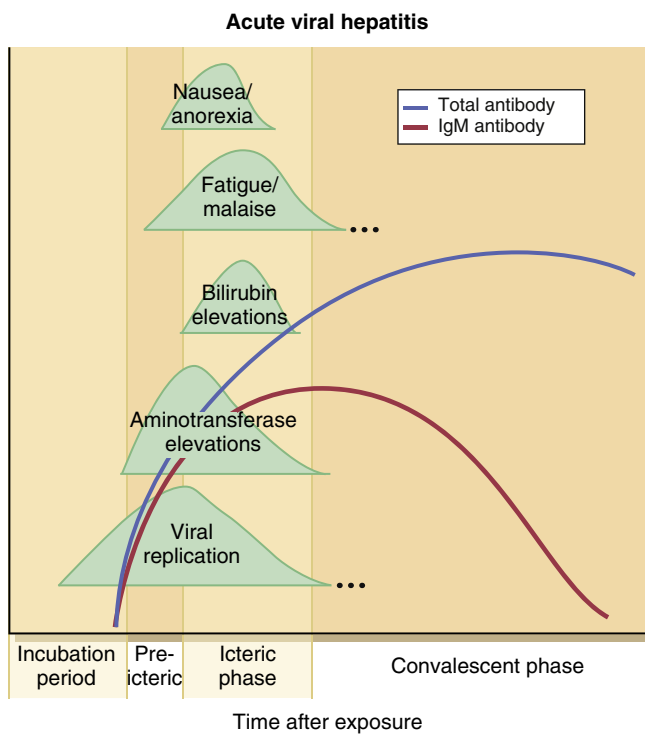

Fig. 42.1 Typical clinical, laboratory, and serological course in acute self-resolving viral hepatitis. IgM, Immunoglobulin M.

Fig. 42.2 Serologic course of acute hepatitis A. ALT, Alanine aminotransferase; HAV, hepatitis A virus; IgM, immunoglobulin M.

Alanine aminotransferase (ALT) and aspartate aminotransferase (AST) are released from acutely damaged hepatocytes, and serum levels can rise to 20-fold or more above normal. An elevated serum bilirubin level (>2.5 to 3 mg/dL) results in jaundice and is defined as icteric hepatitis. Values higher than 20 mg/dL are uncommon and correlate in a general way with the severity of disease. Elevations in serum alkaline phosphatase (ALP) are usually limited to three times normal levels except in cases of cholestatic hepatitis. A complete blood cell count most commonly shows mild leukopenia with atypical lymphocytes. Anemia and thrombocytopenia may also be present. The icteric phase of acute viral hepatitis may last days to weeks and is followed by gradual resolution of symptoms and laboratory values.

Diagnosis

Acute viral hepatitis can be diagnosed either directly, by detecting the nucleic acids of the infecting virus, or indirectly, by demonstrating an immune response in the host (Tables 42.2 and 42.3). Epstein-Barr virus and cytomegalovirus hepatitis are part of the differential diagnosis and also may be diagnosed by the appearance of specific antibodies of the immunoglobulin M (IgM) class.

In acute hepatitis B, hepatitis B surface antigen (HBsAg) and e antigen (HBeAg) are present in serum. Both are usually cleared within 3 months in acute self-limited infection, but HBsAg may persist in some patients with uncomplicated disease for 6 months to 1 year. Clearance of HBsAg is followed after a variable period by the emergence of antibodies against hepatitis B surface antigen (anti-HBs), which confers long-term immunity. Antibodies against hepatitis B core antigen (anti-HBc) and e antigen (anti-HBe) appear in the acute phase of the illness, but neither provides immunity. During the serologic window period, anti-HBc IgM, a marker of active viral replication suggesting recent infection, may be the only evidence of HBV infection (Fig. 42.3).

Every patient who is HBsAg positive should be tested for antibodies against HDV (anti-HDV IgG), which persist even after the patient has cleared HDV infection. Active HDV infection is now confirmed by the detection of serum HDV RNA with sensitive real-time polymerase chain reaction (PCR) assays. However, because of the variability of the genome sequence, assays of HDV RNA can produce false-negative results. Testing of anti-HDV IgM antibodies still has a role in patients who test negative for HDV RNA but have clinical features of HDV-related liver disease. While there is no diagnostic feature, suspicion for active HDV co-infection should be higher in acute liver failure from acute HBV infection.

Acute hepatitis C can be detected within 2 weeks after exposure with the use of a sensitive PCR assay for HCV RNA. Serum antibodies

TABLE 42.2 Serologic Markers of Viral Hepatitis

Agent	Marker	Definition	Significance
HAV	Anti-HAV IgM	IgM antibody to HAV	Marker of acute or recent infection
	Anti-HAV IgG	IgG antibody to HAV	Marker of acute or previous infection; post vaccination; confers protective immunity
HBV	HBsAg	Hepatitis B surface antigen	The presence of HBsAg indicates that the person is infectious
	HBeAg	Hepatitis B e antigen	Transiently positive in acute infection; may persist in chronic infection; reflection of active viral replication and high infectivity
	Anti-HBs	Antibody to surface antigen	Marker of acute self-limited infection; post vaccination; confers protective immunity
	Anti-HBe	Antibody to e antigen	Transiently positive in convalescence; positive in chronic infection before seroconversion; usually a reflection of low infectivity
	Anti-HBc IgM	IgM antibody to core antigen	Marker of acute or exacerbation of chronic infection
	Anti-HBc IgG	IgG antibody to core antigen	Appears at the onset of symptoms in acute infection and persists for life; not seen in vaccinees without prior infection
HCV	Anti-HCV	Antibody to HCV	Marker of acute and chronic infection; does not provide immunity
HDV	Anti-HDV IgM	IgM antibody to HDV	Positive in acute infection, negative in past infection but persists in a large proportion of patients with chronic infection
	Anti-HDV IgG	IgG antibody to HDV	Positive in all individuals exposed to HDV, and persists long-term, even after viral clearance
HEV	Anti-HEV IgM	IgM antibody to HEV	Marker of acute or recent infection ^a
	Anti-HEV IgG	IgG antibody to HEV	Marker of chronic or previous infection ^a

HAV, Hepatitis A virus; HBV, hepatitis B virus; HCV, hepatitis C virus; HDV, hepatitis D virus; HEV, hepatitis E virus; IgG, immunoglobulin G; IgM, immunoglobulin M.

^aSerologic testing is unreliable, and seroconversion might never occur in immunosuppressed persons.

TABLE 42.3 Interpretation of Diagnostic Markers in Hepatitis B

	HBsAg	HBeAg	Anti-HBc IgM	Anti-HBc IgG	Anti-HBs	Anti-HBe	Blood HBV DNA
Acute infection	+	+	+	+	-	+/-	High
Acute self-limited infection	-	-	+	+	+	+/-	-
Vaccinated	-	-	-	-	+	-	-
Chronic infection							
HBeAg positive	+	+	-	+	-	-	High
HBeAg negative	+	-	-	+	-	+	Low
Immune escape	+	-	-	+	-	+	High
Occult infection	-	-	-	+	-	+/-	Very low
Reactivation of chronic infection	+	+	+/-	+	-	+/-	High

anti-HBc IgG, Immunoglobulin G antibody against hepatitis B core antigen; *anti-HBc IgM*, immunoglobulin M antibody against hepatitis B core antigen; *anti-HBe*, antibody against hepatitis B e antigen; *anti-HBs*, antibody against hepatitis B surface antigen; *HBeAg*, hepatitis B e antigen; *HBsAg*, hepatitis B surface antigen; *HBV DNA*, hepatitis B virus deoxyribonucleic acid.

to HCV develop within 12 weeks after exposure, or within 4 to 5 weeks after biochemical abnormalities are discovered. Importantly, these are not neutralizing antibodies and do not confer immunity (Fig. 42.4). At onset of symptoms, 30% of patients will be missed if checked by serum enzyme immunoassay (EIA) for HCV antibody alone.

Commercial EIAs for hepatitis E to detect both IgM and IgG class antibodies are also available but may lack sensitivity and specificity. Diagnosis of HEV infection should be established by PCR assays in immunosuppressed patients, because serologic testing is unreliable, and seroconversion might never occur.

Complications

Cholestatic hepatitis. In some patients, most commonly during HAV infection, a prolonged but self-limited period of cholestasis (total bilirubin >10 mg/dL) occurs that is characterized by marked conjugated hyperbilirubinemia, elevation of ALP, and pruritus. Further investigation may be required to rule out biliary obstruction (see Chapters 40, 41, and 45).

Relapsing hepatitis. For unknown reasons, up to 10% of patients can experience a relapse of HAV infection after an initial resolution. This is characterized by biochemical relapse, but often milder clinical symptoms, and will typically resolve spontaneously.

Fig. 42.3 Kinetics of hepatitis B virus (HBV) markers during acute self-resolving hepatitis B. The arrow indicates infection. *HBc*, Hepatitis B core; *HBeAg*, hepatitis B e antigen; *HBs*, hepatitis B surface; *HBsAg*, hepatitis B surface antigen; *IgM*, immunoglobulin M.

Fig. 42.4 Kinetics of hepatitis C virus markers during acute self-resolving hepatitis C. *ALT*, Alanine aminotransferase; *ULN*, upper limit of normal.

Fulminant hepatitis. Massive hepatic necrosis occurs in fewer than 1% of patients with acute viral hepatitis; it leads to a devastating and often fatal condition called acute liver failure. This condition is discussed in detail in [Chapter 43](#).

Chronic hepatitis. Hepatitis A does not progress to chronic liver disease, although occasionally it has a relapsing course. Persistence of elevated levels of ALT and AST, viral antigens, or nucleic acids beyond 6 months in patients with hepatitis B or C suggests evolution to chronic hepatitis, although slowly resolving acute hepatitis may occasionally exhibit such test abnormalities for up to 12 months with eventual complete resolution. About 60% of organ transplant recipients infected with HEV fail to clear the virus and go on to develop chronic hepatitis. Chronic hepatitis is considered in detail later in this chapter.

Rare complications. Acute viral hepatitis may rarely be followed by aplastic anemia, which tends to affect mostly male patients and results in a mortality rate greater than 80%. Pancreatitis, myocarditis, pericarditis, pleural effusion, and neurologic complications including

Guillain-Barré syndrome, aseptic meningitis, and encephalitis have also been reported. Extrahepatic manifestations such as cryoglobulinemia and glomerulonephritis are associated with hepatitis B and C, and polyarteritis nodosa is associated with hepatitis B. These manifestations are more common in patients who fail to clear acute HBV or HCV and develop chronic hepatitis.

Management

Unless complicated by fulminant hepatitis, cases of acute hepatitis A, B, and E are usually self-limited and are managed by supportive care including rest, maintenance of adequate hydration and dietary intake, and avoidance of alcohol use. Hospitalization may be needed for patients who cannot tolerate oral intake and for those with evidence of deteriorated liver function, such as hepatic encephalopathy or coagulopathy.

In general, hepatitis A and E may be regarded as noninfectious after 3 weeks, whereas hepatitis B is potentially infectious to sexual contacts throughout its course, although the risk is low once HBsAg has been cleared. Studies of antiviral therapy in acute hepatitis B have not shown clear benefit, although some experts advocate the use of nucleos(t)ide analogues, specifically in the setting of acute liver failure due to hepatitis B. Treatment of acute hepatitis C is not always needed because 20% to 50% of patients will spontaneously clear the virus. This typically occurs within 6 months of the time of infection. If a decision is made to initiate treatment, current guidelines suggest monitoring HCV RNA for 12 to 16 weeks before starting treatment to allow for possible spontaneous clearance. Because of the safety and efficacy of direct acting antivirals (DAAs), the same regimen of medication for chronic hepatitis C is recommended for acute HCV.

Prevention

In patients with hepatitis A or E, both feces and blood contain virus during the prodromal and early icteric phases. General hygiene measures should include handwashing by contacts and careful handling, disposal, and sterilization of excreta, contaminated clothing, and utensils. HAV vaccination is appropriate for children older than 12 months of age, travelers to endemic areas, individuals with immunodeficiency or chronic liver disease, and those with high-risk behaviors or occupations. HAV vaccination is preferred over immunoglobulin for postexposure prophylaxis, based on results from randomized trials. With the availability of two candidate vaccines, one of which is already licensed for use in China, HEV prevention through vaccination is now a realistic possibility.

HBV is rarely transmitted by body fluids other than blood; however, it is highly infectious, and strict adherence to universal precautions is mandatory. Efforts at preventing hepatitis B have involved the use of hepatitis B immunoglobulin (HBIG) and recombinant HBV vaccines. Prophylaxis with HBIG after blood or mucosal exposure should be given within 7 days along with HBV vaccine. Preventive vaccination is currently recommended for high-risk individuals—health care professionals, patients undergoing hemodialysis, patients with chronic liver disease, residents and staff of custodial care institutions, and sexually active homosexual men—and is advocated universally for children. In the United States, the first hepatitis B vaccination is recommended to be given within 12 to 24 hours of birth.

No accepted prevention strategies other than universal precautions are available for HCV, and serum immunoglobulin is not useful for postexposure prophylaxis. The advent of widespread blood product screening for hepatitis C has made such infection after transfusion a rarity.

Alcoholic Liver Disease

Alcohol abuse continues to be a major cause of liver disease in the Western world. The three major pathologic findings resulting from

alcohol abuse are fatty liver, alcoholic hepatitis, and cirrhosis. These findings are not mutually exclusive and may all be present in the same patient. The first two conditions are potentially reversible. Alcoholic cirrhosis is discussed in [Chapter 44](#).

Mechanism of Injury

The mechanisms of liver injury caused by alcohol are complex. Ethanol and its metabolites, acetaldehyde and nicotinamide adenine dinucleotide phosphate, are directly hepatotoxic and cause a large number of metabolic derangements. Induction of cytochrome P-450 (i.e., CYP2E1) stimulates reactive oxidant species and cytokine pathways, particularly tumor necrosis factor- α (TNF- α). These are critical in initiating and perpetuating hepatic injury, as well as causing fibrosis through stellate cell activation. Excess alcohol leads to increased intestinal permeability, and the resultant endotoxemia from bacterial lipopolysaccharide leads to hepatic inflammation from upregulation of TNF- α .

Hepatotoxic effects from alcohol vary considerably among individuals based on dose, duration, drinking patterns, sex, ethnicity, genetic factors, and comorbidities that may affect the liver. The amount of alcohol ingested is the most important risk factor for the development of alcoholic liver disease. Women have a lower threshold of injury than men and have decreased amounts of gastric alcohol dehydrogenase as compared to men. The risk of cirrhosis is increased in men who drink greater than 60 to 80 grams of alcohol daily and women who drink more than 20 grams of alcohol daily. Malnutrition and other forms of chronic liver disease may potentiate the toxic effects of alcohol on the liver.

Clinical and Pathologic Features

Alcoholic fatty liver may manifest as incidentally discovered hepatomegaly or elevated aminotransferase levels on screening blood tests. Vague discomfort in the right upper quadrant of the abdomen may be the only symptom. Jaundice is rare, and aminotransferases are only mildly elevated (<5 times normal). Liver biopsy shows either diffuse or centrilobular fat occupying most of the hepatocytes.

Alcoholic hepatitis is a distinct entity characterized by acute hepatic inflammation that carries a high morbidity and mortality in its most severe form. It is characterized on liver biopsy by the histologic triad of Mallory bodies, infiltration by polymorphonuclear leukocytes, and a network of interlobular connective tissue surrounding hepatocytes and central veins (pericellular, perivenular, and perisinusoidal fibrosis). Patients with alcoholic hepatitis may be asymptomatic, or they may be extremely ill with hepatic failure. Other common symptoms are anorexia, nausea, vomiting, weight loss, and abdominal pain. For those with fever, infection needs to be ruled out. Rapid onset of jaundice is commonly present and may be pronounced, with cholestatic features that require differentiation from biliary tract disease (see [Chapters 40, 41, and 45](#)). Physical examination may reveal cutaneous signs of chronic liver disease, including spider angiomas and palmar erythema. In addition, gynecomastia, parotid enlargement, testicular atrophy, and loss of body hair may be found. The presence of ascites and hepatic encephalopathy can occur. Aminotransferases are only moderately increased (200 to 400 U/L) in alcoholic hepatitis compared with other forms of acute hepatitis. The ratio of AST to ALT almost always exceeds 2:1, in contrast to viral hepatitis, in which the aminotransferases are usually increased in parallel. The white blood cell count may be strikingly increased.

Diagnosis

A history of excessive and prolonged alcohol intake is frequently difficult to obtain from patients with alcoholic liver disease. However,

historical, clinical, and biochemical features of alcoholic hepatitis are often sufficient to establish the diagnosis. Many patients suspected or found to imbibe alcohol excessively may have causes in addition to alcohol contributing to liver disease (e.g., chronic viral hepatitis). Therefore, when other causes of liver disease are suggested, and alcohol intake is uncertain, appropriate serologic testing and a liver biopsy may be needed to establish a diagnosis.

Treatment

Complete abstinence from alcohol is the most important step. Meticulous supportive care, including enteral feeding for those with severe anorexia, is the cornerstone of treatment for acute alcoholic hepatitis. In the absence of contraindications (i.e., infection, gastrointestinal bleeding, or renal failure), some patients with alcoholic hepatitis may benefit from treatment with corticosteroids. A calculated discriminant function (DF) value greater than 32 (where $DF = 4.6 \times [\text{prothrombin time (in seconds)} - \text{control (in seconds)}] + \text{total bilirubin [in mg/dL]}$) may identify a subgroup of patients who are more likely to benefit from the use of corticosteroids, but these patients have advanced liver disease and a high mortality rate. Similarly, a Model for End-stage Liver Disease (MELD) score greater than 21 predicts a 90-day mortality of 20%. Pentoxifylline, an oral TNF- α antagonist, was shown to reduce the risk of renal failure but not mortality in a single randomized trial but has not shown benefit in other trials.

Complication and Prognosis

Alcoholic fatty liver disease completely resolves with cessation of alcohol intake. Alcoholic hepatitis can also resolve, but it commonly progresses either to cirrhosis, which may already be present at the time of initial diagnosis, or to hepatic failure and death. The development of encephalopathy, ascites, acute kidney injury, and gastrointestinal bleeding from varices often complicates alcoholic hepatitis (see [Chapter 44](#)). Patients with a DF greater than 32 have a high risk of death. The Lille model combines six reproducible variables (age, renal insufficiency, albumin, prothrombin time, bilirubin, and evolution of bilirubin at day 7) and is highly predictive of death at 6 months and helps guide corticosteroid therapy if initiated. A score greater than 0.45 predicts a 6-month survival rate of 25%, compared with 85% survival when the score is less than 0.45.

Drug-Induced Liver Injury

Drug-induced liver injury (DILI) refers to liver injury caused by drugs or other chemical agents and represents a special type of adverse drug reaction. More than 1000 medications and supplements are known to cause hepatotoxicity. Antibiotics remain the drugs most commonly responsible for DILI in the United States and Europe; the annual incidence of antibiotic-associated DILI is 1 in 10,000 to 100,000 individuals.

DILI may be classified by the pattern of liver injury observed. *Acute hepatocellular injury* is characterized by elevated levels of serum ALT and minimal elevations of serum ALP. *Cholestatic injury* is characterized by a disproportionately elevated level of ALP, which is synthesized and released by injured bile ducts. Liver injury that has both hepatocellular and cholestatic features is called *mixed liver injury*. DILI can also be classified into two broad categories, predictable and unpredictable, depending on the hepatotoxins involved. Predictable hepatotoxins, such as acetaminophen and carbon tetrachloride, cause dose-dependent liver injury. Acetaminophen is now the leading cause of life-threatening acute liver failure in the United States and Europe. Unpredictable hepatotoxins cause DILI in a so-called idiosyncratic fashion. Idiosyncratic reactions are difficult to predict and are not dose dependent. They generally tend to occur within the first 3 months of

initiating a medication. They occur relatively rarely in individuals with unique genetic and environmental characteristics.

Clinical and Laboratory Manifestations

DILI symptoms are similar to those associated with viral hepatitis and include malaise, anorexia, nausea and vomiting, right upper quadrant abdominal pain, jaundice, acholic stools, and dark (tea-colored) urine. Patients with cholestatic DILI may also have pruritus. Fever and rash, hallmarks of hypersensitivity, may be present with DILI caused by certain drugs such as anticonvulsants and sulfamethoxazole-trimethoprim. Cholestatic or mixed hepatitis related to amoxicillin-clavulanic acid (Augmentin) may develop shortly after the drug has been stopped, usually within 2 to 3 weeks. Nitrofurantoin (Macrobid) characteristically causes a chronic hepatitis after many weeks, months, or even years of therapy and is often associated with the presence of serum antinuclear antibodies (ANA).

Diagnosis

The diagnosis of DILI is challenging because of the lack of specific or uniform clinical features or laboratory tests in the majority of cases. A high level of suspicion for DILI is essential for diagnosis, as is the exclusion of other possible causes of liver injury. Generally, DILI occurs within the first 3 months of initiation of a medication but can occur after longer periods. The Russel-Uclaf Causality Assessment Method (RUCAM) provides objective and consistent assessment but can be cumbersome for routine clinical use. Moreover, a study conducted by Grant and Rockey suggested that expert opinion outperforms RUCAM in making a diagnosis of DILI. There is definitely a need for a simple, accurate, and reproducible method for diagnosing DILI.

Hepatitis E appears to be a small but important alternative diagnosis for suspected DILI. Of 318 patients in the multicenter U.S. Drug-Induced Liver Injury Network (DILIN) with suspected drug hepatotoxicity, 9 (3%) were found to be positive for HEV IgM.

Treatment

The mainstay of management of DILI is withdrawal of the offending agent and supportive care, which is usually sufficient in cases of mild to moderate DILI. Rechallenge of the implicated drug should be avoided. Specific therapies are available for some types of DILI. Timely administration of *N*-acetylcysteine (NAC) for acetaminophen overdose can be lifesaving. NAC may also improve outcomes of patients with early acute liver failure from etiologies other than acetaminophen. Corticosteroids are probably ineffective for DILI from most drugs; however, a short course of steroids is sometimes used for treatment of immune-mediated DILI with the manifestations of rash, fever, and eosinophilia. Ursodeoxycholic acid is safe and may possibly hasten the resolution of jaundice and pruritus.

Complication and Prognosis

With supportive care and discontinuation of the offending drug, mild to moderate DILI usually resolves rapidly. Cholestatic liver injury may take many weeks and even months to completely resolve. Occasionally, cholestatic DILI can progress to permanent bile duct injury with so-called vanishing bile duct syndrome. Patients may develop progressive liver injury or develop acute liver failure manifesting with encephalopathy and coagulopathy, and may need liver transplantation.

CHRONIC HEPATITIS

Chronic hepatitis is defined as a sustained inflammatory process in the liver lasting longer than 6 months. On initial presentation, chronic hepatitis can be difficult to differentiate from acute hepatitis on

clinical or histologic criteria alone. Except for hepatitis A, acute viral hepatitis, especially that caused by HBV or HCV, can ultimately lead to chronic hepatitis. Nonalcoholic steatohepatitis (NASH) is now the most frequent cause of chronic hepatitis in the United States and Western Europe. Several drugs can cause chronic hepatitis including methyl dopa, isoniazid, minocycline, propylthiouracil, and hydralazine. In contrast to acute hepatitis, an etiologic agent is sometimes difficult to identify in cases of chronic hepatitis. The pathogenesis of these idiopathic forms may represent quiescent autoimmune disease, undetected past DILI or NASH, antibody-negative viral infection, or misdiagnosed cholestatic liver injury (e.g., primary biliary cirrhosis [PBC], primary sclerosing cholangitis [PSC]).

Chronic Viral Hepatitis

In Western countries, acute HBV infection usually occurs in adults; 5% to 10% of patients fail to clear the virus and develop chronic hepatitis. In other areas, vertical transmission and childhood acquisition is common. Children who are infected within 2 years of birth have a much higher rate of chronic hepatitis B. HBV infection without evidence of any liver damage may persist, resulting in asymptomatic hepatitis B carriers. In Asia and Africa, many such carriers appear to have acquired the virus from infected mothers during infancy (vertical transmission).

Patients who are HBsAg and HBeAg positive and have high blood HBV DNA (>20,000 IU/mL), coupled with elevated serum aminotransferases, are in a high replicative phase (see Table 42.3). In contrast, patients in a low replicative phase are HBsAg and anti-HBe positive, have low blood HBV DNA (<20,000 IU/mL), and have near-normal or normal aminotransferase levels. These patients likely have HBV with precore and/or core promoter mutation. Patients infected with HBV in a high replicative phase are at high risk for cirrhosis and hepatocellular carcinoma. Such patients, and those who have already progressed to early cirrhosis, are the primary candidates for antiviral therapy.

Currently, eight drugs are approved for the treatment of adults with chronic hepatitis B in the United States, including interferon- α and its pegylated form and six nucleos(t)ide analogues (lamivudine, telbivudine, adefovir dipivoxil, tenofovir disoproxil, entecavir, and tenofovir alafenamide). The primary aim of therapy is to eliminate or permanently suppress HBV and thus reduce the activity of hepatitis and slow or limit the progression of liver disease. It is important to start therapy with a nucleos(t)ide analogue that has a high genetic barrier to resistance, such as entecavir or tenofovir, as first-line therapy. Long-term follow-up studies have shown interferon-based therapy increases HBsAg seroclearance over time. HBsAg seroclearance is less common in patients who are treated with nucleos(t)ide analogues rather than interferon-based therapy. All patients with chronic HBV are at risk for hepatocellular carcinoma and should undergo screening based on age, sex, and ethnicity. The risk of hepatocellular carcinoma decreases with decreasing viral load.

In patients with HBV and HDV coinfection, the fate of HDV is determined by the host response to HBV, which in more than 95% of adults results in viral clearance. By contrast, HDV superinfection of an individual with chronic hepatitis B usually results in chronic HDV infection. Treatment with nucleos(t)ide analogues is not effective in reducing HDV replication. The accepted practice for treatment of chronic HDV infection is weekly pegylated interferon for at least 48 weeks. In patients with a high concentration of HBV DNA, the addition of a potent nucleos(t)ide analogue to inhibit HBV replication is logical, but long-term effectiveness has yet to be defined.

Chronic hepatitis C develops in up to 75% of individuals who are acutely exposed to HCV (Fig. 42.5). Approximately 1.6% of the United States population (4.1 million people) are positive for antibodies to HCV (anti-HCV), and 2.4 million of them have chronic infection. Up

Fig. 42.5 Kinetics of hepatitis C virus (HCV) markers during acute hepatitis C that evolves toward chronic infection. *ALT*, Alanine aminotransferase; *ULN*, upper limit of normal.

to 20% of HCV cases progress to cirrhosis, usually within 20 to 30 years after infection. HCV has six major genotypes, of which genotype 1 is the most common in the United States, followed by genotypes 2 and 3. The genotype helps determine the treatment regimen and duration of therapy. The goal of antiviral therapy is to achieve a sustained virologic response (SVR12) or cure, defined as an undetectable HCV RNA level 12 weeks after treatment discontinuation. The current medications for hepatitis C are very effective and achieve cure in 98% to 99% of treatment naïve patients. These newer second-generation direct-acting antivirals target HCV replication, and have dramatically increased cure rates, shortened treatment duration, and minimized side effects. These medications work via novel mechanisms of action that target HCV enzymes needed for replication such as NS5B polymerase, NS3/4 protease, and the HCV protein NS5A. Pegylated interferon- α and ribavirin are now historical medications for treatment of chronic hepatitis C, where patients were treated for 24 or 48 weeks with SVR rates of 50% and a high incidence of side effects.

Among organ transplant recipients, the consumption of game meat, pork products, or mussels may result in HEV infection, which is most commonly asymptomatic without jaundice. About 60% of such infections become chronic, and up to 10% of patients progress to cirrhosis. Treatment includes careful reduction in immunosuppression, which results in viral clearance in 30% of patients on ribavirin monotherapy.

Autoimmune Hepatitis

Autoimmune hepatitis (AIH) has several clinical forms that share typical histologic findings including significant hepatic inflammation with a preponderance of plasma cells and fibrosis. Type 1, or classic, AIH is characterized by the presence of hypergammaglobulinemia, as well as the autoantibodies ANA or anti-smooth muscle antibodies (ASMA) in up to 80% of cases. Type 2 AIH is characterized by the presence of anti-liver/kidney microsomal antibodies (anti-LKM1) and the absence of ANA and ASMA. The type 1 variant can affect people of any age or gender, whereas the less common type 2 variant primarily affects girls and young women. A third type of AIH with antibodies to soluble liver antigen or liver-pancreas antigen (anti-SLA/LP) is no longer considered a unique entity because these antibodies may be found in type 1 and 2 variants as well. There are also uncommon overlap variants of AIH that have features of both AIH and other liver diseases such as PBC or PSC.

There are no pathognomonic features of AIH, and the diagnosis is made by a combination of factors. A simplified diagnostic algorithm that includes the presence of autoantibodies, hypergammaglobulinemia, typical liver histology, and absence of viral hepatitis has proved useful in identifying patients with AIH. Extrahepatic manifestations such as amenorrhea, rashes, acne, vasculitis, thyroiditis, and Sjögren's syndrome are common. Evidence of hepatic failure and the presence of chronic disease on liver biopsy are often discernable at the time of diagnosis. Indications for treatment include abnormal liver function tests and significant hepatic inflammation on biopsy.

Corticosteroids are the mainstay of treatment, typically in combination with azathioprine as a steroid-sparing agent. This regimen is efficacious in most patients (>80%) and in many instances prolongs survival.

Nonalcoholic Fatty Liver Disease

Nonalcoholic fatty liver disease (NAFLD) has a spectrum of presentations from simple steatosis, which usually does not progress to advanced liver disease, to NASH, which may exhibit or lead to cirrhosis. It is the most common cause of abnormal liver function tests among adults in the United States and Western Europe. NAFLD is commonly seen in people with central obesity, hypertension, diabetes, and hyperlipidemia, although it can be observed in persons with normal weight as well. Insulin resistance plays a central role in the pathophysiology of NAFLD. Estimates indicate that about 80 to 100 million Americans have NAFLD; of these, 18 million have NASH and almost 20% have signs of advanced disease (i.e., bridging fibrosis, cirrhosis) on histologic examination.

Liver biopsy is the "gold standard" for diagnosis of NASH. The NAFLD Activity Score has been developed and represents the sum of scores for steatosis, lobular inflammation, and hepatocyte ballooning that are typically seen on liver biopsy. It ranges from 0 to 8, with a score of 5 or higher considered diagnostic of NASH. Liver biopsy is invasive, costly, and can cause complications including a small mortality risk (0.01% to 0.1%). The use of liver biopsy has declined with newer noninvasive assessments of liver fibrosis and steatosis. Liver biopsy predominantly is used when there is diagnostic uncertainty to the etiology of disease. Radiologic imaging studies based on ultrasound and MRI can determine fibrosis by measuring liver stiffness with transient elastography technology and can also estimate the degree of steatosis.

Currently, this is no FDA-approved treatment available for NASH. Clinical trials of agents that therapeutically target the development of hepatic steatosis and fibrosis are underway and have shown beneficial effects on hepatic fibrosis. However, weight reduction with a goal of 5% to 7% of body weight loss and regular exercise are associated with biochemical and histologic improvement and are important components of therapy. Vitamin E and pioglitazone have been shown to improve hepatic inflammation in nondiabetic patients with NASH, but they are not routinely recommended because of questions regarding long-term safety and side effects.

Genetic and Metabolic Hepatitis

Hemochromatosis is an autosomal recessive genetic disorder that causes low levels of the iron regulatory hormone hepcidin causing defective sensing of iron stores and leads to excessive absorption of iron from the digestive tract. In the United States, about 1 of every 250 Caucasians have the condition; however, clinical expression is variable. Elevated ferritin and transferrin saturation values are typically used to screen patients with evidence of chronic liver disease and guide the need for further genetic testing. Most patients with hemochromatosis are homozygous for the C282Y mutation in the *HFE* gene, and a subset of

individuals who are heterozygous for both C282Y and the H63D mutation may also develop iron overload. Iron overload is very uncommon among those who are homozygous for the H63D mutation. Genetic mutations in a number of other proteins involved in iron sensing have also been associated with iron overload but are not routinely tested in clinical practice.

Hemochromatosis is a systemic disease that causes iron deposition in parenchymal cells in various organs including the liver, heart, pancreas, and pituitary glands. Patients may develop liver cirrhosis and cancer, heart failure, diabetes mellitus, hypogonadism, and arthralgias. A high index of suspicion is required to detect the disorder in early stages. The standard treatment for hemochromatosis is therapeutic phlebotomy. For patients who cannot undergo phlebotomy, chelation therapy may be offered.

Wilson's disease is an autosomal recessive genetic disorder that results from mutations in the *ATP7B* gene located on chromosome 13. These mutations result in excessive accumulation of copper in a number of organs, most notably the liver, cornea, and brain. The prevalence of the disease is approximately 1 in 30,000 live births in most populations. Wilson's disease can occur at any age. Measurement of the 24-hour urine copper excretion, slit lamp examination of corneas for Kayser-Fleischer rings, and direct measurement of hepatic copper confirm the diagnosis. Patients should receive lifelong chelation treatment with either penicillamine or trientine. Zinc may be used to maintain stable copper levels in the body.

α_1 -Antitrypsin deficiency (AAT) is an autosomal recessive genetic disorder of chromosome 14 that causes retention of AAT in the liver, resulting in liver damage. AAT is a protease inhibitor of the proteolytic enzyme elastase. The normal gene product is designated as PiM, and

the deficiency variants are PiS (50% to 60%) and PiZ (10% to 20%). The most common carrier phenotypes are PiMS and PiMZ, and the disease phenotypes are PiZZ, PiSS, and PiSZ. Low serum AAT and diastase-positive staining of hepatocellular AAT inclusions on liver biopsy support the diagnosis. Phenotypic testing in the serum has been the traditional gold standard for the diagnosis. However, genotypic testing is now available and widely used. Lung disease results from a loss of protective effects in patients with low levels of circulating AAT. AAT replacement therapy is an option for those with lung disease but is not useful for patients with liver disease.

For a deeper discussion on this topic, please see Chapters 139, "Acute Viral Hepatitis," and 140, "Chronic Viral and Autoimmune Hepatitis," in *Goldman-Cecil Medicine*, 26th Edition. ❖

Acute Liver Failure

Anil Seetharam, Michael B. Fallon

DEFINITIONS

Acute liver failure (ALF) is an infrequent condition characterized by rapid deterioration of liver function resulting in altered mentation and coagulopathy in individuals without preexisting liver disease. A widely accepted working definition includes International Normalized Ratio (INR) greater than 1.5 and any degree of altered mentation (encephalopathy) in a subject without preexisting cirrhosis and illness of less than 26 weeks' duration. Associated multisystem organ dysfunction and encephalopathy with chance for brainstem herniation mandate prompt recognition and transfer to an intensive care unit (ICU). Though etiologic specific treatment and supportive measures can be employed, liver transplantation remains the only chance for cure in those who do not spontaneously recover.

PATHOGENESIS

ALF develops as a result of severe, unrelenting inflammation with hepatocyte necrosis and collapse of the liver's architectural framework. This feature contrasts with the changes of cirrhosis and complications of portal hypertension that dominate chronic liver disease (see [Chapter 44](#)). ALF may result from infection with hepatotropic viruses A, B, C, D, or E (see [Chapter 42](#)) or from herpes simplex virus (HSV). Additionally, dose-dependent or idiosyncratic exposure to hepatotoxins such as acetaminophen, isoniazid, halothane, valproic acid, or mushroom toxins (*Amanita phalloides*) can produce ALF. Reye's syndrome, a disease that predominantly affects children, and acute fatty liver of pregnancy often resemble ALF; and are characterized by microvesicular fatty infiltration and little hepatocellular necrosis. Rare causes of ALF include: Wilson's disease, hepatic ischemia, autoimmune hepatitis, and malignancy ([E-Figs. 43.1 and 43.2](#)).

CLINICAL PRESENTATION

The clinical presentation includes progressive jaundice and hepatic encephalopathy without clinical evidence of underlying chronic liver disease. Other common but nonspecific symptoms include nausea, vomiting, loss of appetite, right upper abdominal pain from hepatomegaly, fever, fatigue, dark urine, and clay-colored stools. Typically, the features of impaired hepatic synthetic and metabolic function predominate, with portal hypertension much less common compared to patients with established cirrhosis.

DIAGNOSIS

The clinical presentation of ALF can be dramatic, with jaundice and advanced systemic manifestations as the first indication of a severe and potentially life-threatening illness. A thorough medical history

is essential and focused on potential exposure to viruses and hepatotoxins, pregnancy, an event associated with hypotension, and clues to suggest autoimmune causes.

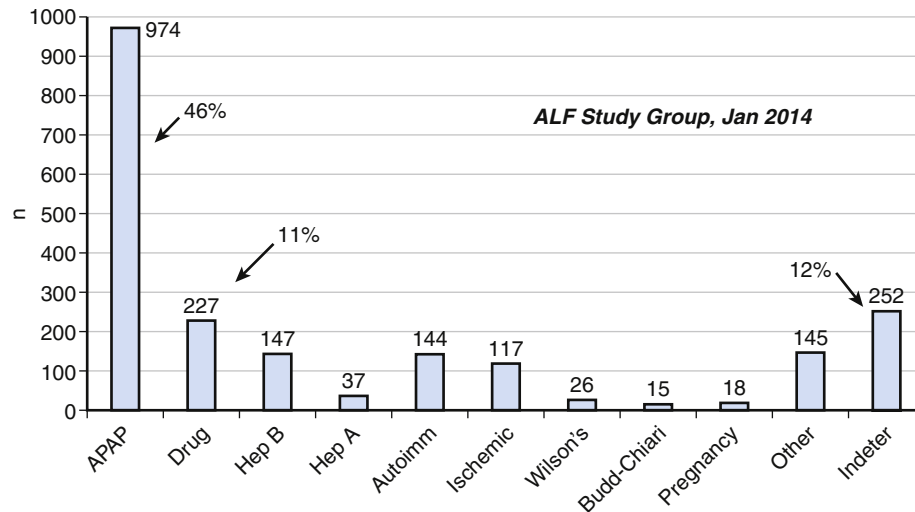

Early laboratory testing should focus on assessing the severity of hepatic dysfunction and on detection of possible acetaminophen exposure, for which specific antidote treatment must be promptly initiated. Further specialized laboratory testing is designed to identify specific viral causes—with tests for anti-hepatitis A immunoglobulin M (IgM), hepatitis B surface antigen (HBsAg), anti-hepatitis B core antigen (anti-HBc) IgM, hepatitis D antigen, anti-hepatitis C antibody and/or hepatitis C virus RNA, anti-hepatitis E IgM, anti-varicella IgM, and herpes simplex IgM—or other causes (e.g., ceruloplasmin level or autoimmune markers). Acute fatty liver of pregnancy may progress to ALF in the peripartum period; however, a pregnancy test should be performed in all females of childbearing age because viral illnesses (HSV, hepatitis E) may have a more severe course in pregnancy.

A negative serum acetaminophen level does not exclude acetaminophen overdose because the drug is rapidly cleared from the blood. Importantly, acetaminophen overdose accounts for approximately 50% of all cases of ALF and 20% of all cases of presumed indeterminate causes in Western countries. Small quantities of acetaminophen (or acetaminophen-containing compounds) may precipitate ALF in the context of consistent alcohol use due to constitutive activation (by ethanol) of cytochrome pathways creating toxic acetaminophen metabolites.

Imaging of the liver including ultrasound with Doppler may be utilized to assess liver architecture and blood flow into/out of the liver. Though not obligatory, a liver biopsy may be considered to assess for etiology; biopsy is often performed via the transjugular route secondary to coagulopathy and acuity of illness.

TREATMENT

Treatment of ALF is largely supportive, because specific treatment for the underlying cause of liver failure is often not available. However, many processes that result in widespread liver cell necrosis and ALF are transient events, and liver cell regeneration with recovery of liver function often occurs if patients survive the initial insult. Acetaminophen toxicity and hypotension causing hepatic necrosis are representative. In contrast, ALF resulting from viral hepatitis or idiosyncratic drug-induced liver injury (DILI) typically has a longer time course and an uncertain prognosis. In either case, meticulous supportive treatment in an intensive care unit setting has been shown to improve survival. Patients with ALF should be treated in centers with experience with this disease and with a liver transplantation program. Numerous systemic complications can result from ALF, and each must be thoroughly identified and treated ([Table 43.1](#)). As liver failure progresses,

TABLE 43.1 Management of Selected Problems in Fulminant Hepatic Failure

Organ System	Pathogenesis	Supportive Measures
Hepatic encephalopathy	Diminished hepatocyte function	Identification of treatable causes (e.g., hypoglycemia, drugs used for sedation, sepsis, gastrointestinal bleeding, electrolyte imbalance, decreased P_{O_2} , increased P_{CO_2}) Lactulose and rifaximin
Cerebral edema	Systemic and local inflammation and circulating neurotoxins, including arterial ammonia	Elevate head of bed 20–30 degrees Hyperventilate (P_{CO_2} reduction) ICP monitor placement Mannitol
Renal	Prerenal kidney injury from diminished effective circulating volume, acute tubular necrosis, or functional leading to acid/base/electrolyte imbalance	Continuous renal replacement therapy
Cardiovascular	Low systemic vascular resistance Diminished central vascular tone compromises peripheral tissue oxygenation	Intravenous resuscitation with normal saline and changed to half-normal saline containing 75 mEq/L sodium bicarbonate if acidotic Vasopressor support to maintain a mean arterial pressure of at least 75 mm Hg or a cerebral perfusion pressure of 60–80 mm Hg
Hematologic	Concomitant reduction in levels of both procoagulant and natural anticoagulant proteins, in conjunction with elevation of factor VIII (FVIII) and Von Willebrand factor, resulting in reduced thrombin generation capacity	Vitamin K 10 mg IV \times 1 Fresh-frozen plasma, platelets, and rFVIII generally reserved for active bleeding or need for invasive procedure Acid suppression to prevent luminal GI tract bleeding
Infectious	Immune dysfunction	Surveillance cultures of blood, urine, and tracheal aspirate when applicable Low threshold to initiate broad-spectrum antibiotic and antifungal therapy

a syndrome of multisystem organ failure can result; this can include encephalopathy, coagulopathy, infection, and renal failure.

Hepatic encephalopathy is often the first and most dramatic sign of liver failure. The precise pathogenesis of hepatic encephalopathy in ALF remains unclear and is likely multifactorial; however, it differs from that associated with chronic liver disease or portal hypertension in two important aspects. First, it often responds to therapy only when liver function improves, and second, it is frequently associated with hypoglycemia or cerebral edema, two other potentially treatable causes of coma. Therapy for hepatic encephalopathy in ALF differs slightly from the principles outlined in Chapter 44. Use of lactulose may be considered (orally or through a nasogastric tube) but should be discontinued if there is no significant improvement in mentation. Rifaximin, a non-absorbable antibiotic, can be given as an adjunct orally or per tube. Intubation is often necessary to protect the airway from aspiration and to allow ventilation in patients with advanced encephalopathy.

Cerebral edema, the pathogenesis of which is unknown, is a leading cause of death in ALF. Differentiation between cerebral edema and hepatic encephalopathy can be difficult, and computed tomography of the head is often unreliable as observable architectural changes of edema may lag behind clinical progression. Measurement of intracranial pressure (ICP) can be considered, although it is associated with complications including bleeding. The goal is to maintain an ICP of less than 20 mm Hg while maintaining a cerebral perfusion pressure (calculated as mean arterial pressure minus ICP) greater than 60 mm Hg. Supportive measures to limit ICP elevation include: control of agitation, head elevation of 20 to 30 degrees, hyperventilation, systemic vasopressors to maintain mean arterial pressure, administration of mannitol, barbiturate-induced coma, and urgent liver transplantation.

As hepatic synthetic function deteriorates, *hypoglycemia* can occur as a result of impaired hepatic gluconeogenesis and insulin degradation. All patients at risk should receive 10% glucose IV infusions with frequent monitoring of blood glucose levels. Other metabolic abnormalities commonly occur, including hyponatremia, hypokalemia, respiratory alkalosis, and metabolic acidosis. Therefore, frequent

monitoring of blood electrolytes and pH is indicated. Renal replacement therapy may be employed to regulate acid/base/electrolyte balance, with continuous modes preferred over intermittent hemodialysis.

Bleeding occurs frequently and is commonly caused by gastric erosions in the setting of impaired synthesis of clotting factors and prolonged prothrombin times. All patients should receive vitamin K and prophylactic gastric acid suppression. Fresh-frozen plasma administration is reserved for when clinically significant bleeding occurs or if major procedures, including ICP monitoring and central line placement, are performed. Studies in ALF have found a concomitant and proportional reduction in plasma levels of both procoagulants and natural anticoagulant proteins, in conjunction with a significant elevation in plasma levels of factors-VIII (FVIII) and Von Willebrand factor, resulting in an overall efficient, albeit reduced, thrombin generation capacity in comparison with healthy controls. Global hemostasis as assessed with thromboelastography (TEG) may be normal by several compensatory mechanisms, even in patients with markedly elevated INR.

Up to 80% of patients with ALF develop infection at some point in their illness; both bacterial (\approx 80% of infections) and fungal (\approx 20% of infections) have been implicated. Patients are at higher risk for infection as a result of impaired immunity resulting from liver failure and the need for invasive monitoring. Severe infection may occur without fever or leukocytosis. Therefore, frequent cultures are recommended and warranted with abrupt changes in status, and there should be a low threshold for beginning antibiotic therapy.

Although often employed to guide evaluation, no single prognostic model discriminates those who will spontaneously recover and those who will require transplant. The United States Acute Liver Failure Group (ALFSG) prospectively enrolled over 1900 subjects with ALF managed with and without transplantation and aimed to develop a model for ALF to predict transplant-free survival at 21 days. Clinical demographics and laboratory parameters were collected at enrollment and recorded serially up to 1 week. Variables of prognostic value adopted in the predictive model included: admission coma grade, liver

failure etiology and vasopressor requirement, as well as admission INR and bilirubin values. The model correctly predicted outcome in 66.3% of subjects, slightly outperforming historic King's College Criteria and the Model for End-stage Liver Disease (MELD) score.

Liver transplantation (see [Chapter 44](#)) has been performed with success in patients with ALF and is the treatment of choice for patients who appear unlikely to recover spontaneously. Because of high risk of abrupt clinical deterioration, the optimal approach is for potential candidates to be transferred to transplantation centers before significant complications develop (e.g., coma, cerebral edema, hemorrhage, infection). ALF subjects who meet transplant program criteria for listing in the United States are granted status 1A, placing them at the highest priority on the waiting list.

PROGNOSIS

Etiology of ALF and the degree of hepatic encephalopathy are key determinants of prognosis. Patients with ALF resulting from acetaminophen overdose or viral hepatitis A or B have a better survival rate than

do patients with Wilson's disease or those with indeterminate etiology. The short-term survival rate for patients with ALF in coma is 20% without liver transplantation.

Currently, ALF accounts for approximately 8% of all liver transplants, as per data from the Scientific Registry of Transplant Recipients (SRTR) with 1-year survival rates of 84% in the United States. Patients who survive without transplantation also have an excellent prognosis because liver tissue usually regenerates normally regardless of the cause of ALF.

Cirrhosis of the Liver and Its Complications

Shivang Mehta, Michael B. Fallon

LIVER CIRRHOSIS

Definition

Cirrhosis is a slowly progressive disease that is characterized by formation in the liver of fibrous and scar tissue that eventually replaces normal hepatocytes and impairs portal blood flow. Fibrosis can be a self-perpetuating result of many initial processes, including infectious, inflammatory, toxic, metabolic, genetic, and vascular insults that lead to liver damage. Most of the clinical features of cirrhosis develop as a result of portal hypertension, hepatocellular dysfunction, or altered cellular differentiation.

Etiology

Alcoholic liver disease, nonalcoholic steatohepatitis (NASH), and hepatitis C virus infection are the most common causes of cirrhosis in industrialized nations; hepatitis B virus is the major cause in Asia and in most of Africa. There are many other significant causes of cirrhosis, including biliary cirrhosis (primary and secondary), autoimmune hepatitis, inherited diseases (e.g., α_1 -antitrypsin deficiency), and drug-induced injury, that require specific evaluation. However, a significant number of patients with cirrhosis at presentation have no readily identifiable cause. These cases are referred to as idiopathic or cryptogenic in origin, and it remains a diagnosis of exclusion. Common and uncommon conditions that may lead to cirrhosis are listed in [Table 44.1](#). Chronic active hepatitis, nonalcoholic fatty liver disease (NAFLD)/NASH, and α_1 -antitrypsin deficiency are discussed in [Chapter 42](#).

Pathology

The typical sequence of events that leads to development of cirrhosis involves significant hepatocyte injury followed by ineffective repair that results in hepatic fibrosis. The injury can be acute or chronic in nature, depending on the mechanism. The fibrotic response to injury leads to development of nodules surrounded by fibrous tissue that consist of foci of regenerating hepatocytes, formation of fibrovascular membranes, rearrangement of blood vessels, and finally cirrhosis. This disruption of the normal hepatic lobular architecture distorts the vascular bed and contributes to development of portal hypertension and intrahepatic shunting. On gross morphology, cirrhosis can be referred to as macronodular (>3 mm regenerating nodules), commonly seen as a result of chronic active hepatitis, or micronodular (<3 mm regenerating nodules) a typical feature of alcoholic cirrhosis or cirrhosis of mixed origin.

Clinical Presentation

Symptoms of liver cirrhosis are often nonspecific in the early stages and include fatigue, malaise, weakness, weight change, anorexia, and nausea. With progression of portal hypertension or loss of hepatocytes, increased abdominal girth, sexual dysfunction, altered mental status,

and gastrointestinal bleeding may be noted. Physical findings depend on the stage at presentation. [Table 44.2](#) highlights the pathogenic mechanisms underlying these diverse signs and symptoms.

Diagnosis

Owing to significant reserves of liver function, patients with cirrhosis are often asymptomatic and the diagnosis is established incidentally at the time of physical examination or laboratory testing. Alternatively, patients abruptly experience specific life-threatening complications of cirrhosis, most notably variceal bleeding, ascites, spontaneous bacterial peritonitis, and hepatic encephalopathy (HE). If cirrhosis is suspected on clinical grounds, the diagnosis can be made reliably by a combination of clinical, laboratory, and radiologic findings in most cases. Although liver biopsy is still considered the “gold standard” for accurate diagnosis, new noninvasive modalities to estimate fibrosis have come to the forefront. The predominant modalities utilized to assess fibrosis non-invasively are FibroSure, FibroScan (ultrasound with shear wave elastography), and magnetic resonance elastography (MRE). With these advances, biopsy is now done more often to assess the stage and severity of disease, assign prognosis, and monitor the response to treatment.

Laboratory Findings

Hepatocellular dysfunction leads to impaired protein synthesis (hypoalbuminemia), hyperbilirubinemia, low levels of blood urea nitrogen (BUN), and elevated serum ammonia levels. Portal hypertension causes hypersplenism, which results in anemia, thrombocytopenia, and leukopenia. Patients with ascites often develop dilutional hyponatremia as a result of avid renal retention of sodium (Na^+) and water. The liver enzymes alanine aminotransferase (ALT) and aspartate aminotransferase (AST) are good markers of active hepatocyte necrosis, whereas elevations of alkaline phosphatase and bilirubin out of proportion to ALT and AST suggest intrahepatic or extrahepatic biliary obstruction. FibroSure is a laboratory test that consists of a panel comprising total bilirubin, GGT, α_2 -macroglobulin, haptoglobin, and apolipoprotein A1 corrected for age and sex to provide a surrogate for advanced fibrosis validated in populations with hepatitis B and C.

Radiology

Various radiologic modalities including ultrasound (with and without Doppler imaging of the portal and hepatic venous vasculature), computed tomography, and magnetic resonance imaging have complementary profiles in the evaluation of suspected cirrhosis. Findings supportive of the diagnosis of cirrhosis include relative enlargement of the left hepatic and caudate lobes as a result of right lobe atrophy, surface nodularity, and features of portal hypertension such as ascites, intra-abdominal varices, and splenomegaly.

TABLE 44.1 Common Causes of Cirrhosis

Alcohol abuse
Nonalcoholic steatohepatitis

TABLE 44.2 Clinical Features and Pathogenesis of Cirrhosis

Signs and Symptoms	Pathogenesis
Constitutional	
Fatigue, anorexia, malaise, weakness, weight loss	Liver synthetic or metabolic dysfunction
Cutaneous	
Spider angiomas, palmar erythema	Altered estrogen and androgen metabolism
Jaundice	Decreased bilirubin excretion
Caput medusae	Portosystemic shunting due to portal hypertension
Endocrine	
Gynecomastia, testicular atrophy, decreased body hair in men	Altered estrogen and androgen metabolism
Decreased libido, virilization, and menstrual irregularities in women	
Gastrointestinal	
Abdominal pain	Hepatomegaly, hepatocellular carcinoma
Abdominal swelling	Ascites due to portal hypertension
Gastrointestinal bleeding	Variceal hemorrhage due to portal hypertension
Hematologic	
Anemia, leukopenia, thrombocytopenia	Hypersplenism secondary to portal hypertension
Ecchymosis	Decreased synthesis of coagulation factors
Neurologic	
Altered sleep pattern, somnolence, confusion, asterix	Hepatocellular dysfunction: inability to metabolize ammonia to urea

Transient elastography (FibroScan) is a newer noninvasive modality that provides an indirect measure of liver fibrosis and cirrhosis by calculating liver stiffness. Abnormal liver stiffness suggests underlying fibrosis; in the presence of clinical and laboratory features of cirrhosis, this finding may obviate the need for diagnostic liver biopsy in some patients. Other modalities include ultrasound with shear wave velocity

(50 Hz), which uses velocity within the liver to determine stiffness. MRE is an addition to imaging provided by MR that incorporates acoustic vibrations across the entire liver to determine liver stiffness. It is currently the most accurate noninvasive modality but is limited by availability and cost. Biopsy is more invasive and is usually reserved for situations in which the results of noninvasive studies are indeterminate or the cause of the liver disease is in doubt.

COMPLICATIONS OF CIRRHOSIS

The major sequelae of cirrhosis are illustrated diagrammatically in Fig. 44.1 and can be categorized broadly into features of hepatocellular dysfunction and portal hypertension. The pathophysiologic interrelationships among these complications are described in the following sections.

Hepatocellular Dysfunction

The loss of hepatocyte mass that occurs in cirrhosis results in impaired synthesis of many important proteins, which in turn leads to hypoalbuminemia, deficient production of vitamin K–dependent coagulation factors, and diminished capacity for hepatic detoxification (see Chapters 40 to 43 for details). In addition, there is a decline in the capacity for conjugation and excretion of bilirubin.

Portal Hypertension

Under normal circumstances, the portal circulation is a low-pressure system with only small changes in pressure as blood flows from the portal vein, through the liver, and into the inferior vena cava. The hepatic venous pressure gradient (HVPG), which reflects sinusoidal pressure, is the gradient between the wedged hepatic venous pressure and the free hepatic venous pressure measured by direct catheterization. Normal HVPG values range between 3 and 5 mm Hg. In cirrhosis, the distortion of hepatic architecture by fibrous tissue and regenerative nodules, along with an increased intrahepatic vascular tone, leads to increased resistance to portal venous flow and resultant portal hypertension. Portal hypertension is defined as an HPV greater than 5 mm Hg, and clinically significant complications typically develop at values greater than 10 mm Hg.

Although cirrhosis is the most important cause of portal hypertension, any process that increases resistance to portal blood flow through the presinusoidal, sinusoidal, or hepatic venous outflow tracts may result in portal hypertension (Table 44.3). In addition, cirrhosis is associated with increased cardiac output, which leads to greater splanchnic blood flow, further aggravating portal hypertension. It is important to recognize that the HVPG is reliably increased only in sinusoidal portal hypertension.

With sustained portal hypertension, portosystemic collaterals are formed that have the benefit of decreasing portal pressures at the expense of bypassing the liver. Major sites of collateral formation include the gastroesophageal junction, retroperitoneum, rectum, and falciform ligament of liver (abdominal and periumbilical collaterals). Clinically, the most important collaterals are those connecting the portal to the azygos vein through the dilated and tortuous vessels (varices) in the submucosa of the gastric fundus and esophagus.

VARICEAL HEMORRHAGE

Definition and Pathology

Varices are abnormally large veins that are most commonly recognized near the gastroesophageal junction or the stomach wall. Gastroesophageal varices usually develop when the portal pressure

gradient (HVPG) exceeds 10 mm Hg, and the risk for variceal rupture increases when the gradient is higher than 12 mm Hg. Bleeding occurs most commonly from large varices in the esophagus when high tension in the walls of these vessels leads to rupture. Among gastric varices, fundal varices have the highest rate of bleeding and may bleed with portal pressure gradients of less than 12 mm Hg.

Clinical Presentation

Variceal bleeding usually manifests as painless hematemesis, melena, or hematochezia, which typically leads to hemodynamic compromise due to higher portal pressures. Bleeding is further aggravated by impaired hepatic synthesis of coagulation factors and thrombocytopenia from hypersplenism.

Treatment

The management of gastroesophageal varices includes prevention of initial bleeding (primary prophylaxis), treatment of acute variceal hemorrhage, and prevention of rebleeding (secondary prophylaxis) (Fig. 44.2). If varices are large, primary prophylaxis is commonly undertaken with nonselective β -adrenergic receptor blocking (NSBB) agents such as propranolol and nadolol. Surveillance for varices using esophagogastroduodenoscopy (EGD) is advocated only if endoscopic band ligation (EBL) is the initial treatment modality. EGD is recommended every 2 to 8 weeks until obliteration of varices, then in 3 to 6 months, after which surveillance can be done every 6 to 12 months. Periodic EBL is also effective if the patient has contraindications or intolerance to β -blockers. Isosorbide mononitrate therapy should not be used for prophylaxis because it has been shown to increase adverse events. EBL and NSBB should not be used in combination to prevent first variceal bleed.

When varices are present, 5% to 15% of patients experience an initial episode of bleeding annually, and this episode carries a significant mortality risk of 7% to 15% at 6 weeks. Management includes stabilization (airway, breathing, and circulation) and blood transfusions to maintain a hemoglobin level of 7 to 8 g/dL. Combined pharmacologic and endoscopic therapy is the current standard for control of bleeding and is superior to either therapy alone. Prophylactic intravenous antibiotics should be administered early because they reduce the risk for infection, rebleeding, and death.

Current pharmacologic therapy consists of octreotide, a somatostatin analogue, which is widely used because of a good safety profile. This agent is best instituted before endoscopic examination. Endoscopic therapy includes EBL or sclerotherapy or both. EBL is the preferred modality given the lower incidence of adverse effects and complications. In patients with gastric variceal hemorrhage, endoscopic variceal ablation with cyanoacrylate glue is superior to EBL, although this therapy is not approved in the United States. Balloon tamponade (Sengstaken-Blakemore tube, Linton tube, or Minnesota tube) or esophageal stenting have been used as temporary measures reserved only for cases in which endoscopic therapy has failed in the setting of massive hemorrhage. A recent meta-analysis in limited studies for esophageal stenting versus

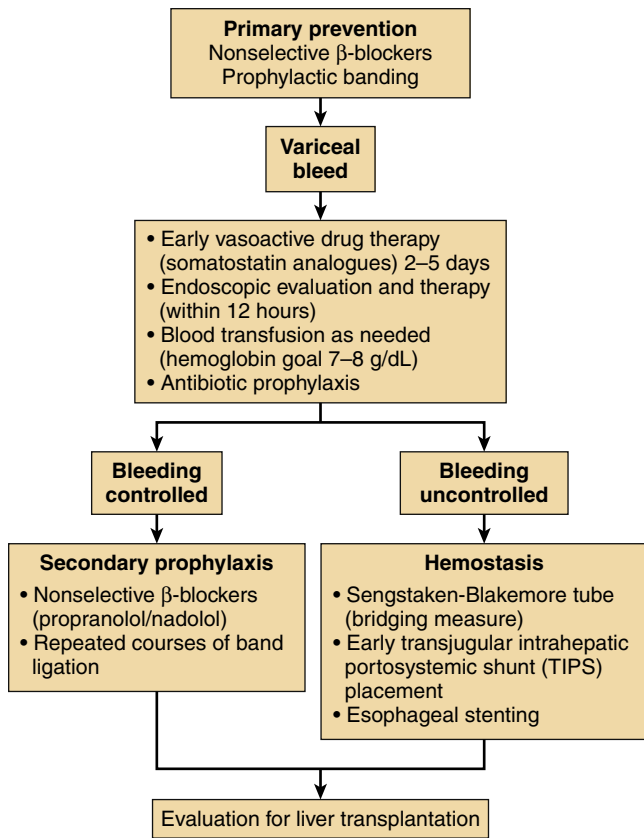

Fig. 44.2 Prevention and treatment of variceal bleeding.

balloon tamponade revealed esophageal stenting to have improvement in bleeding control despite issues with stent migration. Also, there is evidence that early (within 72 hours of admission) placement of a transjugular intrahepatic portosystemic shunt (TIPS) in a subset of patients with advanced liver disease improves survival after bleeding. The most common side effect of the TIPS is postprocedural encephalopathy.

Recommendations for secondary prophylaxis to prevent rebleeding include a combination of nonselective β -blockers (propranolol and nadolol) and variceal obliteration through repeated courses of EBL. In patients who undergo TIPS, the patency must be assessed using Doppler ultrasound on a regular basis.

Prognosis

Overall, the frequency and mortality rates from variceal bleeding appear to be decreasing in the United States over the past 2 decades. However, variceal hemorrhage is life-threatening, and after an initial episode the risk of rebleeding approaches 60% with a mortality rate of approximately 33% if secondary prophylaxis is not instituted.

ASCITES

Definition and Pathology

Ascites represents the accumulation of excess fluid in the peritoneal cavity. Although cirrhosis is the most common cause of ascites, there are also other important causes (Table 44.4). The precise sequence of events leading to the development of cirrhotic ascites remains debated.

Diagnosis

Physical examination is relatively insensitive for detection of small volumes of ascites, but bulging flanks, shifting dullness, and evidence of portal hypertension (e.g., distended veins over the abdominal wall

TABLE 44.4 Classification of Ascites

SAAG High (>1.1 g/dL)	SAAG Low (<1.1 g/dL)

Massive liver metastases	
Myxedema	
Mixed ascites	

SAAG, Serum-ascites albumin gradient.

and caput medusae) become evident with increasing amounts of fluid. Abdominal ultrasound is both sensitive and specific and is widely used in screening. When fluid is present, abdominal paracentesis is the quickest and most direct approach for confirmation of the presence of fluid in the abdominal cavity and initial characterization of the cause. In addition to standard measures such as cell count, the serum-ascites albumin gradient (SAAG), which is proportional to the sinusoidal portal pressure, is calculated as follows:

$$\text{SAAG} = (\text{Serum albumin concentration}) - (\text{Ascitic fluid albumin concentration})$$

An elevated SAAG (>1.1 g/dL) correlates well with portal hypertension as the likely cause of fluid accumulation (see Table 44.4).

Clinical Presentation

Patients usually report increasing abdominal girth, fullness of the flanks, and weight gain with or without peripheral edema. Ascites becomes clinically detectable with fluid accumulation greater than about 500 mL. Shifting dullness to percussion is the most sensitive clinical sign of ascites, but about 1500 mL of fluid must be present for reliable detection.

Treatment

Management of cirrhotic ascites depends on the cause. Patients with high SAAG (>1.1 g/mL), which is used as a surrogate measure for elevated portal pressures, usually respond to salt restriction (<2 g/day) and diuretics to stimulate renal Na^+ loss. The administration of spironolactone, an aldosterone antagonist, supplemented with a loop diuretic (e.g., furosemide), is effective in about 90% of patients. Diuresis should be monitored closely because aggressive diuretic therapy may result in electrolyte disturbances (e.g., hyponatremia, hypokalemia) and hypovolemia, leading to impaired renal function and potentially precipitating HE. Water restriction is implemented when the serum sodium concentration is less than 120 to 125 mEq/L.

Prognosis

Refractory ascites occurs in up to 10% of patients with cirrhosis and is defined as the persistence of tense ascites despite maximal diuretic therapy (spironolactone, 400 mg/day, and furosemide, 160 mg/day) or the development of azotemia or electrolyte disturbances at submaximal doses of diuretics. Treatment includes repeated large-volume paracentesis and colloid volume expansion with albumin (6 to 8 g/L of fluid removed), TIPS placement in appropriate candidates, and eventually liver transplantation (Fig. 44.3). Peritoneovenous shunts are rarely used and are reserved for patients who are not candidates for paracentesis, TIPS, or transplantation.

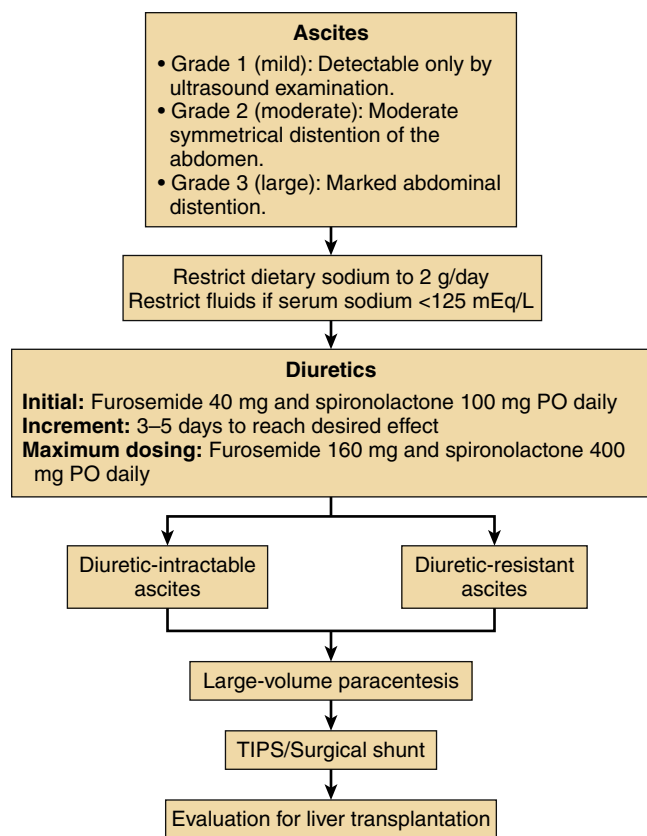

Fig. 44.3 Management of ascites in cirrhosis. *TIPS*, Transjugular intrahepatic portosystemic shunt.

SPONTANEOUS BACTERIAL PERITONITIS

Definition and Pathology

Cirrhotic patients may develop infection of ascitic fluid in the absence of an obvious source of contamination or surgically treatable source, a condition known as acute spontaneous bacterial peritonitis (SBP). The exact mechanism of contamination of the ascitic fluid is unclear. Factors such as bacterial overgrowth, altered motility, and increased intestinal permeability causing transient translocation of bacteria into the bloodstream and eventual seeding of the peritoneal fluid may contribute. The microbiology of SBP includes most commonly *Escherichia coli* and Enterobacteriaceae (*Klebsiella*). Gram-positive organisms such as *Streptococcus (viridans)*, *Enterococcus*, and *Pneumococcus* species may also be found. With the use of prophylactic antibiotics for SBP there has been a shift to gram-positive organisms being isolated. Anaerobes are uncommon, and a single organism is isolated on culture in most cases; the presence of multiple organisms suggests bowel perforation or other causes of peritonitis.

Clinical Presentation

Clinical features may include fever, abdominal pain, and signs of peritoneal irritation, particularly in advanced cases. Often, early infection is clinically silent or manifests with worsening of HE, diarrhea, ileus, or renal insufficiency.

Diagnosis

Diagnostic paracentesis should be considered in any patient with cirrhotic ascites who deteriorates clinically. The diagnosis of SBP is highly likely if a high concentration (>250 cells/mm³) of polymorphonuclear leukocytes (PMNs) is present in the ascitic fluid, and this finding

should prompt empiric therapy while blood and ascitic fluid culture results are pending. The use of rapid bedside diagnostic methods such as leukocyte esterase reagent strips is not routinely recommended in view of their low sensitivity. However, inoculation of both aerobic and anaerobic blood culture bottles with the first samples of peritoneal fluid retrieved at bedside significantly increases the yield of capturing potential pathogens.

Treatment

Patients are usually treated with intravenous third-generation cephalosporin (e.g., ceftriaxone, 2 g every 24 hours); quinolones, in particular ciprofloxacin, are routinely used in the United States, provided that the patient does not have prior exposure and is not in overt shock. Response to treatment is usually seen within 72 hours; therapy is continued for a minimum of 5 days and can extend up to 14 days. Repeat peritoneal fluid analysis may be done if recovery is delayed or to ensure that the ascitic fluid is sterile after treatment. The administration of intravenous albumin on day 1 (1.5 g/kg) and day 3 (1 g/kg) has been shown to decrease the incidence of renal dysfunction and to improve short-term survival in SBP.

Prognosis

There is a high rate of recurrence, up to 70% within 1 year, and the 1-year mortality rate with a prior episode of SBP is 50% to 70%. Long-term antibiotic prophylaxis is indicated to reduce the recurrence rate to approximately 20%. Short-term prophylaxis should be considered for patients with cirrhosis and ascites who are hospitalized with upper gastrointestinal bleeding. Common prophylactic regimens for SBP include fluoroquinolones (ciprofloxacin, 500 mg/daily; norfloxacin, 400 mg/day) and trimethoprim-sulfamethoxazole (1 double-strength tablet daily). Long-term antibiotic prophylaxis can lead to infection with resistant extended-spectrum β -lactamase (ESBL)-producing organisms or methicillin-resistant *Staphylococcus aureus* (MRSA).

HEPATORENAL SYNDROME

Definition and Pathology

Hepatorenal syndrome (HRS) is a form of functional renal failure that occurs in the presence of significant hepatic synthetic dysfunction and ascites. Three mechanisms of kidney dysfunction have been proposed: splanchnic arterial vasodilation, renal arterial vasoconstriction, and cardiac dysfunction.

Clinical Presentation and Diagnosis

Patients with HRS typically have advanced ascites and other manifestations of cirrhosis but are not otherwise symptomatic. However, some patients may notice decreased urine output or signs of encephalopathy. There is no single laboratory or imaging study that can be used alone to diagnose HRS. However, the 5-year probability of developing HRS in patients with cirrhosis and ascites is 40%, and HRS develops in approximately 30% of cirrhotic patients who are admitted with SBP. Therefore, a high clinical suspicion is warranted along with a systematic approach to diagnosis based on fulfillment of certain criteria.

The International Club of Ascites (ICA) developed updated diagnostic criteria incorporating new definitions of acute kidney injury (AKI) in 2015:

1. Cirrhosis with ascites
2. Diagnosis of AKI according to ICA-AKI criteria: 50% increase in the serum creatinine level from baseline which is known or presumed to have occurred within the 7 days prior OR Rise of 0.3 mg/dL (26.4 μ mol/L) in the serum creatinine level in less than 48 hours

3. Lack of response after at least 2 days of diuretic withdrawal and volume expansion with albumin (1 g/kg of body weight/day, to a maximum of 100 g/day)
4. Absence of shock
5. Lack of current or recent treatment with nephrotoxic drugs
6. Absence of parenchymal kidney disease as indicated by proteinuria of more than 500 mg/day, microhematuria (>50 red blood cells/high-power field), or abnormal renal US findings

HRS has two types, HRS-AKI type 1 and HRS-CKD (chronic kidney disease) type 2. HRS-AKI is characterized as an increase in serum creatinine 0.3 mg/dL or greater within 48 hrs or 50% or greater from baseline value according to ICA consensus document *and/or* urinary output 0.5 mL/kg body weight or less for longer than 6 hours. HRS-CKD is defined as eGFR less than 60 mL/min per 1.73 m² for 3 months or greater in the absence of other (structural) causes.

Typically, the kidneys are histologically normal and can regain normal function in the event of recovery of liver function (e.g., after liver transplantation). Severe cortical vasoconstriction has been demonstrated angiographically, and such vasoconstriction reverses when these kidneys are transplanted into patients who do not have cirrhosis.

Treatment and Prognosis

The mortality rate is high in HRS, and so prevention is important. In all patients with cirrhosis, precipitating factors (e.g., diuretics, lactulose, nonsteroidal anti-inflammatory drugs, angiotensin-converting enzyme inhibitors) should be avoided if possible. Patients should be promptly diagnosed and treated for any signs of SBP, and colloid (albumin) should be administered if rising creatinine levels are observed. Prevention of variceal bleeding should also be optimized by primary and secondary prophylaxis.

Studies have shown an increased mortality rate with AKI among hospitalized cirrhotic patients. Several medical therapies are currently under review, including use of terlipressin, a vasopressin V₁ receptor analogue, in combination with albumin for type 1 HRS. Other studies have evaluated the combination of octreotide and midodrine (an α -adrenergic agonist) and intravenous albumin. Placement of TIPS has also been reported to stabilize or even improve renal function, mainly in patients with HRS-CKD. However, a significant limitation of TIPS is the possibility of worsening hepatic function in decompensated cirrhosis. Liver transplantation has become the accepted treatment for HRS because it is the only known therapeutic intervention that reverses the process. It is limited by rapid progression of HRS and lack of available organs.

HEPATIC ENCEPHALOPATHY

Definition

HE is a complex, reversible neuropsychiatric syndrome that occurs in patients with chronic liver disease, portal hypertension, or portosystemic shunting. HE is also seen in patients with acute liver failure. HE develops in about 30% to 45% of cirrhotic patients, and when it is present, the survival probability is approximately 23% at 3 years.

Pathophysiology

The pathogenesis of HE in the setting of cirrhosis is thought to be multifactorial and may differ in acute and chronic liver disease. Contributors include the inadequate hepatic removal of potential endogenous neurotoxins, altered permeability of the blood-brain barrier, and abnormal neurotransmission. Elevation of blood ammonia levels, derived from both amino acid deamination and bacterial hydrolysis of nitrogenous compounds in the gut, has been the best studied factor, but its specific role in the pathogenesis of HE remains uncertain. Many other potential contributors to HE have been investigated,

including increased tone of the inhibitory GABA_A/benzodiazepine neurotransmitter system, activation of the astrocytic 18-kDa translocator protein (PTBR), production of endogenous benzodiazepine-like compounds, altered cerebral metabolism, zinc deficiency, increase in serotonin levels, upregulation of H1 receptors, altered melatonin production, and deposition of manganese in the basal ganglia.

Clinical Presentation

The clinical features of HE include disturbances of higher neurologic function such as intellectual and personality disorders, dementia, inability to copy simple diagrams (constructional apraxia), disturbance of consciousness, disturbances of neuromuscular function (asterixis, hyperreflexia, myoclonus), and, rarely, a Parkinson-like syndrome and progressive paraplegia. One of the earliest manifestations of overt HE is alteration of the normal sleep-wake cycle.

Diagnosis

There is no laboratory or imaging study that allows a specific diagnosis of HE. Rather, it is a clinical syndrome. Blood levels of ammonia are commonly measured, but elevated levels are neither sensitive nor specific for HE. Neuropsychometric and neurocognitive tests such as the Portosystemic Encephalopathy Syndrome Test (PSET) and the earlier Stroop Color-Word Test evaluate the patient's attention, concentration, fine motor skills, and orientation and have been shown to be highly specific for the diagnosis of HE, but they are reasonably labor intensive. Therefore, a smartphone-based application known as EncephalApp was created incorporating the Stroop test that is validated for use in detection of covert/minimal HE. It is imperative that reversible causes of neurologic dysfunction, such as hypoglycemia, subdural hematoma, meningitis, and drug overdose, be considered and excluded early in the differential diagnosis of altered mental status in patients with cirrhosis.

Classification of Hepatic Encephalopathy

There are three major types of HE: type A (Acute), which is associated with acute liver failure; type B (Bypass), which is associated with portosystemic shunts in the absence of liver disease; and type C (Cirrhosis), which is associated with liver cirrhosis and is subdivided into episodic, persistent, and minimal types.

HE has been further graded based on the West Haven Criteria from 0 to 4. A new nomenclature, termed the Spectrum of Neurocognitive Impairment in Cirrhosis (SONIC) classification, has been proposed to improve recognition of earlier forms of HE that require specialized testing for detection and to facilitate research studies. Patients are divided into those who are unimpaired, those with covert HE, and those with overt HE (Table 44.5).

Treatment

Treatment of HE starts with identifying and addressing any precipitating factors (Table 44.6), reducing and eliminating substrates for the generation of nitrogenous compounds, and preventing ammonia absorption from the bowel. Protein restriction was considered to be important in preventing excess ammonia production in the past; however, studies have demonstrated that dietary restriction of protein is not of significant benefit. Short-term protein restriction may be considered for patients with severe encephalopathy, but long-term restriction is associated with worsening malnutrition. Treatment with formulas rich in branched-chain amino acids has shown no benefit in improving encephalopathy or mortality.

Nonabsorbable disaccharides (e.g., lactulose) are the mainstay treatment of HE. These agents are fermented to organic acids by colonic bacteria, processes that lower stool pH and trap NH₄⁺ in the colon, thereby decreasing absorption. In addition, the cathartic effect

Hypovolemia: most often induced by diuretics

of lactulose eliminates ammonia and other nitrogenous compounds. Patients are usually directed to achieve two to three soft stools per day as the goal of lactulose therapy. Reduction and elimination of nitrogenous compound substrates can also be achieved by administering enemas and using nonabsorbable antibiotics such as rifaximin in patients who do not tolerate or respond to lactulose. Rifaximin (Xifaxan), 550 mg PO twice daily, is approved by the US Food and Drug Administration for the treatment of HE and has a favorable side effect profile; however, cost is the limiting factor. Other agents that affect intestinal motility and ammonia generation are being evaluated, including acarbose and probiotics.

HEPATOPULMONARY SYNDROME AND PORTOPULMONARY HYPERTENSION

The effects of cirrhosis and portal hypertension on the pulmonary circulation manifest as two distinct disorders, hepatopulmonary syndrome (HPS) and portopulmonary hypertension (PoPH).

Hepatopulmonary Syndrome

HPS occurs in 5% to 30% of patients with cirrhosis and is a progressive disease. It is characterized by gas exchange abnormalities (increased alveolar-arterial gradient and hypoxemia) resulting from intrapulmonary vascular dilation. The vascular dilation leads to vascular remodeling and angiogenesis, resulting in impaired oxygen transfer from the alveoli to the central stream of red blood cells within capillaries. Usually, this functional intrapulmonary right-to-left shunt significantly improves with the administration of 100% oxygen. HPS also has been reported in cases of hepatic venous outflow obstruction without cirrhosis.

Diagnosis

HPS is diagnosed based on high clinical suspicion and measurement of a widened alveolar-arterial oxygen gradient on room air in the presence or absence of hypoxemia. The gradient is calculated by analyzing arterial blood gases. HPS is graded from mild, in which the arterial partial pressure of oxygen (P_{aO_2}) is greater than 80 mm Hg) to very severe ($P_{aO_2} < 50$ mm Hg). Intrapulmonary shunting is demonstrated by contrast echocardiography, in which agitated saline is injected into a peripheral vein during the performance of two-dimensional echocardiography. Delayed appearance of microbubbles in the left cardiac chambers (more than three to six cardiac cycles after injection) indicates intrapulmonary vasodilation. Early visualization of microbubbles in the left cardiac chambers indicates intracardiac shunting. Other tests, including chest radiography, computed tomography, and pulmonary function tests, are performed to exclude intrinsic cardiopulmonary disorders.

Clinical Presentation

Clinical features range from subclinical abnormalities in gas exchange to profound hypoxemia causing significant dyspnea. Classically in HPS, the dyspnea is worse on standing and improves when the patient

lies down (orthodeoxia and platypnea, respectively). Patients may also have marked nocturnal hypoxemia.

Screening and Treatment

Screening by pulse oximetry typically targets patients with values lower than 96% at rest on room air for further evaluation; however, recent data suggest that this may not be an appropriate screening tool. Currently, there is no established medical therapy for HPS. Recent evaluation of newer agents such as sorafenib showed no significant improvement. Liver transplantation remains the only option and reverses HPS in most patients. The use of TIPS to treat HPS is not established.

Prognosis

HPS carries a mortality rate of up to 40% in 2.5 years.

Portopulmonary Hypertension

PoPH is defined as the presence of pulmonary arterial hypertension in the setting of portal hypertension.

Diagnosis and Pathology

The diagnosis of PoPH is based entirely on results of right heart catheterization. The diagnostic values include a mean pulmonary arterial pressure greater than 25 mm Hg at rest or 30 mm Hg with exercise, a pulmonary capillary wedge pressure lower than 15 mm Hg, and a pulmonary vascular resistance greater than 240 dynes, all in the presence of portal hypertension or liver disease or both. PoPH is graded according to the mean pulmonary artery pressure, from mild (>25 to 35 mm Hg) to moderate (35 to 50 mm Hg) to severe (>50 mm Hg). Patients with mild PoPH do not appear to have increased operative risk. Moderate PoPH carries a high intraoperative risk and should be medically managed before transplantation. Severe PoPH is generally considered a contraindication to surgery. The exact mechanisms of PoPH are poorly understood. Histologically, it has characteristics similar to those of pulmonary hypertension.

Clinical Presentation

The most common symptom of PoPH is dyspnea on exertion, but many cirrhotic patients with PoPH are asymptomatic.

Treatment

In addition to symptomatic treatment (oxygen for dyspnea and diuretics for volume overload), the medical management of PoPH is similar to that for pulmonary arterial hypertension. The drugs most commonly used in treatment for PoPH are prostacyclins (intravenous, inhaled or subcutaneous), oral treatments including phosphodiesterase inhibitors, and endothelin receptor antagonist.

If moderate PoPH responds to therapy, liver transplantation may be considered. However, it has not been established whether successful liver transplantation reliably reverses PoPH. Liver transplantation is contraindicated in severe PoPH because of high transplant-related morbidity and mortality. However, there were no dedicated randomized clinical trials of these therapies until the PORTICO trial. The PORTICO trial was a double-blind, placebo-controlled, multicenter study of macitentan, an endothelin receptor antagonist. Macitentan showed improved pulmonary vascular resistance without hepatotoxicity. More novel agents are being studied.

Prognosis

Untreated PoPH carries high rates of morbidity and mortality; the mean survival time from diagnosis is 15 months. A study on the U.S.-based Registry to Evaluate Early and Long-term Pulmonary Arterial

Hypertension Disease Management (REVEAL) showed a 5-year survival rate of 40% from the time of diagnosis in patients with PoPH.

HEPATOCELLULAR CARCINOMA

Epidemiology

Liver cancer is the fifth most common cancer in men and the seventh most common in women worldwide; HCC is the most common type of liver cancer. In the United States, approximately 90% of liver cancers are HCC, and cholangiocarcinomas account for most of the rest. In other areas of the world, including sub-Saharan Africa, China, Japan, and Southeast Asia, HCC is one of the most frequent malignancies and is an important cause of mortality, particularly among middle-aged men.

Etiology

HCC often arises from a cirrhotic liver, and it is closely associated with chronic viral hepatitis. Hepatitis B virus DNA has been shown to integrate into the host cell genome, where it may disrupt tumor suppressor genes and activate oncogenes. In areas of high prevalence, vaccination to prevent infection with hepatitis B virus has reduced the incidence of HCC. The exact pathophysiologic mechanisms leading to tumor genesis in patients with other causes of cirrhosis (e.g., hemochromatosis, alcohol, hepatitis C viral infection) remain poorly understood. Risk factors for the development of HCC and its clinical manifestations are listed in (Table 44.7).

Diagnosis

Table 44.8 lists currently used imaging techniques for detection of HCC and the most common findings. A tissue specimen may be necessary to confirm the diagnosis in some cases, but it is not needed if characteristic clinical and radiologic features are present, especially if they are accompanied by a rise in serum α -fetoprotein levels. The Hepatic Carcinoma Early Detection Screening (HES) algorithm for early detection of HCC was developed and has been validated in the Veterans affairs (VA) cohort. The algorithm includes patient's age, ALT level, platelet count, and current and rate of change to AFP level. It has shown an improvement in early detection in patients with cirrhosis in comparison to AFP alone.

Staging

Although many staging systems for HCC are in use, the Barcelona Clinic Liver Cancer (BCLC) system is most commonly used.

Treatment

Patients with well-compensated cirrhosis may undergo surgical resection or liver transplantation, with a 5-year survival rate of up to 70%. Nonsurgical options include percutaneous ethanol injection, transarterial chemoembolization (TACE), and radiofrequency ablation. The first-line treatment for many years was Sorafenib (a receptor tyrosine kinase angiogenesis inhibitor) for use in patients with unresectable HCC. However, recently another agent was approved, lenvatinib, which works by the same mechanism, and both have been shown to prolong survival of these patients. Second-line agents have also been approved, which include regorafenib, cabozantinib, and nivolumab.

Prognosis

In patients with widespread, multifocal disease and in those with vascular invasion, the prognosis is poor, with a 5-year survival rate of 5% to 6%. Accordingly, emphasis is placed on prevention of viral hepatitis and other causes of liver disease and on screening by ultrasound of those who are at higher risk, including patients with known cirrhosis.

 T2-weighted images: hyperintense
 After gadolinium administration, tumor increases in intensity

VASCULAR DISEASE OF THE LIVER

Disorders of the hepatic vasculature are uncommon and include portal vein thrombosis (PVT), hepatic vein thrombosis (Budd-Chiari syndrome), and veno-occlusive disease. Affected patients usually have portal hypertension with or without associated liver dysfunction, which may mimic the presentation of cirrhosis.

Portal Vein Thrombosis**Definition and Etiology**

Thrombosis of the portal vein may develop after blunt abdominal trauma, umbilical vein infection, neonatal sepsis, intra-abdominal inflammatory diseases (e.g., pancreatitis), or hypercoagulable states, and in association with cirrhosis. Myeloproliferative diseases

(including polycythemia vera, essential thrombocytosis, and myelofibrosis) are now being recognized as possible causes of PVT. One study observed that as many as 25% to 65% of patients with splanchnic vein thrombosis in the absence of cirrhosis had a myeloproliferative disease. The Janus kinase 2 (JAK2) mutation is a marker for myeloproliferative disease and is often checked in patients with PVT. The disease produces the manifestations of portal hypertension, but the liver histology is usually normal.

Diagnosis

The diagnosis is established by angiography, but noninvasive imaging modalities such as Doppler ultrasonography, computed tomography, and magnetic resonance imaging may reveal thrombus, collateral circulation near the porta hepatis, and splenomegaly. In long-standing PVT, tortuous venous channels develop within the organized clot, leading to cavernous transformation.

Treatment

In acute PVT, thrombolysis may be attempted, but anticoagulation with warfarin remains the mainstay of therapy. In most patients, recanalization of the thrombus occurs within 6 months after initiation of anticoagulation. Recommendations for duration of anticoagulation after an acute event vary and are usually 3 to 6 months. Long-term anticoagulation may be used in cases of chronic thrombosis, especially when associated with hypercoagulable states.

Concern exists that anticoagulation may precipitate hemorrhage from varices that arise as a consequence of portal hypertension; however, studies have not shown an increased risk for variceal bleeding in anticoagulated patients with chronic PVT. In fact, studies suggest a role for prophylactic anticoagulation (enoxaparin) for prevention of PVT and hepatic decompensation in cirrhosis. If variceal hemorrhage occurs, it is best managed with endoscopic obliteration. Prophylaxis with β -blockers to prevent variceal bleeding may decrease the portal pressure, potentially propagating thrombus, and therefore is not usually recommended. If endoscopic treatment fails, surgical management with portosystemic shunting may be attempted, but this approach is often difficult because of the absence of suitable patent vessels. The use of TIPS has also been studied in nonocclusive PVT and may be beneficial in establishing patency of the portal vein for future interventions such as liver transplantation in lieu of anticoagulation only.

Budd-Chiari Syndrome**Definition and Etiology**

Occlusion of the major hepatic veins or the inferior vena cava, especially in the intrahepatic and suprahepatic segments, causes Budd-Chiari syndrome. Most cases are associated with hematologic disease (e.g., polycythemia vera, paroxysmal nocturnal hemoglobinuria, essential thrombocytosis, other myeloproliferative disorders), pregnancy, oral contraceptive use, tumors (especially HCC), or other causes of a hypercoagulable state (e.g., factor V Leiden mutation, protein C and S deficiency). Abdominal trauma and congenital webs of the vena cava are also related to Budd-Chiari syndrome. About 20% of cases are idiopathic, but many of these patients prove to have early, subclinical myeloproliferative disease or genetic mutations associated with a hypercoagulable state.

Clinical Presentation

Budd-Chiari syndrome can manifest acutely, possibly in association with acute liver failure, or it can manifest as a subacute or chronic illness. Acute disease produces right upper quadrant abdominal pain, hepatomegaly, ascites, and jaundice, whereas the subacute or chronic form produces primarily portal hypertension. Elevation of serum

bilirubin and transaminase levels may be mild, but liver function is often poor, with profound hypoalbuminemia and coagulopathy.

Diagnosis

The diagnosis can be established noninvasively with Doppler ultrasonography, which shows decreased or absent hepatic vein blood flow, and computed tomography, which shows delayed or absent contrast filling of the hepatic veins and hypertrophy of the caudate lobe. Magnetic resonance angiography may also demonstrate these findings. Hepatic venography is especially useful if the results of noninvasive imaging are inconclusive. Venography often shows an inability to catheterize and visualize the hepatic veins; the characteristic spider-web pattern of collateral vessels may also be demonstrated, and the inferior vena cava may appear compressed owing to hepatomegaly or an enlarged caudate lobe. On liver biopsy, centrilobular congestion, hemorrhage, and necrosis (nutmeg liver) are seen, with cirrhosis developing in patients with chronic obstruction.

Treatment

Treatment should be individualized and is dependent on the mode and severity of presentation and the potential cause of the disease. Supportive therapy to relieve ascites and edema (e.g., dietary sodium restriction, diuretics) and chronic anticoagulation may be considered for patients with chronic Budd-Chiari syndrome in whom methods to decompress congestion are not feasible. Thrombolysis followed by anticoagulation is most useful in patients with acute forms of the disease. In selected patients (such as those with venous webs or strictures or single-vessel thrombosis), angioplasty with or without stent placement may be used. Decompressive modalities are most useful before the development of cirrhosis and include transjugular intrahepatic portacaval and side-to-side portacaval shunts. In patients with cirrhosis, liver transplantation followed by continued anticoagulation is often considered the best option.

Veno-Occlusive Disease

Definition and Etiology

Hepatic veno-occlusive disease, also called sinusoidal obstruction syndrome, often occurs after cytoreductive therapy and before bone marrow transplantation but may also follow exposure to other drugs or herbal preparations (e.g., azathioprine, pyrrolizidine alkaloids). Endothelial cell injury leads to obstruction at the level of the hepatic venules and the sinusoids.

Clinical Presentation

The disease is characterized by jaundice, painful hepatomegaly, and fluid retention. Clinical manifestations can be rapidly progressive and lead to multiorgan dysfunction and death in 20% to 25% of patients.

Diagnosis

The diagnosis is clinically suspected when weight gain, epigastric or right upper quadrant abdominal pain, and jaundice develop within the first 3 to 4 weeks after bone marrow transplantation. Laboratory abnormalities include hyperbilirubinemia, elevated transaminases, and, in severe cases, profound synthetic dysfunction. Doppler abdominal ultrasonography may reveal ascites, reversal of portal vein flow, and an elevated hepatic artery resistance index. Liver biopsy is diagnostic and is usually obtained with use of the transjugular approach. The advantages of this approach compared with the percutaneous route include the ability to measure the hepatic venous pressure gradient (which is typically elevated in veno-occlusive disease) and a lower incidence of bleeding.

Treatment

Mild forms of the disease may favorably respond to supportive therapy alone. In moderate to severe disease, treatment has been attempted with tissue plasminogen activator and heparin, antithrombin III, prostaglandin E₁, and glutamine plus vitamin E, although the efficacies of these treatments have not been clearly established. Defibrotide (a mixture of porcine-derived single-stranded phosphodiester oligonucleotides) has been evaluated as a potential treatment option for severe veno-occlusive disease; however, evidence for efficacy has been mixed.

LIVER TRANSPLANTATION

MELD Score

The Model for End-stage Liver Disease (MELD) score was originally calculated based on the serum creatinine concentration, prothrombin time (International Normalized Ratio), and bilirubin level and has been used to predict short-term mortality in cirrhosis and to prioritize patients awaiting liver transplantation. However, in 2016 an adjustment was made to the MELD score to include the serum sodium, now commonly referred to as the MELD-Na. The MELD-Na score ranges from 6 to 40. Higher scores are associated with more advanced disease and increased predicted mortality. Patients are typically considered for liver transplantation when the MELD-Na score reaches 15.

Prognosis

Liver transplantation is a highly successful procedure in patients with progressive, advanced, and otherwise untreatable liver disease. Advances in surgical techniques and supportive care, the use of cyclosporine and tacrolimus for immunosuppression, and careful selection of patients have all contributed to the excellent results of liver transplantation. Between 70% and 80% of patients undergoing liver transplantation survive at least 5 years, usually with good quality of life. The most common indication for liver transplantation in the United States is chronic liver disease resulting from alcohol. Other liver diseases for which transplantation is commonly performed include cirrhosis from NAFLD, hepatitis C virus, autoimmune hepatitis, primary biliary cirrhosis, and primary sclerosing cholangitis. Patients with hepatitis B are candidates for liver transplantation if they can be given hepatitis B immunoglobulin or nucleoside analogues to help prevent recurrence. Excellent results have also been obtained in selected patients with acute liver failure (see [Chapter 43](#)). Liver transplantation for malignant hepatobiliary disease has been less successful because of recurrent disease in the transplanted liver.

For a deeper discussion on this topic, please see Chapter 144, “Cirrhosis and Its Sequelae,” in *Goldman-Cecil Medicine*, 26th Edition. ❖

Disorders of the Gallbladder and Biliary Tract

Stacie A. F. Vela, Michael B. Fallon

INTRODUCTION

The gallbladder and biliary tract transport bile from the liver into the intestines, a process central to digestion of fat and absorption of lipids and fat-soluble vitamins. Gallbladder and biliary tract diseases are among the most common and costly of all digestive disorders. This chapter examines the principal gallbladder and biliary tract disorders, focusing on cholelithiasis. The reader is referred to [Chapter 41](#) for a detailed discussion of bilirubin metabolism and the diagnostic approach to jaundice and to [Chapter 35](#) for a review of the various imaging techniques used to study the biliary tract.

NORMAL BILIARY ANATOMY AND PHYSIOLOGY

[Fig. 45.1](#) outlines the basic anatomy of the liver and biliary tract. The liver produces 500 to 1500 mL of bile per day. The secretory product of individual hepatocytes contains bile acids, phospholipids, and cholesterol, which are transported across the apical membrane and into the canalicular space between cells. These canaliculi merge to form larger intrahepatic bile ducts and then the common hepatic duct. During fasting, tonic contractions of the sphincter of Oddi, located in the region of the ampulla of Vater, divert about one half of the bile through the cystic duct into the gallbladder, where it is stored and concentrated by water resorption. Cholecystokinin, which is released after food enters the small intestine, causes the sphincter of Oddi to relax, allowing delivery of a timed bolus of bile into the intestine. Bile acids are present in millimolar concentrations. They are detergent molecules that possess both fat-soluble and water-soluble moieties. Cholesterol is secreted by the liver to the intestine, where it undergoes fecal excretion (see E-Fig. 41.1 in [Chapter 41](#)). In the intestinal lumen, bile acids solubilize dietary fat and promote its digestion and absorption. Bile acids are, for the most part, efficiently reabsorbed by the small intestinal mucosa, particularly in the terminal ileum. They are then recycled to the liver for re-excretion, a process termed *enterohepatic circulation*.

GALLBLADDER DISORDERS

Gallstones (Cholelithiasis)

Gallstone formation constitutes a significant health problem, affecting 10% to 15% of the adult population. Complications from gallstones are a leading cause for hospital admissions related to gastrointestinal problems. In the United States, gallstone disease leads to more than 750,000 cholecystectomies annually, making this the most common elective abdominal surgery, with estimated costs of \$6.5 billion per year. Gallstones are of two types: 75% are made of cholesterol, and 25% are pigmented stones (black or brown). The latter are composed of calcium bilirubinate and other calcium salts. The risk factors for cholelithiasis are shown in [Table 45.1](#).

Pathogenesis of Cholelithiasis

The three main factors that lead to cholesterol gallstone formation are cholesterol supersaturation of bile, nucleation, and gallbladder hypomotility. These are influenced by both genetic background and intestinal factors ([Fig. 45.2](#)).

The liver is the most important organ in regulating total-body cholesterol stores. Once it is secreted, cholesterol, which is insoluble in water, is solubilized in bile through the formation of mixed micelles with bile acids and phospholipids. In most individuals, there is more cholesterol in bile than can be maintained in stable solution. This is even more pronounced in the setting of insulin resistance. As bile becomes supersaturated, microscopic cholesterol molecules aggregate into coalescent vesicles that crystallize, a process referred to as *nucleation*. The gradual deposition of additional layers of cholesterol leads to the appearance of macroscopic stones. Factors that influence nucleation include bile transit time, gallbladder contraction, bile composition (concentrations of cholesterol, phospholipids, and bile salts), and presence of bacteria, mucin, and glycoproteins, which can act as a nidus to initiate cholesterol crystal formation. The interplay between *pronucleating* and *antinucleating* factors in the gallbladder may determine whether cholesterol gallstones will form from supersaturated bile. Gallbladder sludge is a super-concentrated mixture of bile acids, bilirubin, cholesterol, mucus, and proteins that exhibits various degrees of fluidity and is prone to precipitate into a semisolid or solid form.

The pathophysiologic factors leading to pigment stone formation are less well understood; however, increased production of bilirubin conjugates (hemolytic states), increased biliary calcium (Ca^{2+}) and bicarbonate (HCO_3^-) levels, cirrhosis, and bacterial deconjugation of bilirubin to a less soluble form are all associated with pigment stone formation. Black pigment stones, which are composed primarily of calcium bilirubinate, are formed in sterile bile in the gallbladder and are common in chronic hemolytic states, in cases of cirrhosis, and in patients with ileal resection. Their brown pigment counterparts, composed primarily of calcium salts, are formed in the bile ducts and are seen in the setting of infection of the biliary tract.

Many of the recognized predisposing factors for cholelithiasis and gallbladder sludge can be understood in terms of the pathophysiologic scheme outlined previously:

1. Biliary cholesterol saturation is increased by insulin resistance, estrogens, multiparity, oral contraceptives, obesity, rapid weight loss, and terminal ileal disease, which decreases the bile acid pool.
2. Nucleation is enhanced by biliary parasites, recurrent bacterial infection of the biliary tract, altered intestinal microbiome, and antibiotics such as ceftriaxone, which has a proclivity to concentrate and crystallize with calcium in the biliary tree. Total parenteral nutrition and blood transfusions also promote bile pigment accumulation and *gelfaction* of sludge.

Fig. 45.1 Normal anatomy and histology of the liver and biliary tract. Materials destined for metabolism or excretion by the liver (such as unconjugated bilirubin) enter the sinusoidal bed and cross the endothelial barrier and the space of Disse. Unconjugated bilirubin is taken up by the hepatocyte, conjugated with glucuronide to become water soluble, and excreted into bile across the canalicular membrane of the hepatocyte. The canaliculi empty into bile ductules (BD), which lead to the interlobular (small), septal (medium), and large intrahepatic bile ducts and finally to the main branches of the common bile duct. The portal areas, or portal triads, are composed mainly of portal vein (PV), hepatic artery (HA), and BD branches. During fasting, tonic contraction of the ampulla of Vater, diverts about one half of the bile through the cystic duct into the gallbladder, where it is stored and concentrated to be released later during meal times. Disease at any level of the biliary tree can lead to cholestasis and obstructive jaundice. The *inset* shows an endoscopic retrograde cholangiopancreatography procedure. See Figs. 45.5, 45.6, and 45.7 for radiographic depictions in specific biliary tract disorders.

3. Bile stasis is caused by gallbladder hypomotility (resulting from pregnancy, somatostatin, or fasting), bile duct strictures, choledochal cysts, biliary parasites, and total parenteral nutrition.

Clinical Manifestations of Gallstones

Gallstones develop at some point in 10% to 20% of Americans. Between 50% and 60% of these individuals remain asymptomatic, but about one third develop biliary colic or chronic cholecystitis, and 15% develop acute complications. The natural history of gallstone disease

is outlined in Fig. 45.3. Obstruction of the biliary tract at any level by stones or sludge is the underlying cause of the clinical manifestations of gallstone disease. Obstruction by gallstones can occur at the level of the cystic duct, common hepatic duct, common bile duct, or ampulla of Vater (see Figs. 45.1 and 45.3). Symptoms arise from contraction of the gallbladder during transient obstruction of the cystic duct by gallstones, and persistent obstruction of the cystic duct leads to superimposed inflammation or infection of the gallbladder (i.e., acute cholecystitis). Obstruction of the distal common bile duct may result

TABLE 45.1 Risk Factors for Cholelithiasis**Primary**

Age
 Obesity

 Cirrhosis
 Crohn's disease
 Biliary parasites (e.g., *Clonorchis sinensis*)
 Terminal ileum resection

in abdominal pain, cholangitis (infection of the biliary tract), or pancreatitis (resulting from pancreatic duct obstruction). The presence of a large stone in the cystic duct can cause common bile duct obstruction and is referred to as *Mirizzi syndrome*. Common conditions to consider in the differential diagnosis of gallstone disease are listed in [Table 45.2](#).

Asymptomatic Gallstones

Most gallstones, up to 75%, are clinically “silent,” and they are often uncovered as an incidental finding during abdominal ultrasound performed for another reason. The risk of developing symptoms is low, averaging 2% to 3% per year, 10% at 5 years, and 1% to 2% per year with major complications. Expectant management is an appropriate choice for the general population. Prophylactic cholecystectomy should be considered in those groups who are at increased risk for the development of complications, including (1) patients with diabetes, who have a greater morbidity and mortality from acute cholecystitis; (2) patients with a calcified (porcelain) gallbladder, large gallbladder polyps, or large stones (>3 cm), which are associated with an increased risk for gallbladder carcinoma; (3) patients with sickle cell anemia, in whom hepatic crises may be difficult to differentiate from acute cholecystitis; (4) children with gallstones, because they frequently develop symptomatic disease; and (5) Native Americans, who are predisposed to gallbladder cancer in the setting of gallstones.

Symptomatic Gallstones and Biliary Colic

Symptomatic cholelithiasis is defined by gallbladder pain in the presence of gallstones. *Biliary colic* refers to the constellation of symptoms experienced when the gallbladder contracts against outlet obstruction. Classically, biliary colic starts as a steady ache in the epigastrium or right upper quadrant; it has a sudden onset, reaches a plateau of intensity over a few minutes, and then subsides gradually over 30 minutes to several hours. Referred pain may be felt at the tip of the scapula or right shoulder. Nausea and vomiting may occur, but fever and a palpable mass (signs of acute cholecystitis) are not evident. Other symptoms, such as dyspepsia, fatty food intolerance, bloating and flatulence, heartburn, and belching, may occur in patients with gallstones; however, these symptoms are nonspecific and frequently occur in individuals with normal gallbladders.

Gallstones are best demonstrated by transabdominal ultrasonography; therefore, it is recommended as the initial test to evaluate cholelithiasis. The sensitivity and specificity of ultrasound are greater than 90%, but accuracy drops to 20% for visualization of stones within the common bile duct. This limitation has been overcome by endoscopic ultrasonography (EUS) (Video 45.1) and magnetic resonance cholangiopancreatography (MRCP), both of which have an accuracy of 90% to 95% for detecting cholelithiasis and common bile duct stones. Computed tomography, often done in the emergency department for evaluation of abdominal pain, can identify presence of gallstones but is not as reliable or cost-effective as ultrasound. Oral cholecystography is no longer used for the routine evaluation of gallstones.

If gallbladder removal is indicated, laparoscopic cholecystectomy has replaced open cholecystectomy as the treatment of choice for recurrent biliary pain. Open cholecystectomy is typically reserved for selected high-risk patients (e.g., prior abdominal surgery with adhesions, obesity, cirrhosis). If choledocholithiasis is suspected, laparoscopic cholecystectomy may be accompanied by perioperative endoscopic retrograde cholangiopancreatography (ERCP) (see [Fig. 45.1](#) inset and [Chapter 35](#)) or intraoperative cholangiography. Factors that may predict the presence of choledocholithiasis include jaundice, pancreatitis, abnormal liver test results, and bile duct dilation.

Cholecystectomy relieves biliary pain in virtually all patients with gallstone disease and prevents the development of future complications. Dissolution of cholesterol gallstones by orally administered chenodeoxycholic acid or ursodeoxycholic acid is successful in highly selected patients but is slow and costly and requires lifelong administration. Alternative methods to eliminate gallstones, including contact dissolution and fragmentation of stones, are used rarely.

Acute Cholecystitis

Acute cholecystitis refers to distention, edema, ischemia, inflammation, and secondary infection of the gallbladder. This typically results from obstruction of the cystic duct by gallstones or, less commonly, from gallbladder cancer or sludge. The clinical hallmark of acute cholecystitis is the acute onset of upper abdominal pain that lasts for several hours. The pain gradually increases in severity and typically localizes to the epigastrium or right hypochondrium with radiation to the right lumbar, scapular, and shoulder area. Nausea and vomiting, anorexia, and low-grade fever are common. Unlike biliary pain, the pain of acute cholecystitis does not subside spontaneously. The findings on physical examination in patients with acute cholecystitis may include inspiratory arrest on palpation of the right upper quadrant (Murphy sign), fever, and, less commonly, mild jaundice or a palpable gallbladder.

Complications of acute cholecystitis include emphysematous cholecystitis (in people with diabetes, older adults, and individuals who are immunosuppressed), empyema, gangrene, and perforation of the gallbladder. Gallbladder perforation may occur directly into the peritoneum (“free”) or through a cholecystenteric fistula with gallstone migration and bowel obstruction (gallstone ileus). *Mirizzi syndrome* is the occurrence of profound jaundice resulting from extrinsic compression of the bile duct by an impacted stone in the cystic duct at the gallbladder neck.

The diagnostic approach for suspected acute cholecystitis is similar to that for biliary pain. A transabdominal ultrasound study that demonstrates gallstones, along with pericholecystic fluid, gallbladder wall thickening, and localized tenderness when the ultrasound probe is placed over the gallbladder (ultrasonographic Murphy sign), provides strong supportive evidence for acute cholecystitis. Ultrasound is safe and widely available and has emerged as the initial test of choice because it is noninvasive as well as cost-effective. Radionuclide scanning after intravenous administration of technetium-99m-labeled

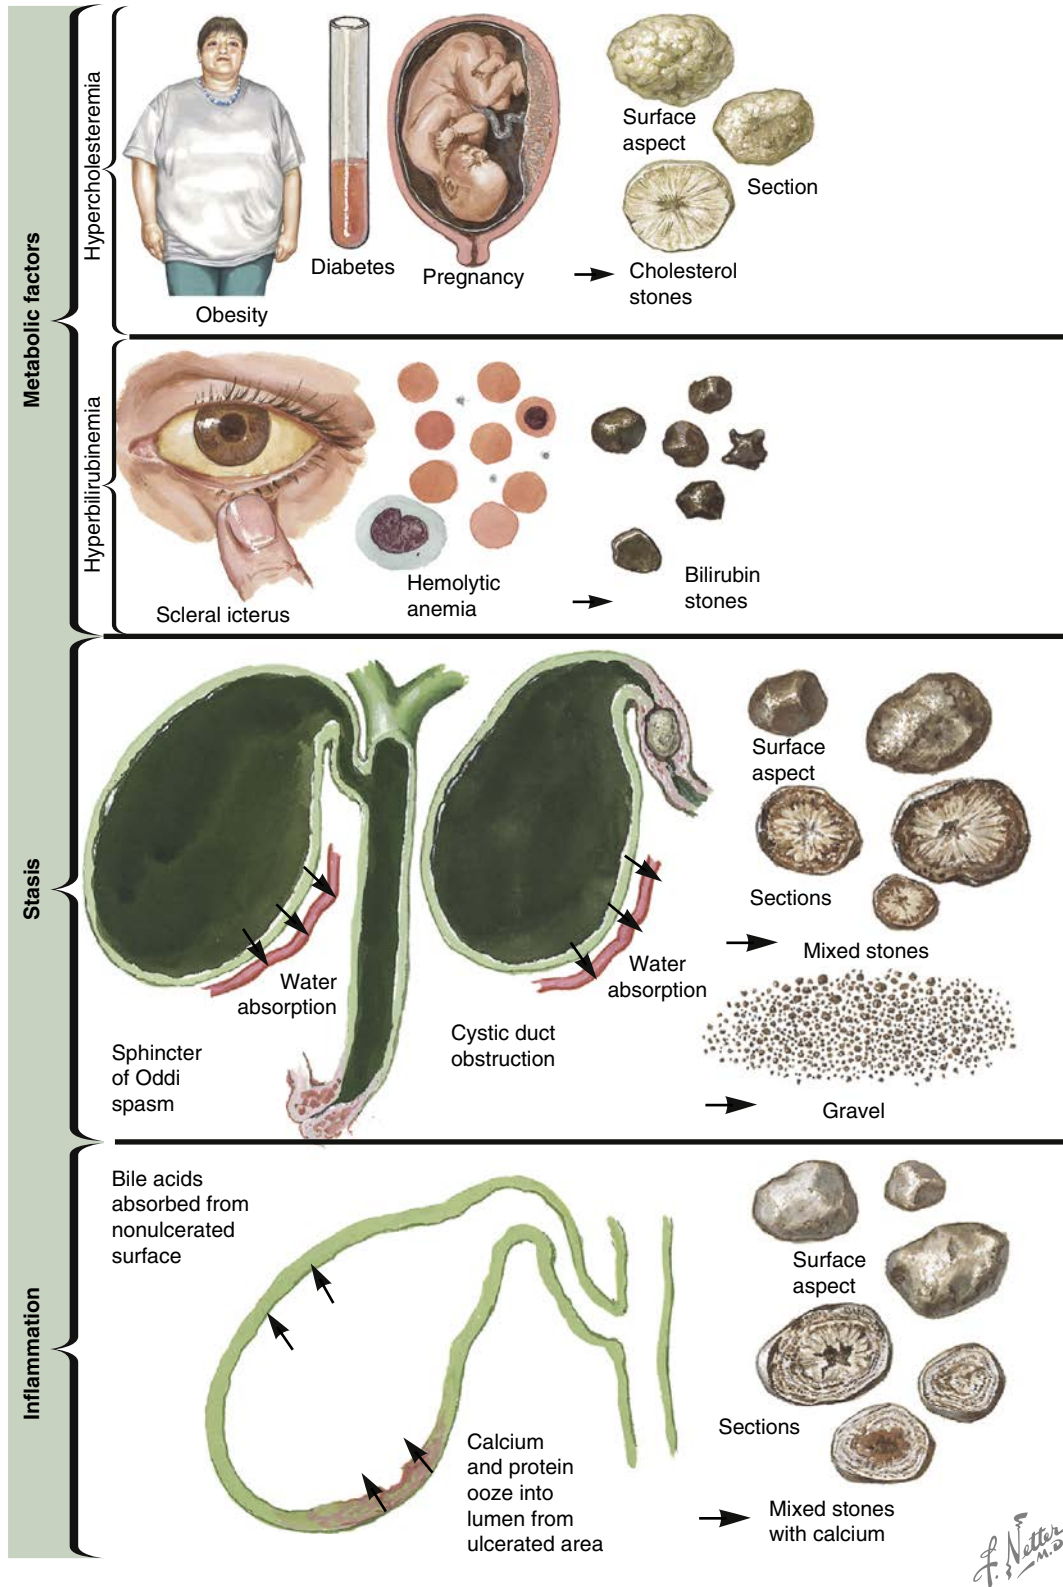

Fig. 45.2 Cholelithiasis: stone formation. (From Reynolds JC, Ward PJ, Martin JA, et al. *The Netter Collection of Medical Illustrations*, 2nd edition, Volume 9, Digestive System, Part III: Liver, Biliary Tract, and Pancreas. Elsevier, 2016, Plate 2-13, Page 116.)

diisopropyl iminodiacetic acid (DISIDA) or hepatobiliary iminodiacetic acid (HIDA) is also accurate. If the gallbladder fills with the isotope, acute cholecystitis is highly unlikely; if contrast material enters the bile duct and duodenum without gallbladder visualization, acute cholecystitis is strongly supported.

Because of the high risk for recurrent acute cholecystitis, most patients need to undergo cholecystectomy, which is often performed within the first 24 to 48 hours after presentation or, less often, 4 to 8 weeks after an acute episode (Fig. 45.4). Cholecystostomy may be performed for patients who have a high operative risk. Antibiotics are

Fig. 45.3 Natural history of asymptomatic gallstones. (A) The clinical syndromes associated with gallstones are shown, and the numbers represent the approximate percentage of adults who develop one or more of these symptoms or complications over a 15- to 20-year period. Over this period, about 30% of individuals with gallstones undergo surgery. (The risk for developing complications of gallstones varies considerably among series. The figures shown represent those derived from more recent studies.) (B) Clinical manifestations of symptomatic gallstones. Locations of blockages associated with various conditions are indicated. (Part B from Reynolds JC, Ward PJ, Martin JA, et al. *The Netter Collection of Medical Illustrations*, 2nd edition, Volume 9, Digestive System, Part III: Liver, Biliary Tract, and Pancreas. Elsevier, 2016, Plate 2-14, Page 117.)

typically used when fever or leukocytosis is present. Expectant management is reserved for patients with uncomplicated disease who are not good operative candidates and those in whom the diagnosis is not clear.

Acalculous Cholecystitis

Acalculous cholecystitis is an acute inflammatory condition in patients without gallstones. It accounts for approximately 5% of all cases of acute cholecystitis and carries higher morbidity and mortality rates than acute calculous cholecystitis. Acalculous cholecystitis is classically associated with the triad of prolonged fasting, immobility, and hemodynamic instability, such as may occur in critically ill patients, especially if they have required total parenteral nutrition or blood transfusions. Gallbladder ischemia and stasis are considered important

in the pathogenesis. It is also seen in patients with AIDS, often in association with cytomegalovirus or *Cryptosporidia* infection. Abdominal pain, fever, and leukocytosis in a patient with the classic triad along with ultrasonographic features of a thickened gallbladder wall and a positive Murphy sign in the absence of gallstones raise suspicion for this entity. As in acute cholecystitis, the gallbladder is not visualized on HIDA scanning. Management includes administration of antibiotics and cholecystectomy. If the patient is seriously ill, the gallbladder can be drained percutaneously as a temporizing measure that can bridge the patient to surgery. If a patient is not a candidate for cholecystectomy, some specialized centers have expertise in endoscopically placing a lumen opposing metal stent directly from the stomach or duodenum into the gallbladder for drainage.

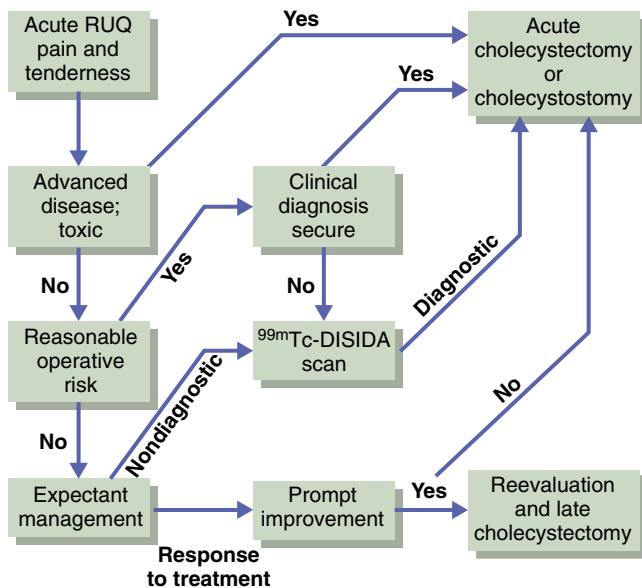

Fig. 45.4 Algorithm for management of right upper quadrant (RUQ) pain and tenderness in patients with suspected acute cholecystitis. This scheme is based on a policy of early operation (conventional or laparoscopic) for appropriate patients and use of cholecystostomy (operative or percutaneous) for patients who are poor operative risks. $^{99m}\text{Tc-DISIDA}$, Technetium-99m-labeled diisopropyl iminodiacetic acid.

Chronic Cholecystitis

Chronic cholecystitis is a term used by pathologists to describe chronic inflammatory cell infiltration of the gallbladder on histopathology. Chronic cholecystitis is thought to be an evolving inflammatory process, caused by repeated episodes of low-grade gallbladder obstruction over a period of days to years resulting in recurrent mucosal trauma and inflammation. The symptoms are those of biliary colic without clinical features of acute cholecystitis. Gallstones are the causative agent in most patients. However, there is little correlation between the number of gallstones and the degree of gallbladder wall inflammation. In approximately 12% of patients with chronic cholecystitis, there are no demonstrable stones. The diagnosis is made in a patient with gallstones who has the clinical signs and symptoms with no other obvious cause. Transabdominal ultrasound is the best initial test, and EUS may be used to demonstrate microlithiasis (gallstones ≤ 3 mm) if gallstones

are not seen on initial imaging. The treatment is laparoscopic cholecystectomy, but conversion to open cholecystectomy is required in up to 5% of cases.

Gallbladder Polyps

Gallbladder polyps are outgrowths of the gallbladder mucosal wall that are seen in up to 5% of normal subjects undergoing gallbladder ultrasonography. Most of these lesions are not neoplastic but are hyperplastic or represent lipid deposits (cholesterolosis). The differential diagnosis includes cholesterol polyps, adenomyomatosis, inflammatory polyps, adenomas, and gallbladder cancer. Factors associated with increased risk of malignancy include age greater than 60 years, size greater than 1 cm, presence of gallstones, and increased size on subsequent imaging. Cholecystectomy is indicated if one or more of these risk factors are present or if the patient has biliary symptoms. Polyps that are smaller than 1 cm should be monitored with periodic ultrasound examination.

Gallbladder Carcinoma

Gallbladder carcinoma is relatively uncommon but has a high case fatality rate. The incidence and mortality are higher in Latin American countries (e.g., Chile) and in Southeast Asia. Carcinoma of the gallbladder often produces advanced disseminated disease with weight loss, jaundice, pruritus, and a large right upper quadrant mass. Symptoms may resemble those of acute or chronic cholecystitis, particularly if the tumor is small. Risk factors include gallbladder polyps, porcelain gallbladder, choledochal cysts, gallstones, and anomalous pancreaticobiliary junction. Although early-stage tumors can be treated surgically, most cases are diagnosed at an advanced stage and are incurable.

Gallbladder Dyskinesia

Gallbladder dyskinesia is a disorder caused by abnormal motility or contraction of the gallbladder in the absence of gallstones resulting in symptoms of biliary colic. Laboratory studies and abdominal imaging findings are usually normal. HIDA scanning may show a decreased gallbladder ejection fraction, or there may be reproducible pain with administration of cholecystokinin (CCK). Cholecystectomy commonly shows acalculous cholecystitis.

BILIARY TRACT DISORDERS

Choledocholithiasis

In Western countries, most stones found in the common bile duct (choledocholithiasis) originate in the gallbladder. Up to 15% of individuals with cholelithiasis develop choledocholithiasis (Fig. 45.5). Less commonly, stones may form de novo in the biliary tree. Common bile duct stones may be asymptomatic (30% to 40%), or they may produce biliary colic and jaundice. Two major complications are acute cholangitis and acute pancreatitis. The diagnosis is supported by the results of liver function tests and abdominal imaging. Transabdominal ultrasound is the initial imaging modality of choice; it has a sensitivity of 20% to 90% for detection of a stone and 55% to 90% for detection of dilation of the common bile duct. EUS and MRCP have replaced ERCP for diagnosis of bile duct stones; the sensitivity and specificity are 94% and 95%, respectively, for EUS and 93% and 94% for MRCP. ERCP is reserved for therapeutic interventions.

Acute Cholangitis

Acute (suppurative) cholangitis is a life-threatening infection of the biliary tract that can occur as a result of choledocholithiasis. The biliary tree is usually a sterile environment. In the setting of obstruction, migration of bacterial pathogens can cause severe infection with a mortality rate up to 30%. The classic clinical manifestations are abdominal

Fig. 45.5 Cholangiogram obtained on endoscopic retrograde cholangiopancreatography demonstrates a common bile duct stone.

pain, jaundice, and fever (Charcot's triad). It is important to note that clinical findings may be absent or atypical in elderly or immunosuppressed patients. Cholangitis can be mild, moderate, or severe and, if severe, rapidly lead to sepsis, shock, and death. Diagnosis is based on a compatible clinical and laboratory picture (abnormal liver function test results and leukocytosis) together with radiologic or endoscopic evidence of common bile duct stones.

Treatment of acute cholangitis includes administration of broad-spectrum antibiotics and prompt removal of stones, typically with ERCP and sphincterotomy (Video 45.2). The timing of ERCP should be planned based on the severity of illness. Cholecystectomy is subsequently performed after the patient has been stabilized.

Gallstone Pancreatitis

Biochemical evidence of pancreatic inflammation complicates choledocholithiasis and acute cholecystitis in up to 30% and 15% of patients, respectively. There are two proposed mechanisms by which gallstones may induce pancreatitis: reflux of bile into the pancreatic duct due to transient obstruction of the ampulla and obstruction at the ampulla secondary to stones or edema. Evaluation of the biliary tree with transabdominal ultrasound, MRCP, or endoscopic ultrasound should be performed in the setting of gallstone pancreatitis to evaluate for choledocholithiasis. Laboratory testing alone can be misleading because edema of the head of pancreas during pancreatitis can cause cholestasis. If choledocholithiasis is confirmed, ERCP with sphincterotomy should be performed. Considering that gallstone pancreatitis recurs in 25% of patients, a cholecystectomy should be performed once the patient has recovered clinically from an attack of pancreatitis.

Biliary Neoplasms

Cholangiocarcinoma and cancer of the ampulla of Vater are uncommon in the United States. Cholangiocarcinoma can arise at any level of the biliary system and is classified as intrahepatic (25%) or extrahepatic (75%). It is more common in older men, occurring predominantly in men 50 to 70 years of age. Risk factors include primary sclerosing cholangitis (PSC), choledochal cysts, chronic ulcerative colitis, liver flukes, and recurrent pyogenic cholangitis (Oriental cholangiohepatitis). Patients with these cancers usually have unremitting painless jaundice, although necrosis and sloughing of the tumor can cause intermittent biliary obstruction and the appearance of occult fecal blood.

Fig. 45.6 Cholangiogram obtained on endoscopic retrograde cholangiopancreatography demonstrates a Klatskin tumor at the bile duct bifurcation.

Cholangiocarcinoma located at the bifurcation of the extrahepatic bile duct (50% of cases) is known as a *Klatskin tumor* (Fig. 45.6). Surgical cure is possible in only a small proportion of patients with cholangiocarcinoma. If the tumor is unresectable, palliative biliary drainage may be indicated. Recently, liver transplant has also become an option for carefully selected patients with localized, but unresectable disease.

Nonmalignant Causes of Biliary Obstruction

Biliary Strictures

Benign biliary strictures usually result from surgical injury or chronic pancreatitis. Biliary strictures resulting from surgical injury may cause symptoms even years after the initial injury. Early diagnosis is important because strictures that partially obstruct are clinically asymptomatic and can cause secondary biliary cirrhosis. Biliary stricture should be suspected in any patient with a history of surgery of the right upper quadrant or chronic pancreatitis who has persistently elevated levels of serum alkaline phosphatase and γ -glutamyl transpeptidase. Endoscopic balloon catheter dilatation with or without stenting or surgical repair is useful in selected patients.

Other Causes of Biliary Obstruction

Structural abnormalities such as choledochal cysts, Caroli's disease (congenital segmental intrahepatic bile duct dilation), and duodenal diverticula may cause bile duct obstruction, often with secondary choledocholithiasis resulting from bile stasis. Hemobilia, with intermittent bile duct obstruction by blood clots, may be caused by hepatic injury, neoplasms, or hepatic artery aneurysms. Biliary parasites should always be considered as a cause of biliary obstruction in the appropriate epidemiologic setting. *Ascaris lumbricoides* is a common cause of cholangitis and jaundice in South America, Africa, and the Indian subcontinent. *Clonorchis sinensis* is the etiologic agent of Oriental cholangiohepatitis in Korea and Southeast Asia and in immigrants to the United States. The liver fluke *Fasciola hepatica* is a leading cause of biliary strictures and cholangitis worldwide, most commonly in the Bolivian Andes.

Primary Sclerosing Cholangitis

PSC is an idiopathic condition of nonmalignant, nonbacterial, chronic inflammatory fibrosis and obliteration of the intrahepatic and

Fig. 45.7 Cholangiogram obtained on endoscopic retrograde cholangiopancreatography demonstrates the characteristic beading of the intrahepatic and extrahepatic bile ducts in a patient with primary sclerosing cholangitis.

extrahepatic bile ducts. It most commonly occurs in young men (two thirds of patients are younger than 45 years of age), often in association with ulcerative colitis. Approximately 70% of patients with PSC have ulcerative colitis. The clinical spectrum of PSC is broad, ranging from asymptomatic patients with abnormal liver enzyme levels (typically an elevated alkaline phosphatase concentration) to patients with recurring episodes of fever, chills, abdominal pain, and jaundice. The diagnosis of PSC is made by MRCP or ERCP, which show characteristic changes (beading) of the intrahepatic and/or extrahepatic bile duct (Fig. 45.7).

No proven therapy exists for PSC, although ursodeoxycholic acid and methotrexate are being used in some centers. Other forms of therapy include prophylactic antibiotics for prevention of recurrent bacterial cholangitis, treatment of pruritus, and repletion of fat-soluble vitamins. Endoscopic dilatation of a dominant biliary stricture during

ERCP is an effective treatment of cholestasis in selected patients. Most patients with advanced PSC eventually progress to end-stage liver disease, and evaluation for liver transplantation is appropriate in advanced disease. One third of patients with PSC will develop cholangiocarcinoma; therefore, thorough clinical and laboratory studies (liver function tests and cancer markers such as CA 19-9) and radiologic follow-up are warranted.

Sphincter of Oddi Dysfunction

Sphincter of Oddi dysfunction is a benign disorder that can lead to noncalculous obstruction of the flow of bile or pancreatic juice at the level of the pancreaticobiliary junction. Patients typically have unexplained biliary-type abdominal pain with or without elevated results on liver function tests and with or without bile duct dilation. In a selected group of patients, endoscopic or surgical sphincterotomy is of value. Identifying those who would benefit can be challenging and controversial because sphincter of Oddi dysfunction can be difficult to discern from functional abdominal pain.

For a deeper discussion of this topic, please see Chapter 146, “Diseases of the Gallbladder and Bile Ducts,” in *Goldman-Cecil Medicine*, 26th Edition. ❖

Hematopoiesis and Hematopoietic Failure

Eunice S. Wang, Nancy Berliner

HEMATOPOIESIS

Hematopoiesis is the process of formation and development of blood cells. The constituents of peripheral blood arise by a complex and carefully regulated process of ontogeny. The pluripotent hematopoietic stem cell (HSC) maintains itself by self-renewal and undergoes multilineage differentiation to generate the appropriate numbers and types of cells in the circulating blood compartment (Table 46.1). The hematopoietic system is unique in that it is constantly undergoing this full cycle of maturation by which a primitive cell develops into a variety of highly specialized end-stage cells, all of which have different lifespans and occur in different quantities.

The bone marrow must have the capacity to produce cells to compensate for the normal rapid turnover of hematopoietic cells resulting from senescence, normal use, and migration into tissue spaces. It must have a reserve capacity to produce additional cells in response to unusual demands that arise from bleeding, infection, or other stresses. Understanding the repeated cycle of cellular ontogeny and self-renewal that meets these challenges provides important insights into normal and pathologic mechanisms in hematology.

Hematopoietic Tissues

Hematopoiesis commences in the embryonic yolk sac, in which early erythroblasts in blood islands form the first hemoglobinized cells. After 6 weeks' gestation, the fetal liver begins producing primitive lymphocytoid cells, megakaryocytes, and erythroblasts, and the spleen becomes a secondary site of erythropoiesis. Hematopoiesis then shifts to its definitive long-term site in the bone marrow, the principal site for lifelong hematopoiesis in the normal host.

Early in life, all fetal bones contain regenerative bone marrow, but the marrow becomes progressively replaced by fat with age. In adults, active marrow resides only in the axial skeleton (i.e., sternum, vertebrae, pelvis, and ribs) and in the proximal ends of the femur and humerus. Consequently, bone marrow samples, which are needed for many hematologic diagnoses, are usually obtained from the iliac crest or sternum. Under pathologic conditions that stress the capacity of the marrow space, as seen in diseases associated with marrow fibrosis (e.g., chronic myeloproliferative diseases) or in severe inherited hemolytic anemia (e.g., thalassemia major), extramedullary hematopoiesis may be reestablished in sites of fetal hematopoiesis, especially the spleen.

Stem Cell Theory of Hematopoiesis

All mature hematopoietic cells are hypothesized to originate from a small population of pluripotent stem cells. Comprising less than 1% of all cells in the bone marrow, these cells bear no distinctive morphologic markings and are best defined by their unique functional properties.

Stem cells have two distinctive characteristics. First, they are highly resilient and productive, capable of continuously replenishing huge

numbers of granulocytes, lymphocytes, and erythrocytes throughout life. The demand for a continuous, fluctuating supply of blood cells requires a hematopoietic system capable of producing large numbers of selected cells in a short time. For example, overwhelming infection by invading microorganisms triggers the release of neutrophils, whereas hypoxia or acute blood loss leads to increased red blood cell production. Second, HSCs represent a self-renewing cell population that is able to maintain its numbers while providing a continued supply of progenitor cells of many different lineages.

Despite their vast proliferative potential, under normal conditions, most HSCs are quiescent, and few cells undergo expansion or differentiation at any one time. However, their ability to proliferate is striking. Studies with lethally irradiated mice have demonstrated the ability of a few transplanted cells (i.e., spleen colony-forming unit [CFU-S] cells) to regenerate multilineage hematopoiesis.

The signals regulating the differentiation of pluripotent stem cells into committed progenitors are unknown. Data suggest that the first step in lineage commitment is a stochastic (chance) event; subsequent stages of maturation are hypothesized to occur under the influence of growth factors, or cytokines (Table 46.2). Cytokines act on different cells through specific cytokine receptors. Receptor activation induces signal-transduction pathways that lead to changes in gene transcription and eventual cell proliferation and differentiation. These growth factors also act as survival factors for the developing hematopoietic cells by preventing *apoptosis* (i.e., programmed cell death). This process occurs in the cellular milieu of the bone marrow, where hematopoiesis depends in part on the nonhematopoietic cells (i.e., fibroblasts, endothelial cells, osteoblasts, and fat cells) that make up that microenvironment. Research in HSC biology has focused on how these cells are regulated by growth factors, unique cell surface ligands, and key interactions between stem cells and the surrounding microenvironmental cells (i.e., mesenchymal stromal cells, adipocytes, immune cells) within specialized marrow regions termed *stem cell niches*.

Hematopoietic Differentiation Pathway

Hematopoiesis has been hypothesized to proceed along a tightly regulated hierarchy (Fig. 46.1) governed by effects of intrinsic transcription factors and cytokines in the bone marrow microenvironment. As more primitive cells mature under the influence of specific regulatory cytokines, they undergo several cell divisions and become *progenitor cells* committed to one lineage. They also lose their self-renewal capacity. Morphologically, these cells are transformed from nonspecific blast-like cells into cells that can be identified by their color, shape, and granular and nuclear content. Functionally, they acquire distinguishing cell surface receptors and responses to specific signals.

Maturing granulocytes and erythroid cells undergo several more cell divisions in the bone marrow, whereas lymphocytes travel to the thymus and lymph nodes for further development. Megakaryocytes cease cellular

TABLE 46.1 Normal Values for Peripheral Blood Cells

Cell Type and Size	Mean	Range
Hemoglobin	Women: 14 g/dL Men: 15.5 g/dL	Women: 12-16 g/dL Men: 13.5-17.5 g/dL
Hematocrit	Women: 41% Men: 47%	Women: 36-46% Men: 41-53%
Reticulocyte count	60,000/ μ L (1%)	35,000-85,000/ μ L (0.5-1.5%)
Mean corpuscular volume		80-100 fL
Platelet count	250,000/ μ L	150,000-400,000/ μ L
Total white blood cell count	7400/ μ L	4500-11,000/ μ L
Neutrophils	4400/ μ L (40-60%)	1800-7700/ μ L
Lymphocytes	2500/ μ L (20-40%)	1000-4800/ μ L
Monocytes	300/ μ L (<5%)	200-950 (4-11%)

TABLE 46.2 Cytokines and Their Activities

Acronym	Name	Effects on Hematopoiesis (and Possible Clinical Applications)
EPO	Erythropoietin	Stimulation of proliferation and maturation of erythroid progenitors; produced by the kidney in response to anemia and hypoxia; important clinically for treatment of anemia associated with low EPO levels (e.g., renal failure, anemia of chronic disease)
G-CSF	Granulocyte colony-stimulating factor	Stimulation of proliferation and maturation of granulocytes; more broad-based effect because also increases release of stem cells in peripheral blood; clinically important for treatment of neutropenia and mobilization of stem cells for transplantation
GM-CSF	Granulocyte-monocyte colony-stimulating factor	Proliferation of granulocyte and monocyte precursors; role unclear in steady-state hematopoiesis (mice deficient in GM-CSF gene still develop normally and no major perturbation of hematopoiesis up to 12 weeks of age)
TPO	Thrombopoietin	Proliferation of megakaryocytes; clinical studies of recombinant TPO were discontinued due to auto-antibody formation in individual patients
M-CSF	Monocyte colony-stimulating factor	Proliferation of monocytes
IL-2	Interleukin-2	Proliferation of T cells
IL-3	Interleukin-3 (multi-colony-stimulating factor)	Proliferation of granulocytes, monocytes; broad-based effects, appearing to increase the proliferation of stem cells; not in use clinically, differentiation of basophils and eosinophils from primitive hematopoietic stem cells
IL-4	Interleukin-4	Proliferation of B cells, differentiation of basophils and eosinophils
IL-5	Interleukin-5	Proliferation of T cells, B cells; proliferation and differentiation of eosinophils, differentiation of basophils and eosinophils
IL-11	Interleukin-11	Proliferation of megakaryocytes; undergoing clinical testing
LIF	Leukemia inhibitory factor	Proliferation of stem cells and megakaryocytes
SCF	Stem cell factor (kit ligand)	Proliferation of progenitor cells; broad-based effects on multiple lineages

division but continue with nuclear replication. Eventually, these cells are released from the marrow as fully functional erythrocytes, mast cells, granulocytes, monocytes, eosinophils, macrophages, and platelets.

Pluripotent Stem Cells

The pluripotent HSC is morphologically indistinguishable and is best identified by its expression of the cell differentiation antigen, CD34,

and by its ability to form pluripotent colonies in vitro. Under the influence of interleukin-1 (IL-1), IL-3, IL-6, FMS-like tyrosine kinase 3 (FLT3), and a specific stem cell factor (KIT ligand [KITLG], or steel factor), this cell matures into a myeloid-lineage stem cell (i.e., granulocyte-erythrocyte-macrophage-megakaryocyte colony-forming unit [CFU-GEMM] cell) or a lymphoid-lineage stem cell. In the presence of granulocyte-macrophage colony-stimulating factor (GM-CSF) and

Fig. 46.1 Development of bone marrow cells. *Ba*, Basophil; *BFU*, blast-forming unit; *CFU*, colony-forming unit; *E*, erythroid; *Eo*, eosinophil; *G*, granulocyte; *GEMM*, granulocyte-erythrocyte-macrophage-megakaryocyte; *GM*, granulocyte-macrophage; *Meg*, megakaryocyte; *NK*, natural killer.

IL-3, the myeloid stem cell further differentiates into daughter cells of its named lineages (see Fig. 46.1). The lymphopoietic stem cell becomes a pre-B cell or a prothymocyte (pre-T cell) and leaves the marrow for further maturation.

Erythroid Lineage

Primitive erythroid precursors arising from the myeloid stem cell are called burst-forming unit–erythroid cells. These cells then differentiate into erythroid colony-forming unit (CFU-E) cells, which are the committed progenitor cells of erythrocytes. CFU-E cells express receptors for erythropoietin (EPO), an 18-kD molecule produced by renal interstitial cells in response to low oxygenation states or anemia. EPO upregulates proliferation of CFU-E cells and promotes their maturation into proerythroblasts and reticulocytes, which begin to synthesize hemoglobin (see Table 46.2).

Granulocyte and Monocyte Lineages

Human GM-CSF acts early in the hematopoietic pathway to regulate maturation of the CFU-GEMM stem cell. Differentiation of this myeloid precursor into specific committed progenitors occurs under the direction of granulocyte CSF (G-CSF) and monocyte CSF (see Table 46.2). Granulocyte CFU cells undergo sequential transformation into easily recognizable myeloblasts, myelocytes, and eventually early polymorphonuclear neutrophils with their characteristic polysegmented nuclei. Monocyte CFU cells, in contrast, retain a single nucleus as they mature from monoblasts to promonocytes to monocytes and sometimes to macrophages.

Other Lineages

Eosinophils and basophils develop from CFU-GEMM cells under the influence of IL-5 and IL-3 plus IL-4, respectively. The acquisition of their specific granular contents helps in distinguishing their precursors from those of early monocytes.

TABLE 46.3 Differential Diagnosis Of Pancytopenia

Primary bone marrow disorders

- Aplastic anemia
- Congenital aplastic anemia syndromes
- Fanconi anemia
- Shwachman-Diamond syndrome
- Congenital dyskeratosis
- Acquired aplastic anemia
- Hypocellular myelodysplastic syndrome
- Myelofibrosis
- Paroxysmal nocturnal hemoglobinuria
- Acute leukemias: acute lymphocytic leukemia, acute myeloid leukemia
- Hairy cell leukemia

Systemic diseases with secondary bone marrow effects

- Metastatic solid tumor to marrow
- Autoimmune disorders: systemic lupus erythematosus, Sjögren's syndrome
- Nutritional deficiencies: vitamin B₁₂, folate, alcoholism
- Infections: overwhelming sepsis from any cause, viruses, brucellosis, ehrlichiosis (mycobacteria)
- Storage diseases: Gaucher's disease, Niemann-Pick disease
- Anatomic defects: hypersplenism

The development of platelets is morphologically distinct from the other lineages. CFU-GEMM cells differentiate into megakaryocyte CFU cells, so named because the cells cease cell division early but not nuclear replication. Megakaryocytes are the only cells in the body with the capacity to double their DNA content (i.e., endomitosis). Over the course of several cell cycles, the maturing megakaryocyte eventually acquires several times the nuclear content of other cells in preparation for its eventual dissolution into platelets with a fraction of the cytoplasm of other hematopoietic cells. Two growth factors, thrombopoietin (TPO) and IL-11, increase platelet counts by promoting megakaryocyte development (see Table 46.2).

Stem Cell Plasticity

Provocative data have challenged the conventional paradigm of hierarchical HSC differentiation. Laboratory evidence has demonstrated that HSCs can be induced to dedifferentiate into more immature progenitors that have the ability to cross lineages and transdifferentiate into myriad non-lymphohematopoietic cells such as vascular endothelial precursors, myocytes, hepatocytes, gastrointestinal epithelial cells, and neurons. This plasticity of HSCs constitutes an intrinsic property of adult stem cells and/or fusion of hematopoietic cells with other tissue cells and supports further investigation of adult HSCs as a dynamic, renewable resource for tissue repair and regeneration.

PRIMARY HEMATOPOIETIC FAILURE SYNDROMES

Diseases of the HSC that disrupt the normal regulated pattern of stem cell development can result in underproduction of mature progeny (i.e., aplastic anemia), overproduction of mature progeny (i.e., chronic myeloproliferative disease), or failed differentiation with the production of excess immature forms (i.e., myelodysplasia and acute leukemia). *Hematopoietic failure*, defined as the inability of HSCs to produce normal numbers of mature blood cells, manifests clinically as peripheral pancytopenia (i.e., decreased production of all blood cell lineages).

Although marrow dysfunction producing pancytopenia can result from several hematologic and nonhematologic causes (Table 46.3), primary bone marrow failure disorders are characterized by a profound

impairment of the ability of the HSC to replenish the stem cell pool. Marrow failure syndromes can arise from intrinsic HSC defects including germline inherited disposition and age-related clonal hematopoietic mutational events. In other cases, marrow failure disorders are the result of extrinsic damage to normal HSCs. The treatment modalities for primary hematopoietic failure disorders include exogenous growth factor administration, immunosuppressive therapy, and allogeneic stem cell transplantation.

Growth Factors in Clinical Use

Discovery of the factors that influence normal hematopoiesis led to important therapeutic applications for patients with defects in hematopoietic cell production. The finding that committed hematopoietic cells of each lineage can be stimulated to proliferate and differentiate by specific cytokines (see Table 46.2) has been therapeutically useful. Advances in DNA technology led to the synthesis and purification of recombinant human (rh) proteins with similar biologic activity *in vivo*. Administration of these products to patients enabled successful manipulation of mature cells in the peripheral blood. For example, exogenous EPO has become a mainstay in the management of anemia caused by renal failure, chemotherapy, and marrow failure syndromes. The use of G-CSF or GM-CSF in patients with febrile neutropenia and documented infection or sepsis after chemotherapy or radiation therapy has reduced hospital stays and shortened the period of high infection risk. Administration of GM-CSF is thought to improve host immune responses to fungal infections. High-dose G-CSF also is routinely used to mobilize CD34⁺ marrow stem cells into the peripheral blood for collection before and after stem cell transplantation in patients with delayed stem cell engraftment (discussed later).

Early trials of TPO growth factors to stimulate platelet production were halted because of development of antihuman TPO antibodies in some patients, leading to severe thrombocytopenia. Second-generation thrombopoietic agents bearing no structural resemblance to TPO but designed to bind and activate the TPO receptor are in clinical use. Romiplostim is a recombinant Fc-peptide fusion protein termed a peptibody that when given as a weekly subcutaneous injection can increase platelet counts, decrease platelet transfusion requirements, and improve quality of life for patients with refractory chronic immune-mediated thrombocytopenia. Eltrombopag is an orally available, small, organic TPO agonist that increases platelet counts and decreases bleeding in similar patients. The clinical utility of eltrombopag when added to immunosuppressive regimens for treatment of aplastic anemia supports its role as an activator of HSC production.

Hematopoietic Stem Cell Transplantation

Types of Transplantations

Improved understanding of HSC biology has fostered the development of techniques to manipulate these cells for therapeutic purposes. The antitumor effects of most chemotherapeutic drugs and radiation therapy are dose dependent, and both cause the major dose-limiting toxicity of myelosuppression. Several modes of stem cell transplantation have been developed.

In *autologous transplantation*, the patient's bone marrow or peripheral blood stem cells (PBSCs) are collected during remission after high-dose chemotherapy or G-CSF administration. These cells are cryopreserved, thawed, and reinfused. This approach incurs a higher risk of relapse as a result of reinfusion of a stem cell product that may remain contaminated with tumor cells and is generally considered therapeutically equivalent to administration of multiple cycles of high-dose chemotherapy with noncurative intent.

In *allogeneic stem cell transplantation (alloSCT)*, abnormally functioning hematopoietic bone marrow is eradicated and replaced with

normal bone marrow or stem cells from a compatible source either from a related or unrelated donor. High-dose chemotherapy with or without total body irradiation is used to destroy the patient's marrow, followed by infusion of new stem cells that engraft and restore normal hematopoiesis. Treatment-related mortality and morbidity occurs due to infectious complications during cytopenic periods and development of *graft-versus-host disease (GVHD)*, an autoimmune phenomenon in which intact lymphocytes in the transplanted marrow attack the host tissues. Despite improvements in supportive care and immunomodulatory therapy, mortality rates associated with transplant remain in the range of 10% to 30% even in younger patients. To mitigate the risk of GVHD, all potential donors and patients are tested for compatibility of human leukocyte antigen (HLA) and major and minor histocompatibility complex (MHC) proteins expressed on all cells. Three major HLA class I antigens (i.e., A, B, and C) and three MHC class II antigens (i.e., DP, DQ, and DR) have been identified. The HLA gene loci are tightly linked on chromosome 6 and are almost always inherited on a single cluster of genes, or *haplotype*. All children are a half-match (i.e., haploidentical) to each of their parents, and full siblings have a 25% probability of being HLA identical to one another. HLA-matched, nonrelated transplants have higher rates of GVHD than transplants from HLA-matched, related donors as a result of other minor HLA incompatibilities. Patients who receive an HLA-mismatched stem cell transplantation risk acute GVHD, marrow rejection, and fatal marrow aplasia. Morbidity and mortality rates associated with non-HLA-compatible transplants can be prohibitive. Patients younger than 50 years are considered the best candidates for this intensive therapy, although this is changing in the setting of newer supportive modalities.

It is now believed that the immunologic effects of transplanted allogeneic cells are as important as or more important than cytoreduction in effecting cure of hematologic malignancies. Evidence indicates that the excellent response of patients to alloSCT may largely be related to the active suppression of the patient's original (residual) or relapsing disease by donor immune cells from the newly transplanted donor graft, referred to as the *graft-versus-leukemia (GVL) effect*. Studies have documented that donor lymphocyte infusions (DLI) can restore remission in patients with early evidence of relapse after alloSCT for chronic myelogenous leukemia. Conversely, procedures that minimize the reactivity between donor and host increase disease relapse. For example, there is an increased rate of relapse among patients who undergo syngeneic (identical twin) stem cell transplantation and patients who receive T-cell-depleted marrow in an attempt to reduce GVHD.

Recognition of the immunologic benefits of alloSCT has led to the development of *reduced intensity* (also known as *non-myeloablative*) allogeneic stem cell transplants. These transplants are now standard of care in adult patients otherwise ineligible for traditional myeloablative transplantation regimens due to age (>55 years old) other comorbidities, or without fully HLA-matched donors available. Conditioning and immunosuppressive regimens are administered in doses sufficient to permit donor stem cell engraftment without aggressive cytoreduction. These so-called "mini" transplants result in chimeric marrows (i.e., part patient and part donor) and are not characterized by significant periods of cytopenias or hematopoietic compromise. Most responding patients convert to a fully donor-derived marrow over time. The use of newer immunosuppressive regimens has also allowed patients to receive transplants from related family members who are only 50% HLA matched (so called *haplotype identical* or *haploidentical* transplants). Almost all patients have compatible half-matched parents, siblings, children, or even grandchildren, thereby allowing for multiple family members to serve as donors. Although feasible and well tolerated in many patients, haploidentical transplants are associated with an enhanced risk of relapsed disease due to reduced GVL effects

and therefore are best utilized for those with optimal disease control at time of the procedure. Although historically used in the treatment of primary malignant stem cell disorders such as leukemia, the therapeutic potential of alloSCT is now increasingly being employed for patients with nonmalignant hematologic conditions (e.g., aplastic anemia, sickle cell anemia, congenital immunodeficiencies), solid tumors (e.g., renal cell carcinoma, melanoma), and particularly autoimmune diseases (e.g., amyloidosis, systemic lupus, multiple sclerosis).

Hematopoietic Stem Cell Sources

Historically, alloSCT has employed donor bone marrow stem cells aspirated from the posterior iliac crest and intravenously infused after myeloablation and immunosuppressive therapy. The process of engraftment or reconstitution of normal hematopoietic function takes several weeks. Patients often require almost daily platelet and red blood cell transfusions, and they are hospitalized during this period of prolonged neutropenia to minimize life-threatening bacterial, viral, and fungal infections. Other complications include severe mucositis, hemorrhagic cystitis, GVHD, relapsed disease, and graft failure.

The discovery that high-dose G-CSF treatment mobilizes large numbers of CD34⁺ hematopoietic progenitor and stem cells from bone marrow sites into circulating blood (i.e., 10-fold to 15-fold increase over baseline levels) has led to the routine use of PBSCs collected by apheresis procedures in place of bone marrow stem cells for allogeneic transplantation. Compared with marrow-derived stem cells, PBSCs engraft more rapidly after myeloablation. Patients receiving allogeneic PBSC transplants have decreased neutrophil recovery time, lower transfusion requirements, fewer inpatient hospital days, and similar rates of acute GVHD and long-term survival outcomes as traditional marrow-transplanted patients. Because PBSC collections often contain 3-fold to 4-fold more CD34⁺ stem cells and 10-fold more lymphoid cells than harvested marrow grafts, higher rates of chronic GVHD may occur.

Umbilical cord blood (UCB) stem cells constitute a rich source of immature CD34⁺ HSCs. In the past, the less stringent HLA-compatibility requirements for UCB HSC matches has allowed the use of these transplants as a therapy for patients lacking fully compatible HLA-matched donors. Although still considered experimental, some transplantation centers have reported long-term outcomes after UCB HSC transplants similar to those for conventional marrow or peripheral PBSC transplants for primary hematologic diseases. However, the relatively limited numbers of CD34⁺ stem cells found in harvested UCB units accounts for a much slower hematopoietic recovery after the procedure and a statistically higher risk for nonengraftment compared with other stem cell sources. For this reason, UCB transplantation procedures have been limited to pediatric patients and smaller adults or to adult patients for whom there is more than one HLA-compatible UCB unit.

Aplastic Anemia

Definition and Epidemiology

Aplastic anemia (AA) is a rare disorder characterized by pancytopenia with a markedly hypocellular bone marrow. This disease was first described in 1888 by Paul Ehrlich, who observed that autopsy bone marrow specimens from a young woman who died of severe anemia and neutropenia were extremely hypoplastic. Later studies demonstrated that patients with severe AA possessed only a fraction of normal pluripotent stem cell numbers despite normal functional marrow stromal cells and normal or even elevated levels of stimulatory cytokines. The incidence of AA ranges from 1 to 5 cases per million people in the general population. It occurs predominantly in young adults (20 to 25 years old) and older adults (60 to 65 years old). The incidence is 3-fold higher in developing countries (e.g., Thailand and China) compared

with industrialized Western nations (e.g., Europe and Israel), a fact that is not explained by differences in drug or radiation exposure.

Etiology

AA arises as either an inherited disorder or an acquired syndrome or as an idiopathic phenomenon. A small number of cases occur in the context of a congenital bone marrow failure disorder, including Fanconi anemia, Schwachman-Diamond syndrome, and dyskeratosis congenita. The most common of these, Fanconi anemia, is an autosomal recessive disorder arising from mutations in genes encoding DNA repair proteins. The known causes of acquired AA are numerous (Table 46.4) and range from myeloablative radiation exposure to common viruses and medications. Prior bone marrow toxicity from drugs, chemicals (e.g., benzene, cyclic hydrocarbons found in petroleum products, rubber, glue, insecticides, chemical dyes), or radiation predisposes to AA because these agents directly injure proliferating and differentiating HSCs by inducing DNA damage. In contrast, cytotoxic chemotherapy, especially with alkylating agents, and radiation therapy target all rapidly cycling cells and often induce reversible bone marrow aplasia. Despite these many causes, most cases of AA are idiopathic.

The etiology of both acquired and congenital AAs appear to be mechanistically linked through abnormal telomere maintenance. Telomeres are repeated nucleotide sequences that cap and protect chromosome ends from degradation. Cell division leads to normal telomere erosion; when telomeres reach a critically short length, cells cease to proliferate, senesce, and undergo apoptosis, often with accompanying DNA damage and genomic instability. Telomerase enzyme in normal HSCs preserves long telomeres and promotes quiescence and a prolonged cellular lifespan. Patients with autosomal dominant dyskeratosis congenita have mutations in the genes for telomerase complexes, predisposing to premature aging and enhanced marrow failure in the setting of accelerated telomere shortening. One third of patients with acquired AA also have short telomeres, likely due to a combination of genetic, environmental, and epigenetic factors.

Autoreactive host lymphocytes can destroy normal hematopoiesis in AA. Bone marrow stromal cells and cytokine levels in patients with AA are normal. The fact that AA also occurs in diseases of immune dysregulation and after viral infections further suggests an immune-mediated mechanism for the disease. One hypothesis is that drug or viral antigens presented to the immune system trigger cytotoxic T-cell responses that persist and destroy normal stem cells. Only 1 in 100,000 patients develops severe AA as an idiosyncratic drug reaction. Whether these individuals have a genetically predisposed sensitivity to common exposures (e.g., nonsteroidal anti-inflammatory drugs, sulfonamides, Epstein-Barr virus) is unknown.

TABLE 46.4 Causes of Acquired Aplastic Anemia

Drugs (dose related): chemotherapeutic agents, antibiotics (chloramphenicol, trimethoprim-sulfamethoxazole)
Idiosyncratic causes (many unproved): chloramphenicol, quinacrine, nonsteroidal anti-inflammatory drugs, anticonvulsants, gold, sulfonamides, cimetidine, penicillamine
Toxins: benzene and other hydrocarbons, insecticides
Viral infection: hepatitis, Epstein-Barr virus, human immunodeficiency virus (HIV)
Immune disease: graft-versus-host disease in immunodeficiency, hypogammaglobulinemia
Paroxysmal nocturnal hemoglobinuria (PNH)
Radiation exposure
Pregnancy

Clinical Presentation

The clinical onset of AA can be insidious or abrupt. Patients often complain of symptoms related to their cytopenias: weakness, fatigue, dyspnea, or palpitations resulting from anemia; gingival bleeding, epistaxis, petechiae, or purpura caused by low platelet counts; or recurrent bacterial infections caused by low or nonfunctioning neutrophils. In some cases, patients will report recent upper respiratory syndrome. Results of the physical examination may be normal or characterized by ecchymoses and bleeding complications. Patients with congenital AA may have various abnormalities.

Diagnosis and Differential Diagnosis

Diagnostic confirmation of AA requires bone marrow biopsy to confirm hypocellularity and to rule out other marrow processes. Normal bone marrow cellularity ranges from 30% to 50% up to age 70 years and is less than 20% after 70 years of age (E-Fig. 46.1A). In contrast, bone marrow cellularity in patients with AA usually ranges from 5% to 15%, with increased fat accumulation and few or no hematopoietic cells and primarily plasma cells and lymphocytes (see E-Fig. 46.1B). In AA, hematopoietic progenitor and precursor cells are morphologically normal but number less than 1% of normal levels, and they are markedly dysfunctional, with a decreased ability to form differentiated progenitor cell colonies in vitro. A hypocellular marrow with evidence of increased blasts, dysplastic hematopoietic cells (e.g., pseudo-Pelger-Huët abnormalities, micromegakaryocytes) (E-Fig. 46.2), and clonal cytogenetically abnormal cells in the peripheral blood or marrow are diagnostic of acute leukemia or myelodysplasia, not AA. In young patients, a diagnosis of Fanconi anemia is made by demonstrating enhanced sensitivity of cultured cells to mitomycin or diepoxybutane-induced chromosomal damage on special testing. Although patients with AA typically have a low reticulocyte count from low red blood cell production and a paucity of blood cells (E-Fig. 46.3A) and macrocytic red cells (see E-Fig. 46.3B) on the peripheral blood smear, these features are non-diagnostic because patients with other primary marrow disorders may exhibit similar findings.

Treatment and Prognosis

Treatment of AA is based on the severity of disease and clinical characteristics. Patients with mild cytopenias can be monitored expectantly. However, patients with severe AA based on peripheral blood cell counts (defined as a neutrophil count $<500/\mu\text{L}$, platelet count $<20,000/\mu\text{L}$, anemia with corrected reticulocyte count $<1\%$, and marrow cellularity of 5% to 10%) have a poor median survival of 2 to 6 months without treatment. Because most of these patients die of overwhelming infections, supportive care with broad-spectrum antibiotics, antifungal agents, and antiviral agents is warranted for those with advanced neutropenia. Red blood cell and platelet transfusions can help patients who are profoundly symptomatic.

Current therapeutic approaches to AA focus on replacing the defective HSCs by stem cell transplantation and controlling an overactive immune response with HSC activation. All young patients with severe AA and an HLA-compatible bone marrow donor should be considered for alloSCT, which offers the best chance for definitive cure. Conditioning regimens for those AA patients with congenital abnormalities must be carefully considered prior to alloSCT. Although long-term survival is excellent for patients younger than 30 years transplanted from a sibling donor (75% to 90%), morbidity due to the transplant itself and the management of long-term complications are continuing problems. Outcomes for patients older than 40 years or patients without any HLA-matched related donor are poor.

The presumed immune mechanisms for drug-induced aplasia have led to immunosuppressive approaches to the treatment of AA in older patients, those without a compatible donor and/or otherwise ineligible for alloSCT. Treatment of AA with traditional chemotherapy such as high-dose cyclophosphamide usually has proved too toxic. However, immunosuppressive therapy (IST) using a combination of anti-thymocyte globulin (ATG) and cyclosporine (a specific T-cell inhibitor) restores marrow function and independence from red blood cell or platelet transfusions in up to 70% of patients with a 5-year survival of 90%. Side effects of ATG include anaphylaxis and serum sickness as a result of foreign antigens in the antisera and are usually self-limited. Eltrombopag is an oral TPO mimetic drug originally developed for its ability to stimulate platelet production by binding to MPL receptors on megakaryocytes. In vitro data suggested that administration of high doses of exogenous TPO also could stimulate proliferation and maintenance of HSCs expressing TPO receptors in spite of high levels of endogenous TPO in AA patients. Treatment of refractory severe AA patients with eltrombopag led to hematologic responses in 44% of patients. Subsequently, eltrombopag was added to frontline ATG and cyclosporine (CSA) for newly diagnosed AA and resulted in overall response rates of 80% to 94% after 6 months with excellent long-term survival. Complete hematologic responses occurred in numerous patients with markedly improved marrow cellularity and numbers of measured hematopoietic stem and progenitor cells. This three-drug combination (ATG, CSA, and eltrombopag) has now become the standard of care for up-front treatment of severe AA patients.

Because endogenous cytokine production is usually high in patients with AA, the routine use of growth factors such as G-CSF, EPO, or stem cell factor typically is ineffective. Despite high endogenous TPO levels in AA patients with refractory disease, long-term administration of eltrombopag as maintenance therapy with or without other immunosuppression (ATG, CSA) may have some effect in long-term sustained blood cell counts. Patients who survive initial treatment of AA remain at increased risk for the emergence of other primary hematologic disorders, such as myelodysplasia, leukemia, and paroxysmal nocturnal hemoglobinuria (PNH). A proportion of AA patients also may relapse with loss of hematologic responses over time. Recurrence may warrant retreatment with ATG, androgens, and newer immunosuppressive agents.

Paroxysmal Nocturnal Hemoglobinuria

Definition, Epidemiology, and Etiology

PNH is a rare disease characterized by intravascular hemolysis, venous thrombosis, and bone marrow failure. The disease arises from expansion of pluripotent HSCs containing a somatic mutation in the phosphatidylinositol glycan complementation class A (*PIGA*) gene. Loss of *PIGA*, which codes for a membrane lipid moiety (i.e., glycosyl phosphatidylinositol [GPI]), produces abnormal hematopoietic cells deficient in dozens of proteins that are normally attached to the cell surface by the GPI anchor. Disease manifestations of PNH result from lack of the GPI-linked proteins (CD55 and CD59) that usually protect red blood cells and platelets from complement-mediated attack. Loss of CD55 or CD59 leads to increased immune destruction of blood cells. The release of hemoglobin from broken red cells causes disease symptoms, specifically sudden irregular episodes of passing dark colored urine. The name “paroxysmal nocturnal hemoglobinuria” arises from the observation that dark urine occurs more frequently at night or in the early morning because the urine has been concentrated over night during sleep. In reality, hemolysis in this disorder is a continuous process and does not occur solely at night but during the day as well when it may not be as obvious to patients or clinicians.

E-Fig. 46.1 Comparison of normal bone marrow (A) with empty bone marrow characteristic of aplastic anemia (B). Notice the differences in overall marrow cellularity. (A) In the normal marrow biopsy, the fat-to-cell ratio is 50:50. Myeloid cells and megakaryocytes are positive for periodic acid–Schiff (PAS) stain, whereas hemoglobin-containing erythroid precursors are negative. The myeloid-to-erythroid ratio is 2:1. An iron-laden phagocyte (*upper right*) stains rust-brown. A small fragment of bone trabecula is seen (*black arrow*) (PAS stain, $\times 100$). (B) In the aplastic marrow biopsy (i.e., aplastic anemia), the fat-to-cell ratio is 95:5. Trilineage hematopoiesis is virtually absent, but rare lymphocytes remain. An osteocyte is embedded in normally calcified bone trabecular (PAS stain, $\times 100$). (Courtesy Maurice Barcos, MD, PhD, Dept Hematopathology, Roswell Park Comprehensive Cancer Center Buffalo, N.Y.)

E-Fig. 46.3 Peripheral blood findings in aplastic anemia. (A) In pancytopenia, the peripheral blood smear shows marked leukopenia. A single lymphocyte with azurophilic cytoplasmic granules is seen. The large granular lymphocytes may cause granulocytopenia through the FAS–FAS ligand apoptotic system (Wright-Giemsa stain, $\times 100$). (B) In macrocytosis, the peripheral blood smear shows normochromic red cell anisopoikilocytosis and macrocytes (Wright-Giemsa stain, $\times 100$). (Courtesy Maurice Barcos, MD, PhD, Dept Hematopathology, Roswell Park Comprehensive Cancer Center, Buffalo, N.Y.)

E-Fig. 46.2 Pseudo-Pelger-Huët abnormalities.

Blood cells arising from abnormal PNH clones can have complete (type III cells) or partial (type II cells) GPI deficiency. The degree of GPI deficiency is associated with the severity of the clinical symptoms. GPI-deficient cells typically coexist in the marrow with various populations of normal GPI-expressing cells (type I cells). Small numbers of abnormal PNH clones in patients with AA or myelodysplastic syndrome (MDS) suggest significant overlap in the causes of these three diseases. This led to reclassification of PNH as classic PNH disease and PNH in the setting of another specified bone marrow disorder. Suppression of normal hematopoiesis by the host immune system directly or indirectly by a preceding or coexistent disorder appears to provide a marrow environment favoring selective expansion of PNH stem cell clones and their deficient blood cell progeny over normal hematopoiesis.

Clinical Presentation

Patients are typically younger individuals with varying chronic complaints of abdominal pain, dysphagia, erectile dysfunction and impotence (in men), and intense lethargy due to smooth muscle dystonia resulting from depletion of circulating nitric oxide levels by free hemoglobin. Not all affected patients exhibit symptoms. Despite the continuous hemolysis, patients may experience acute exacerbations intermittently or frequently during periods of infection, trauma, and stress that may be difficult to manage. In addition to hemolysis, individuals with PNH are susceptible to recurrent potentially life-threatening thromboses and acute as well as chronic renal disease.

Diagnosis and Differential Diagnosis

The diagnosis of PNH is typically made by identification of complete or partial GPI protein deficiency on red cells and granulocytes. Usually this is determined by the loss of CD59, CD55, CD16, or CD24 expression in a clonal population. Laboratory tests reveal ongoing, low-grade intravascular hemolysis with increased lactate dehydrogenase levels correlating with severity of hemolysis and symptoms. Cytopenias, particularly anemia, often render patients transfusion dependent with ongoing hemoglobinuria due to the release of free plasma hemoglobin from intracellular compartments. About 15% of PNH patients have spontaneous resolution of disease without long-term sequelae, suggesting that *PIGA* mutations may appear transiently and disappear spontaneously in normal hematopoietic cell populations for unknown reasons.

Treatment

Eculizumab is a humanized monoclonal antibody that binds with high affinity to the complement protein C5, preventing terminal complement-mediated intravascular hemolysis in patients with PNH. Eculizumab therapy decreases hemolysis and hemoglobinuria, reduces requirements for red blood cell transfusions, improves chronic renal failure, and is associated with significant improvement in quality of life and survival for PNH patients. The incidence of life-threatening thrombotic events is decreased by more than 80%, likely contributing to the significant improvement in overall survival. Although this agent is associated with a theoretical increased risk for meningococcal infections due to complement-mediated blockade, the long-term safety and efficacy of sustained eculizumab therapy administered for more than 5 years appear to outweigh the potential risks of prolonged treatment. A recently developed longer-acting version of eculizumab offers patients who require lifelong therapy with this complement inhibitor increased convenience with less frequent outpatient administration. Newer agents targeting different stages of the complement pathway are currently in clinical investigation for PNH and other complement-activated hemolytic anemias. Other treatment for PNH includes

supportive care with transfusions, iron and folic acid supplementation, and alloSCT in selected patients for curative intent. Documented venous thrombosis is treated with lifelong full anticoagulation.

Prognosis

Despite advances in treatment and adequate anticoagulation, PNH remains a life-threatening disease. Venous thrombosis involving the cerebral and intra-abdominal veins occurs in about one half of patients and is the cause of death for up to one third, although the cause of the increased thrombotic risk is not entirely understood. Other causes of morbidity and mortality are side effects of progressive AA and a 5% long-term risk for leukemic transformation. Historically, the median survival from diagnosis is 10 to 15 years, with one third of patients dying within 5 years of the diagnosis. Whether long-term eculizumab therapy can change the natural history of disease is unknown and is the goal of an international registry of PNH patients.

Myelodysplastic Syndrome

Definition and Epidemiology

MDS is a biologically heterogeneous group of marrow disorders characterized by ineffective and disordered hematopoiesis in one or more of the major myeloid cell lines: erythroid cells, neutrophils and their precursors, and megakaryocytes. Patients have one or more cytopenias despite normal or increased numbers of hematopoietic cells in the bone marrow. Disordered maturation is accompanied by increased intramedullary apoptosis, which contributes to the decreased release of mature cells into the periphery. Primary MDS is predominantly a disease of elderly persons and occurs in about 1 of 500 patients between the ages of 60 and 75 years.

Etiology

Prior exposure to radiation therapy, myelotoxic chemotherapy, and organic chemicals such as benzene and formaldehyde has been linked to the development of what is termed “secondary” MDS. This disorder may occur at any age and comprises 10% to 15% of all diagnosed MDS cases. Therapy-related MDS is defined as MDS arising months to years after prior chemotherapy involving any cytotoxic agent but particularly alkylating agents and anthracyclines, ionizing radiation, radiolabeled antibody therapy, or alloSCT for any cancer or noncancer-related condition. Because therapy-related MDS typically evolves swiftly to more aggressive disease, these cases have been reclassified with therapy-related AML and treated accordingly (see [Chapter 47](#)).

Although the remaining majority of cases of MDS were previously thought to be idiopathic, emerging data have demonstrated that age-related clonal hematopoiesis underlies the development of MDS in many older individuals. Extensive genomic analyses of peripheral blood samples in otherwise healthy individuals have identified certain clonal molecular abnormalities, such as *DNMT3A*, *TET2*, and *ASXL1* mutations, present in hematopoietic cells several years prior to the development of overt hematologic disorders or even abnormal blood counts. Individuals who present with a single cytopenia and at least one clonal mutation in an otherwise normal marrow by morphology or who have a clonal marrow karyotype have been designated to have *CCUS* (*clonal cytopenia of unknown significance*). Increased number of mutations and specific mutations have been associated with increased risk of evolution to hematologic malignancy with highest risk seen in patients with two or more mutations, *RUNX1*, *JAK2V617F*, or *p53* mutations. The ideal management of these individuals, a proportion of whom will inevitably develop myeloid malignancies, is not certain but many physicians will choose to monitor these patients closely with intermittent blood cell counts. MDS is also considered a precursor syndrome with an overall risk of transformation to acute myeloid leukemia (AML) of 25% to

30%. It is now clear that progression from clonal myeloid HSC injury to multilineage hematopoietic failure and enhanced myeloblast growth reflects a continuum of disease ranging from clonal hematopoiesis to MDS and subsequent AML (see [Chapter 47](#)).

Clinical Presentation

Most patients with MDS are referred for evaluation of an incidental finding of peripheral cytopenia. Symptomatic patients usually exhibit findings related to the secondary effects of cytopenias: bleeding and bruising caused by thrombocytopenia, infection caused by leukopenia, or fatigue and dyspnea related to anemia. Physical examination is usually unremarkable, although 25% or more of patients may have splenomegaly. In some patients with MDS, development of skin lesions with fever (i.e., acute febrile neutrophilic dermatosis [Sweet syndrome]) may herald the transformation of MDS into acute leukemia. The disease course of MDS varies widely based on specific prognostic information (see later) including number and severity of cytopenias and karyotypic abnormalities. Although lower-risk MDS patients may live normal lifespans, most patients will eventually die prematurely of cytopenia-related complications, marrow failure, or evolution to AML with a median survival ranging from months to less than 2 years in the highest risk disease.

Diagnosis and Differential Diagnosis

Diagnosis of MDS requires evidence of dysplasia of at least 10% of marrow myeloid hematopoietic cells or 5% to 19% marrow blasts, the presence of peripheral cytopenia in one or more myeloid lineages, and absence of other known causes for the cytopenia. The World Health Organization (WHO) also defines MDS in any marrow regardless of morphology, which contains pathognomonic karyotypic abnormalities, for example, aberrations in chromosome 5 and 7, or 3 or greater aberrations (complex karyotype).

Morphologic evidence of dysplastic changes diagnostic of MDS often require specialized hematopathology review. Review of the peripheral blood smear may show characteristic morphologic abnormalities in addition to cytopenias. Erythroid cells are usually macrocytic, often with basophilic stippling. Neutrophils are often hypogranular and hypolobulated with a characteristic bilobed nuclear morphology called *pseudo-Pelger-Huët abnormality*. This anomaly should be anticipated when automated differential cell counts report unusually large numbers of bands. The bone marrow in MDS is usually normocellular or hypercellular, although 10% of patients may have a hypocellular marrow. Dysplastic changes usually occur in all three cell lines. Erythroid cells appear megaloblastic, with multinucleated cells or asynchronous nuclear-cytoplasmic development. Extremely small micromegakaryocytes and agranular megakaryocytes also may be seen. The myeloid series shows poor maturation with a left shift to earlier hypogranulated myeloid forms. Although elevated numbers of myeloid blasts are common, increasing blast numbers indicate progression to acute leukemia. Electron microscopy of the marrow shows cellular changes (i.e., prominent nuclear chromatin, cytoplasmic vacuoles, and blebs) characteristic of increased apoptosis (see examples in [E-Fig. 46.4](#)).

In the past, MDS was classified based on dysplastic marrow morphology and percentage of blasts as one of five subtypes: refractory anemia (RA), refractory anemia with ringed sideroblasts (RARS), refractory anemia with excess blasts (RAEB), refractory anemia with excess blasts in transformation (RAEBT), and chronic myelomonocytic leukemia (CMML). Later, these five subtypes were expanded to eight subtypes, with recognition of multilineage dysplasia as an important feature (e.g., refractory cytopenia with multilineage dysplasia, refractory cytopenia with multilineage dysplasia and ringed sideroblasts) and the reclassification of CMML

as myeloproliferative-myelodysplastic syndrome (MPN/MDS) ([Table 46.5](#)). MDS with an isolated 5q- cytogenetic abnormality was established as a distinct clinical syndrome. Therapy-related MDS/AML is defined as evidence of marrow dysplasia after prior chemotherapy, radiation therapy, or other myeloablative therapy. Although MDS patients with refractory anemia and excess blasts or refractory cytopenia with multilineage dysplasia usually fare poorly, morphologic classification of MDS correlates only approximately with overall survival.

The natural history and treatment of some MDS subtypes is more closely associated with specific cytogenetic and molecular abnormalities, demanding that careful molecular studies be performed during initial evaluation. For example, MDS characterized by deletion of the short arm of chromosome 7 (7p-) or complex cytogenetic abnormalities such as monosomy 7 or trisomy 8 often have mutations in the p53 tumor suppressor genes and universally poor clinical outcomes. In contrast, patients with MDS featuring an isolated deletion in the long arm of chromosome 5 (i.e., 5q- syndrome) are predominantly older women with a refractory macrocytic anemia, normal or elevated platelet counts, and an overall better clinical prognosis. These patients often live for several years with intermittent red blood cell transfusions, have a low risk of leukemic transformation, and often respond to therapy with lenalidomide (see later).

For the one third to one half of patients with cytopenia and myeloid dysplasia with normal marrow karyotype, the diagnosis of MDS should be one of exclusion after other potential causes of marrow failure and pancytopenia have been evaluated (see [Table 46.3](#)). MDS should never be diagnosed in acute disease states, during chronic hospitalization, or within 6 months of known myelotoxic therapy including irradiation or chemotherapy for any cancer or noncancer-related indication(s). Other causes such as vitamin B₁₂ or folate deficiency, chronic alcohol use, over-the-counter medications or supplements, and infections including human immunodeficiency virus (HIV) infection should be considered. Patients with possible MDS and a hypocellular bone marrow should also be evaluated for AA and/or PNH.

Prognosis

Although several risk classification systems have been developed to predict outcomes of MDS patients, accurate prediction of MDS prognosis remains a work in progress. The original classification (WHO) was developed by an international working group to be employed at initial disease detection and partitions patients based on age, cytopenias, karyotype, and marrow blasts into different risk categories (see [Table 46.5](#)). Based on criticism that the original classification relies only on characteristics of patients at disease onset and includes cases now considered to be acute myeloid leukemia, another WHO classification-based prognostic scoring system (WPSS) was devised emphasizing morphology, karyotype, and transfusion dependence at any time during the MDS disease course ([Table 46.6](#)). The International Prognostic Scale (IPSS) divides MDS patients into five new risk categories and was validated to predict for overall survival and leukemic evolution for MDS at any follow-up time ([Table 46.7](#)). To further complicate things, data derived from multiple international databases and encompassing 7012 patients was analyzed to generate yet another new classification system, the Revised International Prognostic Scoring System (R-IPSS) including more comprehensive karyotypic abnormalities ([Table 46.8](#)). In general, using any of these systems, MDS patients can be divided into three general risk categories: low, intermediate (low to high), or high to very high-risk disease and treated accordingly.

Whole-genome sequencing of untreated MDS samples has revealed that at least 78% of patients carry one or more oncogenic

E-Fig. 46.4 (A) Marrow biopsy section for del(5q)-associated myelodysplastic syndrome (MDS) shows numerous hypobulbated and dysplastic megakaryocytes, moderate granulopoiesis and erythropoiesis, and hemosiderin-laden macrophages (*black arrow*) (periodic acid–Schiff stain, $\times 100$). (B) Corresponding marrow smear shows trilineage dysplasia, including hypogranular myelocytes and band granulocytes, disorderly erythropoiesis with an increase in megaloblastoid pronormoblasts with a binucleate form, and a hypobulbated megakaryocyte with an immature nucleus showing semidispersed chromatin and ample cytoplasm with deficient platelet formation (Wright-Giemsa stain, $\times 250$). (C) Marrow smear from another case of MDS. Dysplastic granulopoiesis with hypogranular myelocytes shows immature nuclei with visible nucleoli, giant metamyelocytes, pseudo-Pelger-Huët neutrophils with typical pince-nez bi-segmented nuclei, and a neutrophil with quadri-segmented, jagged-edge nuclei. An early lobated megakaryocyte with dense chromatin and scant cytoplasm with early giant platelet formation (*black arrow*) is also seen (Wright-Giemsa stain, $\times 250$). (Courtesy Maurice Barcos, MD, PhD, Dept Hematopathology, Roswell Park Comprehensive Cancer Center, Buffalo, NY.)

TABLE 46.5 World Health Organization Classification of Myelodysplastic Syndromes

Class	Definition
Refractory anemia	Blood: anemia, no or rare blasts BM: erythroid dysplasia only, <5% blasts, and <15% ringed sideroblasts
Refractory anemia with ringed sideroblasts (RARS)	Blood: anemia, no blasts BM: $\geq 15\%$ ringed sideroblasts, erythroid dysplasia only, <5% blasts
Refractory cytopenia with multilineage dysplasia (RCMD)	Blood: cytopenias (bicytopenia or pancytopenia), no or rare blasts, $<1 \times 10^9/L$ monocytes BM: dysplasia in $\geq 10\%$ of the cells of two or more myeloid cell lines, <5% blasts, no Auer rods, <15% ringed sideroblasts
Refractory cytopenia with multilineage dysplasia and ringed sideroblasts (RCMD-RS)	Blood: cytopenias (two or more), no or rare blasts, no Auer rods, and $<1 \times 10^9/L$ monocytes BM: dysplasia in $\geq 10\%$ of the cells of two or more myeloid cell lines, <5% blasts, $\geq 15\%$ ringed sideroblasts, no Auer rods
Refractory anemia with excess blasts type 1 (RAEB-1)	Blood: cytopenias, <5% blasts, no Auer rods, $<1 \times 10^9/L$ monocytes BM: unilineage or multilineage dysplasia, 5-9% blasts, no Auer rods
Refractory anemia with excess blasts type 2 (RAEB-2)	Blood: cytopenias, 5-19% blasts, Auer rods $\pm <1 \times 10^9/L$ monocytes BM: unilineage or multilineage dysplasia, 10-19% blasts, \pm Auer rods
Myelodysplastic syndrome—unclassified (MDS-U)	Blood: cytopenias, no or rare blasts, no Auer rods BM: unilineage dysplasia in one myeloid line, <5% blasts, no Auer rods
MDS associated with isolated del(5q)	Blood: anemia, usually normal or increased platelet count, <5% blasts BM: normal to increased megakaryocytes with hypolobulated nuclei, <5% blasts, isolated cytogenetic abnormality of deletion 5q, no Auer rods

BM, Bone marrow.

TABLE 46.6 World Health Organization Classification-Based Prognostic Scoring System (WPSS) for Myelodysplastic Disorders

Factor	SCORING ^a			
	0	1	2	3
WHO category	RA, RARS, 5q-	RCMD, RCMD-RS	RAEB-1	RAEB-2
Karyotype ^b	Good	Intermediate	Poor	—
Transfusion requirement ^c	No	Regular	—	—

5q-, Myelodysplastic syndrome with isolated del(5q) and marrow blasts less than 5%; MDS, myelodysplastic syndrome; RA, refractory anemia; RARS, refractory anemia with ringed sideroblasts; RCMD, refractory cytopenia with multilineage dysplasia; RCMD-RS, refractory cytopenia with multilineage dysplasia and ringed sideroblasts; RAEB-1, refractory anemia with excess of blasts type 1; RAEB-2, refractory anemia with excess of blasts type 2; WHO, World Health Organization.

^aRisk groups were determined as follows: very low (total score = 0), low (1), intermediate (2), high (3 to 4), and very high (5 to 6).

^bKaryotype was as follows: good: normal, -Y, del(5q), del(20q); poor: complex (≥ 3 abnormalities), chromosome 7 anomalies; and intermediate: other abnormalities.

^cRed blood cell (RBC) transfusion dependency was defined as having at least one RBC transfusion every 8 weeks over a period of 4 months.

TABLE 46.7 International Prognostic Scoring System for Myelodysplastic Disorders (IPSS)

Score	Blasts	Karyotype	Cytopenias ^a	Overall Score	Median Survival (Yr)
0	<5%	Normal, -Y, 5q-, 20q-	0-1 cytopenias	0	5.7
0.5	5-10%	All other abnormalities	2-3 cytopenias	0.5-1.0	3.5
1.0		Abnormal 7, >3 abnormalities		1.5-2.0	1.2
1.5	11-20%			2.5 or higher	0.4
2.0	21-30%				

^aCytopenias are defined as hemoglobin <10 g/dL, neutrophils <1500/ μ L, platelets <100,000/ μ L.

mutations. Although more than 40 genes are recurrently mutated in MDS, most are altered in less than 5% of MDS patients, reflecting the enormous biologic heterogeneity of this disorder. Genes implicated in MDS are involved in cell signaling, DNA methylation, chromatin regulation, and most importantly, RNA splicing. Several studies

have shown that several individual gene mutations, including *EZH2*, *DNMT3A*, *SF3B1*, *TET2*, *NRAS*, *TP53*, *RUNX1*, and *ASXL1*, predict MDS outcomes independent of IPSS classification and can improve on prognostication based on clinical features alone. However, none of the current prognostic models for MDS, such as the revised IPSS,

TABLE 46.8 Revised International Prognostic Scoring System for Myelodysplastic Syndromes (R-IPSS)

Prognostic Subgroups (% of Patients)	Cytogenetic Abnormalities	Median Survival (Yr) ^a	Median Evolution to AML, 25% ^b (Yr) ^a	Hazard Ratios OS/AML ^a	Hazard Ratios OS/AML ^c

currently consider somatic mutations. The development of novel prognostic models incorporating mutational signatures is eagerly awaited in order to further refine prognosis and treatment of MDS patients in the near future.

Treatment

Insights into the pathophysiology of ineffective hematopoiesis characterizing MDS has led to several therapeutic options that ideally should be individualized based on patient preference, performance status, disease biology, and importantly, prognostic risk category.

Low to intermediate-low risk patients

Transfusions, iron chelation, and growth factors. Because most patients with MDS are elderly individuals who may not tolerate or desire aggressive intervention without hope of cure, those patients with asymptomatic low-risk disease who remain transfusion independent are typically observed expectantly. Those with symptomatic anemia and thrombocytopenia can receive supportive red blood cell and platelet transfusions to maintain quality of life. Special care should be taken to initiate iron chelators (deferoxamine or oral deferasiprone) to prevent complications of iron overload caused by the delivery of between 200 and 250 mg of iron with each unit of transfused red blood cells. Accumulation of excess iron initially in macrophages and eventually in the hepatic parenchyma, myocardium, skin, and pancreas can lead to secondary hemochromatosis or transfusional iron overload with clinical symptoms of liver and heart failure, hyperpigmentation, and diabetes mellitus. To mitigate this, transfusion-dependent patients with low endogenous serum EPO levels often receive recombinant EPO growth factor to reduce transfusion needs. Similarly, chronic neutropenic individuals with recurrent or refractory infections may benefit from G-CSF or GM-CSF treatment given alone or in addition to EPO and antibiotic regimens to prevent life-threatening infections.

Luspatercept is a first-in-class recombinant fusion protein derived from human activin receptor linked to a protein derived from immunoglobulin G. This agent works by binding to select TGF- β superfamily

ligands to reduce aberrant signaling and enhance late-stage erythropoiesis. By interfering with the signals that suppress RBC production, this drug improves patients' ability to manufacture their own RBCs, therefore reducing the need for transfusions. In a randomized clinical trial, luspatercept safely and effectively reduced transfusion burden in over half of patients with lower risk MDS (defined as very low, low, and intermediate risk) with ring sideroblasts who had not previously responded to or were ineligible for erythropoiesis-stimulating agents.

Immunosuppressive therapy. Certain MDS disease subgroups exhibit significant overlap with AA and PNH because hematopoietic failure in all of these conditions is mediated in part by autoimmune cells selectively targeting the destruction of normal HSCs. Young patients with low-risk MDS disease and exhibiting an HLA-DR15 haplotype have demonstrated a 30% to 50% improvement in counts after T-cell immunosuppressive therapy with ATG or cyclosporine. MDS patients with isolated trisomy 8 with and without demonstrated PNH clones have also been reported to respond to treatment with immunosuppression with or without eculizumab therapy.

5q minus syndrome. Patients with lower-risk MDS characterized by deletions in the long arm of chromosome 5 (5q- aberration) typically have anemia with preserved platelet counts. Many have a disease subtype that is extraordinarily sensitive to therapy with lenalidomide, an immunomodulatory agent that exerts antigrowth effects on MDS cells and their surrounding marrow microenvironment. Complete and durable responses after lenalidomide therapy occur in up to 66% of 5q- syndrome MDS patients and are accompanied by disappearance of the abnormal cytogenetic clone in the marrow in some patients. Defects in ribosomal protein function, specifically the ribosomal subunit protein RPS14, have been identified as the cause of 5q- syndrome MDS, paralleling findings implicating a different ribosomal subunit (RPS19) in the congenital bone marrow syndrome Diamond-Blackfan anemia. Studies have demonstrated that lenalidomide targets aberrant signaling pathways caused by haploinsufficiency of specific genes in a commonly deleted region on chromosome 5 (i.e., *SPARC*,

TABLE 46.9 Suggested Therapies for Bone Marrow Failure Syndromes

Patient Population	Recommended Treatment
Low-risk MDS (LR-MDS)	Transfusions (first line), growth factors, iron chelation, clinical trials (hypomethylating agents)
Low-risk MDS with ringed sideroblasts	Luspatercept (with ringed sideroblasts) (not yet commercially available), transfusions, iron chelation
Del(5q) MDS	Lenalidomide
Hypoplastic MDS	Immunosuppressive therapy (ATG)
Intermediate- to high-risk MDS (HR-MDS)	Hypomethylating agents (azacitidine, decitabine) or intensive AML-based induction chemotherapy (see Chapter 47) ± allogeneic stem cell transplantation, transfusion support, iron chelation, clinical trials
TP53 mutant MDS	Decitabine (10-day regimen)
Therapy-related MDS	Treatment for therapy-related AML (see Chapter 47), hypomethylating agents, allogeneic stem cell transplantation
IDH1/IDH2 mutant MDS	Clinical trials (ivosidenib, enasidenib, venetoclax-based therapy)
Paroxysmal nocturnal hemoglobinuria (PNH)	Eculizumab, anticoagulation (prior thromboses)
Severe aplastic anemia	Immunosuppressive therapy (ATG, CSA, eltrombopag), Danazol (telomere abnormalities), allogeneic stem cell transplant
Clonal hematopoiesis of indeterminate potential (CHIP)/clonal cytopenia of unknown significance (CCUS)	Close monitoring of complete blood cell counts with consideration of marrow biopsy and repeat mutational profiling if progressive cytopenia develop, modification of cardiovascular risk factors

RPS14, *CDC25C*, and *PPP2CA*). The agent specifically targets del(5q) clones while also promoting erythropoiesis and repopulation of the bone marrow in normal cells. Lenalidomide induces responses in up to one third of non-5q- MDS patients who demonstrate a specific defect in erythroid differentiation on gene expression profiling.

Intermediate to high risk MDS patients

Epigenetic therapy. The recognition that epigenetic modifications of the abnormal HSC clones in MDS affect cell growth and apoptosis and are central to disease pathogenesis has led to the successful therapeutic application of two DNA methyltransferase inhibitors (i.e., azacitidine and decitabine) for this disease. These two agents, termed *hypomethylating agents (HMA)*, are hypothesized to reverse the abnormal hypermethylation and gene silencing in abnormal HSCs. Although not curative, HMA are a cornerstone of therapy for higher-risk MDS patients ineligible for and/or unwilling to pursue alloSCT. In a phase III clinical trial of intermediate-2 to high-risk MDS patients, azacitidine significantly prolonged overall survival as compared with cytotoxic chemotherapy or supportive care only. Azacitidine delayed the time to leukemic transformation in two thirds of patients with transfusion-dependent MDS, reduced transfusion requirements, and improved quality of life compared with transfusion support alone. These results were the first to demonstrate that any therapy could alter the natural history of MDS and established azacitidine as the gold standard for treatment. Decitabine, a related compound to azacitidine, is an alternative hypomethylating agent approved for high-risk MDS patients based on the results of multiple studies showing that this agent induced higher remission rates and reduced transfusion needs as compared with supportive care and historical controls. Although decitabine has not yet resulted in an overall survival benefit in MDS patients, the shorter duration of administration (5 days for decitabine vs. 7 days for azacitidine) and the more myelosuppressive nature of this agent has led it to be preferred for some patients with higher-risk MDS with increased white blood cell count and/or blasts.

Hypomethylating therapy resulting in chronic (epigenetic) modification of MDS cells differs from cytotoxic chemotherapy in several ways. Prolonged administration of HMA is needed to induce and

maintain efficacy. Therapeutic responses are often not seen until at least 4 to 6 months after treatment initiation and, once achieved, require ongoing monthly administration to maintain response and transfusion-independence. Moreover, marrow responses are not required as MDS patients receiving azacitidine who did not achieve a defined complete remission still survived significantly longer than patients treated with supportive care alone. Whether outcomes of hypomethylating therapy differ based on mutational status of MDS patients is not clear. One study reported more favorable outcomes in poor prognosis MDS patients characterized by TP53 mutations who received a 10-day decitabine regimen. Despite the positive results of HMA therapy in many individuals with MDS, no patients are ultimately cured of their disease, and durable remissions are infrequent. Patients whose disease has progressed on HMA therapy have short overall survival and therefore ideally should be referred for investigational agents and/or allogeneic stem cell transplantation.

Stem cell transplantation. As in other hematologic stem cell disorders, the only curative therapy for MDS patients remains alloSCT, ideally performed at complete remission. All MDS patients younger than 40 years with an available HLA-matched sibling donor are typically offered transplantation at diagnosis. Long-term disease-free survival rates for patients with low-risk disease are greater than 50%; however, the high transplantation-related mortality, morbidity, and relapse rates associated with mismatched or unrelated donor transplants or with transplantation in older MDS patients have usually limited the use of these transplants to patients with high-risk disease. In the past, patients with intermediate-2 or high-risk MDS (i.e., MDS with cytogenetic abnormalities predisposing to leukemic transformation or high levels of blasts or intermediate-2 or higher scores on IPSS classification systems) (see Tables 46.5, 46.6, 46.7, 46.8, and 46.9) have been offered acute leukemia-based chemotherapy regimens (see Chapter 47) designed to eradicate rapidly proliferating blast cells, not dysfunctional MDS cells. Because such therapy for MDS patients is associated with a high relapse rate within 12 to 18 months and no significant prolongation of overall survival, even for patients who achieve remission, such patients are now increasingly being offered hypomethylating agents. Regardless, subsequent

alloSCT offers the best long-term outcome in the majority of MDS patients.

Outcomes following alloSCT can be predicted based on molecular biology of the MDS disease. Over 90% of MDS patients proceeding to alloSCT will have at least one somatic mutation with certain mutations such as *TP53*, *RAS*, and *JAK2V617F* associated with shorter survival and increased risk of disease recurrence following transplant. Persistence or clearance of any pretransplant MDS-associated gene mutation is also important. Detection of a mutation with a variant allele frequency of at least 0.5% at 30 days after transplant correlated with disease progression. These findings point to the importance of enhancing treatment options for MDS prior to alloSCT for optimal outcomes.

PROSPECTUS FOR THE FUTURE

Modern genomic sequencing technologies have revolutionized research in stem cell biology and marrow failure syndromes by allowing parallel assessment of hundreds of genes, pathways, and biologic processes. The study of HSC function in marrow failure syndromes provides hints of specific molecular pathways disturbed in many diseases of hematopoietic and nonhematopoietic stem cells. These observations are furthering our knowledge about the complex interplay among AA, PNH, and MDS. Understanding stem cells' plasticity and regulatory roles promises new therapeutic avenues for a wide array of diseases.

Characterization of the complex genomic landscape of MDS has revealed that almost 80% of cases are characterized by at least one oncogenic mutation, and more than 40 unique genes are recurrently mutated. Much research remains to be done to determine how best to incorporate this vast amount of information into the prognosis of MDS patients. In addition, it is estimated that up to 10% to 15% of patients with MDS, particularly younger individuals, have disease arising from inherited familial genetic predisposition syndromes with germline mutations in genes such as *DDX1* and *RUNX1* that promote aberrant myeloid cell development. Careful acquisition of personal and family history is therefore key for any individual with marrow failure disorders. Routine referral of MDS patients younger than 50 years of age and/or with appropriate family history or specific gene mutations detected on molecular testing is strongly recommended.

Multiple agents targeting the unique biologic features of ineffective hematopoiesis in marrow failure syndromes have moved into the forefront of treatment for these diseases over the last few years. These include eculizumab in PNH, immunosuppressive drugs and eltrombopag in AA and MDS subsets, azacitidine and decitabine in higher-risk MDS, and lenalidomide in 5q- MDS. Advances in allogeneic stem cell transplantation, specifically the now widespread use of reduced intensity and haploidentical transplantation protocols, has made this option a reality for many individuals who would not have been eligible for this life-extending procedure in the past.

Current clinical trials are actively investigating a new wave of tailored therapies for specific MDS biologic signatures. Examples of this include a p53 reactivating agent (APR-246) for p53 mutant MDS, a telomerase inhibitor (imetelstat) for lower-intermediate-risk MDS, a CD123-directed antibody-toxin conjugate (tagraxofusp) for MPN/MDS, and multiple immune checkpoint inhibitors added to hypomethylating therapy for higher-risk MDS. Ongoing clinical trials are also exploring the potential translation of multiple agents recently approved for acute myeloid leukemia to high-risk MDS patients, given the significant clinical and biological overlap of these two disease states. These included enasidenib for *IDH2* mutant MDS, ivosidenib for *IDH1* mutant MDS, and most importantly, venetoclax plus

azacitidine or decitabine or low-dose cytarabine for MDS independent of mutation status (see [Chapter 47](#)).

Finally, the contribution of hematopoietic stem cells to global health issues is increasingly being recognized and explored. Genomic sequencing has allowed us to discern that many healthy individuals without overt hematologic abnormalities in fact have clonal somatic gene mutations in hematopoietic stem and progenitor cells (termed *clonal hematopoiesis of indeterminate potential* or *CHIP*). The incidence of CHIP appears to increase with age of the individual, likely due to mutational events over time and other yet to be determined genetic and environmental predisposing factors. Over time, individuals with CHIP have an increased risk of developing overt hematologic cancers, particularly therapy-related MDS/AML following exposure to myelosuppressive agents (chemotherapy or radiation) and depending on the specific mutation identified. In many individuals, identification of new cytopenias in these patients (termed *clonal cytopenias of unknown significance* or *CCUS*) may represent the next step in the continuum to development of MDS. CHIP has been associated with other health problems. In one study, presence of CHIP was linked to almost twice the risk of developing coronary heart disease in individuals without other risk factors. Preclinical models of CHIP in mice have demonstrated that CHIP is linked to accelerated atherosclerosis potentially due to higher baseline underlying inflammatory processes. Studies exploring how best to utilize this information for preventive and/or therapeutic purposes are ongoing.

For a deeper discussion of these topics, please see Chapter 147, “Hematopoiesis and Hematopoietic Growth Factors,” in *Goldman-Cecil Medicine*, 26th Edition.

Clonal Disorders of the Hematopoietic Stem Cell

Eunice S. Wang, Nancy Berliner

INTRODUCTION

Malignant transformation involves combined defects in cellular maturation and differentiation. The multistep theory of oncogenesis suggests that these defects are often separable and contribute to a stepwise progression from a normal to a fully transformed cell. The continuous cycling of hematopoietic cells provides a milieu for the development of clonal genetic abnormalities that supports the multistep model. Clonal defects of the hematopoietic stem cell give rise to an array of pre-malignant and malignant disorders. Primary defects of maturation give rise to the myelodysplastic disorders (see [Chapter 46](#)), whereas loss of normal control of proliferation results in myeloproliferative disease encompassing chronic and acute leukemias.

MYELOPROLIFERATIVE NEOPLASMS

Definition and Etiology

Myeloproliferative neoplasms (MPN), previously known as chronic myeloproliferative diseases, are clonal stem cell disorders characterized by leukocytosis, thrombocytosis, erythrocytosis, splenomegaly, and bone marrow hypercellularity. The hallmark of MPN is the failure of a transformed multipotent stem cell to respond to normal feedback mechanisms regulating hematopoietic cell mass. Stem cells from patients with MPN demonstrate clonal colony growth in vitro when they are grown in serum without the addition of exogenous cytokines, and this technique historically was used as a diagnostic test for MPN. MPN have traditionally been divided into four classic disorders based on the predominant hyperproliferative cell type: polycythemia vera (PV), essential thrombocytosis (ET), primary myelofibrosis (PMF; i.e., idiopathic myelofibrosis or agnogenic myeloid metaplasia), and chronic myelogenous leukemia (CML). Hypereosinophilic syndrome, mast cell disease, and other less common diseases characterized by profuse myeloid cell proliferation are also considered MPN but are not traditionally included among these “classic” disease subsets ([Table 47.1](#)).

The pathogenesis of MPN arises from mutational and biologic processes resulting in dysfunctional kinases that promote unabated myeloid growth and expansion. This is often accompanied by aberrant cytokine production affecting the marrow microenvironment, a gradual shift in hematopoietic cell production from the bone marrow to extramedullary sites in the liver and spleen, and altered coagulation. In CML, a well-described reciprocal translocation between chromosomes 9 and 22 termed the “Philadelphia chromosome” results in an Abelson (ABL) leukemia virus–breakpoint cluster region (BCR) fusion protein (BCR/ABL) with constitutive kinase activity. In PV, PMF, and ET, a mutation involving the substitution of a valine for phenylalanine at position 617 (V617F) in the *Janus kinase 2* (*JAK2*) has been identified

in most patients and accounts for the abnormal growth properties that characterize these stem cell disorders. In those patients with MPN lacking an actual *JAK2V617F* mutation, upregulation of JAK-STAT signaling pathways has been demonstrated due to other etiologies, supporting common mechanisms of action in all MPN. Other mutations commonly identified in MPN cells include *CALR*, *ASXL1*, and *RUNX1*.

Clinical complications of MPN arise from the overproduction of one or more lineages in the blood. Over time, all MPN can undergo clonal evolution with acquisition of additional cytogenetic and molecular events leading to blastic transformation and eventually acute leukemia. With the exception of CML, this is an infrequent and late complication. Although all MPN are mechanistically related, significant differences still exist in each clinical disease presentation warranting specific therapeutic considerations for each type as will be discussed.

POLYCYTHEMIA VERA

Definition and Epidemiology

PV, literally meaning “increased numbers of red blood cells in the blood,” is a syndrome characterized by significantly increased red blood cell mass in the peripheral blood resulting from a clonal multipotent hematopoietic stem cell (HSC) defect. PV is relatively uncommon with an incidence of 1 to 3 of 100,000 people and a median age at diagnosis of 65 years.

Clinical Presentation

PV is a primary clonal stem cell disorder of unknown origin that is characterized by predominant erythrocytosis associated with other hematopoietic abnormalities. Although one half of patients have concurrent leukocytosis or thrombocytosis, erythrocytosis is the hallmark and the cause of the most serious clinical complications of this disease. Typically, patients complain of headache, visual problems, mental clouding, and pruritus after bathing. Occlusive vascular events such as stroke, transient ischemic attacks, myocardial ischemia, and digital pain, paresthesias, or gangrene are common. Pulmonary, deep vein, hepatic, and portal vein thromboses may occur. Paradoxically, patients are also predisposed to hemorrhagic events such as gastrointestinal and mucosal bleeding caused by abnormal platelet function and also ischemic necrosis downstream from vascular occlusion. Physical examination may show retinal vein occlusion, ruddy cyanosis, digital ischemia, and splenomegaly.

Diagnosis and Differential Diagnosis

When patients are first diagnosed with an elevated hemoglobin concentration per unit volume (i.e., erythrocytosis), the initial evaluation

TABLE 47.1 World Health Organization 2016 Classification of Myeloid Neoplasms

1. Acute myeloid leukemia
2. MDS
3. MPNs
 - a. Chronic myelogenous leukemia
 - b. Polycythemia vera
 - c. Essential thrombocythemia
 - d. Primary myelofibrosis
 - e. Chronic neutrophilic leukemia
 - f. Chronic eosinophilic leukemia, not otherwise categorized
 - g. Hypereosinophilic syndrome
 - h. Mast cell disease
 - i. MPNs, unclassifiable
4. MDS, MPN
5. Myeloid neoplasms associated with eosinophilia and abnormalities of PDGF-RA, PDGF-RB, or FGF-R1

WHO Classification of Tumours of Haematopoietic and Lymphoid Tissues (Revised Fourth Edition), IARC, 2016. *FGF-R1*, Fibroblast growth factor receptor 1; *MDS*, myelodysplastic syndrome; *MPN*, myeloproliferative neoplasm; *PDGF-RA*, platelet-derived growth factor receptor- α polypeptide; *PDGF-RB*, platelet-derived growth factor receptor- β polypeptide.

TABLE 47.2 Causes of Erythrocytosis

- I. Relative or spurious erythrocytosis (normal red cell mass)
 - A. Hemoconcentration due to dehydration (e.g., diarrhea, diaphoresis, diuretics, water deprivation, emesis, ethanol, hypertension, pre-eclampsia, pheochromocytoma, carbon monoxide intoxication)
- II. True or absolute erythrocytosis
 - A. Polycythemia vera
 - B. Primary congenital polycythemia
 - C. Secondary erythrocytosis due to
 1. Congenital causes (e.g., activating mutation of erythropoietin receptor)
 2. Hypoxia caused by carbon monoxide poisoning, high oxygen affinity hemoglobin, high-altitude residence, chronic pulmonary disease, hypoventilation syndromes such as sleep apnea, right-to-left cardiac shunt, neurologic defects involving the respiratory center
 3. Nonhypoxic causes with pathologic erythropoietin production
 - a. Renal disease (e.g., cysts, hydronephrosis, renal artery stenosis, focal glomerulonephritis, renal transplantation)
 - b. Tumors (e.g., renal cell cancer, hepatocellular carcinoma, cerebellar hemangioblastoma, uterine fibromyoma, adrenal tumors, meningioma, pheochromocytoma)
 4. Drug-associated causes
 - a. Androgen therapy
 - b. Exogenous erythropoietin growth factor therapy

Modified from Hoffman R, Benz EJ, Shattil SJ, et al, editors: Hematology: basic principles and practice, ed 2, New York, 1995, Churchill Livingstone.

should focus on whether this increase reflects an enhanced red cell mass (i.e., absolute erythrocytosis or polycythemia) or a normal red cell mass in the setting of a decreased plasma volume (i.e., relative erythrocytosis caused by reduced intravascular volume or other causes). The latter condition is not true polycythemia (Table 47.2). Polycythemia or

TABLE 47.3 World Health Organization 2016 Diagnostic Criteria for Polycythemia Vera

- Major criteria^{a,b}
1. Hemoglobin (Hgb) >16.5 g/dL (men), >16.0 (women); or hematocrit (Hct) >49% (men), >48% (women) or increased red cell mass (RCM) (more than 25% above mean normal predicted value)
 2. Bone marrow biopsy showing hypercellularity for age with trilineage growth (panmyelosis) including prominent erythroid, granulocytic, and megakaryocytic proliferation with pleomorphic, mature megakaryocytes (differences in size)
 3. Presence of *JAK2* or *JAK2* exon 12 mutation
- Minor criteria
1. Subnormal serum erythropoietin level

From Swerdlow SH, Campo E, Harris NL, Jaffe ES, Pileri SA, Stein H, Thiele J. WHO Classification of Tumours of Haematopoietic and Lymphoid Tissues (Revised Fourth Edition), IARC, 2016.

^aPV diagnosis requires meeting either all three major criteria or the first two major criteria and one minor criterion.

^bCriterion number 2 (bone marrow biopsy) may not be required in cases with sustained absolute erythrocytosis: hemoglobin levels 18.5 g/dL in men (hematocrit 55.5%) or 16.5 g/dL in women (hematocrit 49.5%) if major criterion 3 and the minor criterion are present. However, initial myelofibrosis (present in up to 20% of patients) can only be detected by performing a bone marrow biopsy; this finding may predict a more rapid progression to overt myelofibrosis (post-PV MF).

absolute erythrocytosis is an absolute increase in red cell mass caused by increased red blood cell production. Under normal conditions, the body's ability to increase red blood cell production in states of hypoxemia, anemia, hemolysis, and acute blood loss ensures continuous oxygen delivery to tissues. In response to physiologic stimuli, pluripotent stem cell precursors are activated by erythropoietin (EPO) to differentiate into erythroid progenitor cells and eventually into hemoglobin-carrying erythrocytes. When numbers of mature red blood cells are adequate, a negative feedback mechanism suppresses further EPO production, and the serum hemoglobin level remains normal.

Diagnosis of PV was formerly one of exclusion based on an elevated red cell mass, splenomegaly, thrombocytosis, leukocytosis, lack of hypoxemia and other secondary causes of polycythemia, and elevated levels of leukocyte alkaline phosphatase and serum vitamin B₁₂-binding protein levels. Red blood cells in the peripheral blood often appear microcytic, with or without iron deficiency. Bone marrow examination shows a hypercellular marrow with pronounced hyperplasia of erythroid lineage cells. Cytogenetic features at the time of diagnosis are usually normal. The development of clonal cytogenetic abnormalities heralds transformation in the later stages of disease. The discovery of *JAK2* gene mutations in 97% of patients with PV as well as other mutations (such as *CALR* and *ASXL1*) and findings elucidating the underlying disease pathophysiology led to new diagnostic criteria (Table 47.3). A suspected diagnosis of PV can now be confirmed in individuals with elevated hemoglobin and/or hematocrit levels by testing for a *JAK2* mutation, bone marrow demonstrating trilineage proliferation, and documentation of subnormal serum EPO levels.

Treatment and Prognosis

Early recognition and treatment of PV are important because untreated patients with PV suffer significant morbidity and mortality from thromboembolic complications involving the cerebral, coronary, and mesenteric circulations. Twenty percent of patients show symptoms of arterial and venous thrombosis, and thrombosis remains the most common cause of death. Without treatment, up to one half of patients

with PV may die of thrombotic complications within 18 months of diagnosis. Realization of an individual patient's risk for life-limiting thrombotic complications dictates whether therapy is required to render PV into a chronic, progressive disease.

Low-dose aspirin and treatment of asymptomatic thrombocytosis decrease thromboembolic events in low- and high-risk PV patients and are especially important in older patients with significant cardiovascular risk factors. In younger patients, nonsteroidal anti-inflammatory drugs and antiplatelet agents should be used judiciously because of the risk of gastrointestinal hemorrhage. Patients with advanced age (>60 years), prior history of thrombosis, leukocytosis, high hematocrit values, and clinical cardiovascular factors are at high risk for subsequent vascular events. Although possible, the risk of transformation of PV to acute myeloid leukemia remains relatively low with rates of 2.3% at 10 years and 5.5% at 15 years.

Therapy varies based on risk criteria. For younger patients with lower cardiovascular risk factors, intermittent phlebotomy and aspirin prophylaxis remain the mainstays of treatment and usually result in iron deficiency anemia, which further reduces the rate of red blood cell production.

Cytoreductive therapy is indicated for patients who cannot tolerate and/or fail phlebotomy, older patients with a prior history of and/or coexisting risk factors for cardiovascular events, and those with symptomatic splenomegaly. Commonly used therapies include hydroxyurea (i.e., a low-dose oral cytotoxic agent that does not appear to increase leukemic risk), pegylated interferon- α (i.e., for young patients and women during pregnancy), and anagrelide (i.e., an oral megakaryotoxic agent for treating refractory thrombocytosis). Choice of therapy is often individualized to the patient to best meet their lifestyle requirements given the chronicity of this disease. The main goal of therapy in higher-risk individuals with PV is long-term reduction of red blood cell mass as reflected in maintenance of hematocrit values less than 45% in men (and commonly less than 42% in women). In a multicenter, prospective clinical trial, adult PV patients (largely men) randomized to maintaining a therapeutic hematocrit target of less than 45% using hydroxyurea, phlebotomy, or both had a significantly lower rate of cardiovascular death (2.7% vs. 9.8%) and major thrombosis than those with a hematocrit target maintained at a higher level between 45% and 50%. As with all myeloproliferative disorders, initiation of cytoreductive therapy may precipitate hyperuricemia that results in secondary gout and uric acid stones, warranting treatment with allopurinol.

Although low-dose chemotherapeutic agents (e.g., chlorambucil, busulfan) have historically been used to treat leukocytosis and thrombocytosis not responding to hydroxyurea, these agents have fallen out of favor due to increased toxicity and risk of secondary acute myeloid or myelogenous leukemia (AML). A randomized clinical trial of ruxolitinib, a receptor tyrosine kinase inhibitor targeting constitutively active JAK1/2 signaling pathways, in patients with PV failing prior hydroxyurea therapy, confirmed that this agent is effective in reducing phlebotomy frequency and splenomegaly in refractory patients. Reductions in white blood cell and platelet counts following ruxolitinib therapy were also reported. With effective therapy, the long-term survival of PV patients remains excellent.

ESSENTIAL THROMBOCYTHEMIA

Definition and Epidemiology

ET (also known as primary thrombocythemia) is a pluripotent stem cell disorder predominantly resulting in elevated levels of platelets and white blood cells. Platelet function and length of survival remain normal. ET is an uncommon disorder, with an increasing number of cases found on routine laboratory testing of asymptomatic patients. Although the median age at diagnosis is 60 to 65 years, 10% to 25% of patients are younger than 40 years.

TABLE 47.4 World Health Organization 2016 Diagnostic Criteria for Essential Thrombocythemia

Major criteria^a

1. Platelet count $\geq 450 \times 10^9/L$
2. Bone marrow biopsy showing proliferation mainly of the megakaryocyte lineage with increased numbers of enlarged mature megakaryocytes with hyperlobulated nuclei. No significant left-shift of neutrophil granulopoiesis or erythropoiesis and very rarely minor (grade 1) increase in reticulin fibers
3. Not meeting WHO criteria for *BCR-ABL1+* CML, PV, PMF, MDS, or other myeloid neoplasms
4. Presence of JAK2, CALR, or MPL mutation

Minor criteria

1. Presence of a clonal marker (e.g., abnormal karyotype) or absence of evidence for reactive thrombocytosis

From Swerdlow SH, Campo E, Harris NL, Jaffe ES, Pileri SA, Stein H, Thiele J. WHO Classification of Tumours of Haematopoietic and Lymphoid Tissues (Revised Fourth Edition), IARC, 2016.

CML, Chronic myelogenous leukemia; MDS, myelodysplastic syndrome; PMF, primary myelofibrosis; PV, polycythemia vera; WHO, World Health Organization.

^aET diagnosis requires meeting all four major criteria or first three major criteria and one minor criterion.

Clinical Presentation

Up to two thirds of patients are symptomatic. Vasomotor symptoms include headache, dizziness, visual changes, and erythromelalgia (i.e., burning pain and erythema of feet and hands). Serious arterial thrombotic complications such as transient ischemic attacks, strokes, seizures, angina, and myocardial infarctions may occur. Patients may rarely have purpuric skin lesions or hematomas. The risk for gastrointestinal bleeding is less than 5%.

Diagnosis and Differential Diagnosis

Elevated platelet counts (thrombocytosis) can result as a reactive process arising from other causes (e.g., bacterial infections, sepsis, iron deficiency, autoimmune diseases, malignant diseases), which must be excluded before a diagnosis of ET is considered. The diagnosis requires a platelet count exceeding $450,000 \times 10^9/L$ with mutations in *JAK2*, *CALR*, or *MPL* genes and no evidence of reactive thrombocytosis. Bone marrow histology typically displays predominant proliferation involving the megakaryocytic lineage and little or no granulocytic or erythroid proliferation or reticulin fibrosis. Marrow immunohistochemical and cytogenetic studies are essential to exclude myelodysplasia, myelofibrosis, or the Philadelphia chromosome, which are diagnostic of CML (Table 47.4). Unlike PV, the *JAK2 V617F* mutation is only found in one half of samples from patients with ET but the presence of other clonal markers such as an abnormal karyotype can aid in making the diagnosis.

Treatment and Prognosis

Patients with ET have the most favorable outcomes of all patients with MPN with typical long-term survival rates similar to those of age-matched healthy control patients. Similar to PV, shortened overall survival is associated with high-risk features including advanced age (>60 years), prior history of thrombosis, and leukocytosis. The risk of leukemic transformation is extremely low (3% to 4%) compared with other MPNs. However, morbidity from recurrent hemorrhagic and thrombotic complications is high and cannot be reliably predicted from the platelet count or platelet function abnormalities. Because treatment requires

lifelong administration for disease control, assessment of risk factors and a history of clinical signs and symptoms dictate therapeutic choices. All patients benefit from aggressive management of cardiovascular risk factors including smoking, hypertension, obesity, and hypercholesterolemia.

Although low-dose enteric coated aspirin may be used in all patients to relieve neurologic symptoms and carries a minimal risk for bleeding, excessive thrombocytosis (platelet count $>1000 \times 10^9/L$) can be associated with excessive bleeding due to an acquired von Willebrand syndrome.

Although young and pregnant patients are often not treated until they become symptomatic, older patients (>60 years) and those with a history of thrombosis, long disease duration, or significant cardiovascular risk factors are most likely to benefit from the addition of platelet-lowering agents. Hydroxyurea, an oral cytotoxic and myelosuppressive agent, is the most common first-line agent and is usually well tolerated with low long-term leukemogenic risks. Anagrelide, an oral antiplatelet agent that inhibits platelet aggregation and megakaryocyte maturation, is also used, primarily as a second-line agent after hydroxyurea failure. This agent is associated with acute side effects such as fluid retention, palpitations, hemorrhage with concomitant aspirin use, and an increased risk of transformation to myelofibrosis. Both agents are known teratogens and therefore cannot be used in the significant fraction of patients with ET who are young women of childbearing age. Because patients with ET have a high incidence of fetal wastage, interferon- α (a cytokine that alters the biologic mechanisms of the malignant clone but does not cross the placenta) with low-dose heparin or aspirin prophylaxis is recommended to improve pregnancy outcomes in these patients.

PRIMARY (IDIOPATHIC) MYELOFIBROSIS

Definition and Epidemiology

PMF, also known as idiopathic myelofibrosis or previously as agnogenic myeloid metaplasia, is a clonal stem cell disorder characterized by abnormal excessive marrow fibrosis leading to marrow failure and organomegaly. PMF is a rare chronic disease that usually is seen in elderly persons. The annual incidence of PMF is 0.5 cases per 100,000 people.

Etiology

An abnormal myeloid precursor is thought to give rise to dysplastic megakaryocytes that produce increased levels of angiogenic and fibroblast growth factors. These cytokines act on normal fibroblasts and other stromal cells, a process that stimulates excessive proliferation and collagen deposition (E-Fig. 47.1A-C). Over time, increasing fibrosis of the bone marrow leads to premature release of multipotent hematopoietic precursors into the periphery (see E-Fig. 47.1D-E). These cells then migrate and reestablish themselves in other sites, thereby shifting hematopoiesis out of the bone marrow and into other tissues, specifically the spleen and liver. This process is called extramedullary hematopoiesis. Approximately 5% to 10% of cases of MF arise in individuals with prior diagnoses of PV or ET whose disease evolves over time to MF. These cases are referred to as secondary or post-PV/ET MF and are characterized by the same disease biology and clinical symptoms.

Diagnosis and Differential Diagnosis

Early in the disease, patients may be asymptomatic, with incidental findings of abnormal blood counts on routine laboratory tests. Although low blood counts may occur, overall platelet and red blood cell numbers at diagnosis may be increased or normal depending on the degree of compensatory extramedullary hematopoiesis. Review of the peripheral blood profile commonly reveals leukoerythroblastic changes characterized by teardrop-shaped erythrocytes, giant platelets, and nonleukemic immature myeloid, erythroid, and leukocyte cells.

TABLE 47.5 Causes of Bone Marrow Fibrosis

I. Neoplastic causes
a. Chronic myeloproliferative disorders: chronic idiopathic myelofibrosis, chronic myelogenous leukemia, polycythemia vera
b. Acute megakaryoblastic leukemia
c. Myelodysplasia with myelofibrosis
d. Hairy cell leukemia
e. Acute lymphoblastic leukemia
f. Multiple myeloma
g. Metastatic carcinoma
h. Systemic mastocytosis
II. Non-neoplastic causes
a. Granulomatous diseases: mycobacterial infections, fungal infections, sarcoidosis
b. Paget's disease of bone
c. Hypoparathyroidism or hyperparathyroidism
d. Renal osteodystrophy
e. Osteoporosis
f. Vitamin D deficiency
g. Autoimmune diseases: systemic lupus erythematosus, systemic sclerosis

Diagnosis of PMF is made by demonstration of bone marrow fibrosis with markedly increased reticulin or collagen fibers or increased marrow cellularity. Other underlying causes of neoplastic and non-neoplastic bone marrow fibrosis (Table 47.5) should be ruled out. Testing for *JAK2*, *BCR/ABL*, or other diagnostic mutations and cytogenetic markers should be performed before a diagnosis of PMF is made (Table 47.6). In some cases, early prefibrotic changes in the marrow have been noted that signify an early phase of MF development.

Clinical Presentation

Although many patients are asymptomatic at diagnosis, most complain over time of progressive fatigue and dyspnea related to anemia or early satiety and left upper quadrant pain associated with splenomegaly and splenic infarction. More than one half of these patients develop massive hepatosplenomegaly due to extramedullary hematopoiesis. Patients with more advanced disease typically have constitutional symptoms such as fever, weight loss, night sweats, cachexia, pruritus, and bone pain, which may be debilitating. As the bone marrow failure evolves, complications of neutropenia, thrombocytopenia, and anemia develop as a result of ineffective hematopoiesis due to fibrotic changes and loss of marrow cellularity. Bleeding from occult disseminated intravascular coagulation is a risk as are infections arising from neutropenia. Extramedullary hematopoiesis in the peritoneal and pleural cavities and in the central nervous system (CNS) may also cause symptoms.

Treatment and Prognosis

Median survival of patients with PMF is poor, ranging from 2 to 5 years after diagnosis. The most commonly accepted adverse prognostic factors at onset include age greater than 65 years, hemoglobin concentration of less than 10 g/dL, leukocyte count of more than $25 \times 10^9/L$, a high percentage of circulating blasts ($\geq 1\%$), and constitutional symptoms. Other important clinical factors are leukopenia, thrombocytopenia (platelets $<100 \times 10^9/L$), massive hepatosplenomegaly, red cell transfusion needs, and unfavorable cytogenetic abnormalities. Over time, the disease may progress from a chronic phase to an accelerated phase, with acute leukemic transformation in 8% to 20% of patients. Treatment of PMF-related AML

E-Fig. 47.1 (A) Marrow biopsy with disorganized hematopoiesis due to unsuspected myelofibrosis (*bottom*) is compared with a crush artifact (*top*) (periodic acid–Schiff stain, $\times 50$). (B) Corresponding reticulin stain shows a diffuse increase in overall marrow fibrosis with few marrow cells ($\times 100$). (C) Corresponding collagen stain shows an increase in coarse (*blue*) collagen fibers ($\times 100$). Diffuse deep blue and red staining is seen in the bone trabeculae (*left*). Disorganized and disorderly granulopoiesis with an increase in immature forms and two large dysplastic hypolobulated megakaryocytes can be seen ($\times 100$). (D) Leukoerythroblastosis in peripheral blood smear shows a myeloblast, two hypogranular band neutrophils, a monocyte, and a nucleated erythrocyte (Wright-Giemsa stain, $\times 250$). (E) Teardrop-shaped, anucleate red cells and a normoblast can be seen in the peripheral blood smear (Wright-Giemsa stain, $\times 250$). (Courtesy Maurice Barcos, MD PhD, Dept Hematopathology, Roswell Park Comprehensive Cancer Center, Buffalo, NY.)

TABLE 47.6 World Health Organization 2016 Diagnostic Criteria for Primary Myelofibrosis**Primary Myelofibrosis (PMF): Prefibrotic/Early PMF (pre-PMF)**Major criteria^a

1. Megakaryocyte proliferation and atypia **without reticulin fibrosis > grade 1**, accompanied by increased age-adjusted bone marrow cellularity, granulocytic proliferation, and often decreased erythropoiesis
2. Not meeting WHO criteria for *BCR-ABL1*+ CML, PV, MDS, or other myeloid neoplasm
3. Presence of *JAK2*, *CALR*, or *MPL* mutation or in the absence of minor reactive bone marrow reticulin fibrosis

Minor criteria

1. Presence of one or more of the following, confirmed in two consecutive determinations
 - a. Anemia not attributed to a comorbid condition
 - b. Leukocytosis $\geq 11 \times 10^9/L$
 - c. Palpable splenomegaly
 - d. LDH level above the upper limit of the institutional reference range

Primary Myelofibrosis (PMF)Major criteria^a

1. Megakaryocyte proliferation and atypia accompanied by either reticulin and/or collagen fibrosis (grade 2 to 3)
2. Not meeting WHO criteria for *BCR-ABL1*+ CML, PV, MDS, or other myeloid neoplasm
3. Presence of *JAK2*, *CALR*, or *MPL* mutation or in the absence, the presence of another clonal marker^b or absence of evidence for reactive bone marrow fibrosis

Minor criteria

1. Presence of one or more of the following, confirmed in two consecutive determinations
 - a. Anemia not attributed to a comorbid condition
 - b. Leukocytosis $\geq 11 \times 10^9/L$
 - c. Palpable splenomegaly
 - d. LDH level above the upper limit of the institutional reference range
 - e. Leukoerythroblastosis

From Swerdlow SH, Campo E, Harris NL, Jaffe ES, Pileri SA, Stein H, Thiele J. WHO Classification of Tumours of Haematopoietic and Lymphoid Tissues (Revised Fourth Edition), IARC, 2016.

^aDiagnosis of prefibrotic/early PMF requires all three major criteria and at least one minor criterion. Diagnosis of overt PMF requires meeting all three major criteria and at least one minor criterion.

^bIn the absence of any of the three major clonal mutations, the search for the most frequent accompanying mutations (*ASXL1*, *EZH2*, *TET2*, *IDH1*, *IDH2*, *SRFS2*, *SF3B1*) are of help in determining the clonal nature of the disease.

is usually ineffective. Other causes of nonleukemic death include heart failure, infection, intracranial hemorrhage, and pulmonary embolism.

Medical therapy for PMF is predicated on the risk category of patients. Low-risk, asymptomatic patients may be treated expectantly. All patients with symptomatic anemia benefit from palliative transfusions and administration of recombinant EPO, androgens (e.g., danazol), or low-dose thalidomide or thalidomide derivatives (i.e., lenalidomide) with or without steroids to maintain adequate red blood cell levels. Symptoms caused by excess thrombocytosis and leukocytosis or progressive extramedullary hematopoiesis may be managed with hydroxyurea as a first-line agent or pegylated interferon- α in younger or pregnant patients. Enlarging splenomegaly is best managed with medical therapy because open splenectomy is associated with significant operative morbidity and mortality, and splenic irradiation is poorly tolerated except as a palliative approach. Young patients with intermediate- to high-risk PMF and possible HLA-matched donors should be considered for potentially curative allogeneic stem cell transplantation (SCT) at academic medical centers.

Although not all patients with PMF have the *JAK2 V617F* mutation, almost all have constitutive activation of the JAK1 and JAK2 signaling pathways, rendering them potentially responsive to treatment with novel JAK1/2 inhibitors. Ruxolitinib is the first oral JAK inhibitor approved for the treatment of patients with intermediate- or high-risk myelofibrosis independent of *JAK2* mutational status, including PMF and myelofibrosis arising from prior PV or ET. In two prospective, randomized, phase III clinical trials, ruxolitinib therapy for myelofibrosis patients was compared with placebo (COMFORT-I trial) and

with best available therapy (COMFORT-II trial), respectively. Patients receiving ruxolitinib had significantly greater spleen volume reduction and overall symptom improvement in abdominal pain, early satiety, night sweats, and muscle pain, all of which correlated with overall improvement in quality of life. Updates from both trials have demonstrated significantly prolonged overall survival in the ruxolitinib-treated patients compared with control arms although neither study was designed with this as an end point. Side effects of ruxolitinib include cytopenias, specifically anemia, occurring in the first 6 to 8 weeks of therapy as well as headache, dizziness, and increased risk of herpes simplex virus (HSV) reactivation. Recently a second JAK2 inhibitor, fedratinib, was approved for the treatment of intermediate and high-risk MF as an alternative to and/or failing prior ruxolitinib therapy. Other JAK2 inhibitors are in active clinical development as single agents. Combination therapies evaluating the safety and efficacy of novel mechanistic agents alone and in addition to JAK2 inhibitors are also underway with preliminary results suggesting that even more effective therapies for PMF may be on the horizon.

CHRONIC MYELOGENOUS LEUKEMIA**Definition, Epidemiology, and Pathology**

CML is the most common MPN, accounting for 15% to 20% of all leukemias and occurring in 1 of 100,000 people. The median age at diagnosis is 53 years, but patients of any age may be affected. CML is characterized by a predominant increase in the granulocytic cell line associated with concurrent erythroid and platelet hyperplasia. It is

TABLE 47.7 Definition of Phases of Chronic Myeloid Leukemia

Phase	Definition	Goal of Therapy
Chronic phase (CP)	<10% blasts <20% peripheral blood basophils	Prevent progression to AP/BP, eradicate molecular <i>BCR-ABL</i>
Accelerated phase (AP)	Peripheral blood myeloblasts \geq 10% and <20% Peripheral blood myeloblasts and promyelocytes combined \geq 30% Peripheral blood basophils \geq 20% Platelet count \leq 100 \times 10 ⁹ /L unrelated to therapy Additional clonal cytogenetic abnormalities in Ph+ cells	Control CBC, bring back to CP and avoid progression to BP
Blast phase (BP)	\geq 20% blasts (myeloid or lymphoid) in peripheral blood, marrow, or both Extramedullary infiltrates of leukemic cells	Acute leukemia therapy, bridge to allogeneic stem cell transplant

unique among the MPNs in its etiology and natural history, including an inevitable transformation to acute leukemia if untreated. CML was the first malignant hematologic disease shown to be associated with a specific chromosomal abnormality. More than 95% of patients with CML have a clonal expansion of a stem cell that has acquired the Philadelphia chromosome, a balanced translocation between chromosomes 9 and 22 designated as t(9;22) (q34;q11). This translocation juxtaposes the *ABL* gene from chromosome 9 (region q34) to the *BCR* gene on chromosome 22 (region q11) and generates an oncogenic *BCR/ABL* fusion gene. The gene product, the BCR/ABL protein, is a deregulated, constitutively active cytoplasmic receptor tyrosine kinase that induces a leukemic phenotype in hematopoietic stem cells. Expression of the BCR/ABL fusion protein activates multiple downstream signal transduction pathways which permits proliferation independent of cytokine and stromal regulation and renders cells resistant to chemotherapy and normal programmed cell death.

Diagnosis and Differential Diagnosis

Laboratory tests for CML patients typically demonstrate a markedly elevated white blood cell count (median, $170 \times 10^9/L$), with low leukocyte alkaline phosphatase levels, high uric acid and lactate dehydrogenase levels, and thrombocytosis. Review of the peripheral blood smear in chronic phase CML demonstrates a full complement of myeloid cells in all stages of granulocytic development, including immature myeloblasts (usually <5%), myelocytes, metamyelocytes, basophils, eosinophils, bands, and neutrophils. In contrast, the peripheral blood smear in reactive granulocytic hyperplastic states (i.e., leukemoid reaction) caused by acute infection or sepsis consists predominantly of mature neutrophils and bands with few myelocytes, basophils, or eosinophils. The bone marrow in CML is densely hypercellular, with an overwhelming predominance of myeloid cells at all developmental stages (E-Fig. 47.2). The differential diagnosis of CML includes reactive leukocytosis (e.g., in active infection or sepsis with a profound neutrophilic response) and other MPNs (e.g., myelofibrosis).

Detection of the Philadelphia chromosome on standard cytogenetic studies and/or abnormal BCR/ABL transcripts using reverse transcription–polymerase chain reaction (RT-PCR) or fluorescent in situ hybridization (FISH) analysis is required for the diagnosis of CML. Assessment of the *BCR/ABL* fusion gene by the same methods is used to monitor disease and response to therapy. Exquisitely sensitive and quantitative RT-PCR procedures allow detection of up to a single BCR/ABL-positive cell in 10^5 to 10^6 peripheral cells and permit measurement of disease status in peripheral blood and marrow samples. A subset of patients with CML lacking a detectable Philadelphia chromosome was found to possess detectable BCR/ABL fusion products by RT-PCR, indicating a subchromosomal translocation resulting in the same pathologic gene product.

Clinical Presentation

Up to 40% of newly diagnosed CML patients are initially asymptomatic with diagnoses made on incidental laboratory results. Other patients exhibit fatigue, lethargy, shortness of breath, weight loss, easy bruising, and early satiety. Physical examination usually detects splenomegaly.

The natural history of CML is divided into three phases: chronic, accelerated, and blast phases (Table 47.7). The majority of patients are typically diagnosed during the *chronic phase of CML*, an indolent stage lasting 3 to 7 years. Peripheral white blood cell counts are elevated, with eosinophilia and basophilia (>20%) but few peripheral or marrow blasts (<5%). With control of peripheral blood cell counts, patients are essentially asymptomatic during this period.

Eventually, the disease enters the *accelerated phase*, which is characterized by fever, weight loss, worsening splenomegaly, and bone pain related to rapid marrow cell turnover. The white blood cell count rises with increased numbers of circulating or marrow blasts ranging from 10% to 19%. The increased percentage of peripheral blood basophils (>20%) results in histamine production, with symptoms of pruritus, diarrhea, and flushing. During this phase, patients may develop increasing splenomegaly, persistent thrombocytopenia, or thrombocytosis and leukocytosis, with new clonal cytogenetic abnormalities found in marrow cells.

CML blast crisis phase marks the evolution to acute leukemia, in which marrow is replaced by 20% or more immature myeloid or lymphoid blasts, with accompanying loss of normal mature cellular elements in the marrow and periphery and extramedullary blast proliferation. Untreated patients typically die in a few weeks to months. Of note, two thirds of patients develop acute myeloid leukemia, whereas the others develop acute lymphoblastic leukemia, a finding confirming that the initial neoplastic cell is an early stem cell capable of multilineage differentiation.

Treatment

Chronic Phase CML

Historically, oral cytotoxic agents such as hydroxyurea and busulfan effectively reduced myeloid cell numbers in patients with chronic phase CML but did not alter the long-term prognosis or prevent progression to blast crises.

Oral receptor tyrosine inhibitors of BCR-ABL are the mainstay of current therapy for CML. The first identified inhibitor, imatinib mesylate (formerly known as STI-571), was heralded as the first successful targeted therapy for cancer and ushered in a new era of cancer therapy. Imatinib is a rationally designed competitive oral inhibitor of multiple tyrosine kinases, including ABL, BCR/ABL, platelet-derived growth-factor receptor (PDGFR), and KIT. Inhibition of phosphorylation of BCR/ABL results in blockade of downstream signaling and growth pathways and induces apoptosis of BCR-ABL-positive cells. Preclinical studies demonstrated that imatinib potently inhibited the

E-Fig. 47.2 (A) Marrow biopsy with a leukemoid reaction shows marked advanced granulocytic hyperplasia with a predominance of band and segmented neutrophils (Wright-Giemsa stain, $\times 100$). (B) Leukemoid reaction in the peripheral blood smear shows two myelocytes and numerous segmented granulocytes. An erythrocyte rouleaux formation is also seen (Wright-Giemsa stain, $\times 100$). (C) Marrow biopsy (fat-to-cell ratio of 0:100) in chronic myelogenous leukemia (CML) shows a preponderance of periodic acid–Schiff (PAS)-positive myelocytes. A small cluster of PAS-negative erythroid precursors, a megakaryocyte, and several phagocytes are also seen (PAS stain, $\times 100$). (D) Marrow smear in CML shows disorderly granulopoiesis with increased myelocytes relative to metamyelocytes (i.e., hiatus leukemicus) and frequent mature forms (Wright-Giemsa stain, $\times 250$). (E) Peripheral blood smear in CML shows two myeloblasts, one myelocyte, one metamyelocyte, one segmented neutrophil, one eosinophil, and marked thrombocytosis (Wright-Giemsa stain, $\times 100$). (F) Another field in the blood smear of the same patient shows increased numbers of basophils (Wright-Giemsa stain, $\times 250$). (G) The peripheral thrombocytosis in the same case includes medium-sized and giant platelets (the latter are the same size as the erythrocytes) (Wright-Giemsa stain, $\times 250$). (Courtesy Maurice Barcos, MD, PhD, Dept Hematopathology, Roswell Park Comprehensive Cancer Center, Buffalo, NY.)

TABLE 47.8 Criteria for Hematologic, Cytogenetic, and Molecular Response and Relapse in Chronic Myeloid Leukemia

Complete hematologic response

- Complete normalization of peripheral blood counts with leukocyte count $<10 \times 10^9/L$
- Platelet count $<450 \times 10^9/L$
- No immature cells, such as myelocytes, promyelocytes, or blasts in peripheral blood
- No signs and symptoms of disease with resolution of palpable splenomegaly

Cytogenetic response

- Complete cytogenetic response (CCyR): No Ph-positive metaphases
- Major cytogenetic response (MCyR): 0-35% Ph-positive metaphases
- Partial cytogenetic response (PCyR): 1-35% Ph-positive metaphases
- Minor cytogenetic response: >35 -65% Ph-positive metaphases

Molecular response

- Early molecular response (EMR): *BCR-ABL1* (IS) $\leq 10\%$ at 3 and 6 months
- Major molecular response (MMR): *BCR-ABL1* (IS) $\leq 0.1\%$ or ≥ 3 -log reduction in *BCR-ABL1* mRNA from the standardized baseline, if qPCR (IS) is not available
- Complete molecular response (CMR) is variably described and is best defined by the assay's level of sensitivity (e.g., MR4.5)

Relapse

- Any sign of loss of response (defined as hematologic or cytogenetic relapse)
- 1-log increase in *BCR-ABL1* transcript levels with loss of MMR should prompt bone marrow evaluation for loss of CCyR but is not itself defined as relapse (e.g., hematologic or cytogenetic relapse)

TABLE 47.9 Oral BCR-ABL1 Inhibitors for CML Therapy

Drug Name	Drug Dose	Toxicity Profile
Imatinib mesylate	400 mg po daily	Nausea, vomiting, diarrhea, peripheral and periorbital edema, myalgias, myelosuppression, increased liver function tests, rash, pleural and pericardial effusion
Dasatinib	100 mg po daily	Pulmonary arterial hypertension, pleural and pericardial effusions, headache, myelosuppression, cerebral hemorrhage (rare), ascites, peripheral or pulmonary edema
Nilotinib	400 mg po twice a day (avoid food 2 hrs before and 1 hr after drug)	Peripheral arterial occlusive disease, QTC prolongation, pancreatitis, hepatotoxicity, myelosuppression, hyperglycemia, sudden death, rash
Bosutinib	500 mg po daily	Diarrhea, myelosuppression, liver function abnormalities, fluid retention (pulmonary or peripheral edema, pleural and pericardial effusion), GI upset, rash
Ponatinib	15-45 mg po daily (45 mg daily until remission, then 15-30 mg)	Arterial and venous thrombosis and occlusions including fatal myocardial infarction and stroke (up to 35% of patients), heart failure, hepatotoxicity, cardiovascular risk, severe skin rash, pancreatitis, hepatotoxicity, hemorrhage (cerebral, gastrointestinal), cardiac arrhythmias, fluid retention, hypertension, rash, myelosuppression
Ascimimab (phase 1 trial)	Not yet determined	Pancreatitis, increased lipase levels, fatigue, headache, arthralgias, hypertension, thrombocytopenia

growth of BCR/ABL-expressing CML cell lines and progenitor cells in vitro and prolonged survival in animal tumor models.

Responses to BCR-ABL1 inhibitor treatment for CML are defined as hematologic (i.e., restoration of normal peripheral blood cell counts), cytogenetic (i.e., loss of the Philadelphia chromosome determined by normal karyotypic or FISH analysis), and molecular (i.e., a three log or greater reduction of detectable *BCR/ABL* transcripts below a standard baseline by RT-PCR) remissions (Table 47.8). After diagnosis, patients are typically started on tyrosine kinase inhibitor (TKI) therapy with careful interim monitoring for toxicities and clinical response. Standardized RT-PCR assays for *BCR/ABL* are used to measure disease response on a molecular level at 3, 6, and 12 months after therapy initiation. Initial clinical trials of imatinib in 1998 were notable for a hematologic remission rate of 96% in patients receiving a dose greater than 300 mg per day for 4 weeks. One third of individuals obtained cytogenetic remission after 8 weeks. Imatinib was shown to be superior to these prior therapies in individuals with newly diagnosed chronic phase CML with complete cytogenetic responses in almost 90% of patients and an overall survival of 89%. The fact that patients achieving remission could have stable disease for years, even

decades, demonstrated conclusively that this agent could effectively alter the natural history of this disease.

Despite these results, most patients achieving cytogenetic responses on imatinib demonstrate persistence of *BCR/ABL*-positive leukemic CML stem cells by sensitive molecular testing. Lifelong imatinib therapy may be required to control disease, and even patients with excellent control of chronic phase CML on imatinib therapy remain at risk for eventual disease progression and therapy failure due to development of imatinib-resistant CML cells and/or non-compliance. It is estimated that up to one third of chronic phase CML patients initiated on imatinib therapy will eventually discontinue the drug due to long-term intolerance of drug-induced side effects (e.g., nausea, vomiting, gastrointestinal issues, peripheral and periorbital edema) or development of imatinib resistance.

To address these issues, four new generation TKIs of BCR/ABL have been developed for the treatment of CML: dasatinib, nilotinib, bosutinib, and ponatinib (Table 47.9). All display increased in vitro potency against the BCR/ABL kinase compared with imatinib. At present, four (imatinib, dasatinib, nilotinib, bosutinib) are indicated for initial therapy of chronic phase CML. Multiple randomized clinical

TABLE 47.10 Scoring Systems for Risk Calculation in Newly Diagnosed Chronic Myeloid Leukemia

Risk Score	Calculation	Risk Category
Sokal score ¹	$\text{Exp } 0.0116 \times (\text{age} - 43.4) + 0.0345 \times (\text{spleen} - 7.51) + 0.188 \times [(\text{platelet count} \div 700)^2 - 0.563] + 0.0887 \times (\text{blasts} - 2.10)$	Low <0.8 Intermediate 0.8 – 1.2 High >1.2
Hasford (EURO) score ²	$(0.6666 \times \text{age} [0 \text{ when age } <50 \text{ years; } 1, \text{ otherwise}] + 0.042 \times \text{spleen size [cm below costal margin]} + 0.0584 \times \text{percent blasts} + 0.0413 \times \text{percent eosinophils} + 0.2039 \times \text{basophils} [0 \text{ when basophils } <3\%; 1, \text{ otherwise}] + 1.0956 \times \text{platelet count} [0 \text{ when platelets } <1500 \times 10^9/\text{L; } 1, \text{ otherwise}]) \times 1000$	Low ≤ 780 Intermediate >780– ≤ 1480 High >1480
EUTOS long-term 3 survival (ELTS) score	$0.0025 \times (\text{age}/10)^3 + 0.0615 \times \text{spleen size cm below costal margin} + 0.1052 \times \text{blasts in peripheral blood} + 0.4104 \times (\text{platelet count}/1000) - 0.5$	Low ≤ 1.5680 Intermediate >1.5680 but ≤ 2.2185 High >2.2185

Online calculator for the ELTS score can be found at: https://www.leukemia-net.org/content/leukemias/cml/elts_score/index_eng.html.

Calculation of relative risk based on Sokal or Hasford (EURO) score can be found at: https://www.leukemia-net.org/content/leukemias/cml/euro_and_sokal_score/index_eng.html.

trials comparing imatinib versus dasatinib or nilotinib or bosutinib in patients with newly diagnosed chronic phase CML confirmed that these newer generation TKIs outperformed imatinib as reflected by significantly higher numbers of patients achieving complete cytogenetic and molecular responses at specific time points as compared with imatinib-treated individuals. To date, however, none of these newer TKIs have significantly improved long-term overall or transformation-free survival over imatinib. Moreover, while each of these new generation TKIs have been compared in a randomized fashion with imatinib, none have been compared with any TKI other than imatinib. For this reason, recently available generic imatinib formulations continue to be recommended as the mainstay of upfront therapy for chronic phase CML.

Different scoring systems (Table 47.10) have been developed to predict the outcomes of newly diagnosed chronic phase CML patients. These scores use patient age, spleen size, platelet number, and percentage of myeloblasts as well as peripheral basophilia and eosinophilia to divide patients into low-, intermediate-, and high-risk disease. In the current era of TKI therapy, achievement of cytogenetic and molecular milestones within the first year of therapy has proven to be much more predictive of clinical outcome than these scoring systems. However, calculation of these scores has proven useful to guide selection of upfront therapy at initial presentation. Patients with low and intermediate risk scores may be assigned to standard dose imatinib while higher-risk, particularly younger patients, presenting with very high white blood cell counts and/or massive splenomegaly, may be considered for second-generation TKIs (dasatinib, nilotinib, bosutinib). Alternatively, if imatinib is used in higher-risk patients, closer monitoring for need to switch to another TKI may be warranted. Lastly, given the myriad of TKI agents available for upfront therapy, the excellent overall response (>90% for all TKIs), and the possibility that patients may need to remain on therapy for years if not the rest of their lives, consideration of other factors impacting long-term tolerability and compliance are now given increased importance in drug selection. These include patient preference (i.e., for once a day vs. twice a day administration, with food vs. empty stomach), other medical comorbidities (i.e., cardiovascular vs. pulmonary vs. gastrointestinal) that may be exacerbated by specific TKI associated toxicities, and drug-drug interactions (i.e., proton pump inhibitors and dasatinib) (see Table 47.9).

Perhaps the best indicator of the clinical success of BCR-ABL inhibitor therapy for CML is the fact that it is now possible (with careful monitoring) to permanently discontinue TKI therapy in a proportion of patients with chronic phase disease who have achieved optimal

durable molecular responses on therapy. Candidates for “TKI discontinuation therapy” are individuals with chronic phase CML treated with an approved TKI agent for at least 3 years and who have obtained major molecular responses lasting for at least 2 years. Importantly, patients should have no history of accelerated or blast phase CML or demonstrated clinical or mutational resistance to prior TKI therapy. They must also be willing to undergo monthly to bimonthly visits for at least 2 years after drug discontinuation for frequent molecular testing. Although nilotinib is the only TKI with a regulatory indication for drug discontinuation, results of multiple clinical trials suggest that stopping any TKI in patients meeting these criteria results in 40% to 50% success rate (i.e., patients able to eventually permanently stop therapy). The remaining 50% to 60% will experience recurrence of disease as reflected by reemergence of molecular detectable disease by qPCR. If detected early, almost all (detected by reemergent *BCR-ABL* transcripts off therapy) can resume TKI therapy with re-achievement of major molecular remission. Some patients develop mild to severe musculoskeletal symptoms after discontinuing TKI (termed “TKI withdrawal syndrome”), which is managed with symptomatic medications.

The most common therapeutic strategy for chronic phase CML patients intolerant of or resistant to first-line TKI therapy based on lack of achievement of molecular and cytogenetic milestones is to switch to another TKI. Mutational analysis at the time of relapse (see Table 47.9) is essential because up to one half of CML patients who develop resistance to imatinib have cancer cells carrying single-nucleotide mutations in the *BCR/ABL* gene. These mutations result in conformational changes of the BCR/ABL kinase, altering drug binding and inhibitory effects. For this reason, it is recommended that patients requiring second-line therapy or beyond undergo testing for identification of mutations as a potential guide to therapy. CML patients with disease associated with a mutation at *T315I* are known to be resistant to imatinib, nilotinib, dasatinib, and bosutinib, but not to ponatinib, a third-generation BCR/ABL inhibitor. Use of ponatinib, a highly potent third-generation BCR-ABL inhibitor, is restricted to individuals with chronic, accelerated or blast phase CML who have failed and/or been intolerant to at least two prior TKI therapies or whose mutational testing demonstrates a *BCR-ABL T315I* tyrosine kinase domain mutation conferring resistance to all other TKIs. Ponatinib is not recommended for the treatment of patients with newly diagnosed chronic phase CML due to adverse events of arterial occlusion (including fatal myocardial infarction, stroke, and severe peripheral vascular disease occurring in up to 35% of patients), venous thromboembolism, heart

failure, and hepatotoxicity. In patients with CML that has failed three or more TKIs, treatment with asciminib, a novel allosteric inhibitor of BCR-ABL, has shown promising activity. This agent binds a myristoyl site of BCR-ABL1 protein and thereby locks BCR-ABL1 into an inactive conformation through a mechanism distinct from all other ABL kinase inhibitors. Because asciminib targets both native and mutated BCR-ABL1, it is also effective against CML cells harboring the gatekeeper *T315I* mutation. In a phase 1 trial, almost half (48%) of patients achieved a major molecular response in 12 months, including 8 of 14 patients with prior intolerance or resistance to ponatinib.

Patients whose disease does not respond and/or who are intolerant of multiple TKIs also may receive treatment with omacetaxine mepe-succinate, a natural alkaloid product with proven antitumor activity and efficacy in CML. Its mechanisms of action are distinct from the TKIs and involve inhibition of protein synthesis and induction of apoptosis in tumor cells. Several clinical trials have confirmed the activity of this agent in patients with CML failing multiple TKIs and/or carrying the *T315I* mutation. A major drawback is the need for subcutaneous injections administered twice daily for 7 to 14 days of every 28 days per month and treatment-associated myelosuppression that may warrant dose reduction or interruption.

Accelerated and Blast Phase CML

Unfortunately, the majority of patients with accelerated or blast phase CML treated with new-generation TKI therapies experience only transient hematologic and cytogenetic responses. For these patients, the optimal treatment modality remains TKI therapy with newer-generation agents with or without additional chemotherapy or clinical trials followed by allogeneic stem cell transplantation (alloSCT). The novel allosteric BCR-ABL inhibitor, asciminib, reportedly induced hematologic responses in seven of eight patients with accelerated phase CML with a median duration of response of greater than 11 months. Blast phase CML patients often undergo induction chemotherapy with acute leukemia regimens with concomitant BCR/ABL inhibition. Transplantation, however, remains the only known curative therapy for these patients. Prior to the advent of targeted BCR/ABL kinase inhibitor therapy, young patients with an HLA-matched donor were routinely offered potentially curative alloSCT at the time of diagnosis of chronic phase CML. Evidence indicated that the excellent response (50% to 75%) of CML patients to SCT was partly related to the active suppression of the disease by the newly transplanted graft, called the *graft-versus-leukemia effect*. At present, in the face of the excellent control and low overall toxicity of long-term BCR/ABL inhibitors for chronic phase CML, together with the known 20% to 30% mortality and morbidity rates after alloSCT, transplantation is now viewed as an option only for patients with accelerated or blast phase disease or chronic phase CML failing multiple lines of prior therapy. Following alloSCT, it is now considered standard of care to resume TKI maintenance therapy for at least 12 months in the post-transplant setting to prevent disease relapse.

Prognosis

Overall, the transformation of CML from a progressively fatal cancer to one in which almost 90% of patients are alive with stable disease on oral kinase therapy and 10% can permanently discontinue therapy after 5 years remains one of the crowning achievements in cancer therapy in the past decade. The median overall survival for chronic phase CML patients has risen dramatically from a few months to a few years in the first half of the 20th century to 6 years for interferon-treated patients. In the era of BCR/ABL inhibition therapy, overall lifespan is expected to be almost normal for most patients on long-term TKI therapy with multiple studies demonstrating that the risk of death in these

individuals occurs not due to CML-related complications but rather to increased cardiac and vascular causes. For this reason, a focus of current CML practice is determining how best to balance the long-term toxicities of TKI therapy with its benefits. Although standard of care for CML patients who are responding optimally to treatment remains indefinite continuation of TKI therapy, selected individuals with sustained excellent molecular responses to TKI therapy for at least 3 years are now eligible to discontinue therapy with a 40% to 50% long-term success rate. Despite this therapeutic advance, a true cure for CML disease remains elusive for the majority of patients. Ongoing clinical studies are focused on strategies to further enhance this percentage by targeting CML stem cells and via combinatorial TKI approaches.

ACUTE LEUKEMIAS

Definition and Epidemiology

The acute leukemias are clinically aggressive clonal hematopoietic diseases arising from the malignant transformation of an early hematopoietic stem cell. In adults, acute leukemias are relatively uncommon and occur in 8 to 10 of 100,000 people (compared with 42 of 100,000 for prostate cancer and 62 of 100,000 for breast cancer). Acute leukemias are classified by cell lineage as AML or acute lymphocytic or lymphoblastic leukemia (ALL) based on morphology, cytogenetics, cell surface and cytoplasmic markers, and molecular studies. Between 80% and 90% of leukemia diagnoses in adults are AML. In contrast, 80% to 90% of leukemias in infants and children are ALL, and they constitute the most common cancer diagnosed in this age group.

Pathology

The pathogenesis of acute leukemia is complex and characterized by a high degree of biologic heterogeneity. Many patients with acute leukemia have detectable characteristic clonal chromosomal abnormalities and mutations that drive malignant transformation of normal hematopoietic stem cells bearing myeloid or lymphoid lineage markers. The resultant unchecked proliferation of these immature cells incapable of further differentiation (i.e., blasts) results in marrow replacement by malignant cells, peripheral leukocytosis, with and without severe cytopenias, and rapid hematopoietic failure. Known risk factors for leukemia include high-dose radiation exposure and occupational exposure to chemicals including benzene. Up to 10% of patients with prior malignancies treated with myelosuppressive chemotherapy and/or radiation develop “therapy-related” AML (t-AML). Individuals with t-AML with previous chemotherapy have usually received alkylating agents (e.g., chlorambucil, melphalan, nitrogen mustard) or topoisomerase II inhibitors (e.g., epipodophyllotoxins). Patients with chromosomal instability disorders such as Down syndrome, Bloom syndrome, Fanconi anemia, and ataxia telangiectasia also have an increased incidence of leukemia.

Diagnosis and Differential Diagnosis

To make the distinction between AML and ALL is crucial diagnostically, therapeutically, and prognostically. AML can be distinguished from ALL by cell morphology and the finding of Auer rods (sometimes multiple ones in acute promyelocytic leukemia cells), which are formed by the aggregation of myeloid granules (E-Fig. 47.3C). Further immunophenotyping of blast cells using cell surface antigens, cytochemistry, and immunohistochemistry confirms cells as having a myeloid or lymphoid origin. Morphologic subgroups of ALL and AML were originally defined by the French-American-British (FAB) classification and most recently by the 2016 World Health Organization (WHO) classification, which incorporates newer biologic information, specifically mutations and recurrent cytogenetic aberrations (Table 47.11).

E-Fig. 47.3 (A) Biopsy of acute myelocytic leukemia with maturation shows myeloblasts, promyelocytes, and a myelocyte. (B) Corresponding myeloperoxidase positivity. (C) In the sample of acute promyelocytic leukemia with t(15;17), notice the cytoplasmic hypergranulation and multiple Auer rods in the middle cell. (D) In the sample of acute monoblastic and monocytic leukemia, notice the monoblasts, promonocytes, and monocytes. Clinical Presentation

Patients exhibit clinical evidence of bone marrow failure similar to other hematopoietic disorders. Complications of disease include anemia, infection, and bleeding from peripheral cytopenias. Proliferating blasts infiltrating the bone marrow may cause bone pain. Blasts may also invade other organs and lead to peripheral, mediastinal, and abdominal lymphadenopathy, hepatosplenomegaly, skin infiltration, and meningeal involvement.

Treatment

Therapy for acute leukemias is divided into several stages. *Induction therapy* is directed at reducing the number of leukemic blasts to an undetectable level and restoring normal hematopoiesis (i.e., complete remission). At complete remission, however, significant subclinical disease persists, requiring further therapy. Subsequent *consolidation therapy* involves continuing chemotherapy with the same agents to induce elimination of additional leukemic cells. With development of a wider range of effective agents, *intensification therapy* has been introduced. It involves the use of high-dose therapy with different non-cross-reactive drugs to eliminate cells with potential primary resistance to the induction regimen. *Maintenance therapy* employs low-dose, intermittent chemotherapy given over a prolonged period to prevent subsequent disease relapse. The goal of therapy is to induce remission (>5% blasts in the bone marrow and recovery of normal peripheral blood counts).

Prognosis

Adverse clinical prognostic factors for AML and ALL are similar despite widely different treatment approaches. In both leukemias, cytogenetic and molecular abnormalities represent the best independent predictors of overall survival (Tables 47.11, 47.12, and 47.13). Clinical factors that predict a poor outcome differ by specific leukemia type but generally include older age (>35 years in ALL, >60 years for AML), secondary or therapy-related disease, antecedent hematologic disorder, high initial leukocyte count (50 to 100 × 10⁹/L), poor performance status and comorbidities, extramedullary disease, prolonged time (>4 weeks) or lack of response to initial treatment, and presence of detectable minimal residual disease (MRD) despite morphologic remission.

Acute Myeloid Leukemia

Definition and Epidemiology

AML represents a biologically heterogeneous group of neoplasms with widely divergent clinical outcomes. Long-term cure rates (survival >5 years) range from 5% to 60% after chemotherapy alone, with an overall cure rate of 20% to 30%. AML occurs primarily in older adults, with a median age at diagnosis of 65 years.

Clinical Presentation

Patients most often have complications related to progressively severe cytopenia, such as infection due to leukopenia, shortness of breath or fatigue due to anemia, or bleeding due to thrombocytopenia. AML patients may also have unique acute clinical emergencies requiring immediate stabilization. Leukostasis (i.e., hyperleukocytosis syndrome) caused by high levels of circulating blasts (>80,000 to 100,000) leads to diffuse pulmonary infiltrates and acute respiratory distress. Blast cells may also injure surrounding vasculature, causing life-threatening CNS bleeding and thromboses. High blast cell numbers result in the release of cellular breakdown products (i.e., tumor lysis syndrome), leading to hypokalemia, acidosis, and hyperuricemia with resultant renal failure.

Treatment of leukostasis should be instituted as soon as possible for all patients with white blood cell counts in excess of 100 to 200 ×

10⁹/L. Treatment consists of leukapheresis, hydroxyurea, and initiation of induction chemotherapy to inhibit further production of circulating tumor cells. Hydration, urine alkalinization to reduce uric acid crystallization, allopurinol, or rasburicase, or a combination, should be initiated as indicated. Red blood cell transfusions are often contraindicated in patients with high numbers of circulating blast cells because of the risk of further increases in blood viscosity. CNS complications such as intracranial bleeding, cranial nerve invasion, and leukemic meningitis are treated with emergency whole brain irradiation or radiation directed to affected sites.

Laboratory evaluation of patients with AML typically shows white blood cell counts ranging from neutropenic levels (<1 × 10⁹/L) to extreme leukocytosis (>100,000 × 10⁹/L). Severe thrombocytopenia, normocytic anemia, and circulating peripheral blasts are common. Bone marrow aspirate and biopsy typically show a profusion of myeloblasts (20% to 100%) and depressed production of normal mature cells.

Diagnosis

Diagnostic marrow aspirates and/or peripheral blood samples require evaluation by morphology (see E-Fig. 47.3), flow cytometry, cytogenetic, and molecular analyses to distinguish between AML and ALL and to determine biologic subsets of AML disease for prognostic and therapeutic purposes.

In the past, AML subsets were classified based largely on morphologic criteria and immunohistochemical staining as FAB subtypes M0 through M7, largely defined by the stage of cellular differentiation of the abnormal cells (see Table 47.11). Some FAB subsets correlate with specific clinical syndromes, which helps to determine treatment approaches and prognosis. The most common FAB subtype of adult AML is M2. Patients with AML M3 (i.e., acute promyelocytic leukemia) often exhibit spontaneous bleeding from disseminated intravascular coagulation (discussed later). Patients with AML M4 or M5 disease (i.e., acute monocytic-myelomonocytic leukemias) have high levels of circulating white blood cells and may have swollen gums resulting from tissue infiltration with leukemic blasts. Patients with megakaryoblastic leukemia (AML M7) have significant marrow fibrosis and usually exhibit organomegaly and pancytopenia similar to those seen in patients with myelofibrosis and myeloid metaplasia.

Large-scale genomic analyses of AML samples have revealed the vast molecular complexity of this disease and identified myriad gene mutations capable of further refining AML prognosis in conjunction with karyotype. For instance, up to one third of patients with normal-karyotype AML have constitutive activation of the FMS-like tyrosine kinase 3 (FLT3) receptor as a result of point mutations or internal tandem duplications (ITDs) not seen on routine karyotypic testing. FLT3 ITD mutations in AML patients predict for lower remission rates, high relapse rates, and shorter overall survival compared with FLT3-negative AML patients. Patients with higher FLT3 ITD tumor burden (reflected by the ratio of mutant to wild-type FLT3 or the allelic ratio) have particularly poor prognoses, whereas individuals with low FLT3 ITD allelic ratio may have outcomes similar to FLT3 wild-type patients. Mutations that predict improved overall survival after chemotherapy include biallelic mutations in the transcription factor CCAAT/enhancer binding protein-α (CEBPA) and nucleophosmin 1 (NPM1) in the absence of FLT3 ITDs (see Tables 47.11 and 47.12).

The classification and prognostication of AML was refined in 2016 by the WHO to recognize biologic subtypes with unique genetic abnormalities such as t(8;21), inv(16), t(15;17), and t(9;11) as well as BCR-ABL1, biallelic CEBPA, and RUNX1 mutations. Other categories include AML with myelodysplastic-related changes (defined by

the presence of multilineage dysplasia, prior clinical and pathologic results, and/or characteristic karyotypic aberrations) and therapy-related AML (based on clinical history of prior chemotherapy, irradiation, or other myeloablative therapy preceding AML diagnosis). In the latter case, any marrow dysplasia together with cytopenias is now considered therapy-related AML rather than MDS regardless of blast count (see Table 47.11).

Treatment and Prognosis

Upfront chemotherapy for AML has changed drastically over the last few years due to the advent of multiple new drugs for specific clinical and biological subsets of disease. For decades, it has been known that the clinical factors predictive of poor outcome include advanced age (>60 years old), therapy-related or with antecedent hematologic disorder (termed secondary AML), poor performance status, elevated initial white blood cell counts (>20-30K to >100K), and presence of disease outside the bone marrow. Extramedullary disease includes leukemic involvement in the central nervous system, skin and soft tissues (myeloid or granulocytic sarcoma), and any other organ involvement outside of the bone marrow and peripheral blood. Although these clinical factors are still considered, in this era the most important factors impacting treatment decisions for newly diagnosed patients are (1) overall functionality/comorbidities and (2) AML risk category.

AML is known to be a biologically heterogeneous disease with vast differences in outcomes based on underlying disease. Early AML risk prognostication was based primarily on karyotypic aberrations that have stood the test of time as the most robust independent predictors of response to intensive (cytarabine and anthracycline based) chemotherapy approaches. However, recent advances in genomic and

TABLE 47.13 Prognostic Factors in Acute Lymphoblastic Leukemia

Factor	Favorable	Unfavorable

Sex	Women	Men
Ethnicity	White	African American, Hispanic
Time to remission	Short (7-14 days)	Prolonged time to remission or failure to achieve remission

molecular technologies have shed much light on the role of diverse gene mutations to AML pathogenesis. Genes involved in at least eight different biologic processes have been identified in primary AML samples. The most recent AML risk classification proposed by the European Leukemia Net delineates three risk categories (favorable, intermediate, and poor risk) incorporating diagnostic cytogenetic and molecular information (see Table 47.12). Because the presence of certain “actionable” mutations (specifically *CBF*, *FLT3*, *NPM1*, *IDH1*, and *IDH2*) can significantly alter upfront therapy selection, it is recommended that molecular tests evaluating these aberrations be performed in an expedited manner (turnaround time of 3-5 days) in all suspected AML cases (see Table 47.12).

Treatment based on disease subsets

Patients who are younger than 60 years and/or fit for intensive chemotherapy. The “traditional” induction regimens administered in the inpatient setting consist of 7 days of cytosine arabinoside (i.e., cytarabine) and 3 days of high-dose anthracycline (i.e., daunorubicin or idarubicin) and is commonly referred to as “7+3.” Once morphologic remission (marrow blasts <5%) and count recovery (WBC >1000, platelets >100,000/ μ L) have occurred, an additional two to four cycles of consolidation chemotherapy with high-dose cytarabine with or without anthracycline are administered over 4 to 6 months. Standard 7+3 induction regimens lead to complete remission in 60% to 80% of younger adults with de novo AML. Lower remission rates are achieved for older adults (>60 years) and in patients with antecedent hematologic diseases evolving into AML. After achieving complete remission after induction, patients may be offered additional consolidation chemotherapy or treatment with allogeneic or autologous SCT (see Chapter 46). Decisions about the best time to perform SCT in patients are most often guided by clinical risk factors and prognostic risk category. Although clinical outcomes are improved when patients undergo SCT after initial induction chemotherapy (i.e., during the first complete remission) rather than after disease relapse, chemotherapeutic regimens are also more effective in the first remission than they are after transplantation, and they may be better tolerated than SCT, which carries an overall mortality rate of

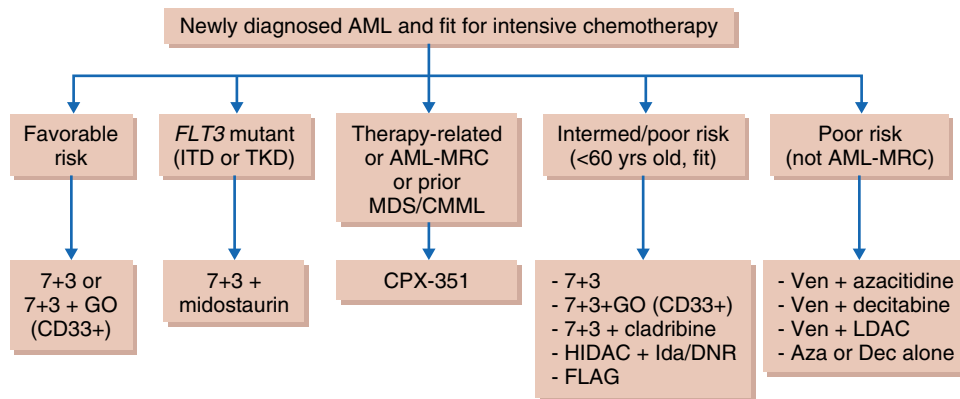

Fig. 47.1 Treatment of patients with newly diagnosed acute myeloid leukemia AML and considered fit for intensive chemotherapy. 7+3, 7 days of continuous infusional cytarabine 100-200 mg/m²/day plus 3 days of anthracycline (daunorubicin 45-90 mg/m²/day or idarubicin 12 mg/m²/day); AML, acute myeloid leukemia; AML-MRC, acute myeloid leukemia with myelodysplastic related changes; CD33+, expressing CD33 surface antigen; CMML, chronic myelomonocytic leukemia (a subtype of MDS); CPX-351, liposomal formulation of cytarabine and daunorubicin; Dec, decitabine; DNR, daunorubicin; FLAG, intensive chemotherapy regimen consisting of fludarabine, intermediate-dose cytarabine, and G-CSF; FLT3, fms-like tyrosine kinase 3; GO, gemtuzumab ozogamicin; HIDAC, high-dose cytarabine; Ida, idarubicin; ITD, internal tandem duplication mutation; LDAC, low-dose cytarabine; MDS, myelodysplastic syndrome; TKD, tyrosine kinase domain mutation; Ven, venetoclax.

25% to 30%. Patients whose AML fails to respond to initial induction therapy have a grim overall prognosis and are eligible for treatment with high-dose cytarabine-containing regimens or low-dose therapy incorporating hypomethylating agents (azacitidine, decitabine) and/or experimental agents in order to obtain remission.

Treatment of younger (<60 years old) individuals with AML should be tailored based on specific AML risk classification (Fig. 47.1). Patients with favorable risk AML characterized by t(8;21), inv(16) or del(16q) aberrations are unusually responsive to induction chemotherapy followed by two to four cycles of high-dose cytosine arabinoside consolidation. Long-term 5-year survival rates of 55% to 60% can be obtained. Further improvement in outcomes has been demonstrated with the addition of gemtuzumab ozogamicin (GO), an antibody drug conjugate directed against the CD33+ surface antigen expressed on the majority of myeloid blasts. In a meta-analysis of five randomized controlled clinical trials, the addition of GO to 7+3-based induction and consolidation therapy improved overall survival by 20% over chemotherapy alone. AML patients with favorable disease features potentially responsive to high-dose cytarabine chemotherapy are encouraged to delay SCT until the time of relapse.

Some cytogenetic aberrations confer poor prognosis and are associated with resistance to and/or early relapse following standard chemotherapy regimens. These “poor-risk” cytogenetics include deletions in chromosome 5 or 7, inv(3q), t(3;3), t(6;9), t(9;22) (also known as the Philadelphia chromosome), monosomal karyotype, and three or more karyotypic abnormalities (i.e., complex karyotype). Mutations associated with poor prognosis are *FLT3-ITD*, *RUNX1*, *ASXL1*, and *TP53*. Remission rates for these poor-risk cytogenetic and molecular subtypes of AML are low; if remission is achieved, patients remain at high risk for AML relapse within the first 12 months due to presence of chemotherapy-refractory disease. Overall survival rates for poor-prognosis AML are 5% to 15%. AlloSCT is recommended for and represents the best chance for long-term cure of patients with poor-risk AML such as disease associated with unfavorable cytogenetic and molecular features, antecedent hematologic disease, or therapy-related or primary refractory disease. Poor-risk AML patients younger than 60 years undergoing allogeneic bone marrow transplantation from a

matched donor have long-term overall survival rates of 40% to 60%, compared with cure rates after conventional chemotherapy of only 5% to 20%. For younger individuals with poor-risk AML appropriate for intensive chemotherapy, the preferred approach is 7+3-based induction (without GO) followed by alloSCT in first remission.

Outcomes of standard cytarabine- and anthracycline-based intensive chemotherapy in patients with therapy-related AML (tAML) or secondary AML (sAML) arising out of antecedent myelodysplastic syndrome (MDS) or with MDS-related changes (AML-MRC) remains dismal. Long-term survival ranges from 10% to 20% regardless of age, and alloSCT is universally considered the only curative approach. Patients 60 years or older with these difficult-to-treat AML subtypes (tAML, sAML, AML, with MRC) achieve improved remission rates and prolonged overall survival, particularly in the context of subsequent alloSCT, following treatment with a liposomal cytarabine and daunorubicin formulation (formerly known as CPX-351) as compared with standard infusion cytarabine and daunorubicin. It has been speculated that the improved drug pharmacokinetics, specifically enhanced marrow drug delivery and retention, may lead to improved eradication of AML blasts in these specific subsets.

FLT3 mutations are the most common gene mutations in AML and constitute an “actionable” mutation because patients with *FLT3*-mutant AML benefit from treatment with oral TKI of mutant *FLT3* signaling pathways, similar to BCR/ABL inhibitors in CML. In newly diagnosed patients with *FLT3*-mutant disease, the addition of midostaurin, a first-generation *FLT3* TKI, to upfront cytarabine and anthracycline induction and consolidation chemotherapy improved overall survival (but not remission rate) as compared to chemotherapy alone. Of note, these improved outcomes were dependent in part on the majority of patients with *FLT3*-mutant AML undergoing alloSCT at time of remission.

The remaining half of AML patients have intermediate-risk cytogenetics, which is defined as a normal karyotype, trisomy 8, t(9;11), or other cytogenetic abnormalities not included in the other groups. These patients have a 30% to 45% long-term survival rate with standard 7+3 chemotherapy (see Table 47.12). Actionable mutations in *FLT3*, *NPM-1*, *IDH1*, and *IDH2* genes occur most frequently in intermediate-risk disease and carry significant therapeutic and prognostic implications. Multiple alternative

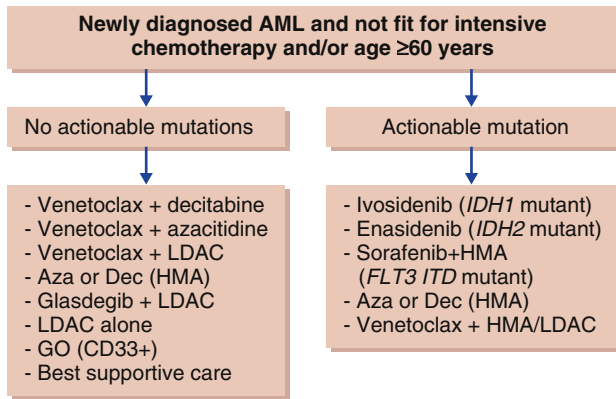

Fig. 47.2 Treatment of patients with newly diagnosed acute myeloid leukemia and considered not fit for intensive chemotherapy and/or age 60 years old or older. *AML*, Acute myeloid leukemia; *Aza*, azacitidine; *CD33+*, expressing CD33 surface antigen; *Dec*, decitabine; *FLT3*, fms-like tyrosine kinase 3; *GO*, gemtuzumab ozogamicin; *HMA*, hypomethylating agents consisting of azacitidine and decitabine; *IDH1*, isocitrate dehydrogenase isoform 1; *IDH2*, isocitrate dehydrogenase isoform 2; *LDAC*, low-dose cytarabine.

induction regimens other than 7+3 have been explored to improve prognosis for intermediate- and poor-risk AML patients. These include substitution of higher-dose intermittent-dosed cytarabine instead of 7-day infusional cytarabine and the addition of other agents (such as cladribine or fludarabine) to cytarabine and anthracycline in attempts to enhance responses. The addition of GO to 7+3 has been shown to improve overall survival in intermediate-risk AML, albeit to a much lesser degree (5.7%) than in favorable-risk patients. Risks of GO include prolonged myelosuppression with associated hemorrhagic complications and increased risk of fatal veno-occlusive disease (VOD), particularly in patients undergoing subsequent alloSCT. Recently, the rate of VOD appears to have been significantly mitigated (4%) by the use of fractionated (i.e., 3 mg/m² on days 1, 4, and 7) GO dosing. Intermediate-risk AML patients with unfavorable prognosis (based on clinical or molecular data) ideally should be offered alloSCT, particularly younger individuals with few comorbidities and related family donors. Those patients who are ineligible for allogeneic transplantation because of advanced age, other medical issues, or lack of HLA-compatible donors may be offered chemotherapy or autologous SCT instead. Whether autologous transplantation improves AML outcomes compared with chemotherapy alone is a matter of debate. However, the long-term survival rates after autologous transplantation range from 20% to 40% and are at least equivalent to consolidation chemotherapy regimens for these patients.

Patients 60 years or older and/or not fit for aggressive therapy now have a number of therapeutic options (Fig. 47.2). Because the median age at diagnosis of AML is 65 years, a sizable proportion of AML patients are elderly individuals with major comorbidities or antecedent hematologic or malignant diseases, rendering them poor candidates for intensive induction chemotherapeutic regimens or myeloablative SCT. Infectious complications remain the major cause of morbidity and mortality during intensive inpatient chemotherapy despite advances in prophylactic growth factor support, antibiotics, and antifungal agents. The low expected remission rates (30% to 50%) and high mortality and morbidity rates associated with induction are additional reasons for many patients to decline aggressive therapy. Fortunately, multiple therapeutic options are now available specifically for treatment of these older adults who in the recent past would have been offered only supportive therapy with hydroxyurea, transfusion support alone, and hospice.

Patients older than 75 years old and/or those unfit for and who choose not to receive intensive therapy now have a panoply of

low-dose chemotherapy options. Historically, chemotherapy regimens for older patients consisted of either low-dose cytarabine (LDAC) or hypomethylating therapy (HMA) (azacitidine, decitabine). These regimens have been well tolerated, but both are associated with disappointing response rates and median survival duration of less than 6 to 7 months. Low-dose subcutaneous cytarabine resulted in remission rates of about 18%, whereas HMA induced remissions ranging from 20% to 47%. Some individuals treated with HMA also experience hematologic improvement, disease stabilization, and prolonged overall survival, even in absence of complete remission.

Combination regimens adding therapeutic agents to HMA or LDAC backbones now constitute the new standard of care for individuals unable to receive intensive chemotherapy. Venetoclax is a highly potent oral inhibitor of BCL-2, upon which AML cells are dependent for viability. The addition of venetoclax to HMA therapy in older unfit patients resulted in remissions in 67% of patients with a median overall survival of 17.5 months. Of note, almost two thirds of patients with traditionally unfavorable prognostic factors including poor-risk cytogenetics, age 75 years old or older, and secondary AML attained complete remission or complete remission with incomplete count recovery. Venetoclax combined with LDAC resulted in slightly lower overall response rates (54%) and in specific subsets including poor-risk cytogenetics (42%) and secondary AML (35%). Patients who had previously received HMA therapy for MDS prior to venetoclax and LDAC therapy also had lower remission rates (33%) as compared to no prior HMA exposure (62%). Adverse events included significant myelosuppression with risk of infection, sepsis, and pneumonia leading to early death in a proportion of patients. Glasdegib is an oral inhibitor of sonic hedgehog signaling important for leukemia stem cell survival and expansion with minimal single agent activity but improved efficacy when combined with LDAC. Addition of glasdegib to LDAC significantly improved remission rate to 19% and extended overall survival to 8.8 months as compared to LDAC alone (4.9 months). Treatment was well tolerated with relatively little myelosuppression or cytopenia. The excellent tolerability of this regimen with relatively little myelosuppression and the ability to treat patients completely in the outpatient setting makes it an option for select individuals. Gemtuzumab ozogamicin monotherapy represents yet another option for these patients with CD33+ AML with survival duration of less than 6 months.

Treatment decisions may also be altered by the presence of actionable mutations in *FLT3*, *IDH1*, and *IDH2* genes. Patients with *IDH1*- or *IDH2*-mutant disease are eligible to receive therapy with oral inhibitors of IDH1 (ivosidenib) and IDH2 (enasidenib), respectively. These agents, originally evaluated in the relapsed/refractory setting, result in overall response rates of approximately 40% and are well tolerated without myelosuppression. One unusual toxicity of IDH inhibitors is development of differentiation syndrome, similar to that seen with treatment of acute promyelocytic leukemia (APL), and characterized by elevated white count, fever, edema, and pulmonary infiltrates. Of note, *IDH1/2*-mutant AML patients also experienced very high response rates (80% to 90%) following venetoclax plus HMA/LDAC, making this the preferred regimen over targeted IDH inhibitors for upfront therapy if tolerable in specific patients.

Addition of a first-generation FLT3 TKI (sorafenib) to HMA therapy is recommended for upfront therapy of *FLT3-ITD*-mutant AML in unfit patients. Use of newer-generation TKIs for this indication is currently under investigation. Venetoclax plus HMA or LDAC is also effective in *FLT3*-mutant AML, raising the question of whether FLT3 TKI or venetoclax is the better therapeutic partner to combine with HMA in *FLT3*-mutant AML. However, recent clinical and preclinical data have suggested that *FLT3* mutations may constitute an overall mechanism of resistance to venetoclax based therapy.

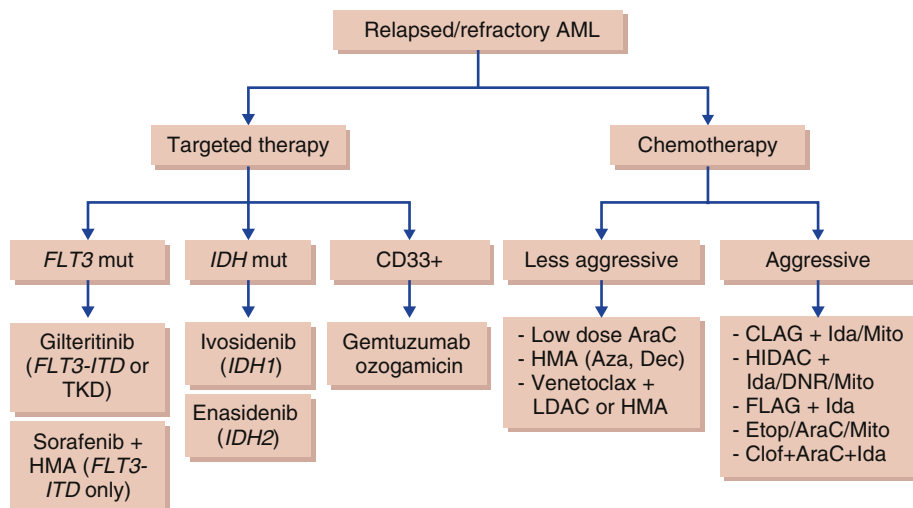

Fig. 47.3 Treatment of patients with relapsed/refractory acute myeloid leukemia. *AML*, Acute myeloid leukemia; *AraC*, cytarabine; *Aza*, azacytidine; *CD33+*, expressing CD33 surface antigen; *CLAG*, intensive chemotherapy regimen including cladribine, intermediate-dose cytarabine, and G-CSF; *Clof*, clofarabine; *Dec*, decitabine; *DNR*, daunorubicin; *Etop/AraC/Mito*, intensive chemotherapy regimen consisting of etoposide, intermediate dose cytarabine, and mitoxantrone; *FLAG*, intensive chemotherapy regimen consisting of fludarabine, intermediate-dose cytarabine, and G-CSF; *FLT3*, fms-like tyrosine kinase 3; *HIDAC*, high-dose cytarabine; *HMA*, hypomethylating agents consisting of azacytidine and decitabine; *Ida*, idarubicin; *IDH*, isocitrate dehydrogenase; *IDH1*, isocitrate dehydrogenase isoform 1; *IDH2*, isocitrate dehydrogenase isoform 2; *ITD*, internal tandem duplication mutation; *LDAC*, low-dose cytarabine; *Mito*, mitoxantrone; *TKD*, tyrosine kinase domain mutation.

Relapsed or refractory disease. Similar to newly diagnosed patients, individuals with AML relapsing following or refractory to standard upfront therapy should be assessed for their overall ability to tolerate aggressive versus less-aggressive therapy and for the presence of actionable mutations (Fig. 47.3).

Next-generation and single cell sequencing technology has demonstrated the importance of repeat molecular testing at the time of AML recurrence. Clonal evolution or emergence as a consequence of prior therapy can lead to a significantly different mutational profile at relapse than at initial AML presentation with significant therapeutic implications. For instance, patients with relapsed/refractory *FLT3*-mutant AML (both ITD and TKD mutations) benefit more from single-agent therapy with a potent next-generation *FLT3* TKI, gilteritinib, than from therapy with either intensive or low-dose chemotherapy. Complete remission rate (37% vs. 17%) and overall survival (9.3 vs. 5.6 months) are both improved with *FLT3* TKI monotherapy over any non-*FLT3* TKI-containing regimen. Patients with relapsed/refractory *IDH1* or *IDH2*-mutant disease can be treated with ivosidenib (*IDH1* inhibitor) or enasidenib (*IDH2* inhibitor) with complete remission rates of 20% and overall response rates of 40%.

Patients with recurrent AML not characterized by actionable mutations may be treated with aggressive intensive salvage chemotherapy regimens (i.e., cladribine or fludarabine containing programs) or low-dose chemotherapy (i.e., venetoclax plus HMA or LDAC, HMA or LDAC or GO alone). If possible, all patients with relapsed/refractory AML should be considered for alloSCT and clinical trials. Experimental therapies for AML including nontraditional alloSCT have resulted in durable long-term remissions in a proportion of older AML patients and should be pursued based on patient preference, overall health status, and availability of an appropriate HLA-matched donor.

Acute Promyelocytic Leukemia

Definition, Epidemiology, and Pathology

APL, formerly known as the FAB M3 subtype of AML (see Table 47.11), is a rare malignancy that represents 10% to 15% of adult AML.

The incidence is increased among younger patients (median age, 40 years). The annual incidence in the United States ranges from 600 to 800 cases. APL is different from other acute leukemias because of its unique disease biology. Morphologically, APL blasts are distinctive immature promyelocytic cells containing large granules and typically high numbers of Auer rods diagnostic of AML. APL is characterized by a chromosomal translocation—t(15;17)(q22;q12)—involving the promyelocytic leukemia gene (*PML*) on chromosome 15 and the retinoic acid receptor- α gene (*RARA*) on chromosome 17. Sequestration of the resulting *PML/RARA* fusion protein with other proteins produces a complex that represses the gene transcription essential for granulocytic differentiation, effectively arresting differentiation of leukemia cells at the promyelocyte stage.

Clinical Presentation

Clinically, patients with APL often exhibit life-threatening bleeding caused by disseminated intravascular coagulation related to high levels of procoagulant factors released from APL granules. Bleeding complications in the CNS and other sites can be rapidly fatal if the disease is not recognized and treated as a medical emergency. All patients suspected of having APL should be started empirically with all-*trans*-retinoic acid (ATRA) therapy (discussed later) and treated aggressively with transfusions of fresh-frozen plasma, fibrinogen, and platelets until resolution of coagulopathy and disease confirmation. Unlike patients with other AML subsets, APL patients typically have cytopenias rather than leukocytosis. High-risk APL patients are defined as those with white blood cell counts greater than $10 \times 10^9/L$.

Treatment and Prognosis

Treated appropriately, APL is the most curable acute leukemia in adults. The centerpiece of APL treatment is the use of agents that induce the terminal differentiation of leukemic promyelocytes followed by senescence and spontaneous apoptosis. ATRA is an oral derivative of vitamin A shown to overcome growth arrest and permit

differentiation of immature APL blast cells into neutrophils by altering the configuration of *PML/RARA* to allow normal gene transcription.

Patients initiated on ATRA must be closely observed for development of retinoic acid or APL differentiation syndrome, which is life-threatening acute cardiopulmonary distress characterized by bilateral pulmonary effusions and infiltrates. This serositis-like disorder is attributed to adhesion of differentiating neoplastic cells to the pulmonary vasculature and carries a 5% to 10% mortality rate. Treatment consists of early initiation of corticosteroids and aggressive diuresis. In severe cases, ATRA should be temporarily withheld.

Although ATRA alone induces clinical remissions in up to 90% of patients with APL, high relapse rates observed after monotherapy led to the practice of combining ATRA with anthracycline with or without cytarabine chemotherapy in initial induction regimens. Using this approach, complete remission rates for APL rose to between 90% and 95%, and more than two thirds of patients with APL treated with standard ATRA-containing induction, consolidation, and maintenance chemotherapy regimens achieved long-term remission.

Relapsed APL patients were treated with arsenic trioxide, a naturally occurring compound used both as a poison and a drug in many countries. Low-dose arsenic therapy promotes APL cell differentiation and apoptosis and induces remission rates in up to 90% of relapsed APL cases. APL differentiation syndrome and prolongation of the QT interval are common side effects of arsenic therapy. Based on its tolerability and non-overlapping cytotoxicities with conventional cytotoxic drugs, arsenic was successfully used for consolidation therapy in APL patients and improved clinical outcomes.

Although highly effective, combination ATRA and chemotherapy regimens for newly diagnosed APL patients are associated with an overall mortality rate of 10% to 20% during the first month of treatment. Most deaths result from uncontrolled hemorrhage, differentiation syndrome, and complications of prolonged myelosuppression after cytotoxic therapy, particularly in older individuals. To address these concerns, a phase III trial randomized lower-risk APL patients to dual-differentiation therapy with ATRA and arsenic only (without cytotoxic chemotherapy) or to standard ATRA and chemotherapy during induction and consolidation. The trial demonstrated that ATRA plus arsenic treatment was not inferior to ATRA plus chemotherapy and was not associated with increased toxicity. Importantly, the trial results led to establishment of differentiation therapy alone without any cytotoxic agents as the standard of care for lower-risk APL patients. Patients with residual *PML/RARA*-positive cells after standard induction and consolidation therapy containing ATRA and arsenic should be considered for autologous or allogeneic SCT. Patients with high-risk APL should continue to receive cytarabine with or without anthracycline drugs in addition to ATRA and arsenic induction, consolidation, and maintenance for curative intent. Given the high cure rates, autologous or allogeneic stem cell transplant is not indicated for APL except for relapsed disease (which often is associated with CNS disease). Newer oral formulations of arsenic are being developed.

Acute Lymphoblastic Leukemia

Definition, Epidemiology, and Pathology

ALL is a neoplasm of immature lymphoblasts expressing markers of B-cell or T-cell lineage. ALL is predominantly a pediatric malignancy, with most cases occurring in children younger than 6 years. In the United States, 5960 new cases were diagnosed in 2018 with 1470 deaths. The median age of onset was 15 years with 27% diagnosed in individuals older than 45 years.

The prior FAB classification system divided ALL into three subtypes (i.e., L1, L2, and L3) based on the morphology of malignant cells (see E-Fig. 47.3). The WHO system reclassified the disease as precursor B-cell or T-cell ALL based on the lineage of specific cell surface

antigens found on these cells during normal maturation (see Table 47.11). T-cell ALL represents 15% to 25% of ALL diagnoses. More than 50% of T-cell ALL cases have activating mutations in *NOTCH1*, a key regulator of T-cell fate. One third of adult and 20% of pediatric B-cell ALL cases are associated with detection of the Philadelphia chromosome, t(9;22).

Clinical Presentation

Patients often present with life-threatening cytopenias, or complications of leukostasis. On examination, enlarged lymph nodes, liver, spleen, or testicles are common. Neurologic symptoms including headaches, cranial nerve deficits, or new neuropathies may be indicative of CNS involvement. Several clinical and biologic features at diagnosis have traditionally been identified as poor prognostic factors for survival (see Table 47.13). These include age (in pediatrics <2 years or >10 years, in adults >35 years), elevated white blood cell count at presentation (>100,000/mcL), precursor T phenotype, chromosome number (pseudo/hypodiploidy or near tetraploidy) and specific chromosome abnormalities (such as complex karyotype or Philadelphia chromosome).

Treatment

Newly diagnosed ALL. Progress in the understanding and treatment of this disease over the last few decades has led to cure rates of greater than 90% for children with ALL. Despite this success, only 20% to 40% of adult patients with ALL achieve cure with elderly individuals demonstrating a five-year survival of less than 20%. The poorer outcomes for adults are attributed to differences in the biologic mechanisms of disease in the different age groups and the inability of older patients to tolerate the intensive chemotherapy or transplantation procedures required to achieve long-term responses.

Standard treatment of ALL is lengthy and involves multiple chemotherapeutic agents given over 2 to 3 years. Induction chemotherapy typically includes vincristine, corticosteroids, and L-asparaginase with the addition of an anthracycline, cytarabine, or cyclophosphamide (or a combination) for adult patients. Given the propensity of ALL cells to reside in the CNS and testes (so-called sanctuaries for leukemia cells because standard systemic chemotherapy does not penetrate into these sites), routine administration of intrathecal chemotherapy at the time of diagnosis, followed by multiple additional treatments to prevent leukemia seeding in the CNS is considered a necessary adjunct to systemic chemotherapy for all patients. Younger patients with CD20+, Ph-negative ALL have been shown to have worse outcomes than those with CD20-negative B-ALL. Addition of anti-CD20 antibody (rituximab) directed against B-cell antigens on abnormal lymphoblasts has been shown to enhance outcomes of chemotherapy for these individuals. The benefit of CD20 antibodies in older patients is less certain.

Current complete remission rates following induction chemotherapy range from 97% to 99% for children and 75% to 90% for adults. After normal hematopoiesis returns, patients typically undergo consolidation and intensification therapy with the same drugs, including high-dose methotrexate, cytarabine, and asparaginase to eradicate disease. Thereafter, maintenance chemotherapy given for up to 2 to 3 years after initial remission achievement is usually recommended for all patients. Prolonged treatment is intended to eliminate slow-growing leukemic clones, prevent further transformation, or destroy occult disease in other sites, particularly the CNS.

Although clinical factors (i.e., older age, Philadelphia chromosome-positive disease, high white blood cell count at presentation, or prolonged time to first remission) are important, current ALL therapeutic approaches in both children and adults are primarily guided by measurable (or minimal) residual disease (MRD) status. MRD is defined as the detection of malignant lymphoblasts by highly sensitive

PCR or multi-parameter flow cytometry following induction and consolidation therapy at the time of morphologic marrow remission. MRD has been established as an independent predictor of disease relapse and shorter survival with or without subsequent alloSCT. Patients with MRD positive CD19+ B-cell ALL are usually treated with blinatumomab (BiTE), a bispecific single-chain antibody that binds the T-cell receptor CD3 on T cells and the B-cell antigen CD19 expressed by malignant lymphoblasts. Dual binding of CD3 and CD19 by BiTE brings reactive T cells close to tumor cells, redirects T cell lysis, and eliminates disease. Administration of BiTE to ALL patients in clinical remission but with evidence of MRD after standard chemotherapy has been shown to eradicate detectable disease in 76% of patients.

In ALL, as in AML, the worse the prognosis, the earlier transplantation should be offered. Patients with MRD+ disease are considered to have chemoresistant disease, and studies have shown that high-risk ALL patients clearly benefit from alloSCT, preferably from an HLA-matched sibling, during the first remission. Unfortunately, outcomes for high-risk ALL patients without an available HLA-matched donor are poor, and these individuals should pursue alternative transplant options or experimental therapies. No significant benefit has been seen with autologous transplantation over standard chemotherapy for these patients. In contrast, low- and standard-risk ALL patients, particularly pediatric patients, with high rates of long-term remission and survival after conventional chemotherapy and maintenance are recommended to avoid allogeneic SCT unless disease recurs.

In the modern era, ALL therapy is increasingly being tailored for specific patient populations (Table 47.14), including adolescent and young adult (AYA) patients as well as elderly individuals and those with Philadelphia chromosome–positive (Ph+) ALL, Ph-like ALL, and T-cell ALL (T-ALL) subtypes.

Age remains an important determinant of ALL therapy. Historically, adult patients diagnosed with ALL receive treatment regimens with attenuated doses or even omissions (i.e., asparaginase) of the same chemotherapy agents routinely used so successfully in pediatric patients. This is due to significantly higher rates of treatment-related toxicities and death in older individuals with medical comorbidities and decreased tolerance of prolonged chemotherapy. In contrast, multiple retrospective and prospective trials have now demonstrated that AYA patients aged 15 to 39 years of age can benefit from “pediatric-inspired” chemotherapy regimens with dose intensification of corticosteroids, vincristine, asparaginase, and intrathecal chemotherapy. This is reflected in improved overall survival rates of over 70%. In

contrast, elderly patients (>60 years old) are increasingly being offered low-intensity regimens designed to preserve outcomes while minimizing toxicity. To further improve responses, recent trials have explored the addition of BiTE and anti-CD20 antibodies to chemotherapy with promising results.

Philadelphia chromosome–expressing (Ph+) ALL is a previously notoriously chemoresistant ALL subtype that occurs much more commonly in adults than children. Treatment has been dramatically altered by the incorporation of newer-generation BCR-ABL1 TKIs into conventional chemotherapy regimens (see Table 47.9). Dasatinib is a second-generation TKI with known CNS penetration that results in superior outcomes over imatinib plus chemotherapy. Ponatinib is a third-generation TKI with activity against ALL cells bearing BCR-ABL1 tyrosine kinase mutations conferring resistance to other TKIs. Although associated with increased cardiovascular and thrombotic complications, ponatinib and chemotherapy results in very high response rates and 3-year remission rates of over 80%. Five-year overall survival for Ph+ ALL now ranges between 60% and 70%, raising the question of whether alloSCT should be performed for all patients or solely for individuals with persistent MRD+ disease following front-line therapy. Upfront TKI therapy in combination with corticosteroids now leads to almost universal remission rates without requiring cytotoxic agents. Older patients with Ph+ALL are now able to receive much less chemotherapy than previously and continue therapy with sustained responses for months if not years.

Genomic analyses have revealed a biologic subset of ALL with similar gene expression patterns as Ph+ ALL but no evidence of BCR-ABL protein or t(9;22). This so-called “Ph-like” ALL subtype occurs in up to 30% of AYA patients and is associated with Hispanic ethnicity and poor outcomes. Discovery of specific kinase mutations in these patients, such as *JAK1*, *JAK2*, *ABL2*, *CRLF2*, has led to clinical trials incorporating specific TKIs (i.e., ruxolitinib, dasatinib) into treatment regimen to enhance antileukemic efficacy.

T-cell ALL occurs far less frequently than B-cell disease and until recently was believed to confer worse prognosis following treatment with standard ALL chemotherapy regimens. Nelarabine is a purine analogue that is incorporated into malignant lymphoblasts, leading to inhibition of DNA synthesis and apoptosis. This single agent resulted in overall response rates of 20% to 30% in patients with relapsed/refractory T-ALL. This agent is being incorporated into upfront treatment regimens, particularly for high risk patients with ALL, with encouraging results to date.

TABLE 47.14 Treatment of Acute Lymphoblastic Leukemia

Treatment	Patient Population	Clinical Notes
Intensive induction chemotherapy	Newly diagnosed pediatric patients	High remission rates of >90%; long-term survival in pediatric patients >90% vs. 30-40% in adults
Pediatric inspired regimens	Newly diagnosed AYA	Improved 3-year survival of 73%; Dose intensification of steroids, IT chemotherapy, asparaginase and vincristine
Low-intensity chemo regimens	Newly diagnosed older adults	Lower-dose chemotherapy with omission of anthracycline
Rituximab (anti-CD20 ab)	Younger patients with CD20+ disease	Added to standard chemotherapy; not indicated for older patients or CD20-negative disease
BCR-ABL1 inhibitors	Ph-positive ALL	Combined with steroids and standard chemotherapy
Blinatumomab (CD19-CD3 bispecific antibody)	MRD+ and Relapsed refractory CD19+ ALL	Toxicities of cytokine release syndrome and CNS effects. Eliminates MRD+ disease in >70%. Overall survival of 7.7 months in relapsed disease.
Inotuzumab ozogamicin	Relapsed/refractory CD22+ ALL	Risk of veno-occlusive disease (15%) and hepatotoxicity, particularly with prior allogeneic stem cell transplant
Tisagenlecleucel (CD19 chimeric antigen receptor T cells)	Relapsed/refractory CD19+ ALL aged 25 and younger	Response rates of 80%. Toxicities of cytokine release and neurologic symptoms require treatment with steroid and anti-IL-6 antibody

Relapsed or refractory disease. Although late recurrences can emerge at any time, most ALL relapses arise within 2 years of the initial diagnosis, with recurrence of chemoresistant leukemia cells in the bone marrow, CNS, or testes. All patients with relapsed ALL should be considered for additional therapy followed by alloSCT, which represents the only known cure for disease. Autologous SCT is not routinely recommended. Overall response rates to multiagent salvage chemotherapy incorporating the same agents used in frontline therapy range from 20% to 50% with duration of second remissions lasting less than 6 months. Other chemotherapy agents specifically indicated for relapsed disease include nelarabine for T-ALL, clofarabine for patients younger than 21 years old, and a liposomal formulation of vincristine in patients receiving at least two prior lines of therapy. Each drug induces clinical responses in up to a third of heavily pretreated patients as a single agent with tolerable toxicities.

Perhaps the most exciting strategies for ALL therapy involve technologies specifically exploiting patient host immune responses to induce responses. Numerous immunotherapies targeting the leukemia cell antigens CD19 and CD22 have entered mainstream therapy for ALL as well as other lymphoid malignancies. BiTE results in significantly improved overall survival (7.7 months) as compared with standard chemotherapy (4 months). Patients with lower marrow disease burden and receiving treatment in first relapse benefit most, with 30% of patients proceeding on to alloSCT. Unique side effects of therapy include neurologic symptoms (ranging from change in mental status to seizures to encephalopathy) and cytokine release syndrome characterized by fever, hemodynamic instability, and life-threatening organ damage. Severity of complications is related to extent of tumor burden and is higher than experienced in BiTE therapy of MRD-positive ALL.

Inotuzumab is a CD22-directed antibody conjugated to a DNA damaging agent (calicheamicin). Binding of this antibody drug conjugate to surface CD22 expressed on the ALL surface leads to its internalization, induction of DNA strand breakage, and cell death. In a randomized controlled trial, inotuzumab induced higher overall responses (88%) in patients with first relapsed ALL than standard chemotherapy (32%). Forty percent of patients receiving inotuzumab underwent subsequent alloSCT. However 15% of patients developed VOD, which was largely fatal and occurred primarily in individuals with prior alloSCT who had received multiple doses of therapy.

Cellular immunotherapies that have revolutionized the treatment of all B-cell malignancies were first validated for the treatment of relapsed B-ALL. Chimeric antigen receptor T (CART) cells are autologous T cells collected from patients with relapsed ALL and genetically modified *ex vivo* to express CD19 chimeric antigen receptors. This effectively reprograms them to recognize and destroy CD19-expressing tumor cells. Infusion of a single dose of CART cells (tisagenlecleucel) following lymphodepleting chemotherapy in individuals (both children and young adults) with multiple relapsed/refractory ALL resulted in the complete eradication of disease in 80% to 90%. Although CART-mediated cytokine release and neurotoxicity can be life-threatening, strategies to mitigate these adverse events with early administration of steroids and the anti-IL-6 antibody (tocilizumab) have allowed CART to be successfully administered at numerous academic centers across the world.

PROSPECTUS FOR THE FUTURE

Insights into the molecular and biologic underpinnings of MPNs and acute leukemia have led to an explosion of novel therapeutic

approaches that have transformed the clinical approach to each of these diseases in the past few years.

Myeloproliferative Disease

The importance of the spectacular success of imatinib as targeted therapy for CML cannot be overstated. As the first successful therapy based on an understanding of pathogenesis, imatinib has become emblematic of the translation of an understanding of disease pathogenesis into tangible innovations in clinical care. At present, there are four additional new-generation TKIs for CML therapy in addition to imatinib. The best indicator of how these agents have altered the natural history of disease is the fact that certain patients with sustained undetectable disease for 2 to 3 years are now able to permanently discontinue TKI therapy without disease recurrence.

Similarly, the discovery of *JAK2* mutations in non-CML myeloproliferative diseases opened new avenues for targeted intervention in diseases for which previous therapy was largely supportive. *JAK2* inhibition now constitutes standard-of-care therapy for PV and MF independent of *JAK2* mutation status. Newer agents are actively being investigated for MPN therapy including hypomethylating agents, *MDM2* inhibitors, antibody-drug conjugates, and anti-fibrosis agents.

Acute Leukemia

Acute leukemias are clinically aggressive malignancies with survival rates of weeks to a few months if untreated. The availability of multiple targeted and nontargeted agents for distinct biological subsets has changed the therapeutic landscape for these diseases. The first acute leukemia exemplifying this was APL. The discovery of the link between the retinoic acid receptor and the origins of APL provided important insights into the unique sensitivity of this disease to ATRA therapy and paved the road for successful implementation of dual differentiation therapy with ATRA and arsenic. This regimen marks the first time that any acute leukemia was cured without cytotoxic chemotherapy or SCT.

At present, pediatric ALL is now considered a highly curable cancer with long-term remission and survival rates of over 90%. Patients with relapsed disease are eligible to receive the latest advances in novel immunotherapeutic approaches. CART therapy has revolutionized therapy not only for ALL but for all B-cell malignancies such as lymphoma and myeloma. However, durability of response and disease relapse remain major issues. It is uncertain whether patients undergoing CART should also pursue subsequent alloSCT. Antibodies including anti-CD20 antibody (rituximab), the CD19-CD3 bispecific agent (blinatumomab), and the CD22 antibody drug conjugate (inotuzumab) have expanded the armamentarium of strategies for ALL. Incorporation of new-generation oral BCR/ABL kinase inhibitors to routine chemotherapy for Philadelphia chromosome-positive ALL has altered expectations for this subtype.

Tailoring of therapy to disease subtype as well as different age groups (pediatric, AYA, and elderly) has led to true personalized therapy. Future directions include moving agents known to be effective in the relapsed/refractory setting to earlier in the treatment course during induction and/or consolidation. Examples include upfront therapy with BiTE and dasatinib for Ph+ disease or inotuzumab plus mini-hyper CVD or CART cells with MRD testing.

In AML, the “gold standard” (7+3) for induction chemotherapy since the 1970s has finally been replaced, at least in older unfit individuals, by venetoclax-based therapy. The latter results in overall response rates of 60% to 70% and provides a new backbone regimen on which to potentially add novel experimental agents. Single-agent inhibitors of mutant *FLT3*, *IDH1*, and *IDH2* have been shown to be superior to conventional chemotherapy in patients with appropriately mutant disease. Newer clinical trials are exploring combinations of targeted agents (*FLT3* and *IDH* inhibitors) with different chemotherapy backbones (i.e., venetoclax plus HMA) or with each other (i.e., venetoclax and gilteritinib). Development

of reduced intensity and haploidentical alloSCT strategies has permitted specific older AML patients the opportunity to be cured of their disease. Similar approaches may soon provide therapeutic entry points into the treatment of other acute leukemias associated with pathognomonic chromosomal translocations and genetic and molecular aberrations.

Disorders of Red Blood Cells

Ellice Wong, Michal G. Rose, Nancy Berliner

NORMAL RED BLOOD CELL STRUCTURE AND FUNCTION

Erythrocytes, or red blood cells (RBCs), deliver oxygen to all the tissues in the body and carry carbon dioxide back to the lungs for excretion. The erythrocyte is uniquely adapted to these functions. It has a biconcave disk shape that maximizes the membrane surface area for gas exchange, and it has a cytoskeleton and membrane structure that allow it to deform sufficiently to pass through the microvasculature. Passage through capillaries whose diameter may be one fourth the resting diameter of the erythrocyte is made possible by interactions between proteins in the membrane (band 3 and glycophorin) and underlying cytoplasmic proteins that make up the erythrocyte cytoskeleton (spectrin, ankyrin, and protein 4.1).

The mature RBC contains no nucleus and is dependent throughout its life span on proteins synthesized before extrusion of the nucleus and release of the cell from the bone marrow into the peripheral circulation. About 98% of the cytoplasmic protein of the mature erythrocyte is hemoglobin. The remainder is mainly enzymatic proteins, such as those required for anaerobic metabolism and the hexose monophosphate shunt.

Defects in any of the intrinsic structural features of the erythrocyte can result in hemolytic anemia. Abnormalities of the membrane or cytoskeletal proteins are the causes of alterations in erythrocyte shape and flexibility. Inborn defects in the enzymatic pathways for glucose metabolism decrease the resistance to oxidant stress, and inherited abnormalities of hemoglobin structure and synthesis lead to polymerization of abnormal hemoglobin (sickle cell disease) or to the precipitation of unbalanced hemoglobin chains (thalassemia). All of these changes result in decreased erythrocyte survival.

Oxygen is transported by hemoglobin, a tetramer composed of two α chains, two β -like (β , γ , or δ) chains, and four heme molecules, each of which is composed of a protoporphyrin molecule complexed with iron. In fetal life, the main hemoglobin is fetal hemoglobin (HbF: $\alpha_2\gamma_2$); the switch from HbF to adult hemoglobin (HbA: $\alpha_2\beta_2$) occurs in the perinatal period. By 4 to 6 months of age, the level of HbF has fallen to about 1% of total hemoglobin. HbA₂ ($\alpha_2\delta_2$) is a minor adult hemoglobin, representing about 1% of adult hemoglobin (Table 48.1).

CLINICAL PRESENTATION

Anemia, defined as a reduction in RBC mass, is an important sign of disease. It may be caused by decreased production of erythrocytes from nutritional deficiencies, primary hematologic disease, or a response to systemic illness. Alternatively, anemia may be caused by increased blood loss or cellular destruction from hemolysis. Hemolysis may occur as a result of intrinsic abnormalities of the RBC, immune-mediated

RBC destruction, or a systemic vascular process. The investigation of anemia is a critical component of the evaluation of the patient and commonly provides valuable insight into systemic illness. Fig. 48.1 provides an overview of the differential diagnosis of anemia.

The symptoms of anemia reflect both the severity and the rapidity with which the reduction in erythrocyte mass has occurred. Patients with acute hemorrhage may exhibit symptoms of hypovolemic shock. Massive hemolysis may result in neurologic impairment or cardiovascular collapse. However, most patients develop anemia more slowly and have few symptoms. Usual complaints are fatigue, decreased exercise tolerance, dyspnea, and palpitations. In patients with coronary artery disease, anemia may precipitate angina. On physical examination, the major sign of anemia is pallor. Patients may be tachycardic and often have significant flow murmurs. Patients with hemolysis often exhibit jaundice and splenomegaly. Patients with iron deficiency may occasionally exhibit signs of pica (i.e., craving for ice or nonfood items such as dirt).

LABORATORY EVALUATION

The key components of the laboratory evaluation of anemia are the reticulocyte count, the peripheral blood smear, erythrocyte indices, nutritional studies, and in some cases the bone marrow aspirate and biopsy.

The *reticulocyte count* allows the critical distinction between anemia arising from a primary failure of RBC production and anemia resulting from increased RBC destruction or bleeding. Erythrocytes newly released from the marrow still contain small amounts of RNA; these cells, termed *reticulocytes*, can be detected with the use of automated counters and fluorescent nucleic acid-binding dyes or manually by staining of the peripheral blood smear with new methylene blue or other supravital stains. In response to anemia, erythropoietin (EPO) production increases, promoting the production and release of increased numbers of reticulocytes. The number of reticulocytes in the peripheral blood therefore reflects the response of the bone marrow to anemia.

The reticulocyte count can be expressed either as a percentage of the total number of RBCs or as an absolute number. In patients without anemia, the normal reticulocyte count is 0.5% to 1.5% of RBCs or 20,000 to 75,000/ μ L. When the anemia is caused by decreased RBC survival, the appropriate marrow response results in a reticulocyte count greater than 2%, with an absolute count of more than 100,000/ μ L. If the reticulocyte count is not elevated, a cause of failure of RBC production should be sought. Reticulocyte counts that are expressed as a percentage of total RBCs must be corrected for anemia because decreasing the number of circulating cells increases the reticulocyte percentage without any increase in release from the marrow.

The *corrected reticulocyte count* is calculated by multiplying the reticulocyte count by the ratio of the patient's hematocrit to a normal hematocrit. An additional calculation, the reticulocyte index or reticulocyte production index (RPI), determines whether the reticulocyte count is appropriate for the degree of anemia. The RPI corrects for both the degree of anemia and release of reticulocytes from the marrow by multiplying the ratio of the patient's hematocrit to a normal hematocrit by the reticulocyte percentage divided by a maturation term. The maturation term signifies the time in days for RBCs to mature (ranging from 1 for a hematocrit $\geq 40\%$ to 2.5 for a hematocrit $< 20\%$). An RPI greater than 3 is considered an appropriate marrow response (e.g., from increased RBC destruction or bleeding) and an RPI less than 2 is an inappropriate marrow response (e.g., a RBC production problem).

Evaluation of the *peripheral blood smear* may provide important clues to the cause of anemia. Erythrocyte morphologic examination is especially critical in the evaluation of anemia associated with

reticulocytosis, wherein an examination of the smear is essential to distinguish between immune hemolysis (which results in spherocytes) and microangiopathic hemolysis (which causes schistocytes or erythrocyte fragmentation). Changes associated with other causes of anemia include sickle and target cells that are characteristic of hemoglobinopathies, teardrop cells and nucleated RBCs associated with myelofibrosis and marrow infiltration, intracorporeal parasites in malaria and babesiosis, and pencil-shaped deformities associated with severe iron deficiency. Examination of myeloid cells and platelets may also be helpful. Hypersegmented neutrophils and large platelets support the diagnosis of megaloblastic anemia, and the presence of immature blast forms may be diagnostic of leukemia. Fig. 48.2 presents some common peripheral blood smear findings in patients with anemia.

In patients with anemia and an elevated reticulocyte count, the vigorous production of new erythroid cells suggests that marrow function is normal and is responding appropriately to the stress of the anemia. Bone marrow examination in this situation is rarely indicated because the marrow will simply show erythroid hyperplasia, usually without revealing any primary pathologic anomaly of the marrow. Evaluation in these cases should be focused on determining whether the cause of RBC consumption is bleeding or hemolysis. In contrast, bone marrow examination is more often required for the evaluation of hypoproliferative anemia. After common abnormalities such as iron deficiency and other nutritional deficiencies have been ruled out, marrow aspiration and biopsy are indicated to search for abnormalities such as marrow infiltration, marrow involvement with granulomatous disease, marrow aplasia, or myelodysplasia.

The *mean corpuscular volume* (MCV) is an extremely helpful tool in the diagnosis of anemia with a low reticulocyte count (hypoproliferative

anemia). The size of the RBCs (measured in femtoliters per cell) is used to characterize the anemia as microcytic (MCV <80), normocytic (MCV 80 to 96), or macrocytic (MCV >96).

EVALUATION OF HYPOPROLIFERATIVE ANEMIAS

Microcytic Anemias

The differential diagnosis of microcytic anemia is outlined in Table 48.2. Microcytosis and hypochromia are the hallmarks of anemias caused by defects in hemoglobin synthesis, which can reflect either failure of heme synthesis or abnormalities in globin production. The leading cause of microcytic anemia is iron deficiency, in which lack of heme synthesis results from the absence of iron to incorporate into the porphyrin ring (see later discussion). Up to 30% of patients with anemia of chronic inflammation have microcytosis. Lead poisoning blocks the incorporation of iron into heme, also resulting in a microcytic anemia.

Sideroblastic anemias arise from failure to synthesize the porphyrin ring, usually as a result of inhibition of the heme synthetic pathway enzymes. Congenital sideroblastic anemia may respond to pyridoxine, a cofactor for several of the heme synthetic pathway enzymes. A more common cause of acquired sideroblastic anemia is alcohol use; ethanol inhibits most of the enzymes in the heme synthetic pathway. Failure of globin synthesis occurs in thalassemic syndromes (see “Hemoglobinopathies”). All these disorders lead to decreased mean corpuscular hemoglobin concentration, resulting in hypochromia and a decrease in RBC size (i.e., low MCV).

Iron Deficiency Anemia

Iron deficiency is the leading cause of anemia worldwide. Although the presentation of classic iron deficiency anemia is linked with a microcytic anemia, early iron deficiency is associated with a normocytic anemia. Consequently, iron deficiency should be considered in all patients with anemia, and iron indices should be a part of the evaluation of any patient with hypoproliferative anemia, regardless of the MCV.

Iron is acquired in the diet from heme sources (i.e., meat) and from nonheme sources (e.g., vegetables such as spinach). Iron from heme is better absorbed than nonheme iron. Iron absorption is increased in iron deficiency, hypoxia, ineffective erythropoiesis, and hereditary

hemochromatosis (most commonly caused by mutations in the *HFE* gene). Iron is absorbed from the proximal small intestine; it is transported in the cell bound to ferroportin and through the plasma bound to transferrin. Its uptake into the RBC precursors is mediated through the transferrin receptor. Iron absorption from the intestine is further regulated by hepcidin (see “Anemia of Inflammation”). Iron outside hemoglobin-producing cells is stored in ferritin. Men and women have

total-body iron concentrations of 50 mg/kg and 40 mg/kg, respectively. Between 60% and 75% of the iron is found in hemoglobin. A small amount (2 mg/kg) is found in heme and nonheme enzymes, and 5 mg/kg is found in myoglobin. The remainder is stored in ferritin, which resides primarily in liver, bone marrow, spleen, and muscle. The capacity for excreting iron is limited, and iron overload occurs in patients with excessive absorption from the gastrointestinal tract (as a result of ineffective erythropoiesis or congenital hemochromatosis) and in those receiving chronic transfusions. Iron overload leads to increased iron deposition in these tissues and secondary deposition in endocrine and other organs, resulting in liver dysfunction, heart failure, diabetes, and other endocrine abnormalities.

The most frequent cause of iron deficiency is occult blood loss. All men and postmenopausal women who are found to be iron deficient should have an evaluation for a source of gastrointestinal blood loss and malignancy, regardless of the detection of occult blood. In premenopausal women, iron deficiency is most frequently related to loss of iron with menstruation (about 15 mg per month) and during pregnancy (about 900 mg per pregnancy). *Helicobacter pylori* infection can cause iron deficiency even in the absence of intestinal bleeding. Dietary deficiency of iron is most commonly seen in multiparous women of childbearing age, in young children whose growth outstrips their intake of iron, and in babies who drink mostly milk at the expense of an intake of iron-containing foods.

Laboratory evaluation. As previously stated, early iron deficiency does not exhibit the hallmark microcytosis and hypochromia that characterize classic iron deficiency. Evaluation of the blood smear in advanced iron deficiency often demonstrates hypochromic RBCs, target cells, and pencil-shaped elongated cells. Iron deficiency is frequently associated with reactive thrombocytosis.

The mainstay of the diagnosis of iron deficiency is the peripheral blood iron indices. These include iron concentration, total iron-binding capacity (TIBC), transferrin saturation, and ferritin concentration. The transferrin saturation is the ratio of serum iron to transferrin concentration; it is normally at least 20%. Iron deficiency results in a decrease in serum iron and an increase in iron-binding capacity, decreasing this ratio to less than 10%. Chronic inflammatory conditions (e.g., infection, inflammation, malignancy) often decrease both iron and TIBC, but the transferrin saturation usually remains above 20%. The ferritin level is a reflection of total-body iron stores. The liver synthesizes ferritin in proportion to total-body iron, and a level of less than 12 ng/mL strongly supports a diagnosis of iron deficiency. Unfortunately, ferritin is an acute phase reactant, and levels rise in the setting of fever, inflammatory disease, infection, or other stresses. However, ferritin levels in response to stress do not often rise above 100 ng/mL, and levels higher than 100 ng/mL usually rule out iron deficiency.

If the indirect measurement of iron indices does not definitively confirm or refute a diagnosis of iron deficiency, a therapeutic trial of iron supplementation may be considered. Alternatively, a bone marrow examination can be performed to provide a direct assessment of marrow iron stores. Presence of iron in the marrow excludes iron deficiency anemia because marrow iron stores will be depleted before there is any fall in RBC production resulting from iron deficiency; conversely, complete absence of marrow iron confirms the diagnosis of iron deficiency.

Treatment. Oral iron supplementation (e.g., ferrous sulfate or ferrous gluconate two or three times daily) has been the standard treatment for uncomplicated iron deficiency, but patient compliance is often limited by gastrointestinal side effects, notably dose-dependent constipation or diarrhea. However, emerging data suggest that standard iron dosing may be counterproductive. A recent study

demonstrated that a large oral dose of iron stimulates an increase in hepcidin (regulator of iron balance), which in turn suppresses further iron absorption up to 48 hours later, supporting an every-other-day dosing strategy. In iron-deficient women without anemia, cumulative iron absorption was superior in those receiving an alternate-day dosing over daily dosing and better tolerated. Larger prospective studies in patients with iron deficiency anemia are needed to confirm these findings. Overall, iron should be administered for several months after resolution of anemia to allow for the reconstitution of iron stores.

In patients with malabsorption, a complete inability to tolerate oral iron, or iron demands that outstrip replacement with oral supplements, parenteral iron may be administered. Historically, intravenous iron, specifically high-molecular-weight iron dextran, has been associated with anaphylaxis and was subsequently removed from markets globally. The newer parenteral iron formulations are safe and effective, including low-molecular-weight iron dextran, ferric gluconate, iron sucrose, ferumoxytol, iron isomaltoside, and ferric carboxymaltose. As previously stated, all male patients and postmenopausal women with iron deficiency require evaluation for a source of gastrointestinal bleeding.

Macrocytic Anemias

Two categories of hypoproliferative macrocytic anemias exist: megaloblastic anemias and nonmegaloblastic macrocytic anemias. Megaloblastic anemias arise from a failure of DNA synthesis and result in lack of synchrony between the maturation of the nucleus and the cytoplasm of hematopoietic cells. Nonmegaloblastic macrocytic anemias usually reflect membrane abnormalities resulting from defects in cholesterol metabolism and are most commonly found in patients with advanced liver disease or severe hypothyroidism. Reticulocytosis greater than 10% causes an elevated MCV on automated blood counts because reticulocytes are larger than mature RBCs.

Megaloblastic Anemias

Megaloblastic anemias result from a block in the synthesis of critical nucleotide precursors of DNA, which leads to a cell cycle arrest in S phase. Cytoplasmic maturation occurs, but maturation of the nucleus is arrested. Cells take on a bizarre appearance, with large immature nuclei surrounded by more mature-appearing cytoplasm. Interference with DNA synthesis affects all rapidly dividing cells, so patients with megaloblastic syndromes often have pancytopenia and gastrointestinal symptoms such as diarrhea and malabsorption. In women, megaloblastic changes of the cervical mucosa occur and may cause abnormal results on Papanicolaou smears. The most common causes of megaloblastic anemia are deficiencies of vitamin B₁₂ or folate, medications that inhibit DNA synthesis or that block folate metabolism, and myelodysplasia.

Cobalamin deficiency. Cobalamin (vitamin B₁₂) is absorbed from animal protein in the diet. The process of cobalamin absorption and metabolism is complex because cobalamin is always bound to other proteins. In the stomach, protein-bound vitamins are released by digestion with pepsin and are bound to haptocorrin (transcobalamin I). Within the proximal duodenum, pancreatic proteases digest cobalamin away from haptocorrin, and cobalamin binds to intrinsic factor (IF), also known as transcobalamin III. IF is secreted by the parietal cells of the stomach and mediates absorption of cobalamin through the cubam receptor in the distal ileum. Within the ileal mucosal cell, the IF-cobalamin complex is again digested, and cobalamin is released into the plasma bound to haptocorrin and transcobalamin II.

Within the cell, cobalamin is a cofactor for two intracellular enzymes, L-methylmalonyl-coenzyme A (CoA) mutase and homocysteine-methionine methyltransferase (Fig. 48.3). Methylmalonyl-CoA

mutase is a mitochondrial enzyme that functions in the citric acid cycle to convert methylmalonyl-CoA to succinyl-CoA. The cytoplasmic enzyme homocysteine-methionine methyltransferase is necessary for the transfer of methyl groups from *N*-methyltetrahydrofolate to homocysteine to form methionine. Demethylated tetrahydrofolate is necessary as a carbon donor in the conversion of deoxyuridine to deoxythymidine. Absence of cobalamin results in a *trapping* of tetrahydrofolate in its methylated form, which blocks the synthesis of thymidine 5'-triphosphate for incorporation into DNA. The megaloblastic changes induced by cobalamin deficiency are mediated through this functional folate deficiency, which explains the similarity in the hematologic abnormalities induced by cobalamin and folate deficiency.

Causes of cobalamin deficiency. The most common cause of cobalamin deficiency is pernicious anemia, an autoimmune disease associated with gastric parietal cell atrophy, defective gastric acid secretion, and absence of IF. Anti-parietal cell and anti-IF antibodies are frequently found in patients with pernicious anemia and other autoimmune conditions such as type 1 diabetes, vitiligo, Graves' disease, Addison's disease, and hypoparathyroidism. Many other lesions in the gastrointestinal tract can interfere with absorption of cobalamin (Table 48.3). Gastrectomy causes loss of parietal cell function and IF secretion. Pancreatic insufficiency interferes with

digestion of the haptocorrin-cobalamin complex, thus hindering the binding of cobalamin to IF and ileal absorption. Resection of the terminal ileum prevents vitamin B₁₂ absorption, as do diseases that affect ileal mucosal function, such as Crohn's disease, sprue, intestinal tuberculosis, and lymphoma. Because the body stores of cobalamin are large and daily loss of cobalamin is low, the stores of cobalamin are adequate for 3 to 4 years if intake stops abruptly; signs of cobalamin deficiency do not develop until defective absorption has occurred for several years. Nutritional cobalamin deficiency is rare and is seen only in individuals who have been on strict vegan diets that exclude all animal products for many years. Infants born to vegan mothers who are breastfed are also at risk for development of cobalamin deficiency.

Folate deficiency. Folate is widely present in foods such as leafy vegetables, fruits, and animal protein. However, because it is destroyed by prolonged cooking, fresh fruits and vegetables are the most reliable sources of folate. Consequently, nutritional folate deficiency is common in malnourished individuals who eat very little fresh fruits and vegetables. Folate deficiency can also be caused by increased demand, as occurs with pregnancy, hemolysis, or exfoliative dermatitis, and by increased losses, which occur with dialysis (Table 48.4). Folate is absorbed in the proximal small intestine, and malabsorption of folate can also lead to folate deficiency.

Other causes of megaloblastic anemia. Drugs and toxins are common causes of megaloblastic anemia. Some drugs, such as methotrexate and sulfa drugs, act as direct folate antagonists and mimic folate deficiency. Purine and pyrimidine analogue chemotherapeutic agents (e.g., azathioprine, 5-fluorouracil) are direct DNA-synthesis inhibitors. Antiviral agents cause megaloblastic changes by unclear mechanisms. Alcohol interferes with folate metabolism, increasing the effect of frequent concomitant nutritional folate deficiency. Myelodysplastic syndrome commonly appears as a macrocytic anemia, with megaloblastic changes primarily in the erythroid series.

Clinical manifestations of megaloblastic anemia. The development of megaloblastic anemia is usually gradual, allowing adequate time for concomitant plasma expansion to prevent hypovolemia. Consequently, patients are frequently severely anemic at presentation. They may have yellowish skin as the result of a combination of pallor from reduced red cell mass and jaundice from ineffective erythropoiesis and intramedullary hemolysis. Some patients have glossitis and cheilosis. With severe anemia, patients usually have an MCV greater than 110 fL/cell, although concomitant iron deficiency, caused by malabsorption secondary to megaloblastic

changes in the intestinal tract, may decrease the macrocytosis. Patients frequently have pancytopenia.

A peripheral blood smear demonstrates large, oval cells (macro-ovalocytes), hypersegmented neutrophils, and large platelets. The bone marrow is hypercellular, with megaloblastic changes and abnormally large erythroid series precursors. In addition, intramedullary destruction of erythrocytes (ineffective hematopoiesis) causes elevated concentrations of bilirubin (hence the jaundice described earlier) and lactate dehydrogenase.

Cobalamin deficiency is associated with neurologic abnormalities that are not seen with other causes of megaloblastic anemia. The neurologic signs may range widely, from a subtle loss of vibratory sensation and position sense caused by demyelination of the dorsal columns to frank dementia and neuropsychiatric disease. The neurologic changes may be present without anemia, especially if a patient with cobalamin deficiency is treated with folate, which may correct the hematologic manifestations of megaloblastic anemia but does not treat the neurologic abnormalities. The neurologic manifestations of cobalamin deficiency are thought to be secondary to loss of function of the mitochondrial enzyme methylmalonyl-CoA mutase. One proposed explanation is that the failure to metabolize odd-chain fatty acids, which results in their improper incorporation into myelin, causes the neurologic dysfunction. This explains why these findings are uniquely seen in patients with cobalamin deficiency and are not seen in those with the megaloblastic anemias caused by abnormalities in the folate pathway.

Serum levels of both cobalamin and folate should be measured in patients with megaloblastic anemia because megaloblastic changes in the gut mucosa can cause concomitant malabsorption of folate in the presence of cobalamin deficiency and vice versa. RBC folate levels better reflect the body folate stores and should be measured if a deficiency is clinically suggested but the serum folate levels are normal. Recent studies have shown, however, that many patients with pernicious anemia may have normal serum cobalamin levels. Homocysteine levels are elevated in cobalamin and folate deficiency, and methylmalonic acid levels are elevated in cobalamin deficiency. These levels should be measured if cobalamin deficiency is suggested but serum cobalamin levels are in the normal range. Anti-IF and anti-parietal cell antibodies may help determine the cause of cobalamin deficiency.

Treatment of megaloblastic anemia. For patients with cobalamin deficiency, both high-dose oral and parenteral cobalamin administration have been shown to be effective. The oral dose should be at least 1000 µg daily. Patients with neurologic abnormalities or medication noncompliance and those who have not responded to oral therapy should receive parenteral therapy with 1000 µg subcutaneously or intramuscularly several times per week for four to eight doses. Maintenance therapy should then be instituted with 1000 µg parenterally monthly. Therapy with cobalamin should be accompanied by folate therapy because concomitant secondary folate deficiency may develop when RBC production increases with the availability of cobalamin. Treatment of pernicious anemia should be continued for life.

Patients with folate deficiency should receive replacement with 1 to 5 mg per day of oral folate. As previously stated, it is critical to be certain that patients are not cobalamin deficient: Replacement of folate may correct the hematologic parameters in patients with cobalamin deficiency, but it will not improve the neurologic sequelae.

After treatment of megaloblastic anemia, a rapid response usually occurs. Reticulocytosis is seen as early as 2 days after therapy and peaks within 7 to 10 days. Despite rapid resolution of neutropenia, hypersegmentation of neutrophils may persist for several days. During this period, rapid cellular proliferation and turnover occur, which may precipitate hypokalemia, hyperuricemia, or hypophosphatemia. Patients

should also be monitored for the development of iron deficiency, which may occur in the face of increased hematopoiesis. Anemia and other cytopenias should respond completely within 1 to 2 months, but the neurologic manifestations of cobalamin deficiency improve slowly and may be irreversible.

Normocytic Anemias

The differential diagnosis of a normocytic hypoproliferative anemia is extensive. Most nutritional anemias that cause microcytosis or macrocytosis begin as a normocytic anemia. Patients with combined nutritional deficiencies may also have a normal MCV. The measurement of EPO levels may be helpful in the diagnosis of anemia resulting from renal failure, and many of the anemias associated with chronic inflammation and endocrinopathies exhibit a depressed EPO level. However, interpretation of EPO levels can be difficult in patients with mild anemia because the levels do not usually rise above the normal range until the hematocrit is depressed below 30%. Even with a hematocrit level of 30%, the EPO level is often in the normal range, but such levels are inappropriately low in the setting of anemia. An elevated EPO level suggests an inadequate marrow response to anemia and increases the likelihood of myelophthisis or primary bone marrow failure. In patients for whom the diagnosis is not clear after routine nutritional and endocrine studies, a bone marrow examination is indicated to rule out primary pathologic conditions of the marrow.

Anemia of Inflammation

The anemia of inflammation (previously called anemia of chronic disease) occurs in patients with chronic inflammatory, infectious, malignant, or autoimmune disorders. Patients have low-serum iron levels, but in contrast to the iron indices in iron deficiency anemia, the iron-binding capacity is also reduced, and the transferrin saturation is usually greater than 10%. Ferritin levels are often elevated, both as an acute phase reactant and as a reflection of decreased iron incorporation. These patients have inappropriately high levels of hepcidin, an acute phase reactant that facilitates the metabolism of ferroportin and reduces both intestinal iron absorption and iron mobilization from macrophages. Cytokines, including tumor necrosis factor, the interleukins, and interferon, also play a role in the anemia of inflammation, both by inducing hepcidin and by directly increasing EPO resistance in erythroid progenitors. Patients have an absolute or relative EPO deficiency, poor iron incorporation into developing erythrocytes, and shortened erythrocyte survival time. The prevalence of anemia of inflammation increases with age; most likely, this is related to age-related comorbidities and mediated through an increase in inflammatory cytokines and a relative EPO resistance.

Treatment of normocytic anemias. The mainstay of therapy for the anemia of chronic inflammation is treatment of the underlying condition and correction of nutritional deficiencies. Iron supplementation should be offered to all patients with a ferritin level lower than 100 ng/mL. Erythroid-stimulating agents (ESAs) have been shown to reduce transfusion needs in many of these patients. However, randomized studies and meta-analyses have shown that their use is associated with an increased incidence of arterial and venous thromboembolic events, an increased risk of mortality from cancer, and a reduced survival time. ESA should be avoided in cancer patients if they are being treated with curative intent, and in all other patients with cancer they should be offered only after a careful discussion of the risks and benefits (grade 1B recommendation).

Anemia of Chronic Kidney Disease

Most patients who have a glomerular filtration rate of less than 30 mL/min have anemia primarily reflecting low EPO levels. ESAs can

HELLP, Hemolysis, elevated liver enzymes, and low-platelet count in association with preeclampsia.

help prevent transfusions in this population; however, their use has been associated with an increased risk of stroke, access thrombosis, hypertension, and even mortality in some studies, especially when the hemoglobin levels were normalized. Therefore, most guidelines recommend a target hemoglobin concentration of 10 to 11.5 g/dL when using ESA in patients with chronic kidney disease (grade IB). As in the management of anemia of chronic inflammation, nutritional deficiencies should be corrected before the use of ESAs. The evaluation and treatment of primary marrow failure syndromes and hematologic malignancies are discussed in [Chapters 46 and 47](#) respectively.

EVALUATION OF ANEMIA WITH RETICULOCYTOSIS

An elevated reticulocyte count in the setting of anemia signals a compensatory response by a normal marrow to premature loss of erythrocytes. Hemolysis is the premature destruction of RBCs in the reticuloendothelial system (extrinsic hemolysis) or in blood vessels (intrinsic or intravascular hemolysis). The only other condition that causes anemia with reticulocytosis is acute bleeding. The differential diagnosis of hemolytic anemia is outlined in [Table 48.5](#).

Whereas examination of the peripheral blood smear is helpful in characterizing any anemia, it is absolutely critical in the evaluation of

hemolytic anemia. Morphologic examination of the erythrocytes is helpful in distinguishing immune hemolysis from microangiopathic hemolytic anemia. In addition, other RBC morphologic abnormalities are characteristic for specific diseases such as sickle cell disease (sickled cells), enzyme defects (*bite* cells), and erythrocyte membrane abnormalities (spherocytes, elliptocytes, stomatocytes).

Immune Hemolytic Anemia

Immune-mediated hemolysis results from coating of the erythrocyte membrane with antibodies or complement, or both. It may be mediated by immunoglobulin G (IgG) antibodies (*warm* antibody) or by IgM antibodies (*cold* antibody). The designations *warm* and *cold* denote the temperature at which maximal antibody binding takes place and the clinical syndromes caused by the two types of antibodies are distinct.

The diagnosis of hemolytic anemia is based on the direct and indirect antiglobulin (Coombs) tests. To perform a direct Coombs test, the patient's erythrocytes are mixed with antisera or monoclonal antibodies directed against human immunoglobulins and human complement. The cells are then monitored for agglutination, the presence of which confirms the presence of antibody or complement on the patient's RBCs. The indirect Coombs test is performed by mixing the patient's serum with ABO-compatible erythrocytes and then combining this mixture with antisera against IgG; the indirect Coombs tests allows for the evaluation of antibody in the patient's serum.

IgG-Mediated (Warm) Hemolytic Anemia

Classic autoimmune hemolytic anemia (AIHA) is caused by IgG antibody directed against erythrocyte antigens. Warm type hemolysis may be primary (idiopathic) or associated with autoimmune disease, lymphoproliferative disorders, or drugs. Patients exhibit acute anemia, jaundice, and an elevated reticulocyte count. Some patients have splenomegaly. The peripheral blood smear demonstrates spherocytes (see [Fig. 48.2E](#)). Laboratory analysis confirms the presence of IgG on the erythrocyte membrane, as demonstrated by a positive Coombs test; in some patients, the erythrocytes are also coated with complement. Some patients do not have reticulocytosis; in them, the antibody may be destroying both reticulocytes and mature erythrocytes.

The mainstay of therapy for AIHA is corticosteroids. Patients are usually treated with 1 to 2 mg/kg of prednisone, and in responding patients, doses are tapered slowly over several months. Patients who fail to respond to prednisone or cannot be tapered off the prednisone can be treated with other immunosuppressive agents, such as cyclophosphamide, azathioprine, chlorambucil, or rituximab. Some patients respond to intravenous immunoglobulin. Splenectomy is effective in many patients who are corticosteroid refractory or corticosteroid resistant, and it is associated with greater sustained response rates than other immunosuppressive therapies in corticosteroid-resistant patients. However, patients who do not respond and who have ongoing hemolysis after splenectomy are at high risk for secondary thromboembolic events.

Warm antibodies mediate *drug-induced hemolysis*. Several mechanisms exist through which drugs may induce AIHA ([Table 48.6](#)). Penicillin produces hemolysis by binding to erythrocytes and acting as a hapten; the antibody is directed against the drug, and hemolysis occurs only in the presence of the drug. Type 2 hemolysis is caused by the formation of an antibody-drug complex that binds to the erythrocyte membrane and activates complement. Drugs associated with this type of hemolysis include quinidine, quinine, and rifampin. Still other drugs, including methyl dopa and procainamide, cause hemolysis by inducing the production of *true* antierythrocyte antibodies

TABLE 48.6 Drug-Induced Autoimmune Hemolytic Anemia

Type	Mechanism	Common Drugs Implicated	Direct Coombs Test	Indirect Coombs Test
1	Hapten mediated	Penicillin Cephalothin	IgG positive Complement positive or negative	Positive only in the presence of drug

IgG, Immunoglobulin G; RBC, red blood cell.

directed against Rh and other RBC antigens. Antibody may persist in the absence of the drug, but not all patients with a positive Coombs test have evidence of hemolysis.

IgM-Mediated (Cold) Hemolytic Anemia

Cold-type immune hemolysis is usually postinfectious. The most common associated infectious agents are *Mycoplasma pneumoniae* and Epstein-Barr virus (EBV). IgM antibodies are produced that are directed against the RBC antigen I (*Mycoplasma*) or i (EBV). The antibodies bind at lower temperatures, present in fingers and toes, and bind complement. During the return to the central circulation, the IgM falls off the RBC, leaving complement bound. The Coombs test is negative for IgG and IgM but positive for complement. Hemolysis is self-limited, is rarely severe, and resolves with supportive therapy. In cases of severe hemolysis requiring transfusion, the patient should be kept warm, and blood should be administered through a blood warmer to minimize further hemolysis.

Cold agglutinin disease is a chronic IgM antibody-mediated hemolysis that is usually seen in association with lymphoproliferative diseases. Hemolysis is usually low grade; if severe, it responds poorly to steroids and splenectomy. Acute severe IgM-mediated hemolysis may respond to plasmapheresis, rituximab, and treatment directed against the lymphoproliferative disorder when present. Supportive therapy includes avoidance of exposure to the cold.

Hemolysis From Causes Extrinsic to the Erythrocyte

Microangiopathic Hemolysis

Microangiopathic hemolytic anemia (MAHA) is caused by traumatic destruction of RBCs as they pass through small vessels. The leading causes of MAHA include thrombotic thrombocytopenic purpura and hemolytic-uremic syndrome (TTP/HUS) (see Table 48.5 and Fig. 48.1). Other causes include pregnancy-related syndromes such as preeclampsia, eclampsia, and the HELLP syndrome (*hemolysis, elevated liver enzyme levels, and low platelet count*); drugs; and metastatic cancers. A similar hemolytic picture can be seen in traumatic hemolysis on a damaged cardiac valve (native or prosthetic).

The finding of schistocytes (fragmented erythrocytes) on the peripheral blood smear confirms the diagnosis of MAHA (see Fig. 48.2D). The presence of normal prothrombin and partial thromboplastin times supports a diagnosis of TTP/HUS over that of disseminated

intravascular coagulation. Diagnosis and management are described further in Chapter 52.

Infection

Hemolysis can be caused by direct infection of RBCs by parasites, as seen in malaria, babesiosis, and bartonellosis. Severe, overwhelming hemolysis can be seen in clostridial sepsis, in which bacterial toxins directly damage the membrane.

Hemolytic Anemias Caused by Disorders of the Erythrocyte Membrane

Inherited Membrane Abnormalities

Hereditary spherocytosis (HS) is caused by heterogeneous congenital abnormalities in proteins of the erythrocyte cytoskeleton (Table 48.7). Most patients with HS have dominantly inherited mutations in spectrin or ankyrin. HS is characterized by hemolytic anemia, splenomegaly, and the presence of prominent spherocytes in the peripheral blood. Spherocytes are the result of *conditioning* of the erythrocytes in the spleen, during which venous sinus endothelial cells and reticuloendothelial cells remove portions of the abnormal membrane that are caused by the disordered cytoskeleton. Spherocytes reflect membrane loss that decreases the membrane-to-cytoplasm ratio. Because a high membrane-to-cytoplasm ratio is responsible for the flexible, biconcave shape of the normal erythrocyte, the erythrocyte loses its biconcave morphologic characteristics and assumes a spherocytic shape with loss of membrane. Spherocytes

are less flexible and may be destroyed in the microvasculature. The laboratory finding characteristic of HS is increased osmotic fragility, which is caused by the loss of distensibility associated with a decrease in surface membrane. HS is usually a mild disorder with well-compensated hemolysis. Patients typically have exacerbations during infections or when given marrow-suppressing medication. Patients with significant hemolysis should receive folate supplementation. Many patients require cholecystectomy for pigment stones. Severe, symptomatic anemia is treated with partial or total splenectomy.

Hereditary elliptocytosis (HE) is caused by dominantly inherited mutations affecting the interactions between membrane proteins and underlying cytoplasmic proteins. The most common abnormalities affect the interactions with spectrin and protein 4.1, which causes the RBCs to assume an elliptical shape. As in HS, patients usually have mild hemolysis and splenomegaly.

Hereditary pyropoikilocytosis (HPP) is a rare recessive disorder that is frequently caused by the inheritance of two different membrane disorders (e.g., one allele for HS and one for HE). Patients have severe hemolysis with microspherocytes and elliptocytes on the peripheral blood smear. As with HS, treatment for symptomatic anemia in HE and HPP is splenectomy.

Hereditary stomatocytosis is caused by autosomal dominant mutations leading to abnormalities in RBC permeability and volume, either in an overhydrated form (OHS), dehydrated form (DHS) or near normal form. These rare membranopathies are heterogeneous in presentation with syndromic and nonsyndromic forms with varying degrees of hemolytic anemia and are confirmed with genetic testing. Treatment is supportive but splenectomy should be avoided due to increased risk of thrombosis in certain types and care should be made to distinguish from hereditary spherocytosis for which splenectomy is the indicated therapy.

More information on hemolytic anemias caused by inherited membrane disorders can be found in Chapter 152, "Hemolytic Anemias: Red Cell Membrane and Metabolic Defects," in *Goldman-Cecil Medicine*, 26th Edition.

Acquired Membrane Abnormalities

Paroxysmal nocturnal hemoglobinuria. Paroxysmal nocturnal hemoglobinuria (PNH) is an acquired clonal disease that is associated with an abnormality of complement regulation. Normal erythrocytes are protected from complement-mediated cell lysis by the presence of membrane proteins, including decay-accelerating factor (DAF or CD55) and membrane inhibitor of reactive lysis (MIRL or CD59). Both these proteins are members of a family of proteins that are anchored to the membrane by a glycosyl phosphatidylinositol (GPI) anchor. Patients with PNH have clonal mutations in phosphatidylinositol glycan A (PIG-A), the enzyme required for synthesis of GPI. These mutations arise in the hematopoietic stem cell, and subsequently all hematopoietic cells lack GPI-anchored proteins. Absence of GPI-anchored proteins from erythrocytes renders them susceptible to complement-mediated lysis. The diagnosis can be made by flow cytometric documentation of the absence of CD55 or CD59 on the surface of RBCs or leukocytes.

PNH is a clonal stem cell disorder with several unique characteristics. Patients suffer from episodic acute intravascular hemolysis with a release of free hemoglobin that results in the hemoglobinuria for which the disease is named. The dark, hemoglobin-pigmented urine is most prominent in the morning after concentrating overnight during sleep. Patients are also susceptible to venous thrombotic complications, including Budd-Chiari syndrome, portal vein thrombosis, cerebrovascular thrombosis, and peripheral veins. The disease is associated with a risk for development of myelodysplasia, myelofibrosis, acute

leukemia, or aplastic anemia. Furthermore, patients with aplastic anemia who respond to immunosuppressive therapy frequently develop PNH-like clones. In the past, treatment has been largely supportive. However, treatment with eculizumab and ravulizumab, monoclonal antibodies that bind to the C5 component of complement, have been shown to reduce hemolysis and transfusion requirements in this disease. Eculizumab also reduces thromboembolic events; this end point has not yet been addressed in the more recently approved ravulizumab. Young patients should be considered for allogeneic stem cell transplantation.

Spur cell anemia. Spur cells (acanthocytes) are cells with abnormal membrane morphology found in patients with advanced liver disease, severe malnutrition, malabsorption, or asplenia. The membrane acquires protrusions as a result of the presence of abnormal lipids. The changes may be associated with mild hemolysis, although in patients with advanced liver disease, it is difficult to distinguish hemolysis from hypersplenism. Similar changes may be observed in patients with abetalipoproteinemia.

Hemolytic Anemias Caused by Disorders of Erythrocyte Enzymes

Glucose-6 Phosphate Dehydrogenase Deficiency

Glucose-6-phosphate dehydrogenase (G6PD) is a critical enzyme in the hexose monophosphate shunt pathway. By maintaining intracellular stores of reduced glutathione, it protects erythrocytes from membrane and hemoglobin oxidation (Fig. 48.4). The gene for G6PD resides on the X chromosome, and therefore almost all patients with G6PD deficiency are male. Most G6PD mutations are found in African and Mediterranean populations, most likely because they confer resistance to malaria. The African form of G6PD deficiency is relatively mild, whereas the Mediterranean form is severe.

Absence of G6PD renders erythrocytes sensitive to oxidative stress. In the setting of infection, inflammation acidosis, or oxidant drugs, hemoglobin may precipitate within the cells, causing hemolysis. Many drugs are associated with hemolysis in the setting of G6PD deficiency, including sulfonamides, antimalarials, dapson, aspirin, and phenacetin. The diagnosis should be considered in male patients of African or Mediterranean extraction who have evidence of hemolysis in the

setting of acute infection or recent exposure to oxidant drugs. Patients with the Mediterranean variant of G6PD deficiency may develop hemolysis on exposure to fava beans (favism). Cells with precipitated hemoglobin contain Heinz bodies that can be visualized with crystal violet staining of the peripheral blood smear. These inclusions are removed in the spleen, resulting in the additional finding of bite cells in the blood smear. The diagnosis can be confirmed with measurement of G6PD levels in the peripheral blood. However, reticulocytes and young RBCs in patients with G6PD deficiency have a higher enzyme level; consequently, if the diagnosis is probable, the patients with a normal G6PD level should be retested at a time removed from the acute episode, when the percentage of young RBCs is high. The mainstay of preventing hemolysis in these patients is avoidance of oxidative stress, especially drugs implicated in causing hemolysis. Splenectomy is recommended only for patients with severe episodic or chronic hemolysis.

Other Enzyme Deficiencies

Enzyme deficiencies as rare causes of hemolytic anemia have been reported involving almost all of the enzymes of the glycolytic pathway. The most common of these is pyruvate kinase deficiency. Autosomal genes encode these enzymes, and the pattern of inheritance is therefore autosomal recessive.

More information on hemolytic anemias caused by inherited enzyme deficiencies can be found in Chapter 152, "Hemolytic Anemias: Red Cell Membrane and Metabolic Defects," in *Goldman-Cecil Medicine*, 26th Edition.

Hemoglobinopathies

Hemoglobinopathies are disorders caused by mutations that result in the synthesis of quantitatively or qualitatively abnormal hemoglobins. The most common of these are the sickle syndromes and the thalassemias, which, like G6PD deficiency, arose in areas of the world with endemic malaria.

Sickle Cell Disease

Sickle cell disease, the most common of the sickle syndromes, arises from a point mutation that causes a substitution of valine for glutamic acid in the sixth amino acid of the β -globin gene. It has arisen as an independent mutation in diverse populations in Africa, India, the Mediterranean, and the Middle East. The substitution of a hydrophobic for a hydrophilic residue renders the deoxygenated sickle hemoglobin (HbS) less soluble and therefore susceptible to polymerization and precipitation. The rate of precipitation of HbS is exquisitely sensitive to the intracorporeal concentration of deoxygenated hemoglobin. Sickling is therefore increased in settings in which that concentration is increased, either by changes in cellular hydration (dehydration) or by changes in the oxygen dissociation curve (e.g., hypoxia, acidosis, high altitude).

Acute manifestations. Most of the acute complications of sickle cell disease are related to vaso-occlusion (Table 48.8). Painful crises, secondary to occlusions of the microvasculature and ischemia of organs and tissues, can occur anywhere, with pain most commonly experienced in the extremities, chest, abdomen, and back. Painful crises are commonly precipitated by infections, dehydration, rapid changes in temperature, and pregnancy. Often, however, no obvious precipitating cause is found for an acute painful crisis.

Vaso-occlusion in the pulmonary circulation can be a particularly ominous complication of sickle cell disease. It results in the *acute chest syndrome*, which is characterized by chest pain, hypoxemia, and pulmonary infiltrates. The roles of infection, infarction, and in situ thrombosis in the acute chest syndrome are indistinguishable, but all patients should receive antibiotics for presumed pneumonia. Because hypoxemia predisposes to further sickling and increasing respiratory

TABLE 48.8 Clinical Manifestations of Sickle Cell Disease

Acute Manifestations	Chronic Manifestations
Vaso-occlusive crisis	Chronic renal disease
Painful crisis	Isosthenuria

Hemorrhagic stroke	Avascular necrosis
Aplastic crisis	Skin ulcers
Splenic sequestration	
Osteomyelitis	

compromise, the acute chest syndrome is life-threatening and is an indication for emergent exchange transfusion.

Neurologic events are a major cause of morbidity in patients with sickle cell disease. Acute large-vessel occlusions occur in children, with a recurrence rate of 70% if untreated; such strokes are an indication for long-term exchange transfusion, which has been shown to decrease the rate of repeated occlusions. For reasons that are poorly understood, such large-vessel occlusions rarely occur in adults. Adults may suffer hemorrhagic strokes as a result of aneurysmal dilation of proliferative vessels that form in response to repeated micro-occlusions in the cerebral vessels.

Any toxic or infectious insult that transiently suppresses bone marrow activity can cause an *aplastic crisis*. The shortened survival time of the RBC in sickle cell disease renders patients highly dependent on vigorous ongoing marrow activity, and short intervals of decreased reticulocyte formation can cause profound anemia. Most dramatic are infections associated with parvovirus B19, which directly infects erythroid precursors. Supportive care is usually all that is required. However, some patients go on to develop bone marrow necrosis, with a leukoerythroblastic picture; this development may be further complicated by bone marrow embolization to the lungs.

Certain vascular beds are especially prone to complications of sickle cell disease. The renal medulla is highly susceptible to damage by vaso-occlusion because its high tonicity and low oxygen tension both significantly increase the concentration of HbS. All patients with sickle cell disease develop defects in the ability to concentrate urine, and by adulthood, they are uniformly isosthenuric. Acute episodes of hematuria secondary to papillary necrosis are common.

The spleen is another site in which recurrent sickling uniformly occurs. Although in childhood the spleen can sequester blood cells, by adulthood all patients have become functionally asplenic from repeated infarctions of the microvasculature. This contributing factor increases the susceptibility of patients with sickle cell disease to infections with encapsulated organisms. Acute infection remains a significant cause of death. For unclear reasons, patients with sickle cell disease are particularly prone to osteomyelitis, and there is an unusually high incidence of *Salmonella* as the responsible organism.

Chronic manifestations. Sickle cell disease used to be a disease of childhood. As more patients survive to adulthood, it has become clear that repeated episodes of vaso-occlusion lead to damage to almost every end organ (see Table 48.8). Renal failure and pulmonary failure are leading causes of death in adult patients with sickle cell disease. Other long-term complications include chronic skin ulcers, retinopathy, and liver dysfunction. In addition, most patients require cholecystectomy for pigment stones.

TABLE 48.9 Thalassemic Syndromes

Disorder	Genotypic Abnormality	Clinical Phenotype
β-Thalassemia		
Thalassemia major (Cooley's anemia)	Homozygous β^0 -thalassemia	Severe hemolysis, ineffective erythropoiesis, transfusion dependency, iron overload
Thalassemia intermedia	Compound heterozygous β^0 - and β^+ -thalassemia	Moderate hemolysis, severe anemia, but not transfusion dependent; iron overload
Thalassemia minor	Heterozygous β^0 - or β^+ -thalassemia	Microcytosis, mild anemia
α-Thalassemia		
Hydrops fetalis	--/--	Severe anemia, intrauterine anasarca from congestive heart failure; death in utero or at birth
Hemoglobin H	α -/--	Microcytic anemia and mild hemolysis; not transfusion dependent
α -Thalassemia trait	$\alpha\alpha$ -/ (α -thalassemia 1) or - α -/ α (α -thalassemia 2)	Mild microcytic anemia
Silent carrier	- α / $\alpha\alpha$	Normal complete blood count

Treatment. Treatment of sickle cell disease remains largely supportive. Painful crises are treated with fluid, oxygen supplementation, and analgesics. Patients with any indication of infection should receive antibiotics. Patients with symptomatic anemia should be transfused. Exchange transfusion is indicated for chest syndrome, stroke, bone marrow necrosis, and priapism. More controversial indications for exchange transfusion include intractable pain and slow response to other supportive measures. The goal of exchange transfusion is to achieve a level of 30% to 40% HbS. As previously mentioned, patients who have sustained a thrombotic large-vessel stroke should undergo chronic exchange transfusion.

Hydroxyurea has been the main disease-modifying agent for patients with sickle cell disease. Treatment with hydroxyurea, an agent that increases the concentration of HbF in patients with sickle cell disease, reduces the incidence of vaso-occlusive crises. The efficacy of hydroxyurea in patients with recurrent crises has been demonstrated in a randomized study, and follow-up studies have revealed a survival advantage for patients treated with hydroxyurea. More recently, three additional agents have been approved; two further reduced sickle cell crises (L-glutamine and crizanlizumab) and the last increased hemoglobin levels (voxelotor). In a randomized study, L-glutamine therapy demonstrated significantly fewer sickle cell crises with most patients on both arms already receiving hydroxyurea. L-glutamine is hypothesized to reduce oxidative stress and potential pain crises by increasing reduced nicotinamide adenine dinucleotide in sickle cells. In another randomized trial, crizanlizumab, a P-selectin inhibitor, also significantly reduced sickle cell crises. P-selectin initiates the process of leukocyte adhesion to vascular endothelium during inflammation that leads to vaso-occlusion. Most recently, voxelotor, an agent that inhibits HbS polymerization by stabilizing the oxygenated hemoglobin state, has led to decreased hemolysis and improved anemia and is now an approved therapy.

The only curative treatment for sickle cell disease is allogeneic stem cell transplant although lack of donor matches remains a barrier.

Other Sickle Syndromes

Hemoglobin C. Hemoglobin C (HbC) is caused by another substitution, glutamic acid to lysine, in the sixth position of the β -globin chain. Homozygous HbC causes very mild symptoms of anemia and is usually clinically silent. Patients with hemoglobin S-C (HbSC) are compound heterozygotes for HbS and HbC. These patients are asymptomatic, although the clinical manifestations are milder than in

patients with homozygous HbS (HbSS). They have a higher hematocrit, but the higher viscosity increases the degree of retinopathy. They do not sustain splenic infarctions; unlike patients with HbSS, they usually have splenomegaly. Consequently, they occasionally have episodes of acute splenomegaly associated with profound decreases in hemoglobin concentration and hematocrit (splenic sequestration crisis). Although such crises also occur in children with HbSS, functional asplenia prevents this complication in adults with HbSS.

Sickle cell β -thalassemia. Patients who are double heterozygotes for HbS and β -thalassemia have a spectrum of disease dependent on the level of β -globin that they produce. Sickle cell β^+ -thalassemia is a milder disease than HbSS, probably because of the decreased intracorporeal concentration of HbS. Patients with sickle cell β^0 -thalassemia (see discussion that follows) produce no normal β chains and have essentially the same phenotype as patients with HbSS.

Thalassemia

The thalassemic syndromes (Table 48.9) are a heterogeneous group of disorders associated with decreased or absent synthesis of either α - or β -globin chains. Severe thalassemic syndromes are associated with severe hemolytic anemia and are diagnosed in early childhood. However, mild forms of thalassemia minor frequently cause mild microcytic anemia with little or no evidence of hemolysis. These syndromes are often confused with iron deficiency because of the decreased MCV.

β -Thalassemia. Over 100 mutations have been described that lead to β -thalassemia, causing a decrease or absence of expression from the β -globin locus. The decreased expression of β -globin can be caused by structural mutations in the coding region of the gene, which result in nonsense mutations, truncated messenger RNA (mRNA), and no expression of intact globin from the affected allele (β^0 -thalassemia). However, a large number of mutations that result in decreased transcription or translation or altered splicing of the β -globin mRNA result in reduction but not elimination of globin-chain expression from the affected allele (β^+ -thalassemia).

Defective globin-chain synthesis in β -thalassemia causes both decreased normal hemoglobin production and the production of a relative excess of α chains. The decrease in normal hemoglobin synthesis results in a hypochromic anemia, and the excess α chains form insoluble α -chain complexes and cause hemolysis. In mild thalassemic syndromes, the excess α chains are insufficient to cause significant hemolysis, and the primary finding is a microcytic anemia. In severe

forms of thalassemia, hemolysis occurs both in the peripheral blood and in the marrow, with intense secondary expansion of the marrow production of RBCs. The expansion of the marrow space causes severe skeletal abnormalities, and the ineffective erythropoiesis also provides a powerful stimulus to absorb iron from the intestine.

The clinical spectrum of β -thalassemia reflects the heterogeneity of the molecular lesions causing the disease (see Table 48.9). β -Thalassemia major results from homozygous β^0 -thalassemia, leading to severe hemolytic anemia; such patients are diagnosed in infancy and are transfusion dependent from birth. Patients with β -thalassemia intermedia also have two β -thalassemia alleles, but at least one of them is a mild β^+ mutation. These patients have severe chronic hemolytic anemia but do not require transfusions. Because of ineffective erythropoiesis, the patients chronically hyperabsorb iron and may develop iron overload in the absence of transfusions. β -Thalassemia minor is usually caused by heterozygous β -thalassemia, although it may reflect the inheritance of two mild thalassaemic mutations. These are the patients in whom iron deficiency is often misdiagnosed. Iron studies show normal to increased iron with normal iron saturation. Documentation of a compensatory increase in HbA₂ and HbF on hemoglobin electrophoresis confirms the diagnosis.

α -Thalassemia. α -Thalassemia is almost always caused by mutations that delete one or more of the α -chain loci on chromosome 16. Four α -chain loci exist with two, almost identical, copies of the α -globin gene on each chromosome. The spectrum of α -thalassemia therefore reflects the lack of one, two, three, or all four α -globin genes (see Table 48.9). In general, the clinical manifestations of α -thalassemia are milder than those of β -thalassemia for two reasons. First, the presence of four α -chain genes allows for adequate α -chain synthesis unless three or four loci are deleted. Second, β -chain tetramers are more soluble than their α -chain counterparts and do not cause hemolysis. Patients with the loss of a single α -chain gene are silent carriers and have a normal hematocrit and MCV. Patients with deletion of two α chains, either on the same chromosome ($--/\alpha\alpha$, called α -thal 1) or on different chromosomes ($-\alpha/-\alpha$; α -thal 2), are microcytic and mildly anemic. Patients who inherit one α -thal 1 allele and one α -thal 2 allele ($--/-\alpha$) have hemoglobin H disease. Hemoglobin H is the product of excess β -chain production, specifically β_4 ; it causes mild hemolytic anemia and minimal or no intramedullary erythrocyte destruction. Inheritance of the homozygous α -thal 2 allele results in no functional α -chain loci and is incompatible with life. The fetus is unable to make any functional hemoglobin beyond embryonic development because HbF also requires α chains. Free γ chains form tetramers, termed *hemoglobin Barts*. Hemoglobin Barts have an extremely high oxygen affinity, and failure to release oxygen in peripheral tissues results in severe congestive heart failure and anasarca, a clinical picture termed *hydrops fetalis*. Affected fetuses are stillborn or die soon after birth.

Treatment. Though management of patients with thalassemia is mainly supportive (transfusion therapy, folic acid supplementation, iron chelation as needed), a disease-modifying erythroid maturation agent, luspatercept, has recently been approved. Luspatercept binds to specific TGF β ligands that inhibit aberrant Smad2/3 signaling and results in improved erythropoiesis. A randomized trial of luspatercept demonstrated lowered transfusion burden in adults primarily with β -thalassemia.

More information on the thalassemias, sickle cell disease, and other hemoglobinopathies can be found in Chapter 153, "The Thalassemias," and Chapter 154, "Sickle Cell Disease and Other Hemoglobinopathies," in *Goldman-Cecil Medicine*, 26th Edition.

PROSPECTUS FOR THE FUTURE

Anemia is increasingly recognized as a marker of increased morbidity and mortality in adults with a wide range of medical conditions, including renal failure, malignancy, cardiac disease, inflammatory conditions, and other chronic diseases. Advances in understanding the pathophysiology of anemia of chronic inflammation are contributing to knowledge of iron metabolism and the roles cytokines play in hematoipoiesis. These developments are paving the way for the development of new therapies for patients with anemia and iron overload. Ongoing progress in stem cell transplantation will contribute to the ability to treat and potentially cure various hemoglobinopathies, and gene therapy approaches are also being piloted.

Clinical Disorders of Granulocytes and Monocytes

Ellice Wong, Michal G. Rose, Nancy Berliner

INTRODUCTION

Leukocytes, or white blood cells (WBCs), provide the main defense against bacterial infection. Granulocytes (primarily neutrophils) and monocytes are phagocytic cells that can kill ingested bacteria through the generation of reactive intermediates. Monocytes also release inflammatory mediators that increase the activity of lymphocytes. Lymphocyte function is discussed in [Chapter 50](#).

NORMAL GRANULOCYTE DEVELOPMENT, STRUCTURE, AND FUNCTION

Neutrophils

Neutrophils (i.e., polymorphonuclear leukocytes) are the predominant WBC in the peripheral blood. They are morphologically recognizable by their characteristic segmented nucleus and cytoplasmic granules that are functionally important ([Fig. 49.1](#)).

Neutrophils achieve intracellular killing of bacteria through chemotaxis, margination, adhesion, and phagocytosis ([Fig. 49.2](#)). *Chemotaxis* is the ordered movement of the cell toward an attracting stimulus, such as bacterial formyl peptides or complement fragments (i.e., C3b and C5a). In *margination*, neutrophils move toward endothelial cells lining the blood vessel walls. Neutrophils attach to endothelial cells by interaction of neutrophil surface glycoproteins (i.e., CD11b/CD18) with endothelial adhesion molecules (i.e., intercellular adhesion molecule 1 and endothelial leukocyte adhesion molecule 1) in a process called *adhesion*. In response to a chemotactic stimulus, the adherent neutrophils move toward the target along the endothelial surface.

The leukocyte adhesion deficiency (LAD) syndromes are associated with impaired migration of leukocytes (particularly neutrophils) from the vasculature into tissues resulting in neutrophilia, inability to form pus, impaired wound healing, and recurrent bacterial infections. This rare group of congenital diseases is characterized by beta integrin defects, selectin receptor abnormalities, as well as loss of the C3b receptor (which mediates opsonin-induced phagocytosis). Disease therefore results both from failure of adhesion and from failure to phagocytose opsonized bacteria.

Phagocytosis requires recognition of target bacteria or debris by the neutrophil. Targets are opsonized by the surface binding of immunoglobulin or complement factor C3b. The neutrophil has surface receptors for C3b and the Fc portion of immunoglobulin G, which allows recognition and binding to the opsonized target. The target then becomes engulfed in a phagocytic vacuole, which fuses with neutrophil granules inside the cell.

Intracellular killing occurs by oxygen-dependent and oxygen-independent mechanisms. Contents of the primary granules, including cathepsin G, defensins, and lysozyme, break down the bacterial cell

wall and kill the target organism. However, the major mechanism of bacterial killing is the *respiratory burst*. Stimulation of the neutrophil activates a membrane-bound oxidase complex, which generates superoxide through the transfer of an electron from reduced nicotinamide-adenine dinucleotide phosphate (NADPH). The interaction of superoxide with water generates hydroxyl ions. Myeloperoxidase catalyzes the formation of hypochlorite ion from hydrogen peroxide and chloride. The NADPH oxidase is a multisubunit enzyme. Absence or decreased activity of any one subunit impairs bacterial killing and results in chronic granulomatous disease, a congenital illness in which patients are predisposed to life-threatening bacterial infections.

More recently, *neutrophil extracellular traps (NETS)* have been proposed as an extracellular mechanism for neutrophil-induced antimicrobial activity. Activated neutrophils have been shown to release nucleic acids with histones and granule proteins extracellularly to trap and kill bacteria.

Neutrophil granules give neutrophils their characteristic appearance and have important functions in neutrophil-mediated activation and killing. *Primary granules* arise early in myeloid differentiation and are found in neutrophils and monocytes. They contain a large number of proteins, including myeloperoxidase, acid hydrolases, and neutral proteases. These granules fuse with the phagocytic vacuole and aid in the digestion of ingested bacteria. *Secondary granules* arise later in the differentiation pathway and give the neutrophil its characteristic granular (electron-dense) appearance. These granules contain lactoferrin, transcobalamin, and the matrix-modifying enzymes collagenase and gelatinase. On neutrophil stimulation, the granules are released into the extracellular space. Lactoferrin and transcobalamin act as antibacterial proteins by sequestering iron and vitamin B₁₂ away from bacteria, and collagenase and gelatinase break down connective tissue at the site of inflammation.

Abnormalities in neutrophil granules have been described in rare clinical syndromes. Absence of myeloperoxidase produces surprisingly mild symptoms and may be associated with defects in control of fungal infections. Secondary granule deficiency is rare and is associated with a slight increase in the risk of bacterial infections.

Eosinophils and Basophils

In addition to neutrophils, eosinophils and basophils are granulocytes that arise from myeloid precursors in the bone marrow. They transit rapidly from the marrow to the blood and into the peripheral tissues, where they play a role in allergic and inflammatory reactions. Like neutrophils, they have secondary granules that give them a characteristic appearance and are functionally important. Both cell types occur in small numbers under normal conditions.

Although eosinophils are capable of phagocytosis, most of the activity of these cells is mediated through the release of granule

Fig. 49.1 Normal granulocytes and monocytes in peripheral blood. (A to C) Neutrophils (i.e., polymorphonuclear cells). (D) Eosinophils. (E) Basophils. (F) Monocytes. (Courtesy Robert J. Homer, MD, PhD, Yale School of Medicine, New Haven, Conn.)

contents. The eosinophil numbers are elevated in parasitic and helminthic infections, in which these cells are thought to play a role in the allergic response to those organisms. Cell numbers are also elevated in allergic reactions and in collagen vascular diseases, linking their function to immunomodulation. Hypereosinophilic syndromes, in which extremely high levels of eosinophils can be seen, are rare, and hypereosinophilia can be associated with

damage to the lung, peripheral nervous system, and endocardial tissues. The differential diagnosis of eosinophilia is outlined in [Table 49.1](#).

Basophils play a role in immediate hypersensitivity reactions and chronic inflammatory conditions including tuberculosis, ulcerative colitis, and rheumatoid arthritis. Their numbers are also notably increased in chronic myeloid leukemia.

TABLE 49.1 Differential Diagnosis of Eosinophilia

Causes	Comments
Infection ^a	Especially parasites; less commonly mycobacteria
Allergic diseases ^a	Drugs, asthma, allergic rhinitis, atopy, urticaria
Pulmonary diseases ^a	Churg-Strauss disease, Löffler's pneumonia, pulmonary infiltrates with eosinophilia
Drug reactions ^a	Usually disappears when drug discontinued
Malignancy ^a	Paraneoplastic, angioimmunoblastic T-cell lymphoma, Hodgkin's and non-Hodgkin's lymphoma
Connective tissue diseases ^a	Rheumatoid arthritis, eosinophilic fasciitis, vasculitis
Primary hypereosinophilic syndrome	More than 6 months of >1500 eosinophils/ μ L with no other apparent cause

^aReactive forms.

Monocytes

Monocytes arise from a common myeloid precursor along with granulocytes under the influence of granulocyte-macrophage colony-stimulating factor (GM-CSF) and macrophage colony-stimulating factor (M-CSF). Most circulating monocytes are marginated along the walls of blood vessels. They migrate from the vessels into tissues, where they develop into macrophages.

The monocyte-macrophage lineage has many diverse functions. These phagocytic cells perform chemotaxis, phagocytosis, and intracellular killing in much the same manner as neutrophils. They are especially important in killing infectious mycobacterial, fungal, and protozoal species.

Monocytes interact with other components of the immune system. They are antigen-presenting cells for T lymphocytes, they are capable of cellular cytotoxicity, and they secrete cytokines. The macrophages (i.e., differentiated monocytes) that process antigens and present them to T lymphocytes take on different forms in different tissues such as Langerhans cells in the skin, interdigitating cells in the thymus, and dendritic cells in the lymph nodes. Antigen-presenting cells are non-phagocytic, and the process by which they internalize antigen is not fully understood. Protein antigens are partially digested and expressed on the cell surface in association with major histocompatibility complex class II (Ia) antigens. This feature permits interaction with and activation of helper T cells. Other macrophages, such as Kupffer cells of the liver and alveolar macrophages of the lung, play an important role in removing particulate and cellular debris and senescent erythrocytes from the circulation.

Monocytes are capable of antibody-dependent and antibody-independent cytotoxicity against tumor cells. Cytotoxicity is increased by tumor necrosis factor, interleukin-1, and interferon, which are secreted by monocytes. Monocytes secrete large numbers of immunomodulatory proteins (e.g., tumor necrosis factor, interleukin-1, interferon), cytokines (e.g., granulocyte colony-stimulating factor [G-CSF], GM-CSF), coagulation proteins, cell adhesion proteins, and proteases.

Monocytosis can be present in inflammatory as well as primary hematologic conditions. Infections such as tuberculosis, endocarditis, and syphilis are commonly associated with a reactive monocytosis. Hematologic malignancies such as chronic myelomonocytic leukemia, juvenile myelomonocytic leukemia, and some types of acute myeloid leukemia have clonal monocytosis as a hallmark feature. A reactive monocytosis has also been observed in some lymphomas.

Monocytopenia is observed in stress states including severe sepsis and as a result of myelosuppressive chemotherapy. Low monocyte

counts can also be found in acquired bone marrow failure states including aplastic anemia and myelodysplastic syndrome (MDS) and in hairy cell leukemia. Monocytopenia associated with natural killer cell deficiency and B-cell lymphoma have been linked to disorders involving GATA2 or SAMD9L mutations.

DETERMINANTS OF PERIPHERAL NEUTROPHIL NUMBERS

Most granulocyte precursors are in the bone marrow, where maturation occurs over 6 to 10 days. Marrow precursors represent 20% of the granulocyte mass, and the storage pool represents 75% of the granulocyte mass. Peripheral neutrophils represent only 5% of the total granulocyte mass.

Neutrophils circulate in transit between the marrow and peripheral tissues. More than one half of the circulating neutrophils adhere to the vascular endothelium (margination). The half-life of a neutrophil in the circulation was thought to be 6 to 12 hours, but more recent studies suggest it may be as long as 3 to 4 days. After neutrophils migrate into tissues, they survive another 1 to 4 days. The peripheral neutrophil count therefore represents a sampling of less than 5% of the total granulocyte pool and is taken during a very short interval of the total neutrophil lifespan.

The peripheral white cell count is a poor reflection of granulocyte kinetics. Abnormalities in neutrophil number can occur rapidly and may reflect a change in marrow granulocyte production or a shift among various cellular compartments. An elevated peripheral white cell count may result from increased marrow production, or it may reflect mobilization of neutrophils from the marginated pool or release from the marrow storage pool. Similarly, a low granulocyte count may reflect decreased marrow production, increased margination or sequestration in the spleen, or increased destruction of peripheral cells.

The *total peripheral white cell count* represents the sum of lymphocytes, monocytes, and granulocytes. The significance of an elevated or depressed leukocyte count depends on the nature of the cellular elements that are increased or decreased. *Leukocytosis* is a nonspecific term that may denote an increase in lymphocytes (i.e., lymphocytosis) or neutrophils (i.e., neutrophilia). In rare cases, increases may reflect excessive numbers of monocytes, eosinophils, or basophils.

Extreme elevation of the white blood cell count to more than 50,000 cells/ μ L of blood with the premature release of early myeloid precursors is called a *leukemoid reaction*, which may be associated with inflammation and infection. It requires consideration of a diagnosis of myeloproliferative disease, especially chronic myelogenous leukemia (CML). Evaluation of the peripheral blood smear may reveal characteristic changes that provide clues to the underlying disorder. A leukoerythroblastic smear shows immature granulocytes, teardrop-shaped erythrocytes, nucleated erythrocytes, and increased platelets. These changes reflect marrow infiltration (i.e., myelophthisis) by fibrous tissue, granulomas, or neoplasm. As with leukocytosis, leukopenia may reflect lymphopenia or neutropenia. Neutropenia is generally defined by an absolute neutrophil count of less than 1500 cells/ μ L, although institutional laboratory reference ranges may vary slightly.

NEUTROPHILIA

Neutrophilia usually results from other processes, and it rarely indicates a primary hematologic disorder (Table 49.2). However, patients with a persistently elevated neutrophil count, especially when associated with an elevated hematocrit or platelet count, should be evaluated to rule out a primary myeloproliferative neoplasm. Peripheral blood evaluation for

TABLE 49.2 Differential Diagnosis of Neutrophilia**Primary Hematologic Disease**

Congenital neutrophilia
Leukocyte adhesion deficiency
Myeloproliferative disorders

Due to Other Disease Processes

Infection (acute or chronic)
Acute stress
Drugs (e.g., steroids, lithium)
Cytokine stimulation (e.g., granulocyte colony-stimulating factor)
Chronic inflammation
Malignancy
Myelophthisis
Marrow hyperstimulation
Chronic hemolysis, immune thrombocytopenia
Recovery from marrow suppression
Asplenia
Smoking
Metabolic and endocrine disorders (e.g., pregnancy, eclampsia, thyroid storm, Cushing disease)

the BCR/ABL fusion product can be performed to consider CML, and assays for JAK2 V617F, JAK2 exon 12, calreticulin, and MPL mutations can help to consider non-CML myeloproliferative neoplasms.

Neutrophilia related to acute infection, stress, toxic exposures like smoking, or corticosteroid administration primarily reflects demargination and is usually transient. Persistent neutrophilia usually reflects chronic bone marrow stimulation. Nevertheless, a bone marrow aspirate and biopsy are rarely indicated in the work-up of neutrophilia. The exception is for patients who demonstrate leukoerythroblastic changes, for which a bone marrow examination and culture may be indicated to consider tuberculosis or fungal infection, marrow infiltration with tumor, or marrow fibrosis. Cytogenetic and molecular studies should be performed to help eliminate the diagnosis of marrow malignancies, and the marrow should be cultured for mycobacteria and fungi.

NEUTROPENIA**Differential Diagnosis**

Neutropenia may reflect decreased production, increased sequestration, or peripheral destruction of neutrophils (Table 49.3). Patients should first be evaluated for splenomegaly to consider the possibility of sequestration.

For patients who are asymptomatic and for whom previous studies are unavailable, the possibility of constitutional or cyclic neutropenia should be entertained and can be evaluated by serial peripheral blood counts. The normal neutrophil count varies among ethnic groups and is most commonly lower in individuals with African ancestry as compared to white individuals (i.e., constitutional or benign ethnic neutropenia [BEN]). The absence of the red blood cell Duffy antigen has been demonstrated to be associated with BEN. As the Duffy antigen is utilized by the parasite *Plasmodium vivax* to enter the red blood cell, it is believed that positive selection for the null allele enabled individuals in West Africa to be protected against malaria and have a survival advantage. Cyclic neutropenia is a relatively benign disorder, in which cyclical changes occur in all hematopoietic cell lines but are most dramatic in the neutrophil lineage. At the nadir of the neutrophil counts, patients may have infections, but the condition is often clinically silent.

TABLE 49.3 Differential Diagnosis of Neutropenia

Decreased Production of Neutrophils	Increased Peripheral Destruction
Congenital and/or constitutional cause	Sepsis
Constitutional neutropenia	Immune destruction
Benign chronic neutropenia	Drug related
Kostmann syndrome	Associated with collagen vascular disease
Cyclic neutropenia	Isoimmune (in newborns)
Postinfectious cause	Large granular lymphocyte leukemia
Nutritional deficiency (B ₁₂ , folate, copper)	Hypersplenism and/or sequestration
Drug-induced cause	
Primary marrow failure	
Aplastic anemia	
Myelodysplastic syndromes	
Acute leukemias	

In contrast, patients with congenital agranulocytosis or severe congenital neutropenia (SCN) exhibit profound neutropenia and infections in the perinatal period. Kostmann syndrome is a subset of SCN that was described more than 50 years ago as an autosomal recessive disorder; later studies demonstrated that SCN can reflect autosomal dominant, autosomal recessive, X-linked, or sporadic mutations.

About 50% of autosomal dominant SCN and almost 100% of cyclic neutropenia cases are associated with inherited mutations in the neutrophil elastase gene. The mutations are thought to produce a misfolded neutrophil elastase protein, which accumulates in the endoplasmic reticulum and activates the unfolded protein response. This complex cellular stress response coordinates the degradation of misfolded protein in the endoplasmic reticulum and can trigger cellular apoptosis if the stress is severe. Later studies have established that autosomal recessive SCN (i.e., Kostmann syndrome) is caused by mutations in the *HAX1* gene, which encodes a mitochondrial protein that is required for stabilization of the mitochondrial membrane. Absence of HAX1 results in loss of the mitochondrial membrane potential and induction of apoptosis.

Until G-CSF became available, most patients with SCN died in early childhood, but the availability of cytokine therapy has prolonged survival. However, SCN is also associated with a significantly increased incidence of acute leukemia, a complication that has become apparent as patients survive longer. Up to 30% of patients with SCN develop acute myelogenous leukemia over 10 years. Acute myelogenous leukemia in these patients is often associated with truncation mutations in the G-CSF receptor. These acquired somatic mutations may contribute to the pathogenesis of leukemia but do not contribute to the congenital neutropenia. The role of the G-CSF receptor mutations in the pathogenesis of leukemic transformation is controversial, as is the relationship between G-CSF therapy and the acquisition of these mutations.

Neutropenia may occur during or after viral, bacterial, or mycobacterial infections. Postviral neutropenia is especially common in children and probably reflects increased neutrophil consumption and a viral suppression of marrow neutrophil production. Neutropenia may be seen as a complication of overwhelming sepsis and is associated with a poor prognosis.

Drug-induced neutropenia may reflect dose-dependent marrow suppression or an idiosyncratic immune response. The former is one of the most common complications of chemotherapeutic drugs and is also common with antibiotics such as sulfamethoxazole-trimethoprim.

Chloramphenicol causes dose-dependent marrow suppression, although its more ominous complication is the rare idiosyncratic reaction that gives rise to marrow aplasia. Drugs that are most commonly associated with neutropenia include clozapine, sulfasalazine, ticlopidine, and the thionamide antithyroid agents. Most drug-induced neutropenias respond rapidly to discontinuation of the offending agent. The administration of G-CSF may speed recovery.

Autoimmune neutropenia may be seen as a primary disease or as a secondary manifestation of systemic autoimmune disease or lymphoproliferative disease. Primary autoimmune neutropenia is a disorder of infants and young children that resolves spontaneously in more than 90% of patients within 2 years. Secondary autoimmune neutropenia is a common accompaniment to systemic lupus erythematosus. Although not usually clinically severe, neutropenia is often a marker of disease activity.

Neutropenia in rheumatoid arthritis may be associated with splenomegaly (i.e., Felty syndrome) and is part of the spectrum of large granular lymphocyte (LGL) leukemia. LGL leukemia is a clonal expansion of suppressor T cells. Patients who develop LGL leukemia in association with rheumatoid arthritis share a common HLA-DR4 haplotype with patients with Felty syndrome, suggesting that they are in a common spectrum of disease. LGL leukemia is also a relatively common cause of acquired neutropenia in elderly patients in the absence of rheumatoid arthritis. Recent data have linked LGL leukemia to mutations in the *STAT3* gene.

Laboratory Evaluation

Unless the diagnosis of benign ethnic or cyclic neutropenia is likely, the evaluation of the patient with neutropenia should include stopping all potentially offending drugs and performing serologic studies to rule out collagen vascular disease. Unlike the evaluation of patients with leukocytosis, bone marrow examination is indicated early for those with neutropenia and is frequently diagnostic. Neutropenia often reflects primary hematologic disease, and bone marrow examination enables the physician to diagnose marrow failure syndromes, leukemia, and MDS. In the absence of bone marrow failure, other causes of neutropenia may give a characteristic bone marrow picture. All patients undergoing bone marrow examination should have cytogenetic and molecular studies performed to aid in the diagnosis of MDS.

Sudden onset of agranulocytosis that does not affect platelets or erythrocytes typically is attributable to drug or toxin exposure. Bone marrow examination is rarely necessary. If performed, drug-induced neutropenia produces a characteristic maturation arrest of myeloid cells. Rather than actual inhibition of neutrophil maturation, this feature reflects the immune destruction of myeloid precursors that leaves only the earliest cells behind.

Treatment

The therapeutic approach to patients with neutropenia depends on the degree of depression of the neutrophil count. Neutrophil counts between 1000 and 1500 cells/ μL are not usually associated with significant impairment of the host response to bacterial infection and require no intervention beyond that demanded for diagnosis and treatment of the underlying cause. Patients with neutrophil counts between 500 and 1000 cells/ μL should be alerted to their slightly increased risk of infection, although serious problems are rarely encountered in patients with functional neutrophils and counts higher than 500 cells/ μL .

Patients with neutrophil counts lower than 500 cells/ μL are at significant risk for infection, although this is especially true of patients with acute or chemotherapy-induced neutropenia. In contrast, patients with chronic idiopathic neutropenia may be asymptomatic with absolute neutrophil counts below 100. All patients with neutrophil counts below 500 cells/ μL should be instructed to notify the physician at the

first sign of infection or fever, and they must be managed aggressively with intravenous antibiotics regardless of the documentation of a source or infecting organism. Patients with a significantly depressed neutrophil count may exhibit few signs of infection because much of the inflammatory response at the site of infection is generated by the neutrophils themselves.

In patients with severe immune-mediated neutropenia, corticosteroids and intravenous immunoglobulin may be helpful in elevating the neutrophil count and in preventing infectious complications. G-CSF may increase the peripheral white cell count and may help resolve infections in neutropenia induced by drugs, including chemotherapy. It has been efficacious for some patients with immune-mediated neutropenia and those with MDS.

For a deeper discussion of these topics, please see Chapter 158, “Leukocytosis and Leukopenia” in *Goldman-Cecil Medicine*, 26th Edition.

PROSPECTUS FOR THE FUTURE

Significant progress has been made in elucidating the molecular pathogenesis of severe congenital neutropenia and cyclic neutropenia. Compounds that modulate the unfolded protein response may play a role in the treatment of these disorders. Other studies of the molecular basis of myeloid differentiation are establishing the importance of transcription factor function in neutrophil maturation and are providing insights into the pathogenesis of leukemia and myelodysplasia. Their findings may delineate pathways with entry points for therapeutic intervention in myeloid malignancies.

Disorders of Lymphocytes

Iris Isufi, Stuart Seropian

INTRODUCTION

The central cell of the immune system is the lymphocyte. Lymphocytes mediate the adaptive immune response, providing specificity to the immune system by responding to specific pathogens and conferring long-lasting immunity to reinfection. Lymphocytes are derived from hematopoietic stem cells that reside in the bone marrow and give rise to all of the cellular elements of the blood. The two major functional classes of lymphocytes—B lymphocytes (B cells) and T lymphocytes (T cells)—are distinguished by their site of development, antigenic receptors, and function.

The major disorders of lymphocytes include neoplastic transformations of specific subsets of lymphocytes that result in an array of lymphomas or leukemias, congenital or acquired defects in lymphocyte development or function with resultant immunodeficiency, and physiologic responses to infection or antigenic stimulation that lead to lymphadenopathy, lymphocytosis, or lymphocytopenia.

LYMPHOCYTE DEVELOPMENT, FUNCTION, AND LOCALIZATION

B Cells

B cells are characterized by surface immunoglobulins (i.e., antibodies). Their major function is to mount a humoral immune response to antigens by producing antigen-specific antibodies.

B cells develop in the bone marrow in a series of highly coordinated steps that involve sequential rearrangement of the heavy- and light-chain immunoglobulin genes and expression of B-cell-specific cell surface proteins (Fig. 50.1). Rearrangement of the immunoglobulin genes results in generation of a large repertoire of B cells that are each characterized by an immunoglobulin molecule with unique antigenic specificity. Mature B cells migrate from the bone marrow to lymphoid tissue throughout the body and are readily identified by cell surface immunoglobulin and antigens that are B cell specific, including CD19, CD20, and CD21.

In response to antigen binding to cell surface immunoglobulin, mature B cells are activated to proliferate and undergo differentiation to end-stage plasma cells, which lose most of their B-cell surface markers and produce large quantities of soluble antibodies. Neoplastic disorders of B cells arise from B cells at different stages of development, and B-cell lymphomas can have highly varied morphology and cell surface expression of B-cell antigens (i.e., immunophenotype).

T Cells

T cells perform an array of functions in the immune response, including those that are regarded as classic cellular immune responses. T-cell precursors migrate from the bone marrow to the thymus, where they differentiate into mature T-cell subsets and undergo selection to

eliminate autoreactive T cells that respond to self-peptides. In the thymus, T-cell precursors undergo a coordinated process of differentiation that involves rearrangement and expression of the T-cell receptor (TCR) genes and acquisition of cell surface proteins that are unique to T cells, including CD3, CD4, and CD8.

As T cells mature in the thymus, they ultimately lose the CD4 or CD8 protein. Mature T cells are composed of two major groups: CD4⁺ and CD8⁺ cells. After T-cell maturation and selection in the thymus, mature CD4⁺ and CD8⁺ T cells migrate to lymph nodes, spleen, and other sites in the peripheral immune system. Mature T cells constitute about 80% of peripheral blood lymphocytes, 40% of lymph node cells, and 25% of splenic lymphoid cells.

Mature CD4⁺ and CD8⁺ T-cell subsets mediate distinct immune functions. CD8⁺ cells (*cytotoxic T cells*) kill virus-infected or foreign cells and suppress immune functions. CD4⁺ cells (*helper T cells*) activate other immune cells such as B cells and macrophages by producing cytokines and through direct cell contact.

Similar to B cells, T cells express unique TCR molecules that recognize specific peptide antigens. In contrast to B cells, T cells respond only to peptides that are processed intracellularly and bound to (or presented by) specialized cell surface antigen-presenting proteins, designated major histocompatibility complex (MHC) molecules. CD4⁺ and CD8⁺ T cells are MHC class restricted in their response to peptide-MHC complexes. CD4⁺ cells recognize antigenic peptide fragments when they are presented by MHC class II molecules, and CD8⁺ cells recognize antigenic peptide fragments when they are presented by MHC class I molecules. Binding of the TCR by a specific peptide-MHC complex triggers activation signals that lead to the expression of gene products that mediate the wide diversity of helper functions of CD4⁺ cells or cytotoxic effector functions of CD8⁺ cells.

Lymphoid System

Lymphocytes localize to peripheral lymphoid tissue, which is the site of antigen-lymphocyte interaction and lymphocyte activation. The peripheral lymphoid tissue is composed of lymph nodes, the spleen, and mucosal lymphoid tissue. Lymphocytes circulate continuously through these tissues through the vascular and lymphatic systems.

Lymph nodes are highly organized lymphoid tissues that are sites of convergence of the lymphatic drainage system, which carries antigens from draining lymph to the nodes, where they are trapped. A lymph node consists of an outer cortex and an inner medulla (Fig. 50.2). The cortex is organized into lymphoid follicles composed predominantly of B cells. Some of the follicles contain central areas or germinal centers, where activated B cells proliferate after encountering a specific antigen, that are surrounded by a mantle zone. The T cells are distributed more diffusely in paracortical areas surrounding follicles.

Fig. 50.1 The maturation of B lymphocytes. *Top*, The changes in immunoglobulin production and maturation. *Bottom*, The appearance and disappearance of surface markers. *TdT*, Terminal deoxynucleotidyl transferase. (Modified from Ferrarini M, Grossi CE, Cooper MD: Cellular and molecular biology of lymphoid cells. In Handin RI, Lux SE, Stossel TP, editors: *Blood: Principles and Practice of Hematology*, Philadelphia, 1995, JB Lippincott, p 643.)

Fig. 50.2 Structure of the normal lymph node. The cortical area contains the follicles, which consist of a germinal center and a mantle zone. The medulla contains a complex of channels that lead to the efferent lymphatics.

The spleen traps antigens from blood rather than from the lymphatic system and is the site of disposal of senescent red cells. Lymphocytes in the spleen reside in the areas described as white pulp, which surround the arterioles entering the organ. As in lymph nodes, the B and T cells are segregated into a periarteriolar lymphoid sheath that is composed of T cells and flanking follicles composed of B cells.

The mucosa-associated lymphoid tissues (MALTs) collect antigen from epithelial surfaces and include the gut-associated lymphoid tissue (i.e., tonsils, adenoids, appendix, and Peyer patches of the small intestine) and more diffusely organized aggregates of lymphocytes at other mucosal sites.

Lymphocytes circulate in the blood and represent 20% to 40% of peripheral blood leukocytes in adults; the proportion is higher in newborns and children. The majority of peripheral blood lymphocytes are T cells, and the remaining lymphocytes are largely B cells. A small percentage of peripheral blood lymphoid cells represents a third category of lymphoid cells referred to as natural killer (NK) cells. These cells do not bear the characteristic cell surface molecules of B or T cells, and their immunoglobulin or TCR genes have not undergone rearrangement. Morphologically, the cells are large, with abundant cytoplasm containing azurophilic granules, and they are often called *large granular lymphocytes*. Functionally, they are part of the innate immune system, responding nonspecifically to a wide range of pathogens without requiring prior antigenic exposure.

NEOPLASIA OF LYMPHOID ORIGIN

Malignant transformation of lymphocytes leads to a diverse array of lymphoid cancers, including tumors that arise from T cells, B cells, or NK cells. Lymphoid malignancies usually involve lymphoid tissues, but they can arise in or spread to any site. The major clinical groupings of lymphoid malignancies include non-Hodgkin's lymphomas (NHLs), Hodgkin's lymphoma, lymphoid leukemias, and plasma cell dyscrasias.

Non-Hodgkin's Lymphomas

Definition and Epidemiology

The NHLs comprise a heterogeneous group of lymphoid malignancies that have different histologic appearances, cells of origin and

immunophenotypes, molecular biologic factors, clinical features, prognoses, and outcomes with therapy. According to the Surveillance, Epidemiology, and End Results (SEER) database, the NHLs are the seventh most common cancer type, with an estimated 74,200 cases occurring in 2019 and 19,970 patients succumbing to these diseases. The NHLs occur at a median age of 67 and are more common in men and in white individuals. The rate of NHLs increased slowly between 2000 and 2010 but has been decreasing slowly since that time. The annual death rate has fallen an average of 2.2% from 2007 to 2016.

Pathology

In view of the heterogeneity of NHLs, classification systems have been devised to identify specific pathologic subtypes that correlate with distinct clinical entities. These systems have evolved steadily over the past 50 years as correlations between histopathologic and biologic behavior have emerged. Pathologic classification schemes have attempted to correlate malignant NHL subtypes with normal cellular counterparts. The World Health Organization (WHO) classification (Table 50.1) is the most current and incorporates morphologic features, immunophenotype, genetic features, and molecular features, with an emphasis on biologic

TABLE 50.2 Causes of Lymphadenopathy**Infectious Diseases**

Viral: infectious mononucleosis syndromes (cytomegalovirus, Epstein-Barr virus), acquired immunodeficiency syndrome, rubella, herpes simplex, infectious hepatitis

Bacterial: localized infection with regional adenopathy (streptococci, staphylococci), cat-scratch disease (*Bartonella henselae*), brucellosis, tularemia, listeriosis, bubonic plague (*Yersinia pestis*), chancroid (*Haemophilus ducreyi*)

Fungal: coccidioidomycosis, histoplasmosis

Chlamydial: lymphogranuloma venereum, trachoma

Mycobacterial: scrofula, tuberculosis, leprosy

Protozoan: toxoplasmosis, trypanosomiasis

Spirochetal: Lyme disease, syphilis, leptospirosis

Immunologic Diseases

Rheumatoid arthritis

Systemic lupus erythematosus

Mixed connective tissue disease

Sjögren's syndrome

Dermatomyositis

Serum sickness

Drug reactions: phenytoin, hydralazine, allopurinol

Malignant Diseases

Lymphomas

Solid tumors metastatic to lymph nodes: melanoma, lung, breast, head and neck, gastrointestinal tract, Kaposi's sarcoma, unknown primary tumor, renal, prostate

Atypical Lymphoid Proliferations

Giant follicular lymph node hyperplasia

Transformation of germinal centers

Castleman disease

Miscellaneous Diseases and Diseases of Unknown Cause

Dermatopathic lymphadenitis

Sarcoidosis

Immunoglobulin G4 (IgG4) lymphadenopathy

Amyloidosis

Mucocutaneous lymph node syndrome (Kawasaki disease)

Sinus histiocytosis (Rosai-Dorfman syndrome)

Multifocal Langerhans cell (eosinophilic) granulomatosis

Lipid storage diseases: Gaucher's and Niemann-Pick diseases

and therapeutic implications. The most common NHLs encountered in the United States are diffuse large B-cell lymphoma (DLBCL), follicular lymphoma, small lymphocytic lymphoma or leukemia (i.e., chronic lymphocytic leukemia [CLL]), and mantle cell lymphoma.

Etiology

The cause of most NHLs is unknown. In most patients no apparent genetic predisposition or epidemiologic or environmental factor can be identified. Many of the NHL subtypes carry pathognomonic chromosomal translocations that often involve an immunoglobulin locus (or TCR locus in T-cell NHLs) and an oncogene or growth regulatory gene. The cause of these aberrant chromosomal rearrangements is unknown.

Patients with congenital immunodeficiency syndromes or autoimmune disorders are at increased risk for NHL. Oncogenic human viruses play a causal role in some of the less common NHL variants.

Epstein-Barr virus (EBV) is associated with several biologically aggressive NHLs, including acquired immunodeficiency syndrome (AIDS)-related diffuse, aggressive lymphomas, the lymphoproliferative disorders that arise in immunosuppressed patients after organ transplantation, and the form of Burkitt lymphoma that is endemic in Africa. Human T-cell lymphotropic virus type 1 (HTLV-1) is causally linked with adult T-cell leukemia/lymphoma, which is endemic in areas of Japan and the Caribbean basin. The human herpesvirus 8 (HHV-8) of Kaposi's sarcoma has been implicated in a variant of diffuse, aggressive NHL that arises in serosal cavities and is encountered almost exclusively in patients infected with human immunodeficiency virus (HIV).

Several indolent lymphomas have been linked to infectious agents that appear to indirectly promote lymphomagenesis through chronic antigen stimulation, resulting in B-lymphocyte proliferation. *Helicobacter pylori* infection is linked to gastric MALT lymphomas in this manner; eradication of infection with antibiotics is often associated with regression of the lymphoma.

Clinical Presentation

Although numerous subtypes of NHL are recognized, most disease entities may be viewed conceptually as clinically indolent (i.e., low grade) or aggressive (i.e., high grade). Indolent lymphomas typically grow slowly, do not always require therapy, and have a long natural history. A clinical history of recurring and regressing adenopathy may be elicited. Constitutional symptoms such as fever, weight loss, or night sweats occur in about 20% of patients with NHL at the time of onset. These symptoms are more common in patients with aggressive subtypes of NHL. Aggressive lymphomas are associated with limited survival in the absence of therapy.

Most patients with NHL exhibit painless lymphadenopathy involving one or more peripheral nodal sites. NHL can involve extranodal sites, and patients can exhibit a variety of symptoms that reflect the site of involvement. Common sites of extranodal disease include the gastrointestinal tract, bone marrow or focal bone lesions, liver, skin, and Waldeyer ring in the nasopharynx and oropharynx, although virtually any site can be involved. Aggressive subtypes of NHL are more likely than indolent lymphomas to involve extranodal sites.

Central nervous system involvement, including leptomeningeal spread, rarely occurs with the indolent subtypes but does occur with the aggressive variants. The most aggressive NHLs (i.e., Burkitt and lymphoblastic lymphomas) have a particular propensity to spread to the leptomeninges.

Diagnosis and Differential Diagnosis

Many causes of lymphadenopathy exist in addition to lymphoid malignancies (Table 50.2). A thorough history and careful physical examination are important before performing a lymph node biopsy. The investigation of lymphadenopathy can be organized according to the location of the enlarged nodes (i.e., localized or generalized) and clinical symptoms.

Cervical lymphadenopathy is most often caused by infections of the upper respiratory tract, including infectious mononucleosis syndromes, viral syndromes, and bacterial pharyngitis. Unilateral axillary, inguinal, or femoral adenopathy may be caused by skin infections involving the extremity, including cat-scratch fever. Generalized lymphadenopathy may be caused by systemic infections (e.g., HIV, cytomegalovirus), drug reactions, autoimmune diseases, or one of the systemic lymphadenopathy syndromes. If the cause of persistent lymphadenopathy is not apparent after a thorough evaluation, an excisional lymph node biopsy should be undertaken. An enlarged supraclavicular lymph node strongly suggests malignancy and should always be sampled.

The accurate diagnosis of lymphoma requires excisional biopsy of a lymph node or generous biopsy of involved lymph tissue. Fine-needle aspiration or needle biopsy is rarely sufficient. Analysis of the

TABLE 50.3 Staging Evaluation for Lymphomas**Required Evaluation Procedures**

Biopsy of lesion with review by an experienced hematopathologist
 History with attention to the presence or absence of B symptoms
 Physical examination with attention to node-bearing areas (including Waldeyer ring) and size of liver and spleen
 Standard blood work:
 Complete blood count
 Lactate dehydrogenase and β_2 -microglobulin
 Evaluation of renal function
 Liver function tests
 Calcium, uric acid
 Bone marrow aspirate and biopsy
 Radiologic studies, including:
 Chest radiograph (posteroanterior and lateral)
 Chest, abdomen, and pelvic CT scans
 PET scan (in Hodgkin's and aggressive lymphomas)

Procedures Required Under Certain Circumstances

Plain bone radiographs of symptomatic sites or abnormal areas on bone scan
 Brain or spinal CT or MRI if neurologic signs or symptoms
 Serum and urine protein electrophoresis
 Lumbar puncture with cerebrospinal fluid cytology (Burkitt and lymphoblastic lymphoma)

B symptoms, Fever, sweats, and weight loss >10% of body weight; *CT*, computed tomography; *MRI*, magnetic resonance imaging; *PET*, positron emission tomography.

pathologic specimen should include routine histologic examination and immunophenotyping, immunohistochemistry, chromosome analysis, fluorescence in situ hybridization (FISH) testing, and molecular studies. Immunophenotyping can determine the cell of origin (i.e., B cell, T cell, NK cell, or nonlymphoid cell), and the pattern of cell surface antigens aids subclassification. In the case of B-cell NHLs, immunophenotyping can also reveal whether the process is monoclonal in origin (i.e., neoplastic) by determining if surface immunoglobulin is restricted to κ or λ light chain. Immunohistochemistry utilizing stains to assess expression levels of proteins such as MYC and BCL-2 provides prognostic information. In some cases, cytogenetic analysis or molecular studies of immunoglobulin or TCR gene rearrangement may be required to determine the pathologic subtype of lymphoma or to establish a monoclonal process. Chromosome analysis may reveal a complex karyotype often associated with worse prognosis, or deletion of chromosome 17p where the tumor suppressor gene p53 locus is found. FISH probes can identify translocations such as t(8;14) leading to high MYC expression in Burkitt lymphoma, t(14;18) leading to deregulated expression of the BCL-2 gene in follicular B-cell lymphoma, or t(11;14) leading to cyclin D1 (a regulator of the G1-S transition) overexpression in mantle cell lymphoma, among other abnormalities. If a lymph node biopsy is nondiagnostic and unexplained lymph node enlargement persists, biopsy should be repeated.

For patients with bone marrow and peripheral blood involvement, such as in small lymphocytic lymphoma or CLL, the diagnosis may be made based on immunophenotyping of peripheral blood lymphocytes by flow cytometry. Care must be taken to exclude the possibility of aggressive lymphoma with involved lymph nodes or extranodal sites in a patient harboring a low-grade or indolent lymphoma such as small lymphocytic lymphoma that is confined to the blood or bone marrow.

TABLE 50.4 Staging System for Hodgkin and Non-Hodgkin's Lymphoma

Stage ^a	Involvement	Extranodal E Status
I	One node or a group of adjacent nodes	Single extranodal lesions without nodal involvement
II	Two or more nodal groups on the same side of the diaphragm	Stage I or II by nodal extent with limited contiguous extranodal involvement
II bulky	As above with bulky disease ^b	
III	Nodes on both sides of the diaphragm; nodes above the diaphragm with spleen involvement	
IV	Additional noncontiguous extralymphatic involvement	

^aStaging systems for Hodgkin's and non-Hodgkin's lymphomas are similar. For Hodgkin's lymphoma, the presence or absence of symptoms should be documented with each stage designation: A (asymptomatic) or B (fever, sweats, and weight loss >10% of body weight).

^bFor Hodgkin's lymphoma bulky disease includes nodal mass >10 cm or > $\frac{1}{3}$ of the transthoracic diameter

Treatment

After a lymphoma has been diagnosed, patients should undergo complete staging evaluation (Table 50.3). Staging determines the extent of involvement, provides prognostic information, and may influence the choice of therapy. The Lugano modification of the Ann Arbor staging classification is used to stage patients with NHL and Hodgkin's lymphoma (Table 50.4).

A variety of ancillary tests may be performed in specific situations. For example, a test for HTLV-1 and HIV should be performed if adult T-cell leukemia/lymphoma is suspected. Patients with a clinical history suggesting immunodeficiency or behavioral risk factors should be tested for HIV. A gastrointestinal series or endoscopy may be warranted for patients with gastrointestinal symptoms or patients at risk for gastrointestinal involvement (i.e., mantle cell and other lymphomas involving the Waldeyer ring). The choice of therapy is guided by stage, specific subtype, and clinical considerations such as age and the medical condition of the patient. Multiple novel agents are available for therapy of lymphoid neoplasms (Table 50.5). Such agents may be combined or used with traditional chemotherapy.

Lymphoma Subtypes

Indolent non-Hodgkin's lymphomas. The common low-grade or indolent conditions include follicular lymphoma, small lymphocytic lymphoma (which is identical to CLL), and marginal zone lymphomas.

Follicular lymphoma (FL) accounts for 20% of adult lymphomas and is the most common indolent lymphoma. It is a mature clonal B-cell neoplasm that histologically retains nodular architecture in the lymph node, which is infiltrated by small, mature-appearing lymphocytes. The immunophenotype is positive for surface markers (CD10, CD19, CD20, CD21) and negative for CD5. Follicular lymphomas are characterized by the t(14;18) translocation that juxtaposes the immunoglobulin heavy chain (*IGH*) locus with the antiapoptotic B-cell CLL/lymphoma 2 gene (*BCL2*); the *BCL2* protein is uniformly overexpressed in follicular lymphomas, immortalizing affected cells. Additional gain of function mutations and altered T-cell function in the malignant microenvironment are thought to play a role in pathogenesis.

TABLE 50.5 New Therapeutic Agents in Use for Lymphoma and Plasmacytic Disorders

Class	Agents	Target	Mechanism of Action	Indications
Monoclonal Antibodies	Rituximab	CD20	Complement-mediated and antibody-dependent cytotoxicity. Apoptosis of tumor cells	Most B-cell lymphomas
Antibody-Drug Conjugates	Obinutuzumab	CD 38	Antibody bound tubulin inhibitor delivered to tumor cell	Multiple myeloma
	Daratumumab			Hodgkin's lymphoma and CD30+ lymphomas
Imids	Brentuximab	CD 30	Bind cereblon, activating E3 ubiquitin ligase complex	DLBCL
	Polatuzumab	CD79a		Multiple myeloma
	Thalidomide	Cereblon, immune-modulation		NHL subtypes (lenalidomide)
	Lenalidomide			
Kinase Inhibitors	Pomalidomide			
BTK Inhibitors	Ibrutinib	Bruton tyrosine kinase	Blocks B-cell receptor signaling	CLL, MCL, MZL, WM
PI3k Inhibitors	Acalabrutinib			CLL, FL
	Zanubrutinib			
BCL-2 Inhibitor	Idelalisib	Phosphatidylinositol-3-kinase	Blocks B-cell receptor signaling	CLL
	Copanlisib			
Proteasome Inhibitors	Venetoclax	BCL-2	Blocks antiapoptotic protein BCL-2 leading to programmed cell death	
	Bortezomib	Proteasome	Inhibition of toxic protein degradation in malignant cells	Multiple myeloma MCL
CAR-T Cells	Carfilzomib			
	Ixazomib			
	Axicabtagene ciloleucel	CD19	Direct binding of genetically engineered T cell to malignant B cells	DLBCL
	Tisagenlecleucel			ALL

ALL, Acute lymphocytic leukemia; BTK, Bruton tyrosine kinase; CLL, chronic lymphocytic leukemia; DLBCL, diffuse large B-cell lymphoma; FL, follicular lymphoma; IMiDS, Immunomodulatory agents; MCL, mantle cell lymphoma; MZL, marginal zone lymphoma; WM, Waldenström's macroglobulinemia.

Follicular lymphoma is a low-grade, indolent neoplasm with a long natural history (median survival approaches 10 years), but 70% of patients have advanced-stage (III/IV) disease at diagnosis, often with bone marrow involvement, and cure is not considered feasible with standard treatment modalities for most patients. Follicular NHL may eventually transform to a more aggressive lymphoma, characterized pathologically by diffuse large cell infiltrates and clinically by rapidly expanding lymph nodes or tumor masses, rising lactate dehydrogenase (LDH) levels, and the onset of disease-related symptoms.

Management of follicular lymphomas is influenced by the stage. For the rare patient with early-stage (I/some non-bulky II) disease after clinical staging, the appropriate treatment is radiation therapy. With the use of locoregional lymphoid irradiation, more than one half of patients with early-stage disease achieve a durable remission or cure.

For patients with advanced-stage disease, management is more controversial. Although advanced-stage indolent NHL is responsive to a variety of treatments, incurability and long natural history have led to the practice of deferring treatment until symptoms develop. This strategy is referred to as the *watch and wait approach*. A prospective study of early intervention compared observation to the anti-CD20 monoclonal antibody rituximab alone and to rituximab followed by maintenance but found no difference in overall survival or histologic transformation rates. Indications for treatment include cosmetic or mechanical problems caused by enlarging lymph nodes, high tumor burden, constitutional symptoms, and evidence of marrow compromise.

Multiple treatment options are available, including monoclonal antibody therapies, targeted agents, immunomodulatory agents, chemotherapeutic agents, and radiolabeled antibodies. For most patients appropriate treatment includes the chimeric anti-B-cell monoclonal antibody rituximab, with or without systemic chemotherapy. The addition of rituximab to chemotherapy has increased response rates, duration of remission, and in some studies, overall survival (level I evidence obtained from at least one properly designed, randomized controlled trial).

The choice of chemotherapy to employ in combination with rituximab may be influenced by patient age and medical condition. Multiple options are available, and no regimen has proved superior with regard to overall survival. The combination of bendamustine, a unique agent with properties similar to alkylating agents and purine analogues, plus rituximab appeared advantageous compared with the CHOP regimen (i.e., cyclophosphamide, hydroxydaunorubicin [doxorubicin], Oncovin [vincristine], and prednisone) plus rituximab in a randomized trial with regard to toxicity, response rate, and progression-free survival (level I evidence).

Most patients respond to treatment, and at least one third achieve a clinical complete remission. The combination of bendamustine-rituximab results in median time to progression of 5 to 6 years. Treatment with cytotoxic agents is typically discontinued when the maximum response has been achieved, but rituximab may be continued on an intermittent schedule to maintain remission. It has been shown to prolong remission times in randomized studies (level I evidence). Risk of recurrence and cost considerations may influence the use of this therapy because rituximab may also be used at the time of recurrence with similar outcomes.

After a patient relapses, subsequent remissions may be achieved but are often less durable compared to first remission. Therapeutic options for patients who relapse include retreatment with chemotherapy, often with a different drug or combination than that used initially. Patients in relapse can also be treated with rituximab as a single agent. For patients who are refractory to rituximab, several humanized anti-CD20 antibodies have been developed. Obinutuzumab is a humanized glyco-engineered anti-CD20 antibody with enhanced antibody-dependent cellular cytotoxicity function. It has single agent activity in relapsed FL and has shown high response rates in combination with chemotherapy. Immunomodulators such as lenalidomide also have strong activity in combination with anti-CD20 antibodies in the relapsed setting. PI3 kinase inhibitors idelalisib and copanlisib have an overall

response rate of 56% with median response duration of 12 months. Radioactively labeled anti-CD20 antibodies such as ibritumomab tiuxetan (yttrium labeled) have also been used for patients with relapsed or refractory follicular lymphoma and have been associated with high response rates. Administration of radiolabelled antibodies requires treatment in a specialized center with nuclear medicine expertise and has limited the use of these agents. For patients who have clinical or pathologic evidence of transformation to a higher grade of lymphoma, treatment that is appropriate for a diffuse, aggressive histology should be offered (discussed later).

High-dose chemotherapy with autologous or allogeneic stem cell transplantation for follicular NHLs may be appropriate for selected patients with recurrent or refractory disease. Long-term follow-up of patients undergoing allogeneic transplantation suggests that some patients are cured with this modality, but the morbidity associated with allogeneic transplantation has limited its widespread use for indolent lymphomas.

In addition to the follicular NHLs, the MALT lymphomas and closely related marginal zone lymphomas are considered low-grade, indolent subtypes. Given the excellent prognosis, localized nature, and long natural history of the MALT lymphomas, they are usually managed conservatively with local treatment modalities (i.e., radiation or surgery) and avoidance of systemic chemotherapy. The monoclonal antibody rituximab has activity against MALT lymphomas and may be used when systemic therapy is desired. The gastric MALT lymphomas are highly associated with *H. pylori* infection, and remissions may be achieved with eradication of the infection. Antibiotic therapy is therefore first-line treatment for early *H. pylori*-positive gastric MALT lymphoma.

Aggressive non-Hodgkin's lymphomas. Aggressive NHLs include DLBCL, high-grade lymphoma with C-MYC and BCL-2 and/or BCL-6 rearrangements, B-cell lymphoma unclassifiable with features intermediate between DLBCL and classical Hodgkin's lymphoma, Burkitt lymphoma, lymphoblastic lymphoma, anaplastic large cell lymphoma, and peripheral T-cell lymphomas. Most of the aggressive lymphomas are B cell in origin; aggressive T-cell lymphomas are managed similarly but have an overall worse prognosis compared with their B-cell counterparts.

DLBCL is the most common subtype of NHL, constituting up to 30% of adult NHL in Western countries. Patients present with rapidly enlarged nodal masses; about 30% will have fevers, night sweats or weight loss, and 40% may have involvement of organs outside of lymph nodes. In contrast to patients with low-grade NHLs, all patients with aggressive histology should be offered immediate therapy because these lymphomas are life-threatening and potentially curable. The standard initial therapy for all patients with diffuse, aggressive NHL, regardless of stage, is a multidrug chemotherapy regimen that includes an anthracycline in combination with rituximab.

For DLBCL, CHOP plus rituximab (R-CHOP) is the most widely used treatment regimen. Patients with early-stage disease (I/nonbulky II) may be treated with local radiation therapy after a minimum of three cycles of R-CHOP if there is a need to limit exposure to chemotherapy. Patients with advanced-stage disease require six cycles of R-CHOP; the role of local radiation to sites of bulky disease in the setting of advanced-stage disease is not well established. Complete remissions can be achieved with R-CHOP or similar regimens, and more than 50% of patients are cured. Identifying prognostic biomarkers for the subset of patients who respond less well or who suffer early disease relapse is a priority.

In the early 2000s, gene expression profiling (GEP) using microarrays shed significant light into the biologic heterogeneity of DLBCL. Three distinct signatures were identified corresponding to potential

cells of origin (COO): germinal center B-cell-like (GCB), activated B-cell-like (ABC), and primary mediastinal large B-cell lymphoma (PMBL), with approximately 15% of cases remaining unclassifiable. The GCB subtype arises from centroblasts, whereas the ABC subtype arises from a plasmablastic cell just prior to germinal center exit. These gene signatures have prognostic implications, with GCB-DLBCLs having a more favorable overall survival than ABC cases. PMBL displays a GEP profile that resembles that of Hodgkin's lymphoma and has a more favorable prognosis than either DLBCL subtype.

In addition to the COO, molecular subtypes of DLBCL have prognostic impact. Up to 15% of DLBCL cases contain translocations involving the MYC gene on chromosome 8q24 in combination with BCL-2 and/or BCL-6 translocations (referred to as "double or triple hit" NHL). C-MYC is a pro-oncogene that encodes a transcription factor that when dysregulated leads to uncontrolled cellular proliferation and survival. BCL-2 is an oncogene on chromosome 8q21 that when translocated leads to dysregulation of the antiapoptotic protein BCL-2. BCL-6 is a master regulator of the germinal center reaction and a transcriptional repressor. Double or triple hit NHL has the worst clinical outcome and is insufficiently treated with R-CHOP. Most patients have advanced stage disease, elevated LDH, bone marrow and CNS involvement. In general, more intensive regimens such as dose-adjusted EPOCH-R (etoposide, prednisone vincristine [Oncovin], cyclophosphamide, hydroxydaunorubicin [doxorubicin]-rituximab) or HyperCVAD-R (hyperfractionated doses of cyclophosphamide, vincristine, doxorubicin [Adriamycin], dexamethasone-rituximab) are used.

MYC and BCL-2 proteins can be overexpressed in DLBCL in the absence of gene translocation. Such "double-expressor" lymphomas have an intermediate prognosis. Most cases of double-hit lymphoma are of GCB origin whereas most cases of double-expressor lymphomas are of ABC origin.

Many studies have examined alternatives to R-CHOP therapy, including study of more intensive chemotherapy combinations or with addition of new agents such as ibrutinib or lenalidomide. To date, these approaches have largely failed to show improvements in disease control and survival for standard-risk patients and, therefore, R-CHOP remains the default standard of care for initial treatment of most patients.

Published studies of consolidation with high-dose chemotherapy and autologous stem cell transplantation (ASCT) following R-CHOP induction have also been largely negative. In particular, ASCT does not abrogate the negative prognostic impact of C-MYC translocations. In retrospective study, no difference in relapse-free and overall survival with ASCT has been identified in double hit patients who received intensified upfront treatment regimens such as DA-EPOCH-R (dose adjusted EPOCH-R) or HyperCVAD-R. However, a survival benefit for ASCT has been noted in double hit patients treated with R-CHOP, emphasizing the inferior outcomes with R-CHOP in this specific patient population.

Patients who relapse after achieving a remission may be cured with high-dose chemotherapy and ASCT, which is standard therapy if relapsed disease remains responsive to regular doses of chemotherapy. In the pre-rituximab era, cure rates with salvage chemotherapy and ASCT approached 50%. However, the large lymphoma CORAL study showed that patients who received rituximab with CHOP as part of upfront therapy had poor PFS (progression-free survival) of 21%. Patients who relapsed within a year of treatment with R-CHOP had very poor outcomes as well.

This high-risk relapsed patient population is now the target of clinical trials with chimeric antigen receptor T-cell (CAR-T) therapy. In this type of cellular immunotherapy, patients' autologous T cells are

collected and genetically modified to express a chimeric T-cell receptor that recognizes one or more surface antigens, such as CD19, on the lymphoma cell. There are two FDA-approved CAR-T products for patients whose disease does not respond adequately to salvage chemotherapy, tisagenlecleucel and axicabtagene ciloleucel. Complete remission rates are in the order of 40% for a group of patients with otherwise poor outcomes. These therapies are being compared to ASCT in randomized trials. Despite promising efficacy, CAR-T cell therapy can result in considerable toxicities, including cytokine release syndrome, neurotoxicity, cytopenias, hypogammaglobulinemia, and infections. Patients are carefully monitored by a multidisciplinary team of physicians with experience in delivering cellular therapies.

Mantle cell lymphoma. Mantle cell lymphoma (MCL) accounts for 3% to 10% of adult NHL in Western countries and is most common in older male patients. Caucasians have a higher incidence compared to other ethnicities. The median age at presentation is 68. Mantle cell lymphomas are mature B-cell neoplasms that appear to arise in the mantle zone of the lymphoid follicle and display a highly characteristic immunophenotype, expressing the CD5 antigen and other B-cell markers, but CD23 expression is absent, in contrast to CLL. Mantle cell lymphomas are characterized by a pathognomonic t(11;14) chromosomal translocation that juxtaposes the immunoglobulin heavy chain gene (14q32 locus) with the *BCL1* gene, which encodes the growth-promoting protein cyclin D1. Demonstration of the translocation or expression of cyclin D1 protein by immunohistochemistry allows a definitive diagnosis in most cases. Pathologic classification as a blastoid or pleomorphic subtype and a high proliferation rate are features associated with more aggressive behavior and a poor outcome. TP53, Notch-1, and Notch-2 mutations are also associated with an aggressive clinical course. Two MCL subtypes are recognized in the WHO 2016 classification with different clinical manifestations and molecular pathways: Nodal MCL, the most common variant with an aggressive clinical course and multiple oncogenic mutations, and a leukemic, non-nodal subtype of MCL seen in 10% to 20% of patients, who have an indolent clinical course. These latter patients present with lymphocytosis, splenomegaly, and bone marrow involvement.

Patients are usually treated with systemic chemotherapy combined with rituximab, but durable remissions are difficult to achieve. High-dose chemotherapy with autologous stem cell transplantation is often applied during first remission for younger patients and has been associated with more durable remissions (level II-1 evidence, which is evidence obtained from well-designed controlled trials without randomization). Patients with TP53 mutations do not benefit from high-dose chemotherapy and are preferentially enrolled in clinical trials of new agents. Multiple agents and regimens are available for those who are not candidates for transplantation and patients with recurrent disease.

The Bruton tyrosine kinase (BTK) inhibitors ibrutinib and acalabrutinib and the BCL-2 inhibitor venetoclax have shown remarkable activity in relapsed MCL in combination with anti-CD20 antibodies. They are also being investigated as frontline treatment in combination with immunochemotherapy or in chemotherapy-free combinations. CAR-T cell therapy trials are ongoing in MCL and provide hope for patients who have progressed on the BTK inhibitors. Allogeneic SCT can provide a cure in 30% of patients with MCL and is considered in relapsed patients and those with TP53 mutations.

High-grade non-Hodgkin's lymphomas. The two high-grade subtypes, Burkitt lymphoma (BL) and lymphoblastic lymphoma, are rare in the adult population. Nonetheless, these subtypes are important because they are potentially curable with appropriate therapy and often require urgent, inpatient treatment at the time of diagnosis due to their

highly aggressive nature, rapid growth, and tendency to develop tumor lysis on initiation of therapy.

Lymphoblastic lymphoma in adults is an aggressive lymphoma that is considered the lymphomatous counterpart of acute T-cell lymphocytic leukemia. B-cell lymphoblastic lymphoma is less common. Lymphoblastic lymphoma usually afflicts young adult men and involves the mediastinum and bone marrow, with a propensity to relapse in the leptomeninges.

Burkitt lymphoma is a rare B-cell lymphoma in adults that is highly aggressive with a propensity to involve the bone marrow and central nervous system. Burkitt lymphoma is characterized cytogenetically by the pathognomonic t(8;14) translocation that moves the *MYC* oncogene from chromosome 8 to a location close to the enhancers of the antibody heavy-chain genes (*IGH* locus) on chromosome 14. In central Africa, where Burkitt lymphoma is endemic in children, it is usually associated with EBV. However, in the United States, it is uncommon for sporadic Burkitt lymphoma to be EBV positive. Recently, Burkitt-like lymphoma with 11q aberrations has been included in the WHO classification as a provisional entry. The 11q aberrations are particularly frequent in immunocompromised hosts, such as patients after organ transplantation. Recurrent ID3 mutations are found in about 30% of cases of BL, and ID3 has been recently implicated as a tumor suppressor gene with a role in pathogenesis.

Burkitt lymphoma and lymphoblastic lymphomas require treatment with intensive multiagent chemotherapy, including intrathecal chemotherapy to prevent leptomeningeal relapse. These lymphomas undergo rapid tumor lysis on initiation of chemotherapy, and all patients must receive prophylaxis against tumor lysis syndrome before and during their first course of chemotherapy. Prophylaxis includes hydration, alkalization of the urine, allopurinol, and consideration of rasburicase therapy for rapid lowering of elevated uric acid levels.

Prognosis

A variety of prognostic variables have been identified for NHL, and specific prognostic schemes have been devised for common diseases, including DLBCL, follicular NHL, and mantle cell lymphomas. The predictors for poor survival for most subtypes include advanced stage (III/IV) at onset, involvement of multiple extranodal sites of disease, elevated LDH, B symptoms (e.g., fever, night sweats, weight loss), and poor performance status.

The International Prognostic Index (IPI) stratifies patients based on age, performance status, stage, and number of extranodal sites. The likelihood of cure and long-term, disease-free survival ranges from more than 75% for patients with one or no adverse factors to less than 50% for patients with four or more adverse factors.

Factors associated with shortened survival in follicular NHL include older age, advanced stage, anemia, multiple lymph node sites (more than four), and elevated LDH levels. Patients with three or more of these factors have a median survival of 5 years, roughly one half of that of patients with zero or one risk factor. Cytogenetic and molecular abnormalities that result in increased lymphoma cell proliferation and survival are taking center stage as prognostic variables, with some incremental improvement in outcomes with aggressive upfront treatment strategies and cellular therapies.

Aggressive T-cell lymphomas usually fare more poorly than B-cell NHL, and patients are typically considered candidates for investigational studies and upfront transplantation. Anaplastic large cell lymphoma (ALCL) ALK+, however, has a favorable outcome with chemotherapy alone. The anti-CD30 antibody-drug conjugate brentuximab vedotin has strong activity in ALCL and other types of T-cell lymphomas that express CD30.

❖ For a deeper discussion of these topics, please see Chapter 176, “Non-Hodgkin’s Lymphomas,” in *Goldman-Cecil Medicine*, 26th Edition.

Hodgkin Lymphoma

Hodgkin’s lymphoma (HL) is a node-based lymphoid malignancy characterized by the neoplastic Reed-Sternberg (RS) cell in an inflammatory background. Hodgkin’s lymphoma accounts for 10% of lymphomas, with about 8110 new cases diagnosed in the United States in 2019, and it is the most common lymphoma among young adults. The peak incidence of HL occurs between the ages of 20 and 35. The incidence of HL and death rate have declined in the past decade.

The cause of Hodgkin’s lymphoma remains enigmatic. Risk factors include a history of infectious mononucleosis, high socioeconomic status, immunosuppression (e.g., HIV infection, allograft transplantation, immunosuppressive drugs), and autoimmune disorders. Although EBV is frequently detected in patients, a direct causal role has not been established.

Pathology

Hodgkin’s lymphoma is diagnosed by identifying the malignant RS cell in involved lymphoid tissue. The classic RS cell is large and binucleate, with each nucleus containing a prominent nucleolus, suggesting the appearance of owl eyes. Although the cellular origin of the RS cell was debated for decades, molecular studies have confirmed that RS cells are B cells with clonal rearrangement of the germline *IG* locus. Unlike NHL, the bulk of the infiltrate in lymph nodes in HL is usually composed of benign reactive inflammatory cells, and the RS cells can be difficult to find. Immunophenotyping of RS cells shows CD30 (Ki-1) and CD15 positivity and negative CD20, CD45, and cytoplasmic or surface immunoglobulin. EBV is identified in the RS cells in about 50% of cases.

The pathologic subtypes of classic HL include four variants—nodular sclerosing (NS), mixed cellularity (MC), lymphocyte depleted (LD), and lymphocyte rich (LR)—plus the non-classic variant, nodular lymphocyte-predominant (NLP). The NS form is the most common variant (60% to 80%) and is characterized by fibrous bands separating the node into nodules and by the lacunar type of RS cells. It is the predominant type encountered in adolescents and young adults and typically involves the mediastinum and supradiaphragmatic nodal sites. In the MC type (15%), band-forming sclerosis is absent, and RS cells are easily identified in a diffuse inflammatory infiltrate that is more heterogeneous than that seen in the NS variant. The LR variant (5%) is characterized by classic RS cells in a background of small lymphocytes. LD is a rare variant (<1%) that is associated with advanced age, HIV infection, and low socioeconomic status. The pathologic hallmarks of LD HL include a notable paucity of inflammatory cells and sheets of RS cells.

The NLP variant is a distinct entity that is more closely related to indolent NHL than to classic HL. The NLP form is characterized by a nodular growth pattern with variants of RS cells that have polylobated nuclei (i.e., popcorn cells); classic RS cells are usually absent. The immunophenotype of these variant cells is distinct from classic RS cells, with expression of B-cell antigens (CD19 and CD20) and CD45 and absence of CD15 and CD30. The existence of CD20 allows the therapeutic use of rituximab, an agent not typically employed in classic Hodgkin’s lymphoma. The NLP variant accounts for 5% of Hodgkin’s lymphoma cases, has a strong male preponderance, and tends to involve peripheral nodes but spare the mediastinum. The prognosis is excellent, although late relapses are more common than in classic HL.

Clinical Presentation

Hodgkin’s lymphoma arises in lymph nodes, most commonly in the mediastinum or neck, and spreads to adjacent contiguous or

noncontiguous nodal sites, including retroperitoneal nodes and the spleen. As the disease progresses, it may spread hematogenously to involve extranodal sites, including bone marrow, liver, and lung. Unlike NHL, Hodgkin’s lymphoma rarely arises in extranodal sites, although it can involve extranodal sites by contiguous spread from an adjacent lymph node (e.g., vertebrae from retroperitoneal lymph nodes, pulmonary parenchyma from hilar nodes).

Hodgkin’s lymphoma usually produces painless enlargement of lymph nodes, most often in the neck. Mediastinal adenopathy may be found incidentally in an asymptomatic patient on routine chest radiography. Massive mediastinal or hilar adenopathy, with or without adjacent pulmonary involvement, may cause cough, shortness of breath, wheezing, or stridor. At clinical presentation, about one third of patients have constitutional symptoms of fever, night sweats, or weight loss (i.e., B symptoms). Generalized pruritus is associated with the NS subtype, and patients may give a history of troubling pruritus for months to years before the diagnosis. Rarely, patients may also complain of prompt marked chest discomfort induced by alcohol, the etiology of which is uncertain, but has been observed in patients with HL and carcinoid syndromes.

If left untreated, the natural history is one of inexorable, albeit often slow, progression to involve multiple nodal sites, followed by hematogenous spread to the bone marrow, liver, and other viscera. As the disease advances, patients experience B symptoms, malaise, cachexia, and infectious complications. Patients with progressive disease ultimately die of complications of bone marrow failure or infection.

Accurate staging of newly diagnosed HL is important for treatment planning, prognosis, and assessing response to therapy. A modification of the Ann Arbor classification is used (see [Table 50.4](#)), and the suffix A or B is appended to denote the absence or presence, respectively, of B symptoms. The staging work-up of a newly diagnosed patient is similar to that for patients with NHL (see [Table 50.3](#)) and includes a history and physical examination; complete blood work, including erythrocyte sedimentation rate (ESR) and HIV serology; computed tomography (CT) scan of the chest, abdomen, and pelvis; positron emission tomography (PET) scan; and in selected cases, a bone marrow aspirate and biopsy. Additional radiographic tests (e.g., bone films, spinal magnetic resonance imaging [MRI]) should be obtained only if symptoms suggest involvement of these structures. Patients also require evaluation of cardiac and pulmonary function before administration of chemotherapy and testing for hepatitis B due to the risk of reactivation during chemotherapy. The information derived from this noninvasive work-up defines the clinical stage of a patient with HL.

Diagnosis and Differential Diagnosis

The diagnosis requires an adequate biopsy of the involved nodal tissue. Immunophenotyping is routinely performed to confirm the diagnosis made on routine light microscopy and to differentiate HL from morphologically similar NHLs (e.g., T-cell-rich large B-cell lymphoma, anaplastic large cell lymphoma).

Treatment

Hodgkin’s lymphoma is highly curable; the cure rate exceeds 80% with the use of current treatment modalities. The optimal treatment, including the duration of chemotherapy and the use and dose of radiation therapy, is determined by the stage (i.e., early stage [I/II] vs. advanced stage [III/IV]) and additional prognostic features. Because most patients are young adults and experience long-term, disease-free survival, the goal of therapy has shifted to minimizing treatment-related morbidity and mortality without sacrificing curative potential. Primary radiation therapy is rarely used because of delayed toxicities, which include a substantial risk of secondary solid tumors within the

radiation field a decade or more after treatment, including a high risk of breast cancer in young patients. Historically noted long-term sequelae of standard doses of chest irradiation include thyroid dysfunction (usually hypothyroidism) and accelerated coronary artery disease.

Most patients with early-stage (I/II) Hodgkin's lymphoma are treated with the ABVD chemotherapy regimen (i.e., doxorubicin [Adriamycin], bleomycin, vinblastine, and dacarbazine) that may be followed by a course of low-dose radiation (<30 Gy) to involved lymph node sites, which has not been associated with an increased risk of secondary solid tumors. The duration of chemotherapy and the dose of radiation depend on whether the patient has favorable or unfavorable early-stage disease. The definition of favorable disease usually incorporates the absence of a large mediastinal mass, a limited number of involved nodal sites, absence of B symptoms, younger age, and a low ESR. Patients with favorable early-stage disease typically receive two to four cycles of ABVD followed by 20 Gy of radiation, whereas four to six cycles of ABVD and 30 Gy of radiation are required for patients with unfavorable disease (level I evidence). The option for limited course chemotherapy without radiotherapy has also been confirmed as feasible in randomized study. The choice of treatment in early-stage disease requires a detailed conversation with the patient regarding the side effects and potential risks of treatment options.

Patients with advanced-stage (III/IV) Hodgkin's lymphoma are treated primarily with chemotherapy. The ABVD regimen is the most widely used initial treatment in the United States. ABVD is more effective and less toxic than the older MOPP regimen (i.e., nitrogen mustard, vincristine, [Oncovin], procarbazine, and prednisone) and does not cause the long-term sequelae of sterility, infertility, or treatment-induced leukemias associated with MOPP (level I evidence). Long-term toxicity concerns with the ABVD regimen include potential for cardiomyopathy (Adriamycin), pulmonary toxicity (bleomycin), and neuropathy (vincristine). Roughly 60% of patients with stage III or IV disease are cured with six cycles of ABVD. A recent randomized trial confirmed the efficacy of ABVD with elimination of bleomycin after two full cycles of treatment in patients with evidence of early response to treatment.

The intensive regimen of BEACOPP (i.e., bleomycin, etoposide, Adriamycin, cyclophosphamide, vincristine, prednisolone, and procarbazine) has been associated with higher rates of complete response and freedom from treatment failure compared with ABVD-based regimens in patients with advanced disease, although overall survival has not been increased in all studies (level I evidence). BEACOPP is used increasingly in selected patients with high-risk features. Gonadal toxicity with permanent infertility may occur after BEACOPP, and an increased risk of secondary leukemia has been reported. Late sequelae and acute toxicities must be considered when choosing this regimen.

Radiation therapy in combination with chemotherapy is typically not used to treat advanced-stage disease. However, in patients with bulky mediastinal disease, consolidative radiation to the mediastinum after completion of chemotherapy has decreased the rate of relapse.

Evaluating the response to therapy involves repetition of the staging evaluation (i.e., physical examination, CT, and PET) during and at the completion of treatment. A mid-treatment PET scan after two full cycles of ABVD for advanced disease is prognostically informative because persistent metabolic activity in tumor sites correlates with resistance or subsequent relapse of disease. Conversely, patients may be cured despite the common finding of a residual abnormality on CT (e.g., enlarged nodes, residual mediastinal mass) when residual disease is not seen on PET imaging. A persistently positive PET scan during or after treatment with residual radiographic abnormalities is associated with a high rate of subsequent relapse, and these patients should be considered for immediate repeat biopsy or salvage therapy. The

more intensive BEACOPP regimen may increase the primary cure rate in such cases. Most patients destined to relapse do so within 2 years; relapses after 5 years are rare except for patients with the NLP variant.

Patients who relapse or fail to respond after initial therapy have several options for secondary therapy which may still prove curative. Second-line therapy is often employed with a plan to pursue high-dose chemotherapy and autologous hematopoietic cell transplantation, which may be associated with cure in patients with chemosensitive disease (level I evidence).

Effective novel agents to treat recurrent HL include brentuximab vedotin, an immunotoxin composed of a CD30-directed antibody linked to an antitubulin agent, and the checkpoint inhibitors pembrolizumab and nivolumab. Brentuximab is associated with high response rates, including complete responses in more than 30% of patients with relapsed disease after autologous transplantation (level II-1 evidence). A randomized study of brentuximab versus placebo after transplantation for high-risk HL patients showed a significant prolongation of progression-free survival. The checkpoint inhibitors are also highly active agents in HL patients with recurrent or refractory disease. Roughly two thirds of patients are expected to respond to therapy, although complete responses occur in a minority of patients. Allogeneic transplantation may also be considered for medically fit patients and has curative potential. Novel transplant therapy from haploidentical (half-matched) donors incorporating post-transplant cyclophosphamide has shown encouraging results with lower transplant-related morbidity and is an area of active investigation.

Prognosis

Most patients with Hodgkin's lymphoma are cured. Prognostic factors that influence risk of relapse or survival include MC or LD histology, male sex, large numbers of involved nodal sites, age older than 40 years, B symptoms, high ESR, and bulky disease (i.e., mediastinum widening by more than one third or a mass larger than 10 cm). The International Prognostic Score, based on seven variables at diagnosis, is a validated predictor of outcome in advanced disease.

Lymphoid Leukemias

Acute Lymphocytic Leukemias

The acute lymphocytic leukemias that arise from precursor B or T cells are described in detail in [Chapter 47](#).

Chronic Lymphocytic Leukemia and Small Lymphocytic Lymphoma

Definition and epidemiology. B-cell CLL is a malignant disorder of lymphocytes characterized by expansion and accumulation of small lymphocytes of B-cell origin. CLL is essentially identical to B-cell small lymphocytic lymphoma but represents the leukemic form of the disease. CLL is the most common form of leukemia in the United States and affects twice as many men as women. There were 20,720 estimated new cases in 2019 and 3,930 deaths. Although it can occur at any stage of life, the incidence increases with age, and more than 90% of cases are diagnosed in adults older than 50 years of age.

The cause of CLL is unknown. Familial clustering of CLL suggests a genetic basis in some cases. First-degree relatives of CLL patients have an 8.5-fold increased risk of developing CLL and a 2.6-fold increased risk of developing another indolent lymphoma. The risk of developing CLL is increased by exposure to organic solvents, Agent Orange, and insecticides. Dietary and lifestyle factors have not been associated with an increased risk of CLL.

CLL is preceded by a clinically asymptomatic stage involving a proliferation of clonal B cells. This condition is referred to as a monoclonal B lymphocytosis (MBL). MBL is detectable in more than 5% of people

aged over 60. The risk of transformation into CLL requiring treatment is approximately 1% per year. Such patients are observed.

Pathology. The common form of CLL is a clonal proliferation of mature B cells expressing characteristic mature B-cell markers and low levels of surface immunoglobulin M (IgM) that is light chain restricted, reflecting the clonal origin of this malignancy.

The diagnostic immunophenotype of CLL is unique, with expression of CD5 and CD23 along with the mature B-cell markers CD19, CD20 (dim expression), and CD21. Although a pathognomonic chromosomal abnormality has not been identified, 30% to 50% of patients have cytogenetic abnormalities, more so if sensitive assays such as FISH are employed. The most frequent abnormalities involve chromosomes 12 (often trisomy 12), 13, and 14. Cytogenetic abnormalities of chromosomes 17 and 11 are associated with an adverse prognosis.

Mutations that contribute to the development of CLL may occur at any stage of B-cell development. CLL cells originating from B cells that have not passed through and experienced the lymph node germinal center reaction have unmutated immunoglobulin heavy-chain variable-region (IgVH) genes and are defined as unmutated CLL (U-CLL). CLL cells that have incurred immunoglobulin (Ig) somatic mutation express mutated IgVH genes and are defined as mutated CLL (M-CLL). Unmutated IgVH genes are associated with a more aggressive form of CLL.

The B-cell receptor pathway has been recognized as the most prominent pathway activated in CLL cells. The B-cell receptor in CLL is activated via recognition and binding of autoantigens and antigens that are present in the microenvironment. Multiple kinases including BTK, spleen tyrosine kinase (SYK), and phosphatidylinositol 3-kinase (PI3K) are activated. This triggers a signaling cascade that activates downstream pathways, including *NFκβ* pathway, ultimately promoting malignant B-cell survival and proliferation.

Diagnosis and differential diagnosis. The diagnosis of CLL is often made incidentally on a routine blood cell count that shows a leukocytosis with a predominance of small lymphocytes. Flow cytometric analysis of peripheral blood or bone marrow aspirate reveals the characteristic clonal B-cell population that is CD5 and CD23 positive. There is monoclonal expression of either Ig kappa or lambda and weak or absent expression of CD20, CD79b, FMC7. Smears of the bone marrow or peripheral blood reveal a predominance of small lymphocytes with inconspicuous nucleoli; ruptured cells (i.e., smudge cells) are often observed. Examination of involved lymph nodes reveals a diffuse infiltrate of small lymphocytes effacing the normal architecture.

CLL must be distinguished from reactive causes of lymphocytosis and other forms of lymphoma or leukemia. Mantle cell lymphoma may appear similar morphologically and with a similar immunophenotype, although CD23 is typically absent and cyclin D1 expression is detected. An absolute lymphocytosis of more than 5000 cells/ μ L is required for the diagnosis of CLL.

Clinical presentation. CLL cells accumulate in bone marrow, peripheral blood, lymph nodes, and spleen, resulting in lymphocytosis, lymphadenopathy, splenomegaly, and ultimately decreased bone marrow function. CLL is also frequently associated with immune dysregulation, exhibited as hypogammaglobulinemia with an increased risk of bacterial infections and autoimmune phenomena such as Coombs-positive hemolytic anemia or immune thrombocytopenia. Some patients exhibit lymphadenopathy, symptoms related to cytopenias, or recurrent infections. As the disease progresses, patients develop generalized lymphadenopathy, hepatosplenomegaly, and bone marrow failure. Death may occur from infectious complications or bone marrow failure after patients have become refractory to

treatment. In about 5% of cases, CLL transforms to a highly malignant diffuse large cell lymphoma, which may prove rapidly fatal. This transformation is commonly referred to as Richter syndrome.

Treatment. CLL is a low-grade disease typically characterized by a long natural history with slow progression over years or decades. Median survival is in excess of 6 years. The extent of disease (stage) at onset is the best predictor of survival. Genomic aberrations such as 17p or 11q deletions and unmutated IgVH status predict for significantly shorter median survival in patients with otherwise early stage disease.

Because standard therapy is not curative and CLL may have an asymptomatic phase lasting years, specific treatment is often withheld until signs of disease progression or development of symptoms (e.g., bulky lymphadenopathy, constitutional symptoms such as fevers, cytopenias caused by bone marrow infiltration). The rate of rise of the white blood cell count may also be used to predict development of symptoms and the need for therapy.

When treatment is required, multiple options for therapy are available. The patient's age, medical condition, and cytogenetic abnormalities may influence the choice of therapy. Active chemotherapeutic agents include several alkylating agents (e.g., chlorambucil, cyclophosphamide), the nucleoside analogue fludarabine, or the novel agent bendamustine. The fludarabine/cyclophosphamide (FC) regimen became a standard of care in 2005 combined with rituximab (FCR), achieving high complete remission rates. The FCR regimen was shown to improve overall survival in patients with CLL in a randomized phase 3 trial. This came at the expense of higher infection risks, particularly in older patients who tolerate bendamustine and rituximab (BR) better. There is also a risk of marrow stem cell injury. Patients with del(17p) did not respond to fludarabine-based regimens, however, and had a median survival of only 16 months after first-line treatment. FCR has been shown to provide the greatest benefit to young and fit patients with IgVH mutated CLL. Some of these patients have not relapsed with over 10 years of follow-up and may have been cured. For this subgroup of patients, the potential for cure needs to be balanced against the risks associated with FCR, including secondary malignancies.

The monoclonal anti-CD20 antibody rituximab has activity against CLL, but it is most effectively employed in combination with chemotherapeutic agents.

Most patients respond to therapy with significant reductions in tumor burden. Patients with recurrent or refractory disease may respond to a growing list of monoclonal antibodies. Alemtuzumab, a humanized monoclonal antibody to the CD52 molecule that occurs on most lymphocytes, is efficacious, including in patients with a 17p deletion, though the median response duration for this subset of patients is only 8 months. Additional agents include the anti-CD20 antibodies ofatumumab and obinutuzumab, which were shown to improve remission duration in previously untreated patients when administered in combination with chlorambucil (level I evidence).

Improved understanding of the mechanisms of CLL cell proliferation, mediated through BCR and *NFκβ* signaling, has led to the development of a number of targeted inhibitors with favorable efficacy/toxicity profiles in recent years. In 2013 and 2014, respectively, the BTK inhibitor ibrutinib and the PI3K inhibitor idelalisib were shown to be highly active in patients with refractory and high-risk CLL [del(17p), del(11q) and IgHV unmutated]. At 3 years of follow-up an unprecedented 50% of del(17p) patients taking ibrutinib were alive without progression of disease. In 2016, the BCL-2 inhibitor venetoclax was shown to be active in patients with refractory and high-risk CLL. A randomized phase 3 trial comparing venetoclax-rituximab to bendamustine-rituximab showed a major advantage in 2-year PFS (84.9% vs. 26.3%) in the venetoclax-rituximab group. This was true among patients with del(17p) as well, with 2-year PFS of 81.5% versus 27.8%.

Randomized comparisons of ibrutinib with or without rituximab to BR or FCR in untreated patients with CLL also favor ibrutinib-based therapy with improvements in PFS.

With continued use of ibrutinib, resistance mutations may develop and next-generation BTK inhibitors are in development. Combination strategies with BCL-2 inhibitors to circumvent resistance are in phase 3 studies. CAR-T cell therapy has also shown activity in ibrutinib-resistant CLL. While allogeneic transplantation may provide a cure through a graft versus leukemia immune phenomenon, it bears with it potential for significant morbidity and mortality and has been deferred in most CLL treatment algorithms to make room for the promising new targeted therapies.

Patients who develop autoimmune phenomena require treatment with corticosteroids, and intravenous gamma globulin may be used to reduce the frequency of infections in patients who have developed hypogammaglobulinemia. The development of a rapidly enlarging mediastinal mass, constitutional symptoms, and high serum LDH level suggests transformation of the disease to a diffuse large cell lymphoma (i.e., Richter syndrome), which is associated with a poor prognosis.

Plasma Cell Disorders

The plasma cell disorders, or dyscrasias, are a group of clonal B-cell diseases that are related to each other by virtue of their production and secretion of monoclonal immunoglobulin, called the *M protein*. The laboratory hallmark of plasma cell dyscrasias is a homogeneous immunoglobulin molecule (whole or part) that can be detected in the serum or urine by protein electrophoresis. Clinically, these disorders may be characterized by the systemic effects of the M protein and by the direct effects of bone and bone marrow infiltration. Primary amyloidosis, for instance, results in tissue injury through deposition of light chains produced by a clonal population of plasma cells in the absence of an observable proliferation of the plasma cell clone. Waldenström's macroglobulinemia is a disorder with features of NHL and plasma cell disorders. It is discussed in this section because of the distinct clinical effects of the IgM paraprotein produced in this disease.

The most common plasma cell dyscrasia is *monoclonal gammopathy of uncertain significance* (MGUS), followed by multiple myeloma and the closely related plasmacytoma, which is a solitary tumor comprised of clonal plasma cells of bone or extramedullary soft tissue. Less common plasma cell dyscrasias include POEMS (polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy and skin abnormalities) syndrome (see later in the chapter), also known as osteosclerotic myeloma, heavy-chain disease, and primary amyloidosis.

When an M protein is found on serum protein electrophoresis from an individual with no apparent associated disease and in the absence of any other laboratory or clinical evidence of a plasma cell disorder, it is designated as MGUS. MGUS is defined by low serum levels of M protein (<3 g/dL), no urinary Bence Jones protein, less than 10% clonal bone marrow plasma cells, and absence of anemia, hypercalcemia, renal failure, and lytic bone lesions. MGUS is more common than myeloma and increases in frequency with aging, occurring in 3% of the population older than 50 years. MGUS is considered a premalignant condition, and patients are at increased risk (7-fold) for overt myeloma or related malignant plasma cell dyscrasias compared with the general population. Nonetheless, progression of MGUS to a frank plasma cell neoplasm occurs only in about 1% of patients per year.

Distinguishing patients with stable, nonprogressive MGUS from patients in whom multiple myeloma will eventually develop is difficult. The risk of progression is greater among patients with IgA or IgM-type M proteins, in patients with initial concentrations of M protein in excess of 1.5 g/dL, and in patients with an abnormal free κ -to- λ light-chain ratio. Although no definitive evidence has been found that

monitoring patients with the diagnosis of MGUS improves survival, it is recommended that patients undergo annual evaluation, including serum electrophoresis, to detect progression to multiple myeloma before the onset of overt symptoms or complications.

M proteins can be found in benign and malignant conditions other than the plasma cell dyscrasias (Table 50.6). About 10% of patients with CLL have detectable levels of monoclonal IgG or IgM in their sera. M proteins can also be detected in a variety of autoreactive or infectious disorders.

Multiple Myeloma

Definition and epidemiology. Multiple myeloma is a malignant plasma cell disorder characterized by neoplastic infiltration of the bone marrow and bone and by monoclonal immunoglobulin or light chains in the serum or urine. The cause of myeloma is uncertain.

The disease is more common in men than women and in African Americans than white individuals. Myeloma risk increases with age, with a median age of 69 years at diagnosis (SEER data). There were an estimated 32,110 new cases in the United States in 2019. Myeloma risk is increased for patients with first-degree relatives with a plasma cell dyscrasia. Associations have been described with occupational exposures to organic solvents, pesticides, petroleum products, and ionizing radiation; however, most patients with myeloma have no history of exposure to such agents.

Pathology. The tumor cell exhibits features of a differentiated plasma cell that is adapted to synthesize and secrete immunoglobulin at a high rate. Biopsies of bone marrow or targeted bone biopsies of tumor sites reveal infiltration by plasma cells with light-chain restriction, defining clonality. Cell surface markers useful in identifying and enumerating plasma cells include CD38, CD 138, and immunoglobulin light chains; the B-cell marker CD20 is typically absent and aids in distinguishing other lymphoproliferative disorders from myeloma.

Genetic aberrations are detectable in most patients with myeloma if adequately sensitive tests are applied. Standard karyotyping and FISH are performed routinely on marrow samples to determine abnormalities of prognostic significance, including translocations involving the immunoglobulin heavy-chain locus on chromosome 14, hyperploidy, or abnormalities of chromosomes 1, 13, or 17.

Diagnosis and differential diagnosis. Myeloma must be distinguished from related disorders, including MGUS and plasmacytoma. The diagnosis of multiple myeloma is made by identifying some combination of an increase (>10%) in the number of plasma cells in the bone marrow, a serum M protein other than IgM exceeding 3 g/dL, or a clonal protein in the urine. Asymptomatic myeloma (i.e., stage I myeloma or "smoldering myeloma") is diagnosed when clonal plasma cells are found in 10% to 59% of the bone marrow or monoclonal protein occurs in an amount greater than 3 g/dL in the absence of end organ-related injury, significant elevation in clonal free light chains or evidence of bone disease on advanced imaging (whole body MRI or PET-CT scan).

Patients with disease-related organ dysfunction (e.g., anemia, lytic bone lesions, hypercalcemia, renal dysfunction) are considered to have symptomatic myeloma, for which therapy is indicated. Recurrent infection with hypogammaglobulinemia is also considered a criterion for symptomatic myeloma. Solitary plasmacytoma is diagnosed when a single clonal plasma cell tumor is identified in bone or soft tissue in the absence of bone marrow involvement or other end organ-related injury.

Evaluation of the patient with suspected myeloma includes bone marrow biopsy; measurement of hemoglobin, calcium, renal function, and the serum free κ -to- λ light-chain ratio; serum and urine protein electrophoresis; immunoelectrophoresis; and a skeletal survey. PET

TABLE 50.6 Classification of Disorders Associated With Monoclonal Immunoglobulin (M Protein) Secretion

Disorder	M Protein Pattern
Plasma Cell Neoplasms	
Multiple myeloma	IgG > IgA > IgD; ± free light chain or light chain alone ($\kappa > \lambda$)
Solitary myeloma of bone	IgG > IgA > IgD; ± free light chain or light chain alone ($\kappa > \lambda$)
Extramedullary plasmacytoma	IgA > IgG > IgD; ± free light chain or light chain alone ($\kappa > \lambda$)
Waldenström's macroglobulinemia	IgM ± free light chain ($\kappa > \lambda$)
Heavy-chain disease	γ , α , μ heavy chain or fragment
Primary amyloidosis	Free light chain ($\lambda > \kappa$)
Monoclonal gammopathy of unknown significance	IgG > IgM > IgA, usually without urinary light-chain secretion
Other B-Cell Neoplasms	
Chronic lymphocytic leukemia	M protein occasionally secreted; IgM > IgG
B-cell non-Hodgkin's lymphomas; Hodgkin's disease	M protein occasionally secreted; IgM > IgG
Nonlymphoid Neoplasms	
Chronic myelogenous leukemia	No consistent patterns
Carcinomas (e.g., colon, breast, prostate)	No consistent patterns
Autoimmune or Autoreactive Disorders	
Cold agglutinin disease	IgM κ most common
Mixed cryoglobulinemia	IgM or IgA
Sjögren's syndrome	IgM
Miscellaneous Inflammatory, Storage, or Infectious Disorders	
Lichen myxedematosus	IgG λ
Gaucher's disease	IgG
Cirrhosis, sarcoid, parasitic diseases, renal acidosis	No consistent pattern

Ig, Immunoglobulin.

and MRI are considered to further evaluate bone disease and may be necessary for patients with oligosecretory or nonsecretory disease to define disease and evaluate after therapy. Conventional bone scans are less useful due to the osteolytic nature of myeloma.

About 20% of patients with multiple myeloma do not have detectable serum M protein by standard electrophoresis but have circulating free light chains that may be detectable by serum free light-chain assays. Free light chains may appear in the urine (i.e., Bence Jones protein) and can also be detected in a 24-hour urine collection by urine protein electrophoresis. Free light-chain assays are quite sensitive and may provide measurement of clonal protein in patients thought to have non-secretory disease by other methods. Free light chains have a relatively short half-life (2 to 6 hours) in the circulation compared with a half-life of weeks for intact immunoglobulin molecules and may therefore be used to obtain a more rapid assessment of disease response once therapy is initiated. In rare cases, patients may have true non-secretory myeloma with no detectable serum or urine M protein by any assay.

Clinical presentation. The clinical manifestations of multiple myeloma are the direct effects of bone marrow and bone infiltration by malignant plasma cells, the systemic effects of the M protein, and the effects of the concomitant deficiency in humoral immunity that occurs in this disease. The most common symptom is bone pain. Bone radiographs typically show pure osteolytic punched-out lesions, often in association with generalized osteopenia and pathologic fractures. Bony lesions can show as expansile masses associated with spinal cord compression. Hypercalcemia caused by extensive bony involvement

is common in myeloma and may dominate the clinical picture. Anemia occurs in most patients as a result of marrow infiltration and suppression of hematopoiesis and causes fatigue; granulocytopenia and thrombocytopenia are less common.

Patients with myeloma are susceptible to bacterial infections because of impaired production and increased catabolism of normal immunoglobulins. Gram-negative urinary tract infections are common, as are respiratory tract infections caused by *Streptococcus pneumoniae*, *Staphylococcus aureus*, *Haemophilus influenzae*, and *Klebsiella pneumoniae*.

Renal insufficiency occurs in about 25% of patients with myeloma. The cause of renal failure is often multifactorial; hypercalcemia, hyperuricemia, infection, and amyloid deposition can contribute. Direct tubular damage from light-chain excretion also occurs. Because of their physicochemical properties, M proteins can cause a host of diverse effects, including cryoglobulinemia, hyperviscosity, amyloidosis, and clotting abnormalities resulting from interaction of the M protein with platelets or clotting factors.

Several staging or classification systems exist for myeloma. The Revised International Staging System (R-ISS) for myeloma identifies three stages with distinct prognoses based on β_2 -microglobulin and albumin levels, LDH, and cytogenetic/FISH abnormalities (Table 50.7).

Treatment. Most patients with myeloma exhibit symptomatic, advanced-stage disease and require therapy. Patients with asymptomatic myeloma may have an indolent course and do not always require immediate therapy. Disease progression occurs at a rate of 5% to 10% per year, and patients should be monitored for disease progression

TABLE 50.7 Revised International Staging System for Multiple Myeloma

Stage	Criteria	Survival Rate at 5 Years (Months)
I	B2M <3.5 mg/L Albumin ≥3.5 g/dL LDH ≤ ULN Standard-risk chromosomal abnormalities by FISH	82
II	Not stage I or III	62
III	B2M >5.5 mg/L High-risk chromosomal abnormalities or elevated LDH	40

Palumbo A et al. Revised international staging system for multiple myeloma: a report from International Myeloma Working Group. *J Clin Oncol*, 2015;33:2863.

High-risk chromosomal abnormalities include deletion 17p and/or translocation t(4;14) and/or t(14;16).

by serial quantification of M protein and serum free light chains and evaluation for disease-related signs or symptoms. For patients with solitary bone or extramedullary plasmacytomas, particularly in the head and neck region, local radiation therapy can induce long-term remissions and is the treatment of choice. Patients with a solitary plasmacytoma of bone are often found on routine MRI of the spine to have asymptomatic bone disease at other sites and should be treated as symptomatic myeloma.

Patients with symptomatic myeloma require systemic therapy and meticulous supportive care. Although myeloma is not a curable malignancy, systemic therapy prolongs survival and dramatically improves quality of life. Options for treatment have expanded in the past two decades to include multiple novel compounds in three broad classes of agents, the immunomodulatory drugs (IMiDs), proteasome inhibitors, and monoclonal antibodies. These agents may be used as single agents or in combinations for more intensive therapy. The novel agents are typically administered in combination with high doses of dexamethasone, which is a potent antimyeloma therapy. The IMiDs include thalidomide, lenalidomide, and pomalidomide. Proteasome inhibitors include bortezomib, carfilzomib, and ixazomib. The anti-CD38 monoclonal antibody daratumumab was approved for use in the United States in 2015. These agents have largely supplanted traditional chemotherapeutic agents as the cornerstone of initial and secondary therapies because they are efficacious and well tolerated. Multiple combination regimens have been devised that also incorporate chemotherapeutic agents in modest doses.

Thalidomide is the first-in-class IMiD and was initially used as a sedative in the United Kingdom in the 1960s, but it was found to cause birth defects (phocomelia) when used to combat nausea during pregnancy. The antiangiogenic properties of thalidomide subsequently led to its development as an anticancer agent. The molecular target of the IMiD class was recently elucidated as cereblon, an E3 ligase protein crucial to the activity of B cell-specific transcription factors that influence myeloma cell viability. The IMiDs are typically used in combination with dexamethasone, and when used as initial therapy, they have good tolerability and result in high response rates.

Toxicity related to thalidomide includes peripheral neuropathy, constipation, somnolence, and rash. Later-generation IMiDs have a more favorable side effect profile. Myelosuppression is more likely, but neuropathy and constitutional symptoms occur less frequently.

The second-generation IMiD lenalidomide is more commonly used in North America due to its favorable tolerability. A troublesome and unique side effect of the IMiD-steroid combination programs is development of deep vein thrombosis in up to 25% of patients, and some form of preventative therapy is required.

Bortezomib is the first-in-class proteasome inhibitor and is an important therapy for patients with adverse cytogenetic risk factors. Bortezomib is typically administered subcutaneously and may cause thrombocytopenia, asthenia, and neuropathy.

Most patients respond to initial therapy with a reduction in bone pain, hypercalcemia, and anemia in association with a decline in the M protein level. The selection of initial therapy depends on stage, cytogenetic risk, and candidacy for high-dose chemotherapy and autologous stem cell transplantation. The use of high-dose chemotherapy with alkylating agents followed by autologous peripheral stem cell infusion during first or second remission improves progression-free survival and quality of life compared with conventional therapy. Although this approach is not curative, it does represent an important treatment option for some patients and has an acceptable toxicity profile, even in older patients. Allogeneic stem cell or bone marrow transplantation may be associated with durable remission in selected patients, but it carries a high near-term risk of morbidity and mortality. Patients who experience relapse after standard therapy or transplantation may be treated with alternative chemotherapy regimens or with novel combination therapies, including newer agents and chemotherapy drugs. The first-in-class *selective inhibitor of nuclear export*, selinexor was recently added to the antimyeloma armamentarium for patients with relapsed or refractory disease as a fifth-line therapy. CAR-T cell therapy has shown high response rates in clinic trials and is expected to become available as a standard therapy soon.

Supportive care directed toward anticipated complications of myeloma is an important aspect of management. Bone resorption can be reduced with regular injections of the diphosphonates zoledronic acid or pamidronate, reducing pain and pathologic fractures. The monoclonal antibody denosumab targets RANKL, inhibiting osteoclast activity, and may also be used to treat bone disease. Bony lesions, particularly those involving weight-bearing bones, may require palliative irradiation for controlling pain and preventing pathologic fractures. Vertebral bony lesions may lead to spinal cord compression, with increasing back pain and neurologic symptoms. Symptoms suggesting cord compression require prompt evaluation with spinal MRI and, if necessary, local irradiation of involved areas.

Avoidance of nephrotoxins, including intravenous contrast media, is important to prevent renal failure. All patients should receive pneumococcal and *H. influenzae* vaccines, and intravenous gamma globulin may be useful in preventing recurrent infections in patients with profound hypogammaglobulinemia. Use of erythropoietin may alleviate anemia and decrease the need for blood transfusions in patients with treatment-related anemia or concomitant renal insufficiency.

Prognosis. Multiple myeloma is considered incurable, but the overall survival of these patients has improved considerably with the use of newer agents and autologous stem cell transplantation. The five-year survival as reported by the SEER database is 52.2%.

Prognosis depends on stage of disease and cytogenetic profile. Patients with an adverse karyotype, including t(14;16), t(4;14), and 17p deletion, have a less favorable prognosis and are considered for more intensive therapies or clinical investigation. Adverse factors also include advanced stage, impaired renal function, elevated LDH levels, depressed serum albumin levels, and elevated β_2 -microglobulin levels.

Waldenström's Macroglobulinemia

Waldenström's macroglobulinemia (WM) is a malignancy of plasma-cytoid lymphocytes that secrete large quantities of IgM. It is a chronic

disorder affecting elderly patients (median age 64 years) that shares features of the low-grade lymphomas and myeloma. Unlike myeloma, Waldenström's macroglobulinemia is associated with lymphadenopathy and hepatosplenomegaly, and although bone marrow involvement invariably occurs, lytic lesions and hypercalcemia are rare. Diagnostic work-up for WM should include polymerase chain reaction analysis for mutation in the MYD88 gene, which is present in most patients and carries diagnostic and therapeutic relevance.

The major clinical manifestations of WM include symptomatic anemia and the hyperviscosity syndrome caused by the physical properties of IgM. In contrast to IgG, IgM remains largely confined to the intravascular space, and as IgM levels rise, plasma viscosity increases. Epistaxis, retinal hemorrhages, dizziness, confusion, and congestive heart failure may occur as a result of the hyperviscosity syndrome. About 10% of IgM proteins have properties of cryoglobulins, and patients show symptoms of cryoglobulinemia or cold agglutinin syndrome demonstrated as acrocyanosis, Raynaud's phenomenon, and vascular symptoms or hemolytic anemia precipitated by exposure to cold. Some patients with WM may develop a peripheral neuropathy that may antedate the appearance of the neoplastic process.

The approach to and treatment of WM is similar to those of other low-grade B-cell lymphomas. The use of fludarabine or an alkylating agent, typically employed in combination with prednisone and rituximab, is effective in decreasing adenopathy and splenomegaly and controlling the M spike but is not curative. Rituximab has activity against WM, as has the proteasome inhibitor bortezomib. The use of rituximab as a single agent may be complicated by initial worsening of hyperviscosity in patients with high IgM burdens. The novel agent ibrutinib, an inhibitor of Bruton tyrosine kinase, is an effective oral therapy for Waldenström's and may be combined with rituximab. Although complete remissions are rare, patients who respond to therapy have median survivals of 4 years, and some patients survive more than a decade.

Rare Plasma Cell Disorders

Heavy-chain disease is a rare lymphoplasmacytoid neoplasm characterized by production of a defective heavy chain of the γ , α , or μ type. The clinical manifestations vary with the type of heavy chain secreted. The γ -type heavy-chain disease is associated with lymphadenopathy, Waldeyer ring involvement with palatal edema, and constitutional symptoms. The α -type heavy-chain disease, also known as Mediterranean lymphoma, is characterized by lymphoid infiltration of the small intestine with associated diarrhea and malabsorption. The μ -type heavy-chain disease is associated with CLL.

Primary amyloidosis. Primary AL amyloidosis is a systemic illness characterized by deposition of immunoglobulin light chains in organs and tissue, resulting in an array of symptoms caused by organ dysfunction. Congestive heart failure, bleeding diathesis, nephrotic syndrome, and peripheral neuropathy are common complications. Patients with primary amyloidosis may respond to selected treatments similar to therapy for myeloma. The combination of bortezomib, cyclophosphamide, and dexamethasone is effective in some patients. Selected patients may respond well to high-dose chemotherapy and autologous stem cell support, but there are increased risks of morbidity and mortality if significant end-organ dysfunction such as cardiomyopathy occurs. It is important to note that not all amyloidosis is AL (light chain), and documentation of the source and type of amyloid protein is vital to appropriate management.

POEMS syndrome. POEMS syndrome is a rare disorder characterized by polyneuropathy, sclerotic bone lesions, endocrinopathy, monoclonal gammopathy, and skin lesions. The cause of POEMS syndrome is unknown, but the disease may be

progressive, causing severe disability, third spacing of fluid, and elevated vascular endothelial growth factor (VEGF) levels. Monoclonal λ light chains are typically elevated. Limited bone disease may be treated with radiotherapy. High-dose therapy and autologous stem cell transplantation is effective in patients with extensive disease.

For a deeper discussion of these topics, please see Chapter 178, "Plasma Cell Disorders," and Chapter 179, "Amyloidosis," in *Goldman-Cecil Medicine*, 26th Edition.

CONGENITAL AND ACQUIRED DISORDERS OF LYMPHOCYTE FUNCTION

Several congenital disorders affect lymphocyte maturation or function, resulting in immunodeficiency disorders. Acquired disorders of lymphocyte function are far more common than congenital disorders. HIV infection is the most important infectious cause of acquired immunodeficiency (see [Chapter 103](#)). Patients with HIV infection are at increased risk for NHL. NHLs that occur in the setting of HIV have diffuse, aggressive B-cell histology and include DLBCL and Burkitt lymphoma. They are frequently associated with EBV infection and are often advanced stage (III or IV) at diagnosis, with extranodal sites of involvement.

Patients with HIV-associated NHL are potentially curable with the multidrug chemotherapy regimens used for treating NHL found in the general population. Treatment of the underlying HIV infection with highly active antiretroviral therapy (ART) has improved the outcome and prognosis of patients with HIV-associated NHL.

Patients who have undergone allogeneic organ transplantation require potent immunosuppressive drugs (e.g., cyclosporine, tacrolimus, mycophenolate, corticosteroids, methotrexate) to prevent graft-versus-host disease in the case of bone marrow transplantation or allograft rejection in the case of solid organ transplantation. These medications cause defects in T-cell function with an associated immunodeficiency state, which increases risk for a post-transplant lymphoproliferative disorder (PTLD). PTLD is an EBV-associated lymphoproliferative disorder characterized by a polymorphous or monomorphous population of B cells that can be monoclonal or polyclonal. Patients are treated by reducing doses of immunosuppressive drugs whenever possible. Patients with polymorphous disease early after organ transplantation may respond well to this approach. Patients who are not candidates for withdrawal of immunosuppression because of allograft rejection or who develop late monophorphic disease may respond better to treatment with rituximab alone or in combination with chemotherapy.

Normal Hemostasis

Lauren Shevell, Alfred I. Lee

INTRODUCTION

Hemostasis is the physiologic balance of procoagulant and anticoagulant forces that provide structural integrity of vasculature while maintaining circulating blood flow. Vascular damage initiates clotting, which results in a localized platelet-fibrin plug at the site of injury to prevent blood loss. This is followed by clot containment, wound healing, eventual clot dissolution, and tissue regeneration. In healthy individuals, procoagulant and anticoagulant reactions occur continuously and in a balanced fashion so that bleeding is contained while blood vessels simultaneously remain patent to deliver adequate organ blood flow. If any of these processes is disrupted, either from inherited defects or acquired abnormalities, disordered hemostasis may result in either bleeding diatheses or thromboembolic disease.

Traditionally, hemostasis has been conceptualized in two parts: *primary hemostasis*, resulting in adhesion and activation of platelets, and *secondary hemostasis*, resulting in activation and regulation of the coagulation cascade. More recent studies, however, demonstrate a considerable amount of interplay between primary and secondary hemostatic components.

This chapter briefly details the physiologic and interdependent mechanisms of vascular hemostasis, including the normal balance of procoagulant and anticoagulant functions of the blood vessel wall and platelets, receptor-ligand interactions that are critical for hemostasis, as well as the highly complex, interwoven pathways that represent the coagulation cascade.

VASCULATURE PHYSIOLOGY

Blood flow in the arterial system differs from that in the venous system and imposes different coagulation requirements. In the pressurized arteries, relatively minor vascular damage can rapidly result in massive exsanguination; therefore, the procoagulant response in the arteries must rapidly arrest bleeding. Platelets are critical to the arterial response; they initially contain the blood loss and then provide an active surface for soluble coagulation factors to both localize and accelerate formation of fibrin for a strong fibrin clot. In contrast, the slower flow rates in the venous circulation produce slower bleeding, a feature that makes platelets less critical; instead, the balance of venous hemostasis is most dependent on the rate of thrombin generation. These differences are underscored clinically by the antithrombotic agents used in these distinct clinical settings: antiplatelet agents such as aspirin and clopidogrel are used to prevent coronary and cerebral artery thrombosis, whereas anticoagulants such as heparins, warfarin, and direct oral anticoagulants (e.g., direct thrombin inhibitors like dabigatran, or Xa inhibitors like rivaroxaban or apixaban) are used for the treatment and prophylaxis of venous disease.

Vascular endothelial cells (ECs) that line the luminal surfaces of blood vessels contribute both procoagulant and anticoagulant forces depending on circumstances. When the vasculature is intact, healthy ECs exert anticoagulant activity to maintain blood fluidity. This is done through several mechanisms. First, ECs act as a barrier, separating blood from subendothelial procoagulants such as tissue factor (TF) and collagen (Fig. 51.1A). ECs also contribute to hemostatic balance by secreting several products including prostacyclin, nitric oxide, adenosine diphosphatase, and tissue factor pathway inhibitor (TFPI). Prostacyclin and nitric oxide release by ECs leads to vascular smooth muscle relaxation, reducing shear injury. These chemicals also promote the generation of cyclic adenosine monophosphate (cAMP), thus inhibiting platelet activation and aggregation. Adenosine diphosphatase degrades extracellular platelet-released ADP, inhibiting platelet recruitment into the growing platelet clot. TFPI acts by blunting the initiation of the coagulation cascade (described in more detail in the “Termination of Clotting” section).

When ECs are physically damaged or activated, their balance of coagulant properties is shifted to favor a procoagulant state. This is mediated by both the ECs themselves and subendothelial matrix that is exposed when the vascular wall is disrupted. Activated ECs express ligands on their surfaces allowing for platelet adhesion and increased inflammatory responses. These include E-selectin and P-selectin, β_1 and β_2 integrins, platelet EC adhesion molecule-1 (PECAM-1), and von Willebrand factor (VWF) multimers (Table 51.1). On the activated EC surface, VWF multimers localize and promote platelet adhesion, whereas integrins mediate adhesion and subsequent transendothelial migration of leukocytes into the tissues. After EC damage, the exposed subendothelial matrix also binds VWF multimers to further enhance platelet adhesion. Subendothelial procoagulant proteins such as thrombospondin, fibronectin, and especially collagen function both as ligands to capture platelets and as activators of adherent platelets. Collagen, in particular, is both a platelet ligand and a strong platelet agonist and causes platelets to undergo alpha and dense granule release and to express conformationally active ligands such as glycoprotein IIb/IIIa (GPIIb/IIIa, also known as integrin $\alpha_{IIb}\beta_3$) (described in detail later). Another critical procoagulant mediator exposed by EC damage is TF, which is constitutively expressed by subendothelial smooth muscle cells and fibroblasts. As outlined further later, TF is the major initiator of the soluble coagulation system that, along with activated platelets, results in the formation of a definitive platelet-fibrin clot.

VON WILLEBRAND FACTOR

VWF is an essential component of coagulation. Produced by ECs and megakaryocytes, the VWF protein is stored within platelets in alpha granules and within ECs in rodlike granules known as Weibel-Palade

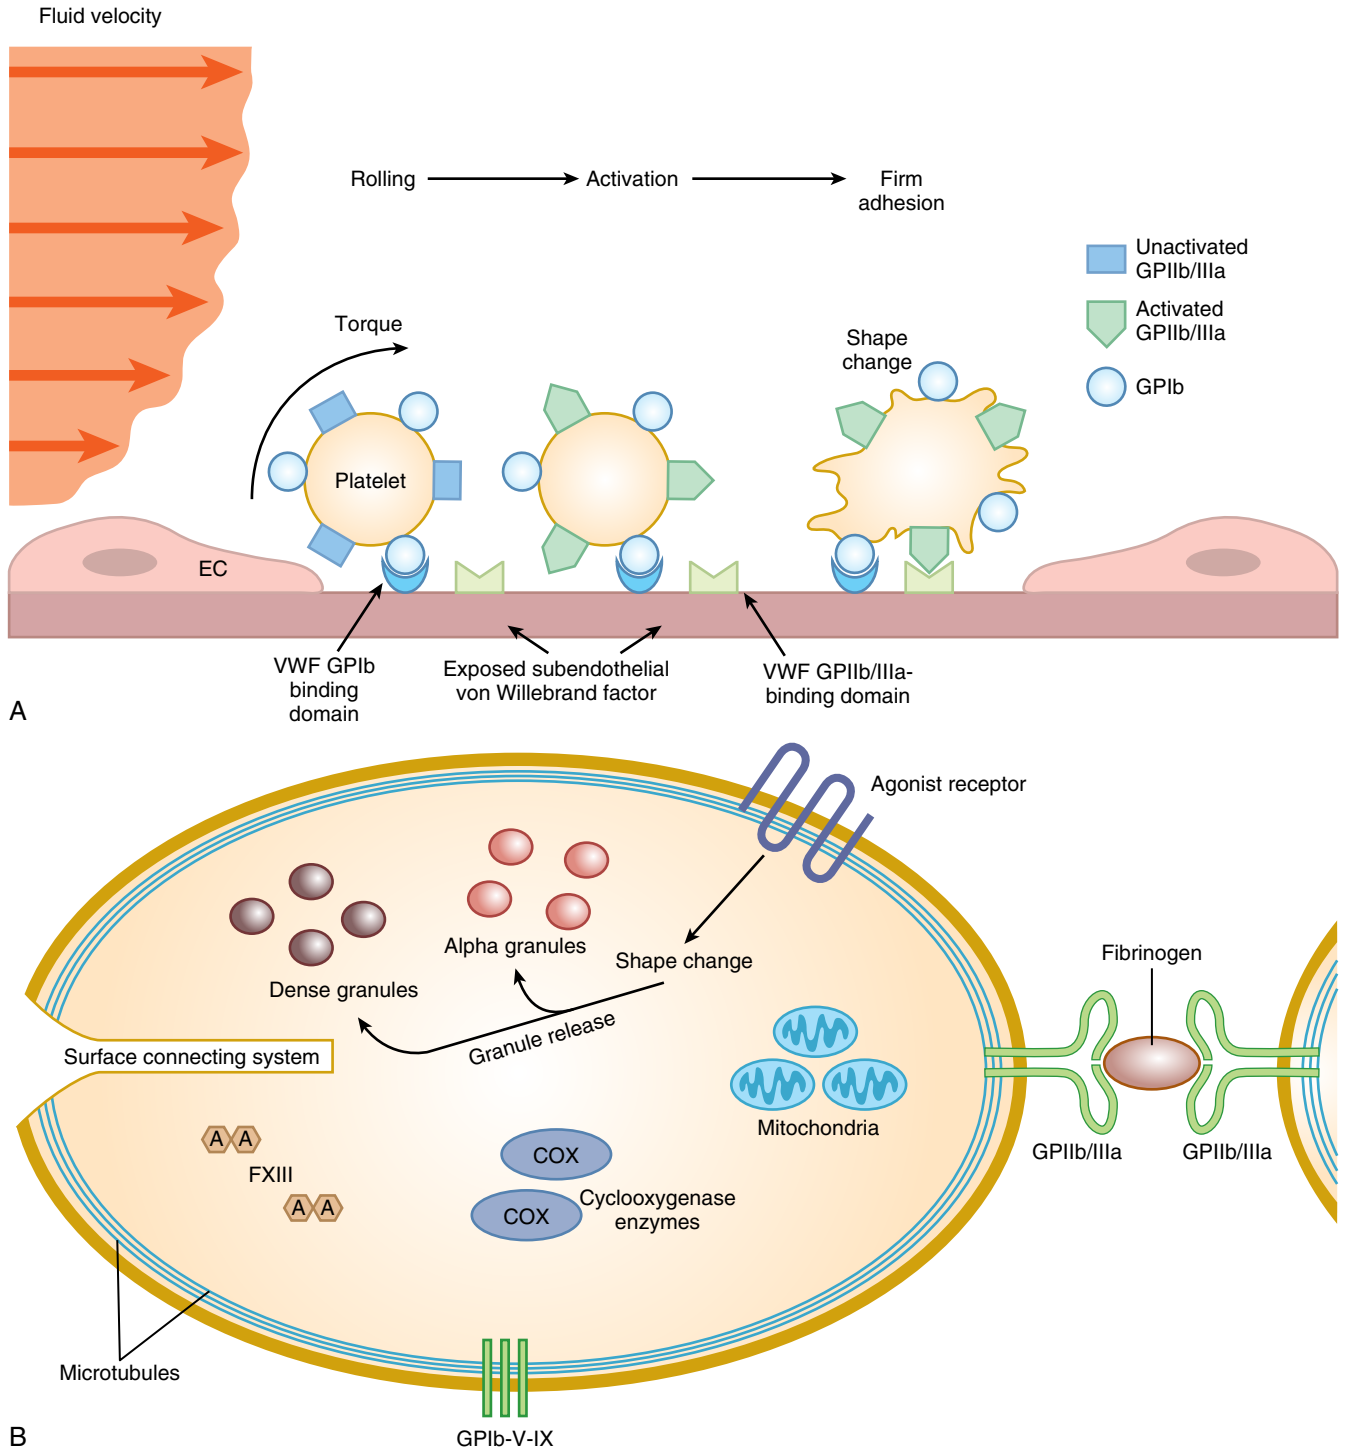

Fig. 51.1 (A) The adhesive interactions that produce stable platelet attachment to subendothelial von Willebrand factor (VWF). The initial attachment between platelet glycoprotein Ib (GPIb) and its binding domain on VWF is rapid but has a short half-life, and the result is a rolling movement caused by torque generated by flowing blood. The VWF-GPIb interaction produces transmembrane signaling that activates the platelet to change shape and simultaneously transforms GPIIb/IIIa into an activated conformation capable of binding to a distinct arginine-glycine-aspartate domain on VWF. This secondary adhesion causes the platelet to firmly adhere to the exposed subendothelial VWF. (B) The internal and external anatomy of a platelet. The platelet consists of several important external, transmembrane, and internal components that help to promote platelet activation, adhesion, aggregation/agglutination, and general coagulation factor-based hemostasis. The most important and most clinically relevant aspects of platelet anatomy are shown. Details regarding the steps leading to platelet activation and release of granules and cytosolic contents are discussed in the text. A, A subunits of factor XIII; COX, cyclooxygenase; EC, endothelial cell; FXIII, factor XIII; GP, glycoprotein complex.

TABLE 51.1 Properties of Endothelial Cell Coagulants

Procoagulant	Anticoagulant
Collagen	Vasodilation

Selectins (E and P)	Thrombomodulin
Vasoconstriction	Tissue factor pathway inhibitor
von Willebrand factor	Tissue plasminogen activator

bodies. In both platelets and ECs, VWF proteins multimerize in the Golgi apparatus; about 95% of VWF multimers are constitutively released into the plasma and can be detected on electrophoretic gels as high-, intermediate-, and low-molecular-weight VWF forms. The remaining 5% of VWF multimers are stored either in platelet alpha granules or in EC Weibel-Palade bodies in the form of ultra-large VWF multimers. Following platelet stimulation or EC damage, ultra-large VWF multimers are released into the plasma and have high affinity for platelets and subendothelial collagen, forming string-like structures that must then be cleaved into smaller VWF proteins for proper function. Cleavage of ultra-large VWF multimers is performed by a metalloproteinase, ADAMTS13 (a disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13). In addition to platelet and subendothelial collagen binding, VWF in the plasma serves as a second role in binding and stabilizing coagulation factor VIII and preventing its degradation.

The importance of VWF is underscored clinically by von Willebrand disease (VWD), the most common inherited bleeding condition in the world, characterized by defects in either the amount or the activity of VWF protein; and alternatively by thrombotic thrombocytopenic purpura, an inherited or acquired disease arising from defects in ADAMT13 that lead to accumulation of ultra-large VWF multimers, causing microvascular thrombosis, platelet consumption, shearing of red blood cells and multiple end-organ complications.

PLATELET PHYSIOLOGY

Platelets are anucleated cells measuring 2 to 4 μm in diameter and are derived from megakaryocyte cytoplasm (Fig. 51.1B). Each megakaryocyte contributes 1000 to 3000 platelets in its lifetime. After platelets are released into the circulation, they survive 7 to 10 days. The normal platelet count ranges between 150,000 to 450,000/ μL ; only approximately 7100 platelets/ μL are required for hemostasis per day if vascular structures are intact (i.e., in the absence of any recent surgeries or trauma) and if there is no increase in normal platelet consumption (e.g., as might occur in sepsis or disseminated intravascular coagulation).

The bleeding time, an *in vivo* measure of hemostasis, is usually less than 8 minutes if the platelet count is within the normal limit. It is used as a screening test for platelet function defects, VWD, and sometimes other bleeding disorders. The bleeding time is dependent on the platelet count and will naturally be prolonged if the platelet count falls to less than 100,000/ μL . Therefore, in the setting of thrombocytopenia, a prolonged bleeding time cannot be used to determine whether bleeding is caused by abnormal platelet function, VWD, another bleeding problem, or thrombocytopenia. Because the bleeding time is an

operator-dependent, highly variable *in vivo* assay that causes trauma to patients, most laboratories now use the Platelet Function Analyzer-100 (PFA-100) (Fig. 52.2), which uses anticoagulated blood to examine the amount of time required for platelets to form a plug in response to either collagen and ADP or collagen and epinephrine (i.e., the “closure time”). The PFA-100 is similar to the bleeding time test in that both may be used to assess platelet function and to screen for VWD but are unable to distinguish between thrombocytopenia and abnormal platelet function when the platelet count is lower than 100,000/ μL .

Platelet Activation

In the setting of vascular injury, platelets are recruited to the area by exposure to local agonists (collagen, epinephrine and thrombin) and by release of agonists within platelets into the local microenvironment (ADP, thromboxane). The most potent platelet activators, collagen and thrombin, interact with their specific platelet receptors to strongly activate platelets. Epinephrine alone is not a powerful platelet agonist, but stimulation of the α -adrenergic receptor on platelets primes them for synergistic activation by relatively weak agonists such as ADP. Platelets also release activating compounds, including thromboxane A₂ (TXA₂), which is formed in the platelet cytosol after cyclooxygenase 1 (COX1)-mediated cleavage of arachidonic acid, which is then released into the clot milieu. TXA₂ is both a platelet agonist and vasoconstrictor and is rapidly degraded to its inert by-product, thromboxane B₂. Notably, the exact roles of different platelet agonists depend on a spatial hierarchy within the platelet plug. Thrombin activates platelets within the core of the hemostatic plug, whereas ADP and TXA₂ activate platelets in the loosely packed shell surrounding the core.

Of particular clinical importance, platelet COX1 activity is irreversibly inhibited by aspirin, which blocks formation of TXA₂ for the lifetime of the platelet through a covalent bond causing steric hindrance of the active site. In contrast, nonsteroidal anti-inflammatory drugs (NSAIDs) reversibly and competitively bind at the active site; thus, the antiplatelet effects of NSAIDs are dependent on the continual presence of plasma levels of the NSAID. COX2 is an induced isoform of the cyclooxygenase enzyme that is present within leukocytes and that mediates inflammation and pain. Mature platelets do not possess COX2 activity, providing the rationale for the development of selective COX2 inhibitors to decrease inflammation without increasing the bleeding risk of platelet dysfunction (as well as decreasing risk for gastrointestinal side effects, which will not be addressed here). However, ECs are reliant on COX2 activity to synthesize the antithrombogenic compound prostacyclin. Downregulation of prostacyclin, coupled with preserved platelet function, tips the hemostatic balance in favor of clot formation. In view of this, large-scale clinical trials have shown that highly selective COX2 inhibitors increase the likelihood of hypertension and vascular events including myocardial infarction and stroke.

Platelet Adhesion

Platelet activation leads to a functional shape change of the platelet from a disk to an irregular sphere with pseudopod extensions, as well as exposure of platelet binding domains. This enhances platelet adhesion capabilities and maximizes the interaction of coagulation factors with the platelet surface. Initial platelet adhesion is primarily mediated by the glycoprotein 1b-IX-V (GP1b-IX-V) complex on the platelet surface binding to multimeric VWF, which is immobilized by adherence to exposed subendothelial collagen. The weak binding of GP1b-IX-V to VWF contributes to transmembrane signaling with downstream effects that include a change in platelet shape (see Fig. 51.1A) and a change in GPIIb/IIIa (integrin $\alpha_{\text{IIb}}\beta_3$) from a low-affinity to a high-affinity state, facilitating binding of the latter to fibrinogen and VWF (see Fig. 51.1B). A deficiency of the GP1b-IX-V complex leads to

Bernard-Soulier syndrome, a congenital bleeding disorder characterized by giant platelets that are dysfunctional.

GPIIb/IIIa (integrin $\alpha_{IIb}\beta_3$) is a member of the integrin superfamily and the most abundant receptor on the platelet surface. Prior to platelet activation, the GPIIb/IIIa ($\alpha_{IIb}\beta_3$) receptor sits on the platelet surface and has low affinity for binding. However, upon platelet activation and its consequent conformational changes, the GPIIb/IIIa receptor adopts a high-affinity conformation that facilitates binding both to VWF, securing platelets strongly on the subendothelial surface, and to fibrinogen, linking platelets together and reinforcing the platelet plug. Further, after binding to VWF, the cytosolic side of the GPIIb/IIIa ($\alpha_{IIb}\beta_3$) receptor binds to the cytoskeleton of the platelet, fostering further changes to platelet shape change and spreading via cytoskeletal reorganization. These roles of GPIIb/IIIa ($\alpha_{IIb}\beta_3$) in platelet adhesion and platelet plug formation provide the rationale for use of GPIIb/IIIa ($\alpha_{IIb}\beta_3$) antagonists in treatment of coronary artery disease. Of note, mutations in the gene encoding GPIIb/IIIa ($\alpha_{IIb}\beta_3$) lead to Glanzmann thrombocytopenia, another congenital bleeding disorder leading to platelet dysfunction.

Platelet Secretion

After activation, dense granules and alpha granules within platelets fuse with the canalicular membrane and liberate their procoagulant contents into the extracellular fluid. Dense granules contain serotonin, ADP, ATP, ionized calcium, and histamine. Serotonin and ADP both activate and recruit platelets to sites of vascular injury. Additionally, serotonin, similarly to TXA₂, acts as a vasoconstrictor. ADP acts purely as a platelet agonist through the G protein-linked P2RY12 receptor and has no vasoactive properties. The importance of dense-granule release is illustrated by the severe bleeding seen in patients with congenital dense-granule deficiencies such as Hermansky-Pudlak syndrome or Chediak-Higashi syndrome.

Alpha granules contain numerous proteins including many adhesive molecules (fibrinogen, VWF, thrombospondin), cellular mitogens (platelet-derived growth factor, transforming growth factor beta), coagulation factors (factor V), and physiologically important receptors (P-selectin, $\alpha_{IIb}\beta_3$). The importance of platelet alpha granules is illustrated in patients with gray platelet syndrome, an inherited deficiency of alpha granules leading to bleeding. Other components within platelets, including factor XIII, are also released upon platelet activation and act as clot stabilizers (see Fig. 51.1B).

COAGULATION

Coagulation Cascade Model

The classical coagulation cascade (Fig. 51.2A), first described over 50 years ago, features two starting points, the intrinsic and extrinsic pathways, that flow in a step-wise waterfall of proteolytic reactions and converge in a common pathway. The common pathway culminates with the generation of thrombin, which converts fibrinogen to fibrin. Fibrin then cross-links platelets and strengthens the platelet plug.

In the classical model, coagulation begins with the extrinsic pathway, which is initiated by the exposure of TF and activated factor VIIa, leading to activation of factor X in the common pathway.

The intrinsic pathway is initiated by the activation of proteins circulating in plasma—namely, factor XII (Hageman factor), high-molecular-weight kininogen (HMWK, also known as Fitzgerald factor), and prekallikrein (PPK, also known as Fletcher factor). This pathway is also referred to as the contact activation pathway because these proteins are activated by contact with negatively charged surfaces. Factor XIIa and HMWK activate factor XI, leading to the activation of factor IX, which in conjunction with factor VIII activates factor X to initiate the common pathway (see Fig. 51.2AB). The importance of the intrinsic coagulation

cascade is demonstrated in patients with hemophilias, which are congenital bleeding disorders due to deficiencies in factor VIII (hemophilia A), factor IX (hemophilia B), or factor X (hemophilia C).

Notably, all procoagulants are produced almost exclusively in the liver aside from factor VIII, which is produced in both liver sinusoidal cells and ECs, and VWF, which is produced in ECs and megakaryocytes. The procoagulant factors II, VII, IX, and X, and the anticoagulant proteins C and S, all undergo post-translational modification in the form of vitamin K-dependent g-carboxylation of the amino terminal domains, which is critical for calcium binding and determining the three-dimensional structure of proteins. The importance of vitamin K-dependent g-carboxylation is demonstrated by the anticoagulant warfarin, which acts by blocking vitamin K epoxide reductase, thereby reducing the generation of these specific proteins.

In the classical coagulation model, the prothrombin time (PT) serves as a measure of extrinsic pathway activity while the activated partial thrombin time (aPTT) measures activity of the intrinsic pathway. Therapeutically, the PT and aPTT are used to guide warfarin and heparin dosing, respectively. Although the classical model of coagulation is workable for some clinical scenarios, more recent models have made strides to more accurately elucidate and depict the physiology and complex interplay of different components of coagulation.

Cell-Based Model of Coagulation

The cell-based coagulation model (see Fig. 51.2B) has largely been established as the most physiologically accurate in vivo model of coagulation. This model proposes that coagulation takes place on the surfaces of different cells in a three-step fashion: initiation, amplification, and propagation.

The *initiation phase* begins as exposed TF on the EC surface binds to picomolar amounts of factor VIIa, present in the circulation at all times. The VIIa-TF complex (termed the extrinsic Xase) activates factors IX and X. The conversion of a small amount of X to Xa produces a tiny amount of thrombin. The nearly trivial amount of thrombin sparks feedback to activate factor XI, leading to *amplification* of thrombin generation. Factor VIII, conveniently brought to the bleeding site by its carrier VWF, is also activated by thrombin, a step that causes release of VWF. Factor VIIIa then complexes with the picomolar amounts of factor IXa generated by the TF-VIIa complex during the initiation phase to create the VIIIa-IXa complex, known as the intrinsic Xase complex. Notably, IXa generation by the TF-VIIa complex is limited by TFPI, so factor IX is secondarily activated by platelet-bound factor XIa (catalyzed by factor XIIa in conjunction with high molecular weight kininogen), providing sufficient amounts of factor IXa in the intrinsic Xase complex. The formation of this complex on the platelet surface heralds the *propagation phase*, and the switch of the primary path of Xa generation from the TF-VIIa complex, the extrinsic Xase complex, to the intrinsic Xase. This switch is of significant kinetic advantage, with the intrinsic Xase complex exhibiting a 50-fold higher efficiency than the extrinsic Xase. More than 96% of the total thrombin that is generated during clotting occurs during the propagation phase. The bleeding diathesis associated with hemophilia is a testament to the physiologic importance of the exuberant thrombin generation engendered by the switch from extrinsic to intrinsic Xase. The aPTT, which measures the initiation phase of clotting begun by an artificial in vitro stimulant, is prolonged by severe deficiencies of either VIII or IX, but it is thrombin generation during the propagation phase, a function not evaluated by the aPTT, that is more impaired in hemophilia.

Thrombin generated during the initiation phase is a potent platelet activator. The activated platelet expresses receptors for VIIIa and IXa, and binding of these active proteases in complex with membrane phosphatidylserine enhances the binding of the enzyme's substrate,

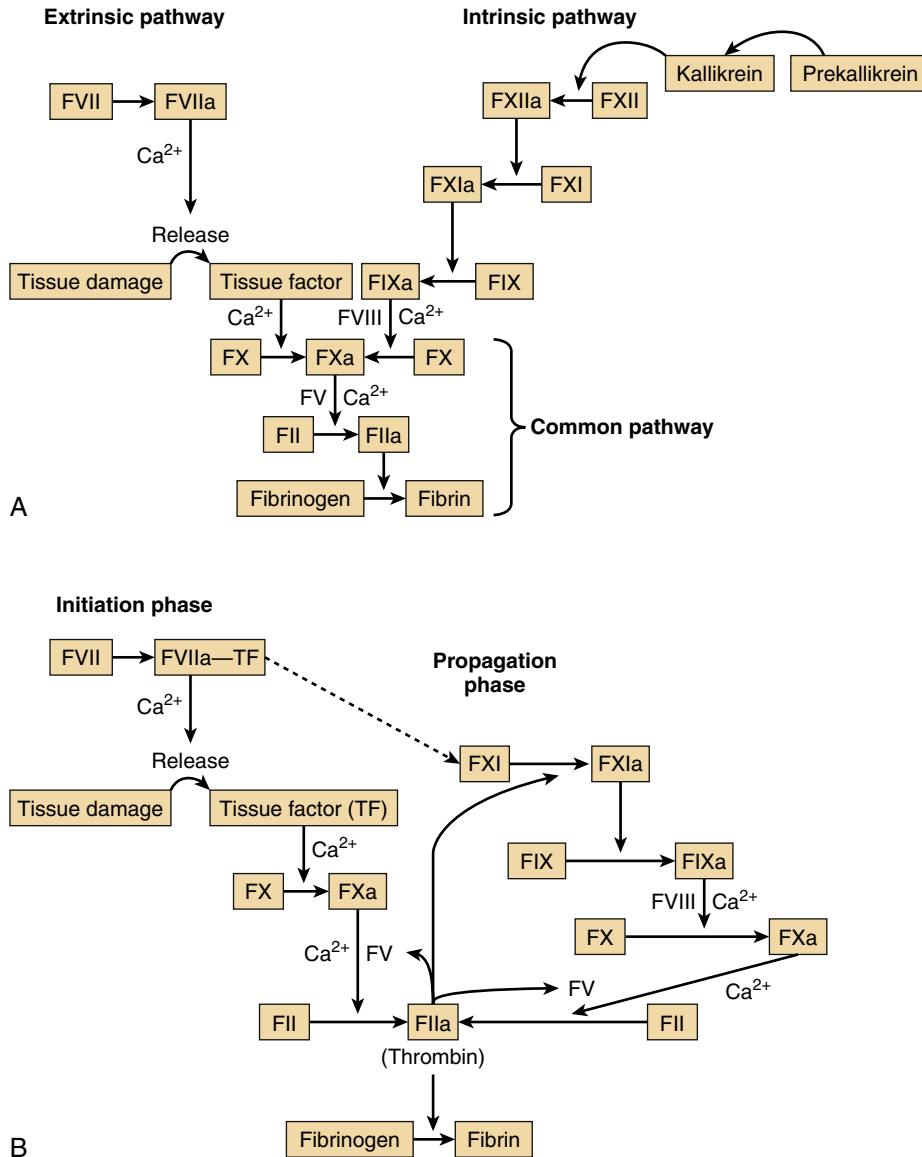

Fig. 51.2 (A) The classic view of the coagulation cascade. The laboratory-defined *extrinsic* and *intrinsic* pathways allow monitoring of anticoagulation by serial measurements of the prothrombin time (PT) and partial thromboplastin time (PTT), respectively. The PT primarily monitors factor VII activity, whereas the PTT is the best measure of XI and the hemophilic factors IX and VIII; both assays will detect deficiency of the common pathway factors (X, V, and II). (B) In the more modern view of the coagulation cascade, initiation of clotting begins with exposure to tissue factor (TF), which combines with small amounts of circulating factor (F) VIIa to form the extrinsic tenase (Xase) complex and generate FXa. FXa forms the prothrombinase complex with FVa and FII, generating small amounts of thrombin (FIIa), which begins to cleave fibrinogen into weak fibrin monomers in the initiation phase of coagulation. Thrombin's ability to activate factors, especially on the activated platelet surface, is responsible for propagation of the coagulant response. Thrombin generates FXIa, which in turn activates FIX; the TF-VIIa complex (before it is shut down by TFPI) also generates FIXa. Thrombin-activated FVIIIa then combines with IXa to form the intrinsic Xase complex, generating large amounts of FXa and prothrombinase complex on the platelet surface to further amplify thrombin generation. The large amounts of thrombin now generate enough fibrin monomers to form stable polymers and fibrin clot. *HMWK*, High-molecular-weight kininogen; *PK*, prekallikrein; *TFPI*, tissue factor pathway inhibitor.

factor X, increasing the kinetic efficiency of the intrinsic Xase complex. The activated platelet (Table 51.2) also enhances coagulation by supplying the developing clot with an activated platelet surface membrane (i.e., anionic lipids, primarily phosphatidylserine) and abundant factor V, stored in platelet granules. Factor V is then promptly activated to Va by the trace amount of thrombin produced by TF-VIIa complex. In

combination with membrane phospholipids and calcium, activated Xa and its cofactor Va form the prothrombinase complex, which cleaves prothrombin to thrombin. The prothrombinase complex is several hundred thousand times more efficient at converting prothrombin to thrombin than free factor Xa acting on prothrombin alone. The role of the procoagulant effects of activated platelets on thrombosis is

highlighted by Scott syndrome, a condition in which the platelet phospholipid membrane does not change in response to activation, and thus phosphatidylserine is not rearranged from the inner membrane surface to the outer membrane surface, leading to decreased thrombin generation and prolonged bleeding as a result of platelet dysfunction.

TABLE 51.2 Procoagulant Properties of Platelets

Receptor-Ligand Interactions Promoting Adhesion

- ^aGPIb-IX-V-VWF
- ^bGPIIb/IIIa-fibrinogen and GPIIb/IIIa-VWF
- ^cGPIa/IIa-collagen
- ^dP-selectin–P-selectin glycoprotein ligand-1

Receptor-Ligand Interactions Mediating Activation

- GPV-thrombin
- GPVI-collagen

Secreted Alpha-Granule Proteins

- Ligands (fibrinogen, fibronectin, thrombospondin, vitronectin, von Willebrand factor)
- Enzymes (α_2 -antiplasmin; factors V, VIII, and XI)
- Antiheparin (platelet factor 4)

Secreted Dense-Granule Agonists

- Adenosine diphosphate, serotonin

Components and Functions of Platelets That Promote Coagulation

- Thromboxane A₂ formation, phosphatidylserine expression

GP, Glycoprotein.

^aGPIb-IX-V complex is also known as CD42.

^bGPIIb/IIIa (integrin $\alpha_{IIb}\beta_3$) complex is also known as CD41.

^cGPIIa is also known as CD29.

^dP-selectin is also known as CD62P and P-selectin glycoprotein ligand-1 as CD162.

Of note, polyphosphate has been shown to have a critical role in coagulation and acts as a procoagulant, initiating clotting through several mechanisms. First, polyphosphate contains numerous negatively anionic charged surfaces leading to activation of plasma factor XII, HMWK, and PPK that set off the intrinsic pathway. Polyphosphate also mitigates the inhibitory effects of TFPI, enhances the activation of factor V and factor IX, and leads to thickened fibrin fibrils by increasing fibrin polymerization.

Termination of Clotting

The rapid production of thrombin at a localized site of vascular injury could quickly lead to extensive clotting if left unchecked; thus, there are several mechanisms in place to ensure proper modulation. This includes endogenous inhibitors of the coagulation pathway (Fig. 51.3) that limit coagulation initiation, dilution of procoagulants at the site of injury by flowing blood, and removal and inactivation of activated factors.

Endogenous anticoagulants can either prevent thrombin generation or inactivate formed thrombin. Among endogenous anticoagulants that target thrombin generation, the earliest in the coagulation process is TFPI. TFPI acts by both inactivating factor Xa and the TF-VIIa complex. TFPI is constitutively released by ECs into the microvasculature. Nascent TFPI has direct activity only against Xa, but after exposure to Xa, TFPI acquires activity against the TF-VIIa complex. Notably, C1 esterase inhibitor also inhibits factors early in the coagulation cascade, including factor XIIa and PK, although a deficiency of C1 esterase inhibitor, which causes angioedema, does not result in a hypercoagulable state.

The most important natural anticoagulant is antithrombin (AT), which inactivates several activated factors in the clotting cascade including factors IIa (thrombin), IXa, Xa, XIa and XIIa. AT is physiologically present at more than twice the concentration of the highest local thrombin concentration that can be reached during clotting. AT activity against thrombin is potentiated 1000-fold by endogenous EC-associated heparin sulfate proteoglycans. This is also the mechanism of anticoagulation employed by the anticoagulant medications

Fig. 51.3 Endogenous anticoagulant pathways. Tissue factor pathway inhibitor (TFPI) shuts off tissue factor (TF) stimulation and blocks the TF-VIIa-X complex; in addition, the clotting cascade is further downregulated by the natural anticoagulants. This inhibition is partly generated by thrombin, which activates thrombomodulin. Circulating antithrombin inhibits thrombin activity and Xa generation of thrombin. The complex of thrombin and thrombomodulin activates protein C (PC) to become activated protein C (APC), which combines with protein S (PS) to cleave and inactivate VIIIa and Va, further blocking thrombin generation.

heparin, low-molecular-weight heparin, and fondaparinux. Platelet surface membranes and platelet factor 4 protect thrombin from inactivation at the clot. However, any thrombin that escapes into the circulation is immediately inhibited by AT, and free thrombin is neutralized instantaneously. Therefore, early thrombin generation is critically dependent on protection by the activated platelet membrane to allow sufficient time to make the transition from initiation to propagation phase. Notably, during the initiation phase, platelet-bound factor Xa is protected from inactivation by both TFPI and AT.

Activated protein C (APC) has anticoagulant, anti-inflammatory, and profibrinolytic properties that make it an important regulator of both thrombosis and inflammation. Like TFPI, protein C becomes activated only after coagulation is underway. Formed thrombin binds to thrombomodulin, a proteoglycan associated with endothelial and monocyte cell surfaces. Thrombomodulin-bound thrombin loses its procoagulant abilities such as activating platelets and fibrin clot formation and instead activates protein C. On the EC surface, nascent protein C binds to EC protein C receptor (EPCR), which positions it for activation by the adjacent thrombomodulin-bound thrombin. In a reaction that is enhanced by EPCR and protein S, APC inactivates factors VIIIa and Va (components of the Xase and prothrombinase complexes, respectively), thereby limiting procoagulant self-amplification. Notably, a common mutation in factor V known as factor V Leiden results in the arginine at position 506 being replaced by glutamine, rendering the mutated factor V resistant to cleavage by APC and resulting in a hypercoagulable state. As with other coagulation factors, the activated platelet membrane protects VIIIa and Va from APC inactivation. In addition to its effects on thrombin generation, APC neutralizes plasminogen activator inhibitor-1 (PAI-1, described further in the fibrinolysis section) to enhance clot remodeling. APC has anti-inflammatory properties as well; recombinant APC reduces production of tumor necrosis factor- α after endotoxin challenge, and protein C-deficient mice exhibit higher levels of proinflammatory cytokines.

Several other molecules have been identified as contributing to antithrombotic effects. As discussed previously, prostacyclin and nitric oxide, both released from ECs, exert antithrombotic properties through vasodilation and inhibition of platelet aggregation and adhesion. Poly(adenosine 5'-diphosphate [ADP]-ribose) polymerase (PARP) protein regulates TF mRNA levels. Activated macrophages and monocytes express TF on their surfaces, and modulating TF mRNA may prevent some degree of thrombosis in the setting of inflammation. Thrombospondin 5 (also known as cartilage oligomeric matrix

protein), an extracellular matrix protein, has been shown to inhibit thrombin and thrombin-dependent platelet aggregation in mouse models.

Fibrin Clot Architecture

The architecture of the fibrin clot is surprisingly variable. Although genetic factors unquestionably play a role in determining clot structure, two dominant factors are the local concentrations of thrombin and fibrinogen, whose reactions yield the fibrin strands. A thrombin-rich microenvironment typically results in thinner, more tightly cross-linked fibers, making the overall fibrin clot virtually impermeable to lytic enzymes. In thrombin-poor locations, the fibrin strands are thicker and the structure more porous, making the clot vulnerable to thrombolysis. Similarly, high fibrinogen concentrations are associated with larger thrombi whose tight, rigid meshwork makes them less deformable and more resistant to lysis. Low fibrinogen concentrations produce a less compact clot that is highly lysis prone. As mentioned previously, one of the major roles of polyphosphate on thrombosis is contributing to thicker fibrin fibrils.

Factor XIII plays a critical role in stabilization of the forming clot. Factor XIII circulates in the plasma and is also stored within platelets (see Fig. 51.1B). Notably, 50% of the total fibrin-stabilizing activity in blood resides in the platelet and is released by activation. Thrombin-activated factor XIIIa binds to fibrin and cross-links the fibrin units, thereby rendering them less permeable and more resistant to lysis. Furthermore, factor XIIIa cross-links the major plasmin inhibitor, α_2 -antiplasmin, directly to fibrin, positioning it for neutralization of any invading plasmin.

Fibrinolysis

The fibrinolytic system (Fig. 51.4) operates to restore patency and prevent fibrin from occluding healthy vessels. During clot formation, factor Xa and thrombin stimulate healthy ECs to release tissue-type plasminogen activator (t-PA) and urokinase-type plasminogen activator (u-PA), both of which activate plasminogen to plasmin. Plasmin then cleaves the fibrin strands of the platelet plug, producing fibrin degradation products, including D-dimer. Additionally, factor XIIIa is also cleaved by plasmin, further destabilizes the platelet plug by reducing fibrin cross-linking.

The vast excess of plasminogen in the plasma dictates that under normal circumstances, the concentrations of t-PA and u-PA comprise the rate-limiting step for plasmin formation. The kinetic efficiency of

Fig. 51.4 Balanced fibrinolysis limits the platelet-fibrin clot. The platelet plug and fibrin matrices are strengthened by incorporation of factor XIIIa into the fibrin clot. Factor XIIIa also binds α_2 -antiplasmin to the clot to protect it from plasmin-mediated fibrinolysis. At the same time, nearby intact endothelial cells (ECs) secrete tissue plasminogen activator (t-PA). t-PA that evades plasminogen activator inhibitor-1 (PAI-1) converts clot-bound plasminogen to plasmin and leads to fibrin clot degradation and release of soluble fibrin peptides and D-dimer. Therefore, detection of circulating D-dimer usually indicates active fibrinolysis.

t-PA is improved by at least an order of magnitude in the presence of fibrin. This helps to keep t-PA most active in the microenvironment of the clot. By contrast, u-PA appears to require binding to activated platelets for its ability to liberate plasmin.

Acting to contain fibrinolysis are plasma mediators that either inactivate formed plasmin (e.g., α_2 -antiplasmin and possibly α_2 -macroglobulin) or block plasmin formation (e.g., PAI-1). α_2 -Antiplasmin rapidly inactivates plasmin in plasma but is present in lower concentrations than plasminogen and thus can become depleted while plasmin continues to be formed. Additionally, the α_2 -antiplasmin protein cross-links to the fibrin clot providing resistance to cleavage by plasmin. PAI-1 is present in several-fold molar excess in the plasma and is also released by both ECs and activated platelets, thereby protecting clots from premature lysis. Plasma levels of PAI-1 are highly variable due to a circadian pattern of secretion; polymorphisms of the *PAI-1* gene leading to higher PAI-1 levels are associated with a higher risk for thromboembolic disease, whereas rare congenital deficiencies in PAI-1 protein are associated with increased bleeding tendencies.

Another mediator that limits fibrinolysis in the vicinity of the clot is thrombin activator fibrinolysis inhibitor (TAFI). TAFI is synthesized in an inactive form by the liver and circulates in the plasma, possibly in a complex with plasminogen. TAFI cleaves specific fibrin lysine residues that would otherwise promote binding of fibrinolytic enzymes (e.g., plasmin). TAFI requires either plasmin or thrombin for activation; however, thrombin activation of TAFI requires extraordinarily large amounts of free thrombin. By contrast, EC-associated thrombomodulin increases thrombin-induced TAFI activation 1250-fold, making this an essential cofactor and one that is predominantly available only at the interface between the blood and the vessel wall.

In addition to the EC surface, macrophages are also critical to fibrinolysis. Macrophages degrade the fibrin clot through lysosomal proteolysis by a plasmin-independent mechanism. The macrophage binds to fibrin and fibrinogen through its surface integrin receptor, CD11b/18; this binding is followed by internalization of the complex into the lysosome, where fibrin and fibrinogen are degraded.

Tissue repair and regeneration are the physiologic end points of clotting, and they eventually lead to dissolution of the fibrin-based clot. Besides t-PA and u-PA, the intrinsic pathway activators kallikrein, factor XIIa, and factor XIa also generate active plasmin from plasminogen. Plasminogen binding to cell surface receptors promotes its own activation to plasmin by placing it in proximity to t-PA and the fibrin clot and protects plasmin from inactivation by circulating α_2 -antiplasmin. Plasmin eventually dissolves the fibrin matrix to produce soluble fibrin peptides and D-dimer and also activates metalloproteinases that further degrade damaged tissue. Fibroblasts and leukocytes migrate into the wound, the latter mediated by selectin binding, and these inflammatory cells act in concert with growth factors secreted by leukocytes and activated platelets to enhance vascular repair and tissue regeneration.

Laboratory Testing of Coagulation

As described previously, for purposes of laboratory testing, the extrinsic pathway of the classical coagulation cascade is measured by the PT, while the intrinsic pathway is measured by the aPTT. The PT is assessed by measuring the interaction of circulating factor VIIa with exogenously added TF (also known as thromboplastin). The PT is

highly sensitive to deficiencies in factors II, V, VII, and X, all of which may be associated with bleeding, but is unaffected by deficiencies in intrinsic pathway factors (i.e., factors XII, XI, IX, or VIII).

Because factors II, VII, and X are also vitamin K–dependent factors, with factor VII having the shortest half-life, the PT is also the main lab test used for monitoring warfarin therapy. The degree of prolongation of the PT by warfarin depends on the strength of the particular thromboplastin agent and the specific coagulation instrument used for the assay. A blood test known as the international normalized ratio (INR), calculated by dividing the patient's PT by a mean control PT, takes these factors into account in order to standardize variations among laboratories in PT measurements and is the preferred test for warfarin monitoring.

The aPTT measurement is based on in vitro contact activation (e.g., plasma stimulation with a negatively charged compound such as kaolin). The aPTT is sensitive to deficiencies of factors in the contact (i.e., PK, HMWK, and factor XII), intrinsic (factors XI, IX, and X), and common (factors II, V, and X) pathways but not in the extrinsic pathway (factor VII). As detailed previously, deficiencies of factors VIII, IX, or XI comprise the basis of the congenital hemophilias A, B, and C, respectively, all of which are characterized by bleeding. By contrast, deficiencies of PK, HMWK, and factor XII, while all prolonging the aPTT, do not result in significant bleeding.

The aPTT is also highly sensitive to unfractionated heparin and is used to monitor heparin activity although the therapeutic index of the aPTT in patients on heparin is rather wide owing to natural fluctuations in aPTT measurements. Alternatively, heparin, low-molecular-weight heparin, and fondaparinux activity may be measured via an anti-Xa activity, which assesses the level of inhibition of factor Xa.

In surgical settings, trauma units, and intensive care units, there may be a need for immediate turnaround in coagulation testing. One specific point-of-care test used for real-time coagulation testing is thromboelastography (TEG), a global test of hemostasis. TEG uses whole blood to monitor all components of hemostasis, including the initiation and termination phases of the coagulation cascade, fibrinolysis, and platelet function. TEG has been demonstrated to improve outcomes in trauma by guiding transfusion therapy and may have roles in surgery and in assessing coagulation status in patients with advanced liver disease, although its utility outside of these indications is uncertain.

Disorders of Hemostasis: Bleeding

Aric Parnes

INTRODUCTION

The complex network maintaining a balance between bleeding and clotting functions in fine equilibrium. However, each component of this network can falter. This chapter describes the imbalances that result in bleeding. It covers platelet disorders, vascular abnormalities, and clotting factor deficiencies. In addition to reviewing the pathophysiology and clinical manifestations of these disorders, it covers a general approach to the evaluation of a bleeding patient and how to treat each disease. How the equilibrium shifts to favor coagulation is covered in a separate chapter.

HEMOSTASIS

Hemostasis, the ability to stop bleeding, can be simplified into two phases called primary and secondary hemostasis. However, the reality is more complex than this because primary and secondary hemostasis frequently interact and blend together. Primary hemostasis reflects an initial phase of platelet activation, adhesion, and aggregation with help from von Willebrand factor. Secondary hemostasis involves the coagulation factors activating in a cascade to augment and stabilize clotting. The clotting cascade is explained in more detail in [Chapter 51](#). To initiate bleeding, the integrity of the endothelium is disrupted most commonly by trauma or surgery but sometimes through a vascular defect. Regardless of the inciting event, collagen and other platelet activators are released from endothelial tissue triggering primary hemostasis, whereas the release of tissue factor activates the clotting cascade.

CLINICAL EVALUATION OF BLEEDING

The evaluation of bleeding requires a careful history and physical examination. The history includes the details of the current bleeding event as well as past bleeding events. Spontaneous bleeding without a traumatic event points to a severe defect in hemostasis. Lifelong recurring bleeding events and a family history of such suggest congenital disease whereas new bleeding despite previous “hemostatic stress tests” such as surgery or dental extraction without bleeding favor an acquired disorder or a medication effect. Disorders of primary hemostasis including causes of thrombocytopenia or platelet dysfunction or diseases of von Willebrand factor lead to mucocutaneous superficial bleeding, but disorders of secondary hemostasis with missing coagulation factors cause deeper bleeding, for example muscle hematomas, hemarthroses, and intracranial hemorrhages. Superficial bleeding can be easy bruising, gum bleeding when brushing teeth, frequent epistaxis, and heavy menstrual bleeding. When uncovering family history, distinguishing between X-linked genetic disease (e.g., hemophilia A and B) and autosomal disease, such as most von Willebrand disease cases, can be vital. The X-linked inheritance pattern for hemophilia A and B

means that more severe disease manifests in males than in females and subsequently may appear to skip generations.

Similar distinctions appear in the physical examination. Hemarthroses result in joint swelling, tenderness, and moderate warmth, and multiple joint hemorrhages cause arthritis and deformity. Without imaging or laboratory tests, hemarthrosis can be indistinguishable from septic arthritis or other causes of joint pain. Platelet disorders classically result in petechiae, small subcutaneous hemorrhages that typically appear on the legs, a result of gravity dependence. Sometimes vascular anomalies can be seen on physical examination. For example, small ectatic vessels, prone to bleeding, can be seen on oral mucosa in hereditary hemorrhagic telangiectasia.

Liver disease can cause bleeding through a decline in production of coagulation factors and a decline in platelet count, due to hypersplenism and decreased thrombopoietin production by the liver. Hallmark features of liver disease can be obvious on examination, such as jaundice and abdominal distension from ascites, but can be overlooked if not searched for. This includes spider angioma, gynecomastia, Dupuytren contracture, and asterixis.

Rare causes of aplastic anemia can be determined by physical examination. Fanconi anemia patients have short stature, café au lait spots, hypoplastic thenar eminences, and absent radii. Dyskeratosis congenita, a disease of short telomeres, leads to leukoplakia, nail dystrophy, and hyperpigmented macules.

Importantly, the timing of a thorough examination and subsequent laboratory testing must be tempered in order to control rapid bleeding and hemodynamic instability. Airway, breathing, and circulation, the A-B-C's, take precedence in emergency situations, and recognizing that bleeding can evolve quickly is critical. Life-threatening hemorrhage requires immediate treatment while simultaneously pursuing diagnostic testing. Life-threatening blood loss is not limited to trauma or gastrointestinal sites but also includes small bleeds near the airway or neck and hemorrhages around other vital organs. Heart rate and blood pressure are first steps in assessing volume of blood loss.

LABORATORY EVALUATION OF BLEEDING

The initial laboratory assessment of the bleeding patient ([Table 52.1](#)) should include complete blood cell counts (CBC), prothrombin time (PT), activated partial thromboplastin time (aPTT), and fibrinogen ([Fig. 52.1](#)). The CBC marks a critical first step in this evaluation because it includes the platelet count as well as hemoglobin and hematocrit, which are essential for monitoring the rate of blood loss (as are vital signs). The CBC also contains the mean corpuscular volume (MCV), measuring the size of the red blood cell. A low MCV can suggest a slower chronic blood loss resulting in iron deficiency. A peripheral blood smear should be examined to confirm thrombocytopenia. Pseudothrombocytopenia occurs when platelets clump from EDTA

TABLE 52.1 Screening Assays for Hemostasis

Laboratory Test	Aspect of Hemostasis Tested	Causes of Abnormalities
Blood counts (CBC) and peripheral blood smear	Platelet count and morphologic features	Thrombocytopenia, thrombocytosis, gray platelet and giant platelet syndromes
Prothrombin time (PT)	Factor VII–dependent pathways	Vitamin K deficiency and warfarin, liver disease, DIC, factor deficiency (VII, V, X, II), factor inhibitor
Partial thromboplastin time (aPTT)	Factor XI–, IX–, and VIII–dependent pathways	Heparin, DIC, lupus anticoagulant ^a , VWD, factor deficiency (XII ^a , XI, IX, VIII, V, X, II), factor inhibitor
Thrombin time	Fibrinogen	Heparin, hypofibrinogenemia, dysfibrinogenemia, DIC
Platelet aggregation and platelet function analysis	Platelet and VWF function	Aspirin, VWD, storage pool disease
Mixing study	Factor inhibitors or deficiencies	Abnormal clotting time corrects for a factor deficiency; does not correct for an inhibitor

DIC, Disseminated intravascular coagulation; VWD, von Willebrand disease; VWF, von Willebrand factor.

^aLupus anticoagulant and factor XII deficiency are not associated with bleeding.

antibodies and are then read as white blood cells instead of platelets by automated counters. Other helpful findings on a peripheral blood smear include schistocytes, suggesting microangiopathic hemolytic anemia. Teardrop cells with immature white and red blood cells characterize the myelophthisic blood smear, indicative of marrow replacement by solid tumor, lymphoma, granuloma, or fibrosis.

PT and aPTT are two commonly used broad measures of the coagulation cascade. PT assesses the extrinsic and common pathways, that is clotting factors, in order of activation: VII, X, V, II, and fibrinogen. aPTT covers the intrinsic and common pathways: Clotting factors XII, XI, IX, VIII, X, V, II, and fibrinogen. Both PT and aPTT become abnormal with deficiencies of the common pathway (X, V, II, and fibrinogen) or multiple clotting factor deficiencies involving both the intrinsic and extrinsic pathways. The International Normalized Ratio (INR) represents a standardized correlate of PT so that measurements of vitamin K–dependent anticoagulation can be compared despite interlaboratory variation. Abnormal PT and aPTT should be repeated to verify the elevation was not in error. Specific factor deficiencies may be suspected based on elevations in PT or aPTT and these factor activities can be tested to confirm the diagnosis and monitor effects of treatment.

Factor deficiencies can be congenital (e.g., hemophilia A) or acquired (e.g., acquired hemophilia, liver disease, disseminated intravascular coagulopathy [DIC]). A mixing study can distinguish a factor deficiency resulting from a decline in production from a decline due to inhibition from an autoantibody. Mixing studies combine patient plasma with control plasma so that missing factors are replaced and the abnormal clotting times correct (i.e., prolonged PT or PTT becomes normal). A positive mixing study does not correct because of the presence of an inhibitor, blocking the factor from the normal control plasma. Mixing studies can also be useful in finding a lupus anticoagulant, which is important for the diagnosis of antiphospholipid syndrome (see [Chapter 53](#)), but a lupus anticoagulant does not affect bleeding and should not be in the differential diagnosis of the bleeding patient.

Fibrinogen can be decreased through a decline in production or consumption, as in DIC. The assay is an easy, rapid, and cheap test to run and should be run early in the evaluation of the bleeding patient. Many fibrinogen assays incorporate function into the quantitative measurement, but since this information may not be readily available, thrombin time is able to measure the function of fibrinogen by adding thrombin to plasma and then measuring the conversion of fibrinogen to fibrin.

Similarly, platelet function may be helpful if a defect in primary hemostasis is suspected, but platelet count and von Willebrand factor testing are normal. Platelet dysfunction disorders can be induced by

many different medications, although they are often not clinically significant and rarely are congenital. Platelet function can be assessed by platelet aggregation studies or Platelet Function Analyzer-100 (PFA-100; [Fig. 52.2](#)), which both use platelet activators to trigger platelet activation and aggregation. Different platelet activators such as adenosine diphosphate (ADP), collagen, epinephrine, and ristocetin may detect subtle differences in platelet function. These tests, not surprisingly, fail to work when platelets are absent or low. Bleeding time, a test measuring the time it takes to stop bleeding after making a small incision in the forearm as a gauge of platelet function, should no longer be performed because numerous studies have shown poor sensitivity, specificity, and reproducibility with significant technician variability.

Testing for von Willebrand disease (VWD) is as complicated as the disease, which has multiple subtypes, each with different means of diagnosing. A typical von Willebrand factor (VWF) panel includes VWF activity (a functional test measured by ristocetin-mediated binding of VWF to platelets, VWF antigen (the quantitative level), and clotting factor VIII, which declines without the presence of its stabilizer, VWF. Other tests that may be required to determine the subtype of VWD include VWF multimer analysis, VWF-factor VIII binding assay, and a measure of platelet aggregation as induced by ristocetin (RIPA). As with any congenital disorder, gene sequencing may be the only way to confirm the diagnosis, but it adds time and expense and is frequently normal in mild cases of VWD.

Additional laboratory tests useful in evaluating bleeding include factor Xa activity for measurement of low-molecular-weight heparin effect, heparin neutralization (with heparinase, hexadimethrine bromide [Polybrene], or protamine), and euglobulin clot lysis time as a measure of fibrinolysis, the time to dissolve a fibrin clot. Currently, the new class of anticoagulants, direct oral anticoagulants (DOACs), do not have readily available methods for measurement of plasma concentrations or activity. Because vitamin C deficiency (scurvy) can cause bleeding, measuring ascorbic acid can be helpful when nutrient deficiency is suspected. Thromboelastography (TEG) and rotational thromboelastometry (ROTEM) use torque to measure clotting of whole blood. These methods have many proponents but remain investigational. A rapid approach to identifying possible causes of bleeding ([Fig. 52.3](#)) considers several major disease categories: (1) VWD, thrombocytopenia, or abnormal platelet function; (2) low levels of multiple coagulation factors resulting from vitamin K deficiency, liver disease, or DIC; (3) single-factor deficiency (usually inherited); and, more rarely, (4) an acquired inhibitor to a coagulation factor such as factor VIII. The laboratory evaluation is most efficient when it is performed in this context.

Fig. 52.1 Basic methodology underlying measurement of prothrombin (PT) and activated partial thromboplastin time (aPTT). (A) Typical laboratory instrument used to perform basic and complex coagulation assays. (B) Plasma specimens are incubated at 37° C and then mixed with tissue factor and phospholipid (PT) or a surface activator and phospholipid (aPTT). The time it takes for clot formation to block light passage through the specimen is measured and compared with a reference range. Prolongation of the PT or aPTT clotting time can be associated with many congenital or acquired coagulation factor defects. Abnormal PT or aPTT values are typically followed by more specific coagulation factor assays, depending on the type of prolongation and the suspected underlying clinical disease.

BLEEDING CAUSED BY VASCULAR DISORDERS

Vascular purpura (i.e., bruising) is defined as bleeding caused by intrinsic structural abnormalities of blood vessels or by inflammatory infiltration of blood vessels (i.e., vasculitis). Although vascular purpura usually causes bleeding in the setting of normal platelet counts and normal coagulation tests, vasculitis and vessel damage may be severe enough to cause secondary consumption of platelets and coagulation factors.

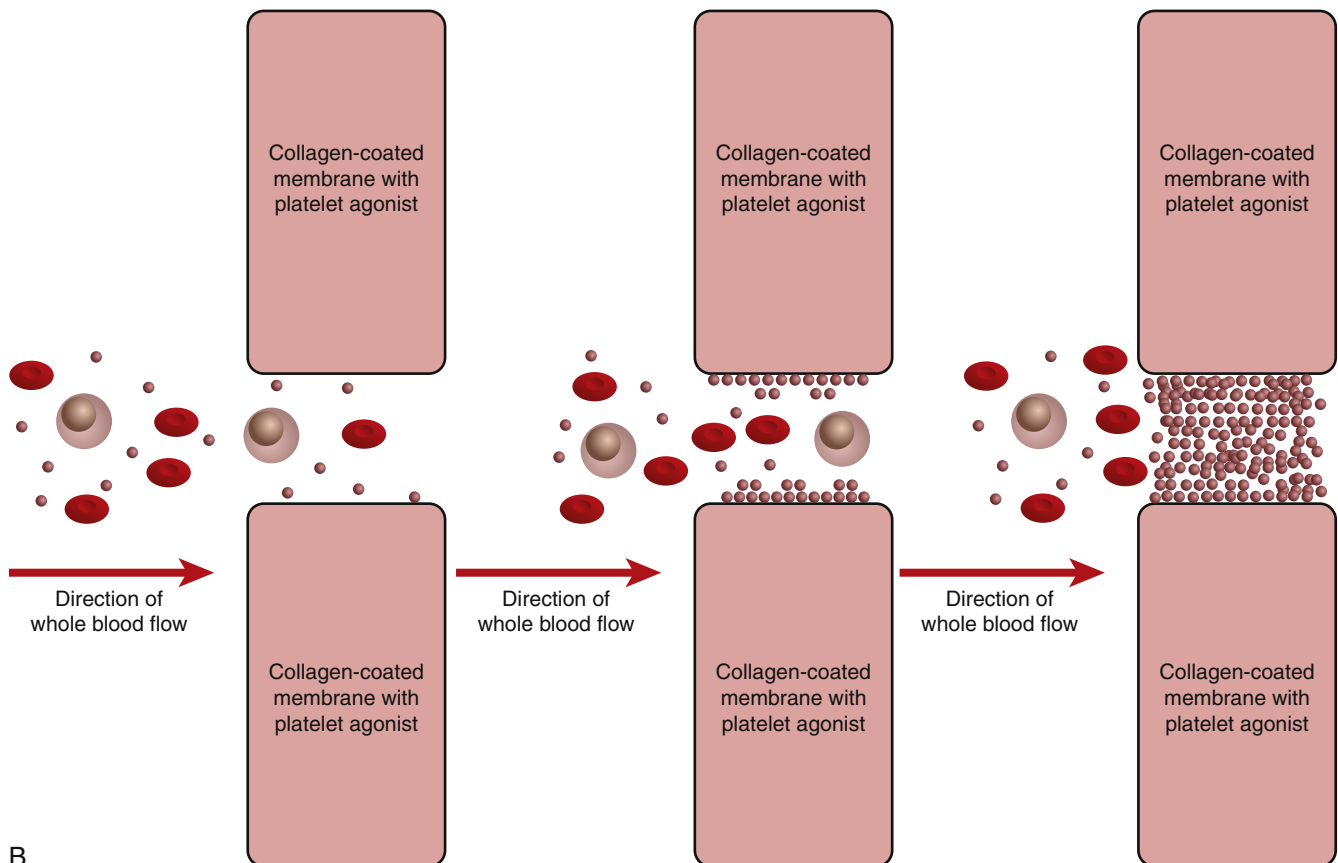

Collagen breakdown and thinning of the subcutaneous tissue that overlies blood vessels is often observed in older patients (i.e., senile purpura), and similar atrophic skin changes are a common effect of steroid therapy. Another acquired cause of vascular purpura is scurvy (i.e.,

deficiency of vitamin C [ascorbic acid]). Patients with scurvy have bleeding around individual hair fibers (i.e., perifollicular hemorrhage) and corkscrew-shaped hair. Bruising occurs in a classic saddle pattern over the upper thighs. The bleeding gums are caused by gingivitis and not by the subcutaneous tissue defect. Edentulous patients with scurvy do not have bleeding gums, and scurvy should not be excluded on this basis.

Congenital defects of the vessel wall can cause bruising. These rare syndromes include pseudoxanthoma elasticum, a defect of the elastic fibers of the vasculature associated with severe gastrointestinal (GI) and genitourinary bleeding, and Ehlers-Danlos syndrome, which is characterized by abnormal collagen in blood vessels and subcutaneous tissue. Both syndromes cause bruising in the skin, but only patients with pseudoxanthoma elasticum develop significant GI bleeding.

A

B

Fig. 52.2 Methodology underlying the Platelet Function Analyzer-100 (PFA-100). (A) Whole blood platelets are streamed toward a collagen-based aperture. The membrane is infused with a potent platelet agonist (i.e., adenosine diphosphate or epinephrine). (B) Streaming the platelets through the instrument channels induces shear-based activation, which in conjunction with the agonists should yield an initial wave of platelet adhesion and aggregation. Over time, activated platelets continue to aggregate, closing off the aperture to whole blood flow. The time it takes for aperture closing is measured in seconds and compared with a reference range. Abnormally prolonged closure times can be associated with von Willebrand disease due to the reliance on adhesion in this assay or with a platelet functional defect due to the reliance on aggregation for complete aperture closure.

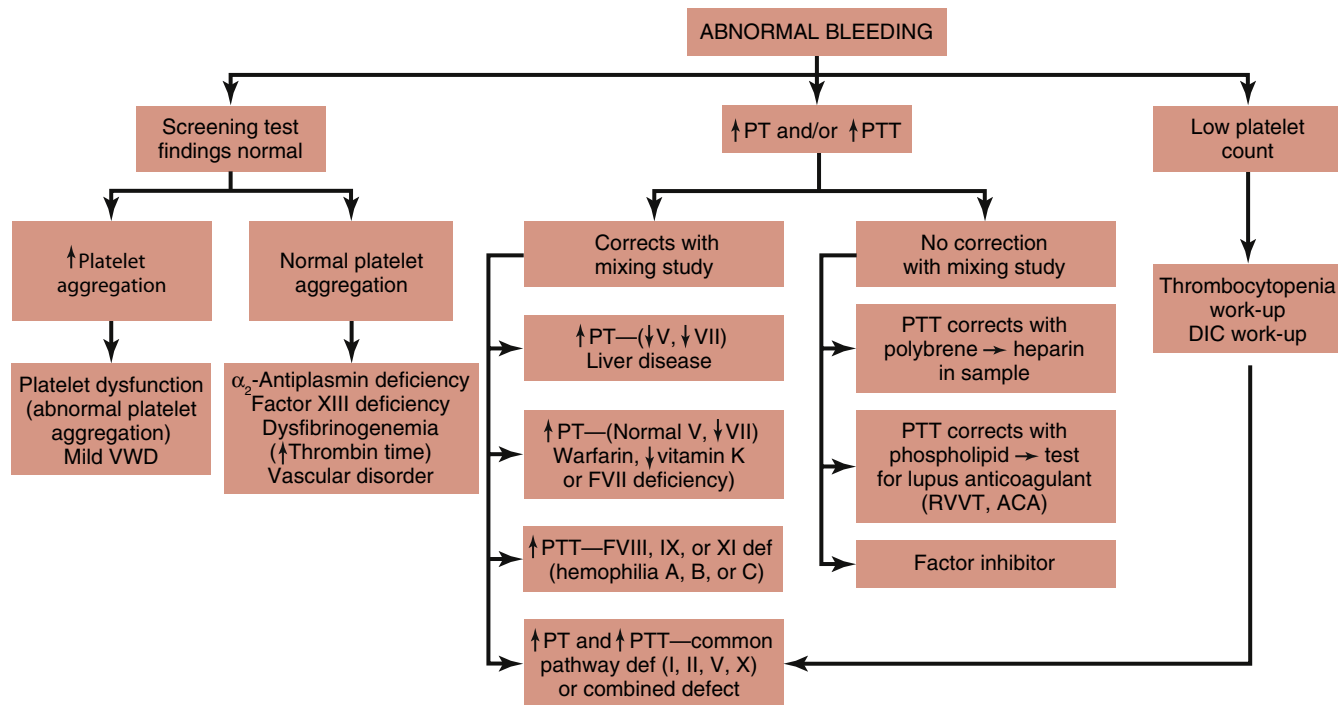

Fig. 52.3 Algorithm for the evaluation of bleeding. Screening laboratory tests for platelet and factor deficiencies are used to narrow the work-up for bleeding, followed by specific factor and other coagulation studies (e.g., mixing studies, D-dimer) to confirm the diagnosis. *ACA*, Anticardiolipin antibody; *DIC*, disseminated intravascular coagulation; *FVIII*, factor VIII; *PFA-100*, Platelet Function Analyzer-100; *PT*, prothrombin time; *PTT*, partial thromboplastin time; *RVVT*, Russell viper venom time; *VWD*, von Willebrand disease; *t*, increased; *↓*, decreased.

Another inherited vessel wall defect associated with GI bleeding is hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu syndrome). This disorder is characterized by degeneration of the blood vessel wall that results in angiomatous lesions resembling blood blisters on mucous membranes, including the lips and GI tract. The frequency of bleeding caused by breakdown of these lesions increases with age, and GI lesions commonly cause significant chronic bleeding, resulting in iron deficiency anemia.

The sudden onset of palpable purpura (i.e., localized, raised hemorrhages in the skin) associated with rash and fever may be caused by aseptic or septic vasculitis. Septic vasculitis can be caused by meningococemia and other bacterial infections and is often accompanied by thrombocytopenia and prolongation of clotting times. One cause of aseptic vasculitis in young children and adolescents is Henoch-Schönlein purpura, a vasculitis of the skin, GI tract, and kidneys that is usually accompanied by abdominal pain from bleeding into the bowel wall. This syndrome may occur after a viral prodrome and appears to be caused by an immunoglobulin A (IgA) hypersensitivity reaction, as evidenced by serum IgA immune complexes and renal histopathologic features resembling IgA nephropathy.

The therapy for bleeding from vascular disorders depends upon the diagnosis. Senile purpura and steroid-induced purpura do not usually require treatment. Scurvy is corrected by vitamin C supplementation. In congenital disorders, including Ehlers-Danlos syndrome, hereditary hemorrhagic telangiectasia, and pseudoxanthoma elasticum, patients should avoid medications (e.g., aspirin) that may aggravate their bleeding tendencies, and they should receive supportive therapy (e.g., iron supplementation, red blood cell transfusion). Systemic administration of estrogen to patients with hereditary hemorrhagic telangiectasia may

help to decrease epistaxis by inducing squamous metaplasia of the nasal mucosa, which protects lesions from trauma.

Treatment of septic vasculitis focuses on appropriate antibiotic therapy. In the case of aseptic vasculitis, steroids and immunosuppressive agents are most effective. When vasculitis is severe enough to cause consumption of platelets and coagulation factors (see section on disseminated intravascular coagulation), transfusions of platelets, cryoprecipitate, and fresh-frozen plasma (FFP) may be indicated.

BLEEDING CAUSED BY THROMBOCYTOPENIA

With thrombocytopenia, bleeding does not occur until platelets are less than 20,000/ μL unless platelet dysfunction accompanies the thrombocytopenia as it frequently does in myelodysplastic syndromes or when aspirin or nonsteroidal anti-inflammatory drugs have been used (Fig. 52.4). Platelets less than 100,000/ μL can be problematic after trauma or during surgery. Since most patients do not bleed from mild thrombocytopenia (50,000 to 150,000/ μL), treatment is often not required, but thrombocytopenia should be investigated to determine the cause, expected trajectory, and a plan for when treatment is needed. Broadly, thrombocytopenia results from a decline in platelet production, hypersplenism/sequestration, or destruction/consumption. However, determining which category to focus attention on can be challenging. Bone marrow biopsy can help because megakaryocyte hyperplasia implies increased production, a means of compensating for peripheral platelet destruction, whereas megakaryocyte hypoplasia suggests decreased platelet production. Still, bone marrow biopsy is often unnecessary in the evaluation. Hypersplenism is usually associated with an enlarged spleen, but splenic overactivity can be seen when the spleen is normal

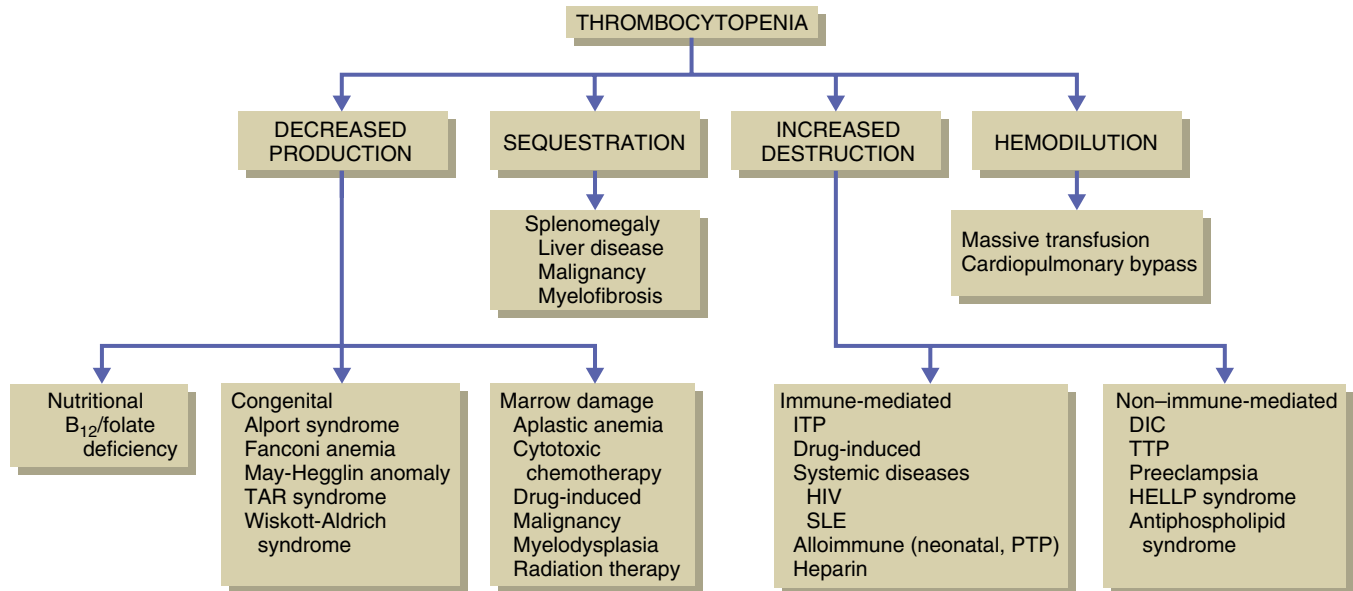

Fig. 52.4 Differential diagnosis of thrombocytopenia. Disorders resulting in a decreased circulating platelet number can be classified by four main pathophysiologic mechanisms: hypoproduction, sequestration, peripheral destruction, and hemodilution. The history, physical examination, and bone marrow evaluation usually narrow the range of possible causes. *DIC*, Disseminated intravascular coagulation; *HELLP*, hemolysis, elevated liver enzymes, and low-platelet count in association with pregnancy; *HIV*, human immunodeficiency virus; *ITP*, immune thrombocytopenic purpura; *PTP*, post-transfusion purpura; *SLE*, systemic lupus erythematosus; *TAR*, thrombocytopenia-absent radius syndrome; *TTP*, thrombotic thrombocytopenic purpura.

in size, as it is in immune thrombocytopenic purpura. Conversely, not all enlarged spleens are associated with hypersplenism (see Fig. 52.4).

Decreased Marrow Production of Platelets

Decreased production of platelets in the bone marrow is characterized by decreased or absent megakaryocytes on the bone marrow aspirate and biopsy. Suppression of normal megakaryopoiesis occurs after marrow damage and destruction of stem cells (such as occurs with cytotoxic chemotherapy); destruction of the normal marrow micro-environment and replacement of normal stem cells by invasive malignant disease, aplasia, infection (e.g., miliary tuberculosis), or myelofibrosis; specific but rare intrinsic defects of the megakaryocytic stem cells; and metabolic abnormalities affecting megakaryocyte maturation.

Drug-Associated Thrombocytopenia

Many drugs cause immune-mediated thrombocytopenia. However, some can have a direct cytotoxic effect on stem cells and megakaryocytes, causing a decline in platelet production. The classic example of this is cytotoxic chemotherapy used to treat malignancies. These medications are used to stop malignant cells from dividing, but they have the same effect on nonmalignant proliferating cells such as in the bone marrow. This myelosuppression frequently results in thrombocytopenia as well as neutropenia and anemia. Other drugs including thiazide diuretics and alcohol can have similar effects. Diagnostic confirmation comes from recovery of platelets after withdrawal of the medication. Recovery usually occurs within 7 days but can take several weeks. After repeated injury, stem cells may not recover, resulting in chronic thrombocytopenia.

Nutrition-Associated Thrombocytopenia

Deficiencies in copper, folate, and vitamin B₁₂ can cause thrombocytopenia. However, they typically will cause other cytopenias prior to

affecting platelet production. Megaloblastic anemia refers to the effects of impaired DNA synthesis on bone marrow causing dyssynchrony between slowed maturation of the nucleus and continued maturation of cytoplasm with unimpaired protein synthesis. This process results in large erythroid precursors called megaloblasts and mature large red blood cells (macrocytes). Certain medications can have this effect: azathioprine, 5-fluorouracil, methotrexate, and others. Folate and vitamin B₁₂ deficiencies are classic causes of megaloblastic anemia and when severe can cause pancytopenia. These deficiencies are most commonly caused by poor absorption either from autoimmune interference of intrinsic factor (pernicious anemia), other causes of atrophic gastritis, celiac disease, or previous gastrointestinal surgery. Less commonly, folate and vitamin B₁₂ deficiency arise from a poor diet (e.g., strict vegans and alcoholics), an inherited defect in transcobalamin, or competition for vitamin B₁₂ absorption from *Diphyllobothrium latum* parasitic infection.

Copper deficiency causes leukopenia and anemia before affecting platelet production. It occurs in two settings, first through malabsorption from celiac disease and past bowel surgeries, and second, through copper transport blockage from zinc excess. Zinc levels should be tested when copper is found to be low. Zinc excess occurs from zinc-containing denture cream and improper use of zinc supplements.

Bone Marrow Invasion

When the bone marrow is replaced by non-marrow elements, space for hematopoiesis becomes limited. In addition, the micro-environment necessary to supply proper nutrients, growth factors, and neuroendocrine stimulation is damaged. The prototypic disease of marrow invasion is myelofibrosis, either primary (a chronic myeloproliferative disease) or secondary, from other myeloproliferative

disease (polycythemia vera, essential thrombocythemia), hematologic malignancy, autoimmune disease, or infection. Rarely, myelofibrosis is associated with systemic mastocytosis and osteogenesis imperfecta. In myelofibrosis, the marrow is replaced by fibrotic strands causing immature erythroid (nucleated red blood cells) and myeloid cells (“left-shift”) to enter the peripheral blood stream. In addition, red blood cells become deformed (teardrop cells) as they squeeze between narrow spaces. This combination of teardrop cells and immature blood cells is called the myelophthistic blood smear. It can be seen when bone marrow is replaced by fibrotic tissue, malignant cells, or granuloma from sarcoidosis or tuberculosis. Confirmation of marrow invasion requires a bone marrow biopsy.

Myelodysplastic Syndrome

Myelodysplastic syndrome (MDS) (see also [Chapter 47](#)) is a clonal stem cell disorder resulting in ineffective hematopoiesis and cytopenias, either unilineage or multilineage. The diagnosis requires a bone marrow biopsy. Dysplasia (abnormal appearing cells) in the bone marrow and cytopenias fulfill the criteria for diagnosis. Subtypes depend on the number of blasts present in the bone marrow (must be <20%), the number of involved lineages, and the presence or absence of ringed sideroblasts, a nucleated erythroid cell with iron-laden mitochondria surrounding the nucleus (requires iron stain to see). The cytopenias tend to progress slowly, over months to years. MDS causes infection through neutropenia, symptoms of anemia, and easy bleeding/bruising from thrombocytopenia. It is also a precursor to acute myelogenous leukemia (AML).

Prior to the advent of next-generation sequencing (NGS), proving clonality in MDS was challenging because about one third of cases have normal cytogenetics. Now, NGS has become a routine part of the diagnostic evaluation and provides prognostic information as well as occasionally targetable mutations for treatment. *RUNX1* is a transcription factor that leads to upregulation of the thrombopoietin receptor. When *RUNX1* has a pathologic mutation as part of MDS or leukemia, patients become thrombocytopenic.

Recent studies have found MDS-associated mutations in people with normal blood counts. These mutations, for example *DNMT3A*, *TET2*, and *ASXL1* among others, confer an increased risk for MDS/AML (and cardiac disease). The state of having MDS-associated mutations but normal blood counts is called clonal hematopoiesis of indeterminate potential (CHIP). Gene sequencing data are rapidly being incorporated into the pathogenesis, diagnosis, and treatment of MDS and other hematologic malignancies.

Other Hematologic Malignancies

Any hematologic malignancy can cause thrombocytopenia through marrow invasion, particularly common in acute leukemias and aggressive lymphomas. Chronic lymphocytic leukemia (CLL) progresses slowly, eventually causing thrombocytopenia from marrow invasion (defined as Rai stage IV). Additionally, CLL at any stage can cause thrombocytopenia through immune-mediated platelet destruction.

Aplastic Anemia

Aplastic anemia can cause severe pancytopenia and occurs when the bone marrow hematopoietic elements are replaced by adipose cells. The diagnosis requires a bone marrow biopsy to show decreased cellularity (hypoplasia). Once the diagnosis is established, the cause for marrow failure must be explored. Aplastic anemia can be caused by congenital or acquired diseases. Congenital causes include Fanconi anemia (mutations in the *FANCA* gene leading to chromosomal instability), dyskeratosis congenital (mutations in the telomerase complex leading to short telomeres), Shwachman-Diamond syndrome

(mutation on the *SBDS* gene leading to ribosomal dysfunction), and amegakaryocytic thrombocytopenia (mutations in the thrombopoietin or thrombopoietin receptor *c-mpl* genes).

Acquired causes of aplastic anemia include medication effects such as chloramphenicol, sulfa, antithyroid medications, gold, allopurinol, and chemotherapy; infections such as hepatitis, HIV, and Epstein-Barr virus (EBV); and paroxysmal nocturnal hemoglobinuria (PNH). PNH is due to an acquired mutation in the gene *PIG-A*, which provides a protective coating around red blood cells (*CD55* and *CD59*). *CD55* and *CD59* prevent complement from binding and hemolyzing red blood cells. When they are absent as in PNH, patients develop chronic hemolysis, causing the dark urine that accumulates overnight, thus the name nocturnal hemoglobinuria. PNH patients frequently develop aplastic anemia (see [Chapter 46](#)).

Aplastic anemia is treated with supportive transfusions of red blood cells and platelets as needed, immunosuppression (anti thymocyte globulin and cyclosporine), platelet growth factors (eltrombopag), and sometimes stem cell transplant. Interestingly, the platelet growth factor eltrombopag increases white blood cells and red blood cells as well as platelets, because thrombopoietin receptors are also on stem cells.

Other congenital diseases causing thrombocytopenia will be discussed in the later sections on platelet dysfunction.

Platelet Sequestration

Up to 30% of circulating platelets are normally sequestered within the spleen at any time. Thrombocytopenia due to sequestration is common when the spleen is enlarged as in advanced liver disease. Platelets continue to decline the larger the spleen becomes. Rarely are platelets less than 50,000/ μ L. Besides chronic liver disease, splenic lymphomas, chronic myelogenous leukemia and other myeloproliferative diseases, hemoglobinopathies, and Gaucher’s disease, an inherited glycolipid storage disease, can cause splenomegaly with cytopenias.

The diagnosis of platelet sequestration may be suspected by physical examination findings or imaging studies demonstrating splenomegaly. Bone marrow studies typically reveal normal megakaryocyte numbers and morphology. Given the lack of specific tests for platelet sequestration, the diagnosis often is one of exclusion of other causes of thrombocytopenia.

Treatment of thrombocytopenia due to splenomegaly frequently depends on the underlying cause of increased spleen size. Splenectomy immediately resolves the thrombocytopenia when the thrombocytopenia is caused by hypersplenism. However, this must be weighed against the potential complications of surgery, an increased risk of thrombosis, and a lifelong increased risk of infection.

Platelet Destruction

Platelets can be removed from circulation by various means. One common process is through an immune mechanism, where antibodies target platelets, either from autoimmune disease (e.g., immune thrombocytopenic purpura [ITP]) or a drug effect. Another manner of platelet destruction is by consumption, for instance the rapid dissipation of platelets in DIC or hemophagocytic lymphohistiocytosis (HLH).

Immune-Mediated Platelet Destruction

Immune platelet destruction typically refers to antibody-mediated clearance. Platelet destruction can be further divided into autoimmune forms (i.e., antibody against self-antigens) and alloimmune forms (i.e., antibody against nonself-antigens). Autoimmune thrombocytopenia is the most commonly encountered form of immune-mediated platelet destruction. It may be a primary disorder directed only at platelets or a secondary complication of another autoimmune disease, such as systemic lupus erythematosus (SLE). Alloimmune-mediated platelet

destruction is rare and encountered in neonates as a result of maternal antibodies formed against fetal platelet antigens or in chronically transfused individuals, who form alloantibodies against foreign platelet antigens.

In autoimmune and alloimmune thrombocytopenia, immune platelet destruction is caused by increased levels of polyclonal antiplatelet antibodies directed against platelet membrane glycoprotein receptors, most often cryptic neopeptides of glycoprotein IIb/IIIa (GPIIb/IIIa) and less commonly glycoprotein Ib (GPIb) or human leukocyte antigens (HLAs). Coating of the platelet with these antibodies leads to opsonization of platelets by Fc receptors on macrophages in the reticuloendothelial system (RES). Antibody-coated platelets are cleared by the spleen and, to a lesser extent, by the liver.

These disorders involve a dramatic increase in marrow platelet production reflected by increased numbers of marrow megakaryocytes. The younger platelets produced have relatively high granule contents, providing increased hemostatic function. Bone marrow examination for increased or normal megakaryocyte numbers can help distinguish platelet destruction from decreased production.

Thrombocytopenia resulting from immune clearance may be severe, and platelet survival is often reduced from the normal 7 to 10 days to less than 1 day. Despite severe thrombocytopenia, serious bleeding or hemorrhagic death is uncommon, partly because the function of young platelets is increased and partly because the number of circulating platelets required to maintain vascular integrity is relatively low, estimated at 7100/ μL per day.

Immune thrombocytopenic purpura. Autoimmune destruction of platelets is referred to as ITP. This can be primary or secondary to other autoimmune diseases (e.g., SLE), hematologic malignancy (especially CLL), or infections, mostly viral. ITP in children is self-limiting in more than 80% of cases and they often recover without treatment. In adults, however, it frequently remains a chronic relapsing and remitting disease. Presentations in children and adults are the same with petechiae on examination and mucocutaneous bleeding. Platelet count is varied but can be extremely low, frequently less than 10,000/ μL and occasionally below the limit of detection. Blood blisters in the mouth (wet purpura) may carry a higher risk for life-threatening hemorrhage such as in the central nervous system and warrant rapid intervention. Hemorrhagic deaths are rare in children (<2%), but mortality is higher if the ITP is chronic. Fatal hemorrhage in adults is approximately 5%.

A characteristic feature of ITP is that the other cell lines are intact, so that only the platelets are affected. There are two caveats to this rule. First, bleeding patients can become anemic, and second, ITP can overlap with warm autoimmune hemolytic anemia (AIHA). When ITP occurs in conjunction with AIHA, the disease is called Evans syndrome and tends to be more resistant to treatment. The confirmatory test for the warm autoimmune hemolytic component is a direct antiglobulin Coombs test, which adds anti-IgG and anti-C3 sera to the patient's serum. The added antibodies bind to the autoantibodies, which are bound to the red blood cells, causing the red blood cells to agglutinate. The agglutination, the mark of a positive test, can be visualized in a test tube.

Besides the Coombs test for Evans syndrome, there is no confirmatory test for ITP, making it a diagnosis of exclusion. Antiplatelet antibody testing has poor sensitivity and specificity and should not factor into treatment decision making, so its diagnostic role is doubtful. Similarly, mean platelet volume (MPV) tends to be increased in ITP because younger platelets are larger, but MPV lacks sensitivity and specificity and cannot be relied upon. Revealing increased megakaryocytes as the bone marrow tries to compensate for the peripheral platelet destruction, bone marrow biopsy can be helpful, particularly

in unclear cases, but is not usually necessary. More often, confirmation of the diagnosis of ITP stands in its response to treatment.

ITP can be associated with HIV and hepatitis. It can also be the presenting manifestation of SLE. Patients should be screened for these diseases and treated if any are present because treating the underlying disease will also help control the ITP.

Therapy for ITP starts with corticosteroids, although treatment is not necessary if platelets are stable above 20 to 50,000/ μL . A recent randomized control trial found faster time to response and more complete responses when using pulse dexamethasone 40 mg daily for 4 days repeated in monthly cycles compared to a prolonged taper of prednisone. An added benefit was decreasing the total long-term exposure to steroids, which comes with many complications including weight gain, infection, and osteoporosis. Response rates were high, but so were relapses. In patients who relapse, repeating cycles of dexamethasone may help, but additional therapeutic options are often necessary. Intravenous immunoglobulins (IVIG) 1 g/kg daily for 1 to 2 days or 400 mg/kg daily for 5 days are two common regimens used as first-line therapy with or without corticosteroids. Its response rates are similar to corticosteroids and it works by mopping up the autoantibody as well as blocking the Fc receptors on splenic macrophages. The order of second-line therapy for ITP is unclear and controversial. Splenectomy, with response rates of approximately 50%, offers a potential cure, but patients frequently opt for noninvasive approaches. Relapses after splenectomy warrant a search for an accessory spleen missed during surgery.

Rituximab is a chimeric monoclonal antibody that targets CD20, a B-cell antigen, thus working by decreasing the autoantibody production. It is given by intravenous infusion, weekly for 4 weeks. Response rates are around 60% but can take weeks to work and relapses often occur after 1 year. Hypersensitivity infusion reactions are common with rituximab. Infection, though rare, is also a concern. Thrombomimetics are a newer class with high efficacy. They work as thrombopoietin agonists and come as a subcutaneous injectable called romiplostim, given in weekly doses, or an oral agent called eltrombopag, mentioned previously as a treatment for aplastic anemia. The newest therapeutic option in ITP is fostamatinib, a small molecule Syk inhibitor, preventing macrophage binding to opsonized platelets, thus decreasing platelet consumption without affecting autoantibody production, similar to one of the mechanisms of IVIG. All of these newer targeted therapies are expensive, so patients need to be intolerant to or have failed steroids before using them.

There are many other treatment options that have been used with moderate success. Anti-Rh(D) immunoglobulin can be used to saturate Fc receptors on splenic macrophages, preventing these cells from consuming platelets. There is probably competitive inhibition and blockade of the mononuclear phagocytic system/RES by sensitized red blood cells in the spleen. However, this only works if patients are blood type Rh(D)+, still have their spleen, and do not have concomitant hemolytic anemia. Danazol, azathioprine, mycophenolate, cyclosporine, and cyclophosphamide can regulate autoimmunity. Platelet transfusions are necessary in bleeding patients even though the transfused platelets will be destroyed along with the endogenous platelets. Platelet transfusions should be continued until bleeding stops.

Drug-induced platelet destruction. Immune-mediated platelet destruction associated with specific drugs is an often overlooked cause of thrombocytopenia. Unlike some of the drugs mentioned earlier (e.g., chemotherapeutic agents) that act by directly suppressing megakaryocyte production, drugs in this category of thrombocytopenia induce an immune response against platelet antigens.

Drugs may induce an autoimmune response by several mechanisms. One is the development of an antibody response against soluble

drug molecules. When soluble drugs bind to the platelet membrane, drug-induced antibodies act to destroy circulating platelets through the RES. Other mechanisms of drug-induced thrombocytopenia include formation of an immunogenic neoantigen through drug-platelet interactions (hapten response) with autoantibodies against drugs cross-reacting with platelet antigens. Occasionally, immune complexes that include the drug and circulating platelets are formed.

Historically, quinidine or quinine-based formulations were among the first class of drugs to be associated with platelet antibodies. The antibodies can be detected by tests using a drug coupled to a carrier protein. As awareness of drug-induced thrombocytopenia has grown, scores of drugs, including antibiotics, anticonvulsants, psychotropic drugs, and antiplatelet agents, have been reported to mediate platelet destruction (Table 52.2).

Heparin also induces thrombocytopenia, but unlike other drugs, this reaction paradoxically leads to a prothrombotic state referred to as heparin-induced thrombocytopenia (HIT) syndrome. The mechanism of heparin-induced thrombocytopenia and its prothrombotic effects are discussed in greater detail in Chapter 53.

When eliciting the medical history from patients with acute-onset thrombocytopenia, a careful review of all medications, particularly those initiated just before the development of low platelet counts, may help to deduce the cause and reverse the platelet count decline. Regardless of the mechanism of induction, development of thrombocytopenia is temporally related to exposure to the drug and is usually rapid. Discontinuation of the offending drug results in an increase in platelet count over days to weeks. For some patients with prolonged thrombocytopenia after drug removal, immunosuppression with steroids or IVIG (2 g/kg in two to three divided doses) may restore baseline platelet counts.

Although confirmation of drug-induced thrombocytopenia can often be made by testing for antibodies with drug specificities, these tests are not routinely available, are performed only by specialty reference laboratories, and take weeks to complete, by which time the offending drug has already been identified by stopping it and recovering the platelet count. When drug-induced thrombocytopenia is suspected, clinicians should not wait for results of drug-specific antibody tests before discontinuing potential offending agents.

Platelet alloimmunization. Patients who receive multiple platelet transfusions such as those with MDS may develop alloantibodies to platelets rendering future platelet transfusions less beneficial. Some do not respond to platelet transfusion at all. Alloimmunization can be assessed by measuring serial platelet counts after receiving a platelet transfusion to confirm the expected rise. Panel reactive antibody testing can also help. This test provides a percentage of HLA antigens that react with the patient's antibodies, giving the likelihood that the patient will consume a random platelet transfusion. In order to overcome this platelet destruction for those who are alloimmunized, HLA-matched platelets can be transfused, but this can take the blood bank days to find the right matched units (see "Platelet Transfusion Failure and Platelet Refractoriness" section).

Fetal and neonatal alloimmune thrombocytopenia. Fetal and neonatal alloimmune thrombocytopenia (FNAIT) occurs when a mother is homozygous for an uncommon platelet alloantigen, most often human platelet antigen 1b (HPA-1b) on the platelet GPIIIa receptor, and a fetus expresses the HPA-1a haplotype inherited from the father. The pathogenesis of alloimmune thrombocytopenia is analogous to the mechanism by which Rh(D) sensitization induces hemolytic disease of the newborn. The mother is exposed to the HPA-1a antigen during a first pregnancy, and during that or subsequent pregnancies, she produces high-titer IgG antibody against HPA-1a.

TABLE 52.2 Commonly Used Drugs Associated With Immune Thrombocytopenia

Drug Class	Examples
Antibiotics	Penicillins Cephalosporins (cephalothin, ceftazidime) Vancomycin Sulfonamides (sulfisoxazole) Rifampin Linezolid Quinine
Antiepileptics, antipsychotics, and sedative-hypnotics	Benzodiazepines (diazepam) Haloperidol Carbamazepine Lithium Phenytoin
Antihypertensives	Diuretics (chlorothiazide) Angiotensin-converting enzyme inhibitors (ramipril) Methyldopa
Analgesics and anti-inflammatories	Acetaminophen Ibuprofen Naproxen
Antiplatelet agents	Abciximab Tirofiban
Anticoagulants	Heparin Low-molecular-weight heparin

These antibodies cross the placenta, react with HPA-1a–positive fetal platelets, and cause peripheral platelet destruction through the RES.

A diagnosis of FNAIT is frequently suspected when in utero fetal bleeding is observed by imaging studies or when an otherwise healthy newborn has unexpected bleeding or bruising associated with thrombocytopenia (typically with platelet counts of 50,000 to 75,000/ μ L or lower). A maternal history of FNAIT is a strong predictor of its occurrence during future pregnancies.

After a diagnosis of FNAIT is suspected, it may be confirmed by examining maternal sera for anti-HPA alloantibodies and through platelet typing of the mother and father. Although bleeding may be severe in cases of FNAIT, the antibody does not necessarily predict whether bleeding will occur in utero, at delivery, or in the first days of life, and it is used primarily for confirmatory purposes.

Transfusion of washed maternal platelets (washed to remove the mother's anti-HPA-1a antibodies) or random platelets lacking the HPA-1a antigen and IVIG are useful for treating bleeding and restoring the platelet count. For newborns who recover from bleeding, there are few long-lasting deficits from FNAIT after circulating maternal antibodies are cleared from the circulation. For future pregnancies, IVIG with or without corticosteroids is given weekly throughout the second and third trimesters to prevent FNAIT.

Post-transfusion purpura. Alloimmune thrombocytopenia can occur in adults after transfusion, known as post-transfusion purpura (PTP). As in neonates, this condition is based on exposure to a common platelet alloantigen that is not present on the patient's native platelets. For instance, PTP can occur after transfusion of a blood product in an individual who lacks HPA-1a and who has been previously alloimmunized to this antigen during a prior pregnancy or transfusion. Because more than 95% of blood donors express HPA-1a and the antigen is shed by platelets, any blood product

concurrent fibrinolysis, leading to a thrombotic microangiopathic vasculopathy and subsequent organ damage. Thrombin activation of platelets and circulating factors eventually overwhelms the bone marrow and liver synthetic capability, respectively, resulting in thrombocytopenia and prolongation of the PT and aPTT.

Although the primary lesion of DIC is thrombin and clot generation, the clinical end point is usually a consumptive coagulopathy with depletion of platelets and coagulation factors. Mucosal bleeding, especially in the GI tract and oozing from intravenous puncture sites are signs of DIC.

Fibrinogen levels decrease in DIC but may be normal in earlier compensated stages and from the acute phase reaction to the underlying disorder, which increases fibrinogen production and secretion. DIC should not be ruled out because fibrinogen is in the normal range. Fibrinolysis in DIC is triggered by fibrin clot formation and the action of tissue-type plasminogen activator. Laboratory testing shows increased levels of fibrin split products (i.e. cleavage of fibrin monomers) and D-dimer (i.e., cleavage of fibrin-fibrin bonds), although these findings are nonspecific. The peripheral blood smear often contains schistocytes. Schistocytes are seen in other microangiopathic hemolytic anemias such as thrombotic thrombocytopenic purpura and hemolytic uremic syndrome (TTP/HUS), but these lead to excessive clotting, not bleeding (see Chapter 53).

Chronic DIC may be triggered by consumption of platelets and factors in large blood clots associated with aneurysms, hemangiomas, and mural thrombi. Another cause of chronic DIC is malignant disease, often adenocarcinoma or acute promyelocytic leukemia. Malignant cells in these disorders promote thrombin formation through secretion of tissue factor, cysteine proteases that activate factor X, induction of platelet-ligand binding, and upregulation of endothelial cell plasminogen activator inhibitor-1 (PAI-1) or cyclooxygenase 2 (COX2). Chronic DIC associated with malignancy usually causes enough factor consumption that the PT and aPTT are prolonged. Clinically, patients exhibit migratory thrombophlebitis (i.e., Trousseau syndrome) or nonbacterial thrombotic (marantic) endocarditis.

Therapy for DIC should be aimed at (1) treatment of the underlying disorder, such as antibiotics for sepsis or chemotherapy for malignant disease; (2) supportive hemostatic therapy, including platelets, cryoprecipitate (for fibrinogen), and FFP (for clotting factors); and (3) disruption of the activation of coagulation factors and platelets. For the last approach, anticoagulation is usually not indicated unless the balance of procoagulant and anticoagulant activity actively favors clotting, such as arterial thromboemboli with mural thrombus or migratory thrombophlebitis. These thrombotic complications of chronic DIC are often resistant to warfarin therapy and usually require more intensive anti-Xa therapy with unfractionated or low-molecular-weight heparin.

can contain HPA-1a. Although not clearly understood, some investigators have speculated that soluble HPA antigens are deposited onto endogenous platelets, resulting in their rapid clearance by anti-HPA alloantibodies.

The diagnosis of PTP can be confirmed by demonstrating anti-HPA antibodies in the serum of an affected individual. Patients are typically treated with IVIG, and additional transfusions must be derived from donors lacking the implicated HPA. Although HPA-1a is the most common cause of alloimmune thrombocytopenia, other platelet alloantigens can cause this clinical syndrome (Table 52.3).

Non-Immune-Mediated Platelet Destruction

Disseminated intravascular coagulation. One of the most common and potentially life-threatening causes of nonimmune platelet destruction is DIC, which is associated with sepsis, malignancy, advanced liver disease, and other disorders that trigger endotoxin release or cause severe tissue damage (Table 52.4). In DIC caused by bacterial sepsis, circulating endotoxin induces expression of tissue factor on circulating monocytes and endothelial cells, a process leading to overwhelming thrombin and fibrin generation. Deposition of fibrin occurs throughout the vasculature, with relatively inadequate

ADP, Adenosine diphosphate; NL, normal; NSAIDs, nonsteroidal anti-inflammatory drugs; PW, primary wave aggregation only; ↓, decreased.

^aAspirin results in decreased aggregation with most collagen doses.

^bIn von Willebrand disease type 2B, patients have increased aggregation with low-dose ristocetin and decreased or normal aggregation with standard doses of ristocetin.

Thrombocytopenia with pregnancy-induced hypertension.

Mild thrombocytopenia in pregnant women called gestational thrombocytopenia represents an effect of hemodilution as plasma volume increases through pregnancy, a normal physiologic response that can bring platelet counts into the range of 100,000 to 150,000/ μ L; these counts are not associated with maternal or fetal bleeding. However, pregnancy-induced hypertension can result in platelet counts of less than 100,000/ μ L, and these conditions can be associated with complications.

The spectrum of pregnancy-induced hypertension includes hypertension progressing to proteinuria and renal dysfunction (i.e., preeclampsia) and then to cerebral edema and seizures (i.e., eclampsia). Thrombocytopenia may appear as a late finding accompanying pregnancy-induced hypertension, often occurring at the time of delivery or late in the third trimester. HELLP syndrome in pregnancy (characterized by hemolysis, elevated liver enzymes, and low platelet counts) is occasionally associated with hypertension. The thrombocytopenia associated with pregnancy-induced hypertension or HELLP may result from abnormal vascular prostaglandin metabolism or placental dysfunction that leads to platelet consumption, vasculopathy, and microvascular occlusions. Both disorders are usually reversed by delivery of the fetus and placenta. Occasionally, IVIG or plasmapheresis is required when the disorder does not resolve after delivery.

Hemophagocytic lymphohistiocytosis. HLH is a deadly disease of T-cell and NK-cell dysregulation causing macrophage activation and extreme cytokine inflammatory responses. Histiocytes ingest blood in bone marrow and other organs. Cytopenias, fever, splenomegaly, liver function abnormalities, coagulopathy, and high levels of ferritin (typically >1000) ensue. In children, congenital causes can be found in perforin or granule fusion defects. In adults, an underlying malignancy (usually lymphoma) catalyzes the syndrome and is fatal without a stem cell transplant. Treatment otherwise entails chemotherapy with etoposide, steroids, and other immunosuppression. When associated with a rheumatologic disease, the name macrophage activation syndrome is used.

Consumption and dilutional thrombocytopenia. In addition to sequestration, hypoproliferative, and destructive causes of thrombocytopenia, low platelet counts occasionally result from consumption and hemodilution. The pathophysiology of thrombocytopenia in these cases is directly attributable to the underlying cause of the bleeding, frequently large-scale trauma.

Overwhelming hemorrhage causes the consumption of endogenous platelets in an attempt to curb bleeding, and platelets are

consumed faster than they can be released by the spleen or generated in the bone marrow. Resuscitative efforts after trauma, including infusion of massive volumes of intravenous fluids, red blood cells, and FFP, result in the dilution of circulating platelet numbers. The combination of platelet consumption and dilution during trauma can have catastrophic consequences and historically has been a leading cause of death in this setting. In addition to identifying the source of a large bleed, aggressive platelet transfusions in the setting of trauma may provide the greatest benefit in overcoming the effects of consumption and dilution (discussed in the “Standard Platelet Therapy” section).

BLEEDING CAUSED BY PLATELET FUNCTION DEFECTS

The ability of platelets to adhere to damaged vasculature and to recruit additional platelets into the clot is essential for primary hemostasis, especially when patients are challenged by trauma or surgery. Unlike bleeding caused by thrombocytopenia, individuals with platelet function defects bleed because their platelets cannot adhere or aggregate appropriately in response to *in vivo* stimuli.

These qualitative platelet disorders are most frequently encountered in individuals with normal or near-normal platelet counts. Evaluation often relies on tests that assess the function (rather than the number) of circulating platelets. From an epidemiologic standpoint, acquired qualitative platelet defects are much more frequently encountered than their congenital counterparts.

Acquired Causes of Platelet Dysfunction

Antiplatelet Therapy

The patient's history and preoperative screening should assess whether patients are taking medications that interfere with platelet function, such as aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs). Aspirin irreversibly blocks arachidonic acid metabolism, and all exposed platelets are irreversibly affected so that affected platelets do not respond to stimulation even after aspirin is discontinued. The characteristic aspirin-induced platelet aggregation pattern is shown in Table 52.5 and Fig. 52.5.

Nonsteroidal anti-inflammatory drugs (NSAIDs) (e.g., indomethacin) reversibly inhibit cyclooxygenase (COX), and platelet function is restored within 48 hours after discontinuing the drug. Bleeding after most surgical procedures that is associated with aspirin or NSAIDs is

A

B

Fig. 52.5 Methodology underlying light transmission aggregometry. (A) Typical laboratory light transmission aggregometer. (B) Platelet function is directly proportional to light transmission in this assay. Platelet-rich plasma, which prevents light transmission, is exposed to various agonists (i.e., adenosine diphosphate, epinephrine, collagen, arachidonic acid, and ristocetin). As platelets begin to aggregate or agglutinate, light transmission increases over time and is typically reflected as a primary or secondary wave of aggregation for most agonists. Low or no increase in light transmission typically correlates with diminished platelet function.

usually mild, so aspirin may not need to be discontinued before surgery, especially considering aspirin-induced platelet dysfunction is desirable in patients at risk for stroke or myocardial infarction.

The aspirin effect is restricted to COX1, and various NSAIDs have different relative affinities for COX1 and COX2. COX2 is an inducible enzyme that is synthesized in endothelial cells in response to inflammatory cytokines. Suppression of COX2 reduces synthesis of endothelial cell prostaglandin I_2 (i.e., prostacyclin), a molecule that exhibits antithrombotic effects through inhibition of platelet aggregation. The net effect of nonselective NSAIDs on the prothrombotic

or antithrombotic balance favors bleeding because NSAID-induced COX1 inhibition means that thromboxane A_2 production in platelets is blocked. In contrast, the increased cardiovascular risk with administration of more selective COX2 inhibitors is probably attributable to the COX2-induced lack of endothelial cell prostacyclin production, coupled with intact platelet function (i.e., no inhibition of thromboxane A_2 by COX2 blockade).

Another category of antiplatelet agents acts independently of the COX1/2 pathways. These drugs are P2Y₁₂ receptor antagonists (e.g., clopidogrel, prasugrel). They disrupt function by irreversibly binding

to the surface receptor for the platelet agonist, ADP. P2Y₁₂ receptor antagonists are primarily used as adjunctive anticoagulant therapy for individuals at risk for thrombosis associated with coronary artery disease and stroke. These drugs can inhibit platelet activation at the site of injury, not unlike the effect in an individual taking aspirin, and further potentiate bleeding.

Regardless of the type of agent used, discontinuing an antiplatelet drug is a reasonable first step for a patient who has moderate to severe bleeding while on the therapy. Discontinuation of aspirin will not help the affected platelets because its inhibition is irreversible, but this will allow newly produced platelets to be free of drug effect and function appropriately at the site of an injury.

Beyond stopping the offending drug, bleeding caused by aspirin or other antiplatelet agents may be addressed by infusion of 1-deamino-(8-D-arginine)-vasopressin (DDAVP, desmopressin), although the results of small clinical trials have been mixed regarding its benefit to platelet function and bleeding cessation. Occasionally, platelet transfusion is necessary. In most cases, a single platelet transfusion of 4 to 6 random donor units (or one apheresis unit) contributes enough normal platelets (>10% of total circulating number) to restore primary hemostasis. Platelet dysfunction and bleeding caused by other drugs is similarly treated by discontinuing the drug and providing platelet transfusions when needed (Table 52.6).

Uremic Platelet Dysfunction

Renal insufficiency can be associated with the accumulation of toxic proteins, which induce high levels of nitric oxide formation by vascular endothelial cells and inhibit platelet function. The uremic state can also suppress platelet secretory pathways and platelet adhesion to exposed endothelium through mechanisms that are not well understood. Nonetheless, the uremic state does put an individual at risk for platelet dysfunction–related bleeding. Because no formal tests are available, the diagnosis should be suspected in individuals with acute or chronic renal failure who demonstrate bleeding.

Short-term treatment of uremic platelet dysfunction includes administration of DDAVP. This increases circulating von Willebrand factor, which can help to overcome some of the uremia-associated platelet deficits. Transfusion of red blood cells also seems to help by

increasing volume, thereby pushing platelets to the margins of the blood vessel, where they become easily activated and more likely to plug the gaps between endothelial cells. Conjugated estrogens are of some benefit for long-term treatment. Platelet transfusions may be marginally useful in patients with life-threatening bleeding and acute renal failure, but the effect of this treatment is short lived because the transfused platelets rapidly acquire the uremic defect. Platelet transfusion should not be considered as a first-line therapy for most forms of uremic bleeding. Ultimately, renal replacement therapy, including dialysis or renal transplantation, may be necessary.

Congenital Causes of Platelet Dysfunction**Platelet Glycoprotein Defects**

Inherited qualitative platelet defects include abnormalities of platelet receptors and granules. Two rare but well-characterized platelet receptor disorders are Bernard-Soulier syndrome and Glanzmann thrombasthenia.

Bernard-Soulier syndrome is caused by decreased surface expression of platelet GPIb, a key receptor for von Willebrand factor and less commonly by diminished GPIb function. The syndrome is characterized by mild thrombocytopenia, large platelets, and mild to moderate bleeding symptoms. The diagnosis is usually made in childhood, but some patients may be discovered in adulthood. Laboratory testing for Bernard-Soulier syndrome shows an absent platelet aggregation response to ristocetin (see Table 52.5 and Fig. 52.5) despite adequate VWF activity.

Glanzmann thrombasthenia is characterized by an increased bleeding time and abnormally low levels of expression of platelet GPIIb/IIIa (receptor for VWF and fibrinogen) or, less commonly, normal expression but absent GPIIb/IIIa function, while platelet count remains normal. Patients usually exhibit bleeding in childhood. Whereas patients with Bernard-Soulier syndrome have an elevated mean platelet volume (MPV), MPV is normal in Glanzmann thrombasthenia. In cases of Glanzmann thrombasthenia, platelet aggregation testing confirms an absent or diminished response to all agonists except ristocetin (see Table 52.5 and Fig. 52.5).

Platelet transfusions correct the bleeding in Bernard-Soulier syndrome and Glanzmann thrombasthenia. However, because of the high risk for alloimmunization with frequent platelet transfusions (particularly because patients lack GPIb or GPIIb/IIIa), this therapy should be used sparingly. Instead, factor VIIa can be used with high efficacy for both diseases. DDAVP has some benefit in Bernard-Soulier syndrome.

Platelet Granule or Secretory Defects

Inherited platelet granule disorders are defined by the type of granule that is absent or defective. Storage pool disease is characterized by a relative decrease or absence of dense granules and correspondingly moderate to severe mucosal bleeding. Release of dense granule contents that recruit and activate platelets is impaired. Storage pool disease has a diminished or absent secondary wave of aggregation in response to most agonists (see Table 52.5 and Fig. 52.5).

Hermansky-Pudlak syndrome is a dense granule deficiency associated with oculocutaneous albinism, nystagmus, and pulmonary fibrosis. Multiple gene defects have been attributed to Hermansky-Pudlak syndrome and cause lysosome dysfunction. Patients may have spontaneous bleeding, but bleeding more often occurs with surgical procedures or trauma. This can be particularly problematic for the patients who undergo lung transplant for pulmonary fibrosis.

Chédiak-Higashi syndrome is a rare dense granule disorder characterized by mild bleeding, partial albinism, and recurrent pyogenic infections. It is caused by a mutation in the *LYST* gene leading to lysosome dysregulation. Large, irregular, gray-blue inclusions (granules)

are seen in neutrophils and other white blood cells. Many patients with Chédiak-Higashi syndrome develop an accelerated phase with HLH.

Gray platelet syndrome is characterized by colorless or gray platelets that lack normal staining on the peripheral smear. Electron microscopy confirms the loss of α -granules or their contents. A mutation in the gene *NBEAL* disrupts vesicle trafficking, leading to a deficiency of the α -granules. Patients with gray platelet syndrome have a history of mild bleeding, and aggregation testing detects diminished responses to epinephrine, ADP, and collagen.

Thrombocytopenia with small platelets is characteristic of Wiskott-Aldrich syndrome, an X-linked recessive disorder with eczema and immunodeficiency that can be diagnosed by the lack of CD43 expression on T lymphocytes. A *WAS* gene mutation results in a defect in the actin cytoskeleton followed by a deficiency in platelet dense granules. Most patients with Wiskott-Aldrich syndrome will not survive without a stem cell transplant.

May-Hegglin anomaly and related myosin heavy-chain 9 gene (*MYH9*) diseases are characterized by giant platelets and Döhle bodies (i.e., basophilic inclusions in leukocytes). Platelet count is low and a family history of bleeding is common because the inheritance pattern is autosomal dominant. Unlike the other diseases in this section, *MYH9* diseases have normal granules and normal platelet aggregation, but the *MYH9* mutation impairs the platelet cytoskeleton, which affects clot retraction. With thrombopoietin agonists, the additional platelets produced are also dysfunctional, but the quantitative increase in platelets may be enough to stop bleeding.

All the platelet dysfunction disorders are treated by avoiding antiplatelet drugs, using hormonal control of menses in women, and transfusing platelets when bleeding occurs.

Platelet Transfusion Therapy

Standard Platelet Therapy

Platelet transfusions derived from the whole blood of healthy donors can be used to stop or prevent bleeding. The two broad categories of platelet transfusion support are based on the conditions previously discussed: prophylactic platelet transfusions for thrombocytopenia in nonbleeding patients and platelet transfusion for acute bleeding.

For the nonbleeding thrombocytopenic patient, several triggers can prompt platelet transfusion in the absence of frank hemorrhage. Patients receiving chemotherapy may be severely thrombocytopenic and should be transfused when their platelet counts are less than 10,000/ μ L to prevent spontaneous bleeding. This is a safe and appropriate threshold for patients with relatively uncomplicated clinical pictures without fever, sepsis, or bleeding. The threshold of 10,000/ μ L, which was rigorously established through several prospective, randomized, controlled trials, significantly decreases the frequency of platelet transfusion and thereby reduces risks associated with multiple blood product exposures. If the patient has complicating circumstances, prophylactic transfusions may be given when platelet counts are lower than 20,000/ μ L, although this threshold is not rigorously based on clinical trial evidence.

For patients undergoing invasive procedures or who suffer trauma, it is reasonable to transfuse platelets when counts are lower than 50,000/ μ L. Higher platelet counts (>100,000/ μ L) are recommended for patients undergoing neurologic surgery. The thresholds of 50,000/ μ L and 100,000/ μ L are based primarily on experience and published guidelines. Clinical trials are lacking in these settings.

For the acutely bleeding patient, the decision to transfuse platelets depends on several factors, of which thrombocytopenia is the most straightforward and useful criterion. Platelet counts higher than 50,000/ μ L are a reasonable goal for most cases of acute bleeding,

whereas counts higher than 100,000/ μ L may be necessary for neurologic bleeding.

Congenital or acquired platelet dysfunction must be considered for acutely bleeding patients. Those with significant bleeding who have taken an antiplatelet drug such as aspirin may benefit from platelet transfusion regardless of baseline counts. Another consideration is the volume of blood products and fluids received. Trauma patients may receive more than 10 units of transfused red blood cells in addition to plasma, volume expanders, and saline solutions. Resuscitation with large fluid volumes (≥ 10 units transfused) reduces the platelet count to less than 50% of baseline, resulting in a significant dilutional coagulopathy. In these scenarios, repeated platelet counts must be obtained and platelets liberally transfused to maintain adequate hemostasis. Similarly, clotting factors need repletion during massive transfusion (see “Dilutional Coagulopathy” section).

Blood banks provide random-donor pooled platelets and apheresis platelets (E-Fig. 52.1). Random-donor pooled platelets consist of platelet concentrates from four to six donors combined (pooled) into one large dose. For the adult patient with uncomplicated thrombocytopenia, a single random-donor platelet concentrate unit typically raises the platelet count by about 8000 to 10,000/ μ L. Between 4 and 6 units pooled together can be expected to raise counts by 30,000 to 60,000 platelets/ μ L. Apheresis platelets are collected from one donor using automated apheresis instruments. The dose of these *single-donor platelets* is almost equivalent to that of a 6-unit platelet pool and is estimated to increase platelet count by up to 50,000/ μ L in an uncomplicated patient.

Based on the expected increments and typical transfusion goals outlined previously, one random-donor platelet pool (6 units pooled together) or one apheresis platelet product should sufficiently raise platelet counts to improve thrombocytopenia and prevent spontaneous bleeding. These doses should also be sufficient to stop or prevent bleeding associated with thrombocytopenia in the setting of invasive procedures, mild to moderate trauma, or bleeding associated with platelet dysfunction. For the complicated patient (e.g., thrombocytopenia with intracranial hemorrhage, massive trauma), additional platelet doses may be necessary to achieve adequate hemostasis.

Platelet Transfusion Failure and Platelet Refractoriness

Platelet transfusions in thrombocytopenic patients are not successful in all cases. Uremia causes an acquired dysfunction of transfused platelets, limiting their hemostatic capabilities *in vivo*. Patients who are thrombocytopenic due to conditions such as ITP usually do not show increased platelet counts after transfusion because circulating autoantibodies cause rapid destruction of both endogenous and infused (exogenous) platelets. This phenomenon, known as platelet transfusion refractoriness, can be caused by many other recipient problems, including fever, sepsis, splenomegaly, and DIC. Although the pathophysiology of refractoriness is well understood for conditions such as ITP or DIC (in which platelets are cleared from the circulation), few data are available to suggest why individuals with conditions such as fever or infection have an inappropriate response to platelet transfusion.

When approaching a patient with platelet transfusion refractoriness, the physician should consider whether it is mediated by nonimmune or immune factors. Immune refractoriness indicates antibody-mediated clearance. For nonimmune-mediated refractoriness, as in fever or DIC, the underlying conditions usually decrease transfused platelet survival over time but do not affect immediate platelet recovery.

A standard diagnostic approach to platelet refractoriness involves measuring the platelet count 10 minutes to 1 hour after completion of the platelet transfusion. The patient with non-immune-mediated

E-Fig. 52.1 An apheresis platelet unit. Platelet units, collected from donors by phlebotomy or apheresis instrumentation, contain a total volume of about 250 to 300 mL, usually corresponding to a total platelet count greater than 3.0×10^6 cells/ μL in the final unit. Platelets are stored at room temperature and typically have a shelf life of 5 days. They are indicated for the prevention or cessation of bleeding associated with thrombocytopenia or platelet function defects.

refractoriness typically shows an initial increase at 10 minutes but then a blunted increase in the platelet count 1 hour after transfusion, with a subsequent decline at a steeper rate than expected because of the underlying disorder. For patients with this type of platelet refractoriness, addressing the underlying illness often increases the effectiveness of platelet transfusions.

For patients with immune-mediated platelet refractoriness, there is virtually no increase in the platelet count, even minutes after completion of a transfusion. The antiplatelet antibodies are most frequently encountered in individuals who have been recurrently transfused. Repeated exposures to transfused products can induce alloantibodies, most commonly to HLA antigens. Over time and with multiple transfusion exposures, the titer of alloantibodies can increase sharply and cause rapid clearance of incompatible platelets after infusion.

For the alloimmunized patient, immunosuppression fails to decrease platelet alloantibodies, and efforts to improve platelet recovery after transfusion are focused on finding compatible platelet units. The first step in managing transfusion of the alloimmunized patient is to provide ABO antigen–matched platelets to minimize clearance caused by naturally occurring ABO antibodies; this is often helpful because platelets express A and B antigens on their surface. If this step fails to yield increases in platelet counts, donor platelets that lack target antigens for the detected alloantibodies should be pursued. One strategy is to use the patient's serum to crossmatch platelet donor units, with selection of those units demonstrating compatibility for subsequent transfusion.

If crossmatch-compatible platelets fail to induce adequate platelet recovery, blood banks should provide platelets that are matched to the recipient's HLA system in the hope of evading HLA-based antibodies. HLA-matched platelets are collected from compatible donors using apheresis at frequent intervals until the patient's platelet count recovers and they are no longer transfusion dependent. Many blood banks and transfusion services have attempted to address the problem of platelet HLA alloimmunization through prevention. They provide blood products that have undergone filtration to reduce their white blood cell content, a process called *leukoreduction*. Because contaminating leukocytes are the primary sources of exposure to HLAs, their removal can be quite effective in preventing subsequent alloimmunization, even in chronically transfused patients.

BLEEDING CAUSED BY VON WILLEBRAND DISEASE

Von Willebrand disease is caused by either a deficiency or dysfunction of von Willebrand factor. Because VWF is a key component to primary hemostasis, its deficiency results in easy bleeding, typically superficial (bruising, mucosal). However, VWF is a stabilizer of factor VIII and when VWF is low, factor VIII is rapidly cleared, resulting in declining factor VIII levels and an elevated aPTT. If factor VIII levels are low enough, patients can have deeper bleeding as in hemophilia A and B with muscle hematomas, hemarthroses, and bleeding into the central nervous system. VWF is synthesized in endothelial cells and megakaryocytes and functions in plasma to mediate platelet adhesion to the damaged site. VWF is a large, multimeric protein; the largest multimers contain the greatest number of adhesive sites and confer greater hemostatic ability than smaller VWF molecules. In patients with low VWF levels, platelet adhesion to damaged vessels is delayed.

VWF is grouped into three main subtypes (E-Table 52.1). Type 1 VWD results from a decline in VWF antigen. Decline in VWF antigen parallels a decline in VWF activity. Type 2 VWD represents a dysfunctional VWF, leading to a more significant decline in VWF activity than VWF antigen. Type 3 VWD is the most severe type. Patients with type 3 VWD do not make any VWF.

Type 1 von Willebrand Disease

Type 1 VWD is the most common type. Although severity can vary significantly, it tends to be mild. The cause is not always clear because many cases of type 1 VWD have a normal VWF gene sequence. Therefore, other factors must be in play such as the rate of VWF secretion, storage, and clearance. Blood type O is associated with a 25% decline in VWF levels. However, this decline does not affect bleeding rates, possibly due to enhanced secretion and decreased clearance of VWF with age. Inheritance of type 1 VWD tends to be autosomal dominant. VWF antigen levels decline in parallel with VWF activity, reported as VWF:ristocetin (RCo), and increasing severity. VWF:RCo measures the ability of the patient's VWF (plasma) to agglutinate normal platelets in the presence of ristocetin. VWF:RCo 30% to 49% is referred to as “low VWF” but not true VWD. Diagnostic criterion for VWD is VWF:RCo less than 30%. Repeating VWF testing is wise because significant variability occurs within individuals and between labs.

VWF levels also increase with age, inflammation, liver disease, and estrogen such as while on oral contraception or during pregnancy. Patients with mild and moderate VWD rarely have bleeding during pregnancy as the baseline VWF levels increase. However, days to weeks after delivery, bleeding becomes more common as levels fall back to the original baseline. Pregnant women should be alerted to this possibility so they contact a provider if postpartum bleeding occurs. Postpartum bleeding should be carefully assessed so it is not dismissed as expected lochia.

Treatment for VWD focuses on modalities to increase VWF. DDAVP increases production of VWF and its release from stores in the Weibel-Palade bodies in endothelial cells. It also increases factor VIII levels. Increased VWF levels can be detected within minutes of DDAVP administration, either intravenous or intranasal. Prior to relying on DDAVP for prevention of bleeding with surgeries or treatment of acute bleeds, a DDAVP challenge should be undertaken, where VWF and factor VIII levels are measured at baseline and then at specified timed intervals (e.g., 1 hour, 2 hours, and 6 hours) after administration of DDAVP to confirm an adequate response. Once this is done, intravenous DDAVP 0.3 µg/kg (capped at 20 µg max dose) can be given 30 to 60 minutes prior to surgeries, and intranasal DDAVP can be prescribed so patients can self-treat at home for bleeds or heavy menstrual periods.

The drawbacks to DDAVP include common side effects such as flushing, headache, malaise, and nausea, but also importantly hyponatremia, which becomes more severe with every dose. This can be circumvented by instructing patients to incorporate a 1-week drug holiday after every three doses and to limit free water intake during DDAVP days. A drug holiday is also important because tachyphylaxis develops, meaning that subsequent doses have diminishing returns on their ability to raise VWF levels (i.e., the third dose does not work as well as the first dose) as VWF stores become depleted. When DDAVP responses are inadequate or when patients do not tolerate DDAVP, VWF concentrates must be used. VWF concentrates come as plasma-derived or recombinant. Recombinant VWF contains no factor VIII, while plasma-derived VWF has factor VIII attached. This is important for treatment decisions because many patients with VWD also have low factor VIII levels. In that situation, both VWF and factor VIII need to be replaced to effectively treat acute bleeding. Thus, if recombinant VWF is used, a separate infusion of factor VIII concentrate also needs to be infused if factor VIII is low. For severely affected patients who need prophylaxis (regularly infused VWF to prevent spontaneous bleeding), either type of product is adequate because factor VIII levels become normal several hours after VWF is infused since the VWF stabilizes endogenous factor VIII. If baseline VWF levels of zero are assumed, VWF concentrates of 50 U/kg intravenous will bring

E-TABLE 52.1 Classification of Von Willebrand Disease

Factor	Type 1	Type 2a	Type 2b	Type 2m	Type 2n	Type 3	Pseudo-VWD	BSS
Inheritance	AD	AD, AR	AD, AR	AD	AR	AR, AD	AD	AR
Platelet count	NL	NL	NL, ↓	NL	NL	NL	↓, NL	↓, NL
PTT	NL, ↑	↑, NL	↑, NL	↑	↑↑	↑↑	↑, NL	NL
VIII	NL, ↓	NL, ↓	↓, NL	NL, ↓	↓↓	↓↓	↓, NL	NL

VWF:Rcof	NL, ↓	↓↓	↓, NL	↓↓	NL	Absent	↓, NL	NL
Multimers	NL, ↓	↓ H/l	↓↓ H	NL	NL	Absent	↓↓ H	NL
RIPA	NL, ↓	↓↓	↑*	↓	NL	↓↓	↑*	↓↓

AD, Autosomal dominant; *AR*, autosomal recessive; *BSS*, Bernard-Soulier syndrome; *H*, high-molecular-weight multimers; *l*, intermediate-molecular-weight multimers; *NL*, normal; *PTT*, partial thromboplastin time; *RIPA*, ristocetin-induced platelet agglutination; *VWD*, von Willebrand disease; *VWF:Ag*, von Willebrand factor antigen level; *VWF:Rcof*, von Willebrand factor:ristocetin cofactor activity; ↑, increased; ↓, decreased; ↑*, increased agglutination in response to low-dose ristocetin.

VWF to 100%. The half-life of these products is about 12 hours, so doses need to be repeated every 12 to 24 hours.

Type 2 von Willebrand Disease

Type 2 VWD is characterized by heterozygous mutations that produce a qualitative defect in the VWF molecule. Because the defect causes a dysfunction in VWF, DDAVP, which will increase the dysfunctional endogenous VWF levels, may not work as well as it does for type 1 VWD.

A variety of VWF mutations can cause VWD type 2A, which result in decreased VWF secretion or increased clearance through ADAMTS-13 (a disintegrin and metalloprotease with thrombospondin-1-like-domains-13). These patients show disproportionately low VWF:RCO activity compared with the VWF antigen level (VWF RCo:Ag < 0.6) and large or high-molecular-weight VWF multimers are absent (see [E-Table 52.1](#)). Platelet aggregation is decreased in response to ristocetin. Patients with type 2A VWD respond to VWF concentrate and less commonly to DDAVP.

Type 2B VWD represents a gain-of-function mutation in exon 28 of VWF that augments VWF binding to the platelet GPIb receptor. This leads to mild thrombocytopenia that worsens with exposure to DDAVP. Therefore, DDAVP is contraindicated in type 2B VWD. High-molecular-weight multimers are absent and platelet aggregation is increased by ristocetin (see [E-Table 52.1](#)). Patients are treated with VWF concentrate.

The same scenario can be found with platelet-type VWD (previously called pseudo-VWD), where the mutation is not on VWF but instead on the GPIb receptor, and this also augments the interaction of VWF with GPIb. GPIb can be sequenced to verify the diagnosis. These patients are treated with platelet transfusions, not VWF, because the VWF is normal.

Type 2M VWD has a VWF mutation causing decreased binding to GPIb, the opposite of type 2B VWD. These patients have normal platelet counts and normal VWF multimers. Gastrointestinal bleeding is more common in type 2M VWD than in other types. Some patients with type 2M VWD respond to DDAVP, but most require VWF concentrate. The platelet version of type 2M VWD is called Bernard-Soulier syndrome, which is caused by a mutation in GPIb leading to decreased VWF binding (see “Congenital Causes of Platelet Dysfunction”).

In type 2N VWD, the abnormal VWF molecule has decreased binding affinity for factor VIII, which decreases factor VIII survival and produces a bleeding phenotype similar to hemophilia A (e.g., hemarthroses) except that it affects males and females equally because it has an autosomal recessive inheritance pattern, unlike the X-linked hemophilia A and B. The diagnosis of type 2N VWD should be considered in females who have hemophilia A. VWF levels are normal because the mutated region is isolated to the factor VIII binding site and not affecting the other functions of VWF. To confirm the diagnosis, tests for VWF binding to factor VIII are available in reference laboratories. The low factor VIII levels respond poorly to factor VIII infusions because the infused factor is rapidly cleared without functioning VWF to stabilize it. Instead, type 2N VWD is treated with VWF concentrates with or without factor VIII concentrates.

Type 3 von Willebrand Disease

Patients with type 3 VWD have a complete deficiency of VWF, often as a result of the inheritance of two abnormal VWF alleles (i.e., compound heterozygous). This VWD type is the most severe and can mimic hemophilia because factor VIII levels are also severely decreased without VWF protection. It does not respond to DDAVP and requires VWF with factor VIII concentrates to treat bleeding. Many patients with type 3 VWD require regular prophylaxis of VWF concentrates infused every 2 to 3 days to prevent spontaneous bleeding.

Acquired von Willebrand Disease

The acquired form of VWD usually appears as a severe, type 2A–like defect without larger VWF multimers in a patient with no history of bleeding. Acquired VWD is caused by abnormal clearance of the larger VWF multimers and is associated with essential thrombocytopenia, monoclonal gammopathies, multiple myeloma, lymphoproliferative disorders, and other malignancies. For some patients, no etiology is apparent. Unlike ITP, acquired VWD is not associated with pregnancy. Acquired VWD has been successfully treated with IVIG and treatment for the underlying disorder. Another cause of abnormal VWF multimer clearance resulting in acquired VWD is critical aortic stenosis (Heyde syndrome). It is corrected with successful surgical repair.

BLEEDING CAUSED BY COAGULATION FACTOR DISORDERS

Unlike disorders of platelets and von Willebrand factor, which favor mucocutaneous bleeding, coagulation factor defects generally cause deeper hemorrhages, such as bleeding into muscle and joints. Because the initial platelet plug is not solidified by secondary hemostasis, the effects are clot breakdown and at times delayed bleeding.

Most patients with significant factor deficiencies have abnormal screening laboratory test results ([E-Table 52.2](#), [Table 52.1](#), and [Fig. 52.1](#)), although patients with mild deficiencies can have bleeding and only borderline-abnormal coagulation factor values. Like other hemostasis abnormalities previously discussed, coagulation factor problems can be classified as congenital deficiencies or acquired.

Congenital Factor Deficiencies

Hemophilia A and B

After VWD, hemophilia A and B are the two most common factor deficiencies, corresponding to factor VIII and factor IX deficiency, respectively. Hemophilia A, with an incidence of 1:10,000 live male births, is approximately four times more common than hemophilia B. They are both X-linked and clinically indistinguishable from each other. Although more prominent in males, females can also have hemophilia as symptomatic carriers and by skewing of X chromosomal inactivation (i.e., favoring one chromosome over the other).

More than 2000 different mutations have been reported to cause hemophilia A and more than 1000 to cause hemophilia B. About 50% of severe hemophilia A patients have an inversion of a major portion of the gene at intron 22 (inversion 22) that results in complete loss of activity. Smaller missense mutations tend to result in mild or moderate disease. One third of cases are de novo, therefore there is no family history.

Hemophilia A and B are stratified by severity: Severe hemophilia is defined as a factor activity of less than 1%, moderate hemophilia as a factor activity of 1% to 5%, and mild hemophilia as a factor activity of 6% to 40%. These distinctions appear small, but are not. Severely affected patients bleed often and spontaneously. Moderately affected patients occasionally bleed spontaneously, whereas mildly affected patients typically bleed only after trauma or surgery. The most common locations for hemorrhages are joints and muscles, but bleeding can occur anywhere. They can be life-threatening, particularly when intracranial. Hemarthroses cause intra-articular inflammation and synovial hyperplasia. Subsequent cartilage and bone damage worsens with repeated hemorrhages. Hemophilic arthropathy results in chronic pain and limitations in joint function. Prior to the advent of prophylaxis, patients often needed joint replacement surgery early in life.

Currently, patients who bleed frequently take factor prophylaxis by self-infusing factor intravenously every few days to maintain detectable baseline factor levels so that spontaneous bleeding does

not occur. When acute hemorrhages occur, patients are instructed to infuse factor as early as possible. Most severely affected patients know how to self-infuse intravenously at home. DDAVP, given intravenously or intranasally, can rapidly raise factor VIII levels in mild hemophilia A patients but not in patients who are severely affected. It does not raise factor IX levels in hemophilia B patients either.

A newly approved therapy for prophylaxis is emicizumab, a bispecific antibody that mimics the function of factor VIII by binding to factors IXa and X. This has several advantages over traditional factor products. First, administration is subcutaneous, not intravenous like all other previous factor products. Second, the half-life is substantially longer. Traditional factor's half-life was roughly 12 hours, some extended to nearly 24 hours by the addition of extra moieties such as polyethylene glycol, albumin, or the Fc receptor domain of immunoglobulin, all slowing the metabolism of factor VIII. Emicizumab's half-life is 30 days. The third advantage of emicizumab is that it is not a clotting factor and, therefore, factor VIII inhibitors do not interfere with its efficacy. The disadvantages of emicizumab are that clotting assays (PTT, factor VIII, and others) no longer provide accurate results and that emicizumab is only used for prophylaxis, so acute bleeds are still treated by infusing factor VIII, although acute bleeds are significantly less common with emicizumab versus traditional factor VIII prophylaxis. Emicizumab works only for factor VIII deficiency, not in hemophilia B.

Inhibitors remain the largest problem for hemophilia patients. In up to one third of hemophilia A patients (much less common in hemophilia B), an alloantibody against factor VIII or IX forms, blocking the utility of factor infusions. In this situation, a bypass to work around the inhibitor in the clotting cascade is required to treat hemorrhage. There are two types of bypass agents: activated factor VII and activated 4-factor prothrombin complex concentrates (aPCC), which contain activated factors II, VII, IX, and X. Inhibitor titers can be measured in Bethesda units (BU); 1 BU is defined as the amount of inhibitor that neutralizes 50% of factor activity. High-titer inhibitors (>5 BU) completely neutralize the activity of infused factor concentrates, while low-titer inhibitors can be out-competed by using higher doses of factor, but at the risk of subsequently increasing the titer level. Inhibitors are sometimes transient, sometimes permanent, and sometimes able to be eradicated by immune tolerance induction, by giving frequent high doses of factor infusions to desensitize patients to the factor. Patients with inhibitors have more severe disease and poorly respond to available treatments. Inhibitors make an already costly disease much more expensive.

Not just a footnote in history, many hemophilia patients continue to struggle with the sequelae of human immunodeficiency virus (HIV) and viral hepatitis after contracting them from contaminated blood and factor products in the 1980s and 1990s. In fact, a large percentage of hemophilia patients died from complications of these infections. Recombinant factor was developed in the 1990s and most patients switched even though plasma-derived factor products became safe again through viral testing and inactivation procedures. In addition, a large randomized control trial has shown that plasma-derived factor leads to fewer inhibitors than recombinant, yet most patients remain on recombinant products.

The future has taken a rapid upward swing for hemophilia patients, with curative therapies for hepatitis C, emicizumab, other novel agents coming soon from development and the imminent arrival of gene therapy through coagulation factor DNA deployed into the liver by a viral vector. Multiple studies for gene therapy have shown early success and are already in phase III trials with approval for wider use expected in the coming years.

Hemophilia C

Hemophilia C refers to factor XI deficiency. Although one step prior to factor IX in the clotting cascade, factor XI deficiency is very different than hemophilia A and B. First of all, bleeding tends to be mucocutaneous, similar to platelet and VWF disorders. Second, bleeding risk does not parallel factor activity level and tends to be mild. For example, some patients with zero factor XI activity rarely bleed. Bleeding risk is best determined by a patient's bleeding history; therefore, the need for presurgical factor replacement depends on whether or not a patient tends to bleed. Factor XI replacement is done with fresh-frozen plasma (FFP) in the United States. Some countries have an available factor XI concentrate. Hemophilia C is inherited autosomal recessively and is common in Ashkenazi Jewish people.

Other Congenital Factor Deficiencies

Factor deficiencies can occur in any clotting factor (see E-Table 52.2). Patients with factor V deficiency usually lack plasma factor V and platelet factor V and have joint and muscle bleeding similar to patients with hemophilia. Some patients who are plasma factor V deficient are asymptomatic until they are challenged with the stress of surgery or trauma, and these patients are thought to have normal platelet factor V levels. Rarely, patients inherit combinations of factor deficiencies, such as combined factors V and VIII deficiencies. Some factor deficiencies have specific factor concentrations available for treatment such as factor VIIa, factor X, and factor XIII. However, others do not have specific concentrates available; those would be treated with FFP.

In neonates, factor XIII deficiency manifests with late umbilical stump bleeding or intracranial hemorrhage. Bleeding is delayed, but severe. Factor XIII deficiency does not affect PT or aPTT. It is diagnosed by screening for increased clot solubility in urea; if the clot dissolves abnormally quickly, an enzyme-linked immunosorbent assay for the precise factor XIII level should be performed. Factor XIII deficiency is treated with factor XIII concentrate or cryoprecipitate. Because of the long half-life of factor XIII, prophylactic therapy for severe deficiency is provided only in single doses on a 3- to 4-week recurring schedule.

Fibrinogen (factor I) functions as a bridging ligand for the platelet receptor GPIIb/IIIa in the platelet-platelet matrix at sites of vascular damage. It also functions in the final steps of the coagulation cascade to form the fibrin clot after activation from thrombin (factor IIa). This dual role leads to a varied phenotype of bleeding with superficial and deeper bleeding when defects in fibrinogen exist. Congenital abnormalities of fibrinogen include low levels (hypofibrinogenemia), absent fibrinogen (afibrinogenemia), and abnormally functioning fibrinogen (dysfibrinogenemia). The diagnosis can be established by screening assays (see E-Table 52.2), laboratory assays to measure fibrinogen levels, and tests such as thrombin time that are designed to measure fibrinogen function. Reptilase time can also confirm dysfibrinogenemia; heparin does not interfere with this assay like it does with thrombin time. PT and aPTT are prolonged in disorders of fibrinogen. Fibrinogen concentrates can be used for replacement, but if not available, cryoprecipitate offers high concentrations of fibrinogen compared to FFP.

Acquired Factor Inhibitors

Acquired inhibitors can occur in congenital hemophilia as described above (see "Hemophilia A and B" section), but they can also occur in those born with a normal coagulation system. Acquired factor VIII inhibitors are the most common and are associated with pregnancy, autoimmune disease, and malignancy, especially lymphoproliferative disorders. Some are idiopathic. The mechanisms underlying acquired factor inhibitors remain poorly understood.

E-TABLE 52.2 Screening Laboratory Results for Coagulation Factor Deficiencies

Deficient Factor	Frequency	PT	PTT	TT
I (fibrinogen)	Rare	↑	↑	↑
II (prothrombin)	Rare	↑	↑	↑
V	1:1,000,000	↑	↑	NL
VII	1:500,000	↑	NL	NL
VIII	1:5000 (male patients)	NL	↑	NL
IX	1:30,000 (male patients)	NL	↑	NL
X	1:500,000	↑	↑	NL
XI	Rare ^a	NL	↑	NL
XI ^b or HMWK ^b or PK ^b	Rare	NL	↑	NL
XIII	Rare	NL	NL	NL

HMWK, High-molecular-weight kininogen; *NL*, normal; *PK*, prekallikrein; *PT*, prothrombin time; *PTT*, partial thromboplastin time; *TT*, thrombin time; ↑, increased over normal range.

^aExcept in those of Ashkenazi Jewish descent (about 4% of whom are heterozygous for factor XI deficiency).

^bNot associated with clinical bleeding.

The diagnosis of an acquired inhibitor can be made by laboratory techniques similar to those detailed for patients with congenital hemophilia. A mixing study can be a critical piece to the evaluation. It mixes control plasma with patient plasma, correcting any deficiencies unless an inhibitor is present since the inhibitor will also block the factor in the control plasma. For the treatment of bleeding, patients with acquired inhibitors to factors VIII or IX are administered factor VIIa or aPCC to promote hemostasis by bypassing the inhibitor. Rituximab, an anti-CD20 agent, has become the mainstay for successful treatment along with steroids and should be started as soon as possible to eradicate the inhibitor.

Acquired factor X deficiency can occur in patients with amyloidosis, a condition in which the abnormal circulating light chains adsorb and clear factor X, producing low levels and severe bleeding.

Vitamin K Deficiency

Bleeding in inpatients and outpatients who are severely ill may be caused by acquired coagulation factor deficiencies from vitamin K deficiency. Because vitamin K is fat-soluble, biliary tract disease can interfere with its absorption. Antibiotics can sterilize the gut and reduce bacterial sources of vitamin K. Other drugs such as cholestyramine directly block vitamin K absorption. Vitamin K deficiency also may reflect poor nutritional status due to malabsorption, chronic disease, or reduced oral intake in patients who are acutely or chronically ill.

Factors II, VII, IX, and X are vitamin K–dependent procoagulant factors and proteins C and S are the natural vitamin K–dependent anticoagulants. In addition to disease-associated vitamin K deficiency, the anticoagulant warfarin blocks vitamin K–dependent γ -carboxylation of factors II, VII, IX, and X and causes an acute decrease in functional factor VII levels because factor VII has the shortest half-life (4–6 hours) of all vitamin K–dependent factors in vivo. Individuals who experience bleeding while on warfarin may be treated with vitamin K or, for life-threatening bleeding, a 4-factor PCC or FFP infusion.

Dilutional Coagulopathy

As with platelets, coagulation factors can be depleted through the dilutional effects of a pure red blood cell transfusion or with the administration of massive amounts of volume expanders or saline solutions. For every 10 units of red cells acutely transfused, there is a concomitant increase in the international normalized ratio (INR) to greater than 2. Acute bleeding and trauma can also lead to consumption of circulating coagulation factors.

In the setting of trauma, it is important to maintain adequate coagulation factor activity through plasma transfusions. Evidence from the trauma literature suggests that transfusion ratios of red cells to plasma should approach 1:1 to optimize hemostasis. However, even this may not fully restore depleted coagulation factors. The effects of dilutional coagulopathy should be monitored by repeated testing of PT and aPTT and supported with a liberal plasma transfusion strategy. As described above (see “Standard Platelet Therapy” section), caregivers must also be vigilant about repletion of platelets.

Liver Disease

Unlike patients with vitamin K deficiency or those receiving warfarin, patients with liver disease have low levels of most factors, not just the vitamin K–dependent factors. The exception is factor VIII. Factor VIII levels are usually normal with liver disease because factor VIII is produced in endothelial cells and megakaryocytes. Seemingly in contrast to this, factor VIII levels in hemophilia A patients normalize after liver transplant because factor VIII is synthesized in endothelial cells within the transplanted liver. If factor VIII levels are decreased

in patients with liver disease, consideration should be given to superimposed DIC.

Evaluating a prolonged PT, measurement of factor VII and a non-vitamin K–dependent factor, such as factor V, is useful. In vitamin K deficiency, the level of factor VII is low, and that of factor V is normal; levels of both factors are low in patients with generalized liver disease. The PT is a sensitive measure of liver function and becomes prolonged in patients with even mild liver disorders; elevation precedes a significant decrease in the albumin or prealbumin levels and is usually coincident with transaminase changes. In patients with mild to moderate liver disease, the PT is prolonged, but the aPTT usually remains within the normal range. In severe liver disease, the PT becomes even more prolonged, and the aPTT also becomes abnormal.

Other causes of bleeding in liver disease include associated DIC, inhibition of platelet function and production, removal of platelets from hypersplenism, and increased levels of tissue plasminogen activator. Treatment of bleeding associated with liver disease is based primarily on replacement of coagulation factors by plasma transfusions, although they only temporarily correct abnormalities. Liver transplantation is the only definitive treatment for these synthetic defects.

Acquired Fibrinogen Loss or Defects

Congenital fibrinogen disorders were described earlier, but more common are acquired causes such as DIC, causing a consumption of fibrinogen, and liver disease, where defects in post-translational modification of fibrinogen lead to dysfunction or dysfibrinogenemia. The abnormal fibrinogen molecules cannot undergo normal cross-linking or polymerization, resulting in bleeding.

BLEEDING IN PATIENTS WITH NORMAL LABORATORY VALUES

Sometimes confirmatory testing of a bleeding disorder can be elusive. Bleeding diathesis from connective tissue disease and vascular causes may have normal coagulation tests. Vitamin C deficiency can lead to bleeding through an acquired connective tissue disease (scurvy). Low VWF and mild deficiencies of clotting factors may not prolong PT and aPTT. Factor XIII deficiency does not affect PT, aPTT, and other tests. Tests of fibrinolysis (plasminogen activator inhibitor-1, alpha-2 antiplasmin, plasminogen, and tissue plasminogen activator) may find rare causes of bleeding. Often cases with significant bleeding histories remain unsolved.

Plasma and Coagulation Factor Transfusion Therapy

For patients with one or multiple defects in coagulation proteins, there are several options for replacement therapy. The most widely used product for replacement of coagulation factors is FFP (E-Fig. 52.2). It is collected from the whole blood of healthy donors and is frozen within 8 hours of collection. It contains normal (i.e., therapeutic) levels of all coagulation factors necessary to maintain hemostasis. FFP is an excellent choice for replacement of coagulation factors for many conditions, including liver failure and deficiencies of factors II, V, X, and XI.

FFP is commonly used with vitamin K therapy for the reversal of warfarin before invasive procedures or for the onset of bleeding. The appropriate dose of FFP is weight based and does not depend on the extent of prolongation in coagulation studies alone. Administration of FFP at 10 to 15 mL/kg should be sufficient to replace deficient coagulation factors and correct abnormal coagulation values. Assuming a volume of about 200 mL per unit of FFP, a reasonable dose for a 70-kg individual is 4 units of FFP. Administration is time sensitive because coagulation factors degrade at standard half-lives on infusion.

E-Fig. 52.2 Single unit of fresh-frozen plasma (FFP). Plasma units, collected from donors by phlebotomy or apheresis instrumentation, contain a total volume of about 200 to 250 mL. FFP possesses all elements found in peripheral blood plasma, including coagulation factors, albumin, complement, and immunoglobulins, although they are primarily administered for coagulation factor defects. FFP is stored in the frozen state (shown) at less than -18°C and must be thawed before issuing and administration. The shelf life while frozen is 1 year.

FFP should be provided immediately before an intended procedure to ensure adequate hemostasis.

In some cases, patients may not be able to tolerate the infusion of the large volume of FFP required to reverse coagulopathic states. Prothrombin complex concentrate (PCC) offers quick reversal of prolonged PT and aPTT without the need for large volumes of FFP. Four-factor PCC is a concentrated, lyophilized, human-derived concentrate containing factors II, VII, IX, and X that can be reconstituted in small volumes and provided by intravenous bolus injection. A 4-factor PCC was approved for clinical use in 2013 by the U.S. Food and Drug Administration (FDA). A variant PCC (FEIBA) containing activated factors II, VII, IX, and X is used as a bypass agent to treat bleeding in the setting of an inhibitor and is administered in doses of 50 to 100 U/kg every 8 to 12 hours.

Vitamin K can be given in addition to plasma infusion or factor concentrates. Oral or parenteral replacement of vitamin K (1 to 10 mg/day for 1 to 3 days) restores coagulation factor synthesis in patients with normal liver function and vitamin K deficiency.

For patients with hemophilia A or B, multiple virally inactivated, human-derived or recombinant factor VIII and IX concentrates are available (see “Hemophilia A and B”). Patients with severe hemophilia often infuse themselves with prophylactic factor on a regular basis (25–50 U/kg three times per week for hemophilia A; 50–100 U/kg twice per week for hemophilia B) and boost their dose or frequency of infusion when they sense internal bleeding, sustain trauma, or undergo dental procedures (see [E-Table 52.3](#)). Patients with mild hemophilia A may not need factor infusions for minor surgery. Their disease is often managed with DDAVP (0.3 µg/kg) or antifibrinolytic agents such as tranexamic acid 1300 mg three times a day or ε-aminocaproic acid 4 g every 4 to 6 hours.

Most patients with hemophilia require factor infusions prophylactically or at times of surgery or trauma. Factor VIII products are infused every 8 to 12 hours, and 1 U/kg of factor VIII concentrate raises plasma factor VIII activity by 2%; 50 U/kg of factor VIII theoretically yields 100% factor VIII activity in a patient with severe hemophilia A. Factor IX has a longer half-life and is infused every 18 to 24 hours; factor IX requires 1 U/kg for a 1% increase in factor IX activity (i.e., 100 U/kg for 100% activity). Major surgery in patients with hemophilia requires intensive factor therapy to achieve normal factor levels (>80%) in the intraoperative period and the early postoperative period to prevent wound hematoma formation. The dose of factors (see [E-Table 52.3](#)) is adjusted downward from this intensity, depending on the severity of the insult, the patient’s response to previous factor infusions, and whether factor inhibitors have developed.

Hemophilia patients with inhibitors need bypass agents, allowing activation of the extrinsic and common pathways of the clotting cascade. Activated 4-factor PCC is given at doses of 50 to 100 U/kg every 6 to 12 hours.

Another widely used bypass agent is activated factor VII (factor VIIa), a recombinant factor protein administered at 90 µg/kg every 2 hours until the bleeding is controlled. This agent is used to control

bleeding in patients with hemophilia inhibitors, acquired hemophilia, congenital factor VII deficiency, and Glanzmann thrombasthenia. It has also been used successfully in Bernard-Soulier syndrome.

Several virally inactivated plasma-derived VWF concentrate products and one recombinant VWF are available. The plasma-derived VWF products also contain factor VIII and are particularly useful for bleeding or prophylaxis in moderate to severe VWD when factor VIII levels are low. Recombinant VWF has no factor VIII, so it would need additional factor VIII infused if factor VIII levels were low, as can happen in VWD.

Cryoprecipitate Transfusion Therapy

Cryoprecipitate is an often overlooked but important blood product for the treatment of a variety of bleeding disorders. It is prepared by thawing frozen plasma and removing the precipitated portion. It contains a narrow array of coagulation factors, but fibrinogen, factor VIII, VWF, and factor XIII occur in high concentrations. A major advantage of cryoprecipitate is that the average single unit is only 10 to 20 mL ([E-Fig. 52.3](#)).

Based on its contents and small volume, cryoprecipitate is useful for the replacement of fibrinogen in DIC or in patients with hypofibrinogenemia or dysfibrinogenemia. The product may be helpful for isolated factor XIII deficiency or factor XIII consumption in DIC. Mounting evidence suggests that the VWF and factor VIII in cryoprecipitate can be used to overcome bleeding in uremia by enhancing the adhesive properties of circulating platelets.

Cryoprecipitate is most frequently administered for hypofibrinogenemia, and appropriate dosing should take into account a patient’s total plasma volume, baseline fibrinogen levels, and goal fibrinogen levels. For most bleeding associated with hypofibrinogenemia, a goal fibrinogen of more than 100 mg/dL is reasonable. For a 70-kg adult with a fibrinogen level less than 100 mg/dL, a 10-unit pool (total volume of about 150 to 200 mL) should be sufficient to provide adequate fibrinogen. For more complex dosage protocols, such as for children, obese patients, or those with extreme hypofibrinogenemia, consultation with the blood bank is strongly recommended for specific calculations.

PROSPECTUS FOR THE FUTURE

Novel modalities continue to be developed for the diagnosis of patients with bleeding disorders. For instance, assays measuring thrombin generation, thromboelastography (TEG), and rotational thromboelastometry (ROTEM) offer a quantitative view of coagulation that may provide greater insight into the source of abnormal bleeding than current tests. Alternatives and improvements in transfusion are also being developed, including cells harvested from induced progenitor cells that can be customized for specific needs. Progress continues to be made in the development and application of novel therapies for hemophilia. Finally, gene therapy and gene editing portend an exciting shift in hematology and medical care, in general.

E-TABLE 52.3 Factor Replacement Guidelines for Hemophilia A and B

Injury	Factor VIII Initial Dose (U/kg) ^a	Factor IX Initial Dose (U/kg) ^b
Dental prophylaxis	15-25	20-50
Hemarthrosis	15-50	30-100

^aDosing intervals should be based on a factor VIII half-life of about 12 hours. Maintenance doses of one half the listed dose may be additionally provided at these intervals.

^bDosing intervals should be based on a factor IX half-life of about 18 to 24 hours. Maintenance doses of one half the listed dose may be additionally provided at these intervals.

E-Fig. 52.3 A pool of cryoprecipitate. Cryoprecipitate units are prepared by thawing fresh-frozen plasma at cold temperatures to yield a concentrated precipitate containing only fibrinogen, fibronectin, von Willebrand factor, factor VIII, and factor XIII. Individual units of cryoprecipitate typically contain 10 to 20 mL. Cryoprecipitate is stored in the frozen state (shown) at less than -18°C and must be thawed before issuing and administration. The shelf life while frozen is 1 year.

Disorders of Hemostasis: Thrombosis

Rebecca Zon, Nathan T. Connell

PATHOLOGY OF THROMBOSIS

The Virchow triad defines the pathologic mechanisms underlying thrombosis: diminished blood flow, damage to the vascular wall, and an imbalance favoring procoagulant over anticoagulant factors. The first two factors are clearly localized to specific vascular beds; although the last element of the triad may be systemic, data show at least partial regulation of the hemostatic balance by anatomic region. For example, congenital deficiency of antithrombin, protein C, or protein S typically leads to venous thromboembolism (VTE) of the lower extremities. In contrast, the inherited hypercoagulable disorders associated with the factor V Leiden and prothrombin G20210A mutations not only produce lower extremity VTE but also are associated with thrombosis of the cerebral veins and sinuses.

This hemostatic regulation in vascular tissues is mediated by multiple factors that include (1) microenvironmental signals, such as shear stress resulting from turbulence in the disrupted flow of damaged vessels, that affect endothelial cell (EC) expression of thrombomodulin, tissue factor, and nitric oxide synthase as well as platelet activation; (2) EC subtype-specific signaling (e.g., shear stress upregulates aortic, but not pulmonary artery, nitric oxide synthase); (3) differences in EC transcriptional regulation of proteins such as von Willebrand factor (VWF) and its cleaving protease, ADAMTS13; and (4) the increasingly appreciated important link between inflammation and thrombosis that is mediated in both physiologies by selectin and integrin ligands.

Atherothrombosis

This section briefly discusses hematologic factors that predispose to thrombosis in the setting of atherosclerotic plaque (atherothrombosis); the pathophysiologic mechanisms of atherogenesis are discussed in [Chapter 8](#).

Atherothrombosis and Fibrinolysis

In addition to EC-directed regulation of hemostasis, the interaction of EC with the fibrinolytic system is important in the development of atherothrombotic disease because it affects the degree of clot propagation. The breakdown of stable fibrin polymers into fibrin split products, including the D-dimer segments that are routinely measured in the laboratory to detect recent thrombosis, is mediated by plasmin. Plasmin is converted from its inactive form, plasminogen, by tissue-type plasminogen activator (t-PA), the activity of which is regulated by plasminogen activator inhibitor-1 (PAI-1). Abnormal levels of both t-PA and PAI-1 are epidemiologically associated with an increased risk for arterial thrombosis, but the degree to which absolute levels contribute to arterial thrombosis remains controversial. For this reason, the current clinical utility of t-PA and PAI-1 measurements is limited.

There is a correlation between higher PAI-1 levels and atherosclerotic disease, which is possibly due to the fact that PAI-1 is markedly increased in generalized inflammation and there is known thrombosis-inflammation interplay. This is especially prominent in patients with type 2 diabetes with acute myocardial infarction and stroke. Elevated PAI-1 levels systemically may prevent thrombi removal from vessels, whereas locally it contributes to increased fibrin deposition in the lumen of the vessels. Currently there are agents that indirectly decrease PAI-1 levels, including angiotensin-converting enzyme (ACE) inhibitors and diabetes medications (including thiazolidinediones and metformin). The first PAI-1 antagonist, tiplaxtinin, has been studied in experimental models and was found to decrease VTE and atherosclerosis, although the clinical trial was discontinued given unfavorable risk-benefit outcomes. Also, meta-analyses have demonstrated PAI-1 4G/5G polymorphisms represent a risk candidate locus for higher VTE risk, which is even further heightened in patients with genetic thrombophilic disorders.

Hyperhomocysteinemia in Arterial Disease

Increased levels of plasma homocysteine (HCY) are linked to atherothrombosis. The rare congenital syndromes (e.g., cystathionine β -synthase deficiency) that are characterized by homocystinuria and hyperhomocysteinemia are associated with both VTE and premature atherosclerosis. Elevated HCY induces EC dysfunction and apoptosis, triggering normal coagulation pathways designed to respond to EC damage but without the corresponding upregulation of EC-dependent anticoagulant function (e.g., activated protein C [APC]). Even moderate elevations in HCY may thus contribute to coronary, peripheral, and cerebral arterial disease. Mildly elevated HCY levels are associated with the thermolabile form of the methylene tetrahydrofolate reductase (MTHFR) enzyme, which results from a polymorphism (C677T) in the coding region of the MTHFR binding site. This isoform occurs in 30% to 40% of the general population and introduces a higher set point for regulation of HCY concentration (the substrate for MTHFR), particularly when a relative folate deficiency exists. In fact, deficiency of any of the vitamin cofactors of HCY metabolism (folate, vitamin B₆, and vitamin B₁₂) may lead to mild hyperhomocysteinemia.

Reduction in HCY levels by supplementation with vitamin B₆, vitamin B₁₂, and folate is probably the most effective means of reducing modest HCY elevations, but such supplementation and ultimately lower HCY levels does not decrease atherothrombotic risk, regardless of the cause of hyperhomocysteinemia or the presence of the MTHFR polymorphism. Therefore, the origin of the connection between high HCY and thrombosis remains incomplete, and the search for associated factors that link HCY and hypercoagulability continues.

Role of Platelets in Atherothrombosis

Although EC-associated abnormalities clearly influence hemostasis, platelet activation and adhesion are also critical to the development of atherothrombosis, especially in patients with acute coronary syndrome or ischemic stroke. Antiplatelet therapies are the primary modalities for maintaining short- and long-term patency in arteries, especially after coronary revascularization. Antiplatelet therapy can be targeted against specific platelet functions, including cyclooxygenase-mediated formation of thromboxane A₂, interaction of adenosine diphosphate (ADP) with its platelet receptor, and binding of the glycoprotein IIb/IIIa complex (GPIIb/IIIa) to fibrinogen for aggregation (Table 53.1).

Aspirin has long been a mainstay in the treatment of myocardial infarction, angina, and stroke because of its irreversible inhibition of platelet cyclooxygenase, a process that blocks the release of thromboxane A₂. Aspirin effectively prevents platelet aggregation over the lifetime of a platelet (7 to 10 days); however, aspirin is usually unable to inhibit platelet activation, secretion, and aggregation by thrombin or other strong agonists such as collagen. Therefore, blockade of other platelet activation pathways is important for patients who are at risk for arterial thrombosis.

Some drugs used to treat stroke or coronary disease (i.e., clopidogrel and prasugrel) specifically block platelet P2Y₁₂, the ADP receptor, from interaction with ADP in the clot milieu, thereby decreasing platelet recruitment by preventing locally released ADP from activating additional platelets.

The CHANCE Trial (2013) and POINT Trial (2018) have shown reduced 90-day stroke risk with the combination of ASA/clopidogrel compared with ASA alone, although results are conflicting between the trials about increased bleeding risk with dual antiplatelet therapy (DAPT). In symptomatic peripheral arterial disease (PAD), where there is poor flow in the extremities due to atherosclerotic plaque, there are benefits with using clopidogrel compared to aspirin (demonstrated by the CAPRIE Trial 1996) but no additional benefit to using both clopidogrel and aspirin together as compared to clopidogrel monotherapy (demonstrated by the MATCH Trial 2004).

Antiplatelet therapy with aspirin and a P2Y₁₂ inhibitor (clopidogrel, prasugrel, or ticagrelor) also reduces the risk of stent thrombosis and subsequent cardiovascular events after percutaneous coronary intervention and should be administered for at least 12 months unless

the patient is at high risk for bleeding. The PLATO Trial (2009) showed, in acute coronary syndrome, prasugrel and ticagrelor further reduce cardiovascular ischemic events compared with clopidogrel, although they are associated with higher bleeding risk. This effect occurs because drug interactions and variant cytochrome genotypes do not significantly affect production of the active metabolites of prasugrel and ticagrelor; the result is greater and more rapid inhibition of P2Y₁₂ receptor-mediated platelet aggregation in most patients. The EUCLID Trial showed that in PAD, there was no improvement with ticagrelor compared to clopidogrel in terms of cardiovascular death, myocardial infarction, or stroke.

Despite its wide use, a significant proportion (up to one third) of patients demonstrate functional platelet resistance to clopidogrel. Under such circumstances, clopidogrel is poorly metabolized to its active form because of the presence of polymorphisms in the cytochrome P-450 gene, *CYP2C19*, that cause loss of function. The more potent inhibitor, prasugrel, is not affected by cytochrome P-450 genotypes, although nongenetic factors such as platelet turnover, absorption, and compliance also play important roles in response variability.

A third avenue for blocking platelet activation targets GPIIb/IIIa, the primary platelet receptor for binding to fibrinogen and VWF. Abciximab, a modified monoclonal antibody, prevents GPIIb/IIIa from binding to fibrinogen and blocks platelet aggregation after angioplasty, stent placement, or pharmacologic thrombolysis. Abciximab has been shown to reduce the incidence of recurrent acute ischemic events after percutaneous coronary revascularization in patients with myocardial infarction or unstable angina, mainly by decreasing the incidence of platelet-mediated thrombosis within the infarct-related vessel during and after the procedure. Other GPIIb/IIIa blockers, including eptifibatid (Integrilin) and tirofiban (Aggrastat), interfere with the GPIIb/IIIa arginine-glycine-aspartate (RGD) binding sites; they are used acutely for parenteral administration in patients with acute coronary syndrome or to maintain coronary patency after percutaneous coronary intervention. Thrombocytopenia is an uncommon (<2%) complication of all the GPIIb/IIIa inhibitors; it is most likely related to exposure of neopeptides on the receptor and immune-mediated platelet destruction. Clearance of the drug typically resolves the thrombocytopenia within 1 week. Platelet transfusion should be considered only if there is significant thrombocytopenic bleeding because of the higher incidence of stent thrombosis after stent implantation with platelet transfusion.

Additional novel strategies for mediating platelet activity include inhibition of cyclic nucleotide phosphodiesterases (e.g., dipyridamole, cilostazol) and blockade of proteinase-activated receptor 1 (PAR-1). Phosphodiesterase inhibitors most likely have multiple mechanisms of action. They result in decreased signal transduction within platelets, which impairs their responsiveness. PAR-1 is one of two principal recognized targets for thrombin stimulation of platelets, the other being PAR-4. The potential benefit of adding phosphodiesterase or PAR-1 inhibitors to aspirin and/or clopidogrel (e.g., prevention of restenosis in atherothrombosis) is being evaluated. As shown in ESPS-2 (1996) and ESPRIT (2006), aspirin/dipyridamole outperformed aspirin alone in secondary prevention of ischemic strokes—current guidelines recommended either aspirin monotherapy or aspirin/dipyridamole as secondary prevention for ischemic stroke. Additionally, for recent stroke, there appears to be no difference in recurrence rates of ischemic stroke when comparing aspirin/dipyridamole to clopidogrel, as shown in the PROFESS Trial (2008). Currently, either of these options or aspirin monotherapy is recommended after noncardioembolic ischemic stroke; aspirin in combination with clopidogrel is not recommended given increased bleeding risk (POINT Trial 2018).

TABLE 53.2 Prevalence and Thrombotic Relative Risk Associations of Laboratory Findings^a

Prevalence in General Population	Venous RR	Arterial RR
Hyperhomocysteinemia (25%)	1-2	1.16
Activated protein C resistance (5%)		
Heterozygous FVL	7	1
Homozygous FVL	20-80	
Prothrombin G20210A mutation (1-2%)		
Heterozygous	2-5	1
Homozygous	>5	1
Platelet GPIIb/IIIa HPA-1b homozygosity (2-3%)		4 (MI in men)
Protein C deficiency (0.2-0.5%)	7	1
Protein S deficiency (0.1%)	8.5	1
AT deficiency (0.02-0.05%)	8	1
Dysfibrinogenemia (rare)	≈1	1.5

AT, Antithrombin; FVL, factor V Leiden; GPIIb/IIIa, glycoprotein IIb/IIIa complex; HPA-1b, human platelet antigen-1b; MI, myocardial infarction; RR, relative risk.

^aData on prevalence and relative risk vary widely, often with conflicting results. This information represents an interpretation of data collected from various sources, mainly meta-analyses.

When using platelet inhibitors, physicians and patients must also consider the risk of bleeding if they are on anticoagulation therapy. RE-DUAL (2017) and WOEST (2013) concluded that in patients on anticoagulation prior to percutaneous coronary intervention (PCI) it is recommended to use additionally only clopidogrel rather than ASA/clopidogrel after PCI given the increased bleeding risk with triple therapy.

Venous Thromboembolism: Inherited Risk Factors

The balance between thrombin formation and anticoagulant pathways has been extensively studied in patients with inherited deficiencies of naturally occurring anticoagulants (Table 53.2). These patients are predisposed to VTE, which includes deep vein thrombosis (DVT) and pulmonary embolism (PE).

Factor V Leiden

The most common inherited disorder leading to VTE is the factor V Leiden (FVL) mutation although it remains a fairly weak risk factor for VTE overall. About 5% of individuals of European ancestry are heterozygous for FVL. The FVL mutation increases VTE risk by decreasing the susceptibility of factor Va to APC-mediated inactivation and by impairing the APC-cofactor activity of factor V in factor VIIIa inactivation, all of which lead to increased thrombin generation. APC resistance can be demonstrated by specialized clotting tests in which the addition of APC fails to inhibit thrombin generation. About one fourth of patients with their first VTE are heterozygous for FVL, and this percentage increases to almost 60% among those with recurrent VTE or a strong family history of VTE.

Heterozygous FVL mutation conveys a 7-fold increased risk for VTE. However, at 50 years of age, only 25% of persons with heterozygous FVL mutation have had VTE, compared with much higher percentages in other inherited thrombophilias. It is with concomitant *acquired* risk factors such as immobilization, pregnancy, or oral contraceptive use that the risk for VTE in persons with FVL mutation becomes more significant. The prothrombin G20210A mutation demonstrates a synergistic effect with FVL mutation, but the MTHFR

mutation does not. Homozygous FVL mutation individuals have a 20- to 80-fold increased risk for VTE. APC resistance *without* the FVL mutation occurs rarely. Factor V Cambridge mutation, although much less common than FVL mutation, has a similar mutation at an APC cleavage site (Arg306) and is associated with APC resistance and thrombosis. Other minor alleles of factor V, including the 6755 A/G (D2194G) R2 haplotype, may enhance APC resistance. When this haplotype is on a different chromosome than the FVL mutation, it diminishes normal factor V transcription and increases the ratio of FVL to normal factor V.

Prothrombin G20210A

Another mutation associated with inherited thrombophilia is the prothrombin G20210A mutation, which occurs in the 3'-untranslated region of the prothrombin gene. This mutation leads to higher than normal prothrombin levels and a 2-fold increased risk for VTE. The heterozygous mutation is present in about 3% of European-derived populations but is identified in about 15% of patients with VTE. Patients homozygous for prothrombin G20210A are rare, but their relative risk for VTE is thought to be about 10-fold. Exactly how the prothrombin mutation affects thrombus development has not been fully defined, but changes in polyadenylation of the prothrombin messenger RNA (mRNA) during transcription appear to be involved. The distribution of circulating prothrombin levels overlaps significantly between those with and without the mutation, so Factor II levels are not helpful in diagnosing the condition. Diagnosis of the G20210A genotype is made by examination of the patient's DNA for this specific mutation; no screening or functional assays are available.

Inherited Deficiency of Natural Anticoagulants

Deficiencies in the natural anticoagulant proteins (antithrombin, protein C, and protein S) are less common than FVL or prothrombin G20210A, but they are more likely to produce symptomatic VTE at an earlier age. Only about one half of the cases of VTE occurring in patients with these deficiencies are associated with acquired risk factors such as pregnancy, surgery, or immobilization. Deficiencies of antithrombin, protein C, or protein S are detected by functional or antigenic assays because some mutations cause a quantitative decrease in the factor, whereas others produce a dysfunctional protein. Many gene mutations have been associated with these deficiencies, but none is predominant. Deficiencies of antithrombin (AT), protein C, and protein S in the aggregate account for fewer than 5% to 10% of all patients with VTE.

Antithrombin is a naturally occurring anticoagulant that complexes with endogenous heparin sulfates to inhibit both formed thrombin and factor Xa. Heterozygous antithrombin deficiency leads to antithrombin activity levels less than 70% of normal and a 20-fold increase in the risk for VTE; VTE usually occurs by the age of 25 years in 50% of such patients. More than 200 associated mutations are known. Homozygous mutations are very rare, likely because of lethality *in utero*.

Acquired causes of antithrombin deficiency are more common. Because antithrombin has a low molecular weight, it is lost in the proteinuria of nephrotic syndrome. Acquired antithrombin deficiency is common in patients receiving asparaginase therapy for acute lymphocytic leukemia and may also be associated with severe hepatic veno-occlusive disease after stem cell transplantation; antithrombin and protein C may be excessively consumed in the damaged hepatic microvasculature. Low levels of antithrombin are also associated with poorer outcomes in severely ill patients. Successful treatment of symptomatic patients with heterozygous antithrombin deficiency has included short-term replacement with fresh-frozen plasma or recombinant AT protein, usually coupled with unfractionated heparin (UFH) anticoagulation; long-term therapy for congenitally deficient

patients has consisted primarily of warfarin although the direct oral anticoagulants have become increasingly popular due to their lack of requiring functional antithrombin activity in order to cause an anticoagulant effect.

The complex of thrombin and thrombomodulin on the EC surface activates protein C; APC coupled with its cofactor, protein S, cleaves and inactivates factors Va and VIIIa. These actions downregulate the prothrombinase and tenase complexes, respectively, to slow the rate of thrombin generation. Like antithrombin deficiency, heterozygous protein C and protein S deficiencies are observed with venous, and occasionally arterial, thrombosis in younger patients (median age at occurrence, 20 to 40 years).

The rare homozygous protein C deficiency manifests in the neonate as *purpura fulminans* with widespread VTE and skin necrosis. A similar clinical presentation has been reported in heterozygous protein C–deficient adults after institution of warfarin therapy without simultaneous heparinization; this is called *warfarin-induced skin necrosis*. About one third of these patients are deficient in protein C on a hereditary basis, whereas the rest appear to have acquired protein C deficiency, possibly associated with vitamin K deficiency. Warfarin is a vitamin K antagonist that inhibits production of vitamin K–dependent protein C synthesis; and because of its short half-life, protein C levels rapidly fall before a decline in the levels of the procoagulant factors II, IX, and X. This imbalance shortly after starting warfarin favors a procoagulant state and may result in widespread microvascular thrombosis. Therefore, patients with active VTE should be fully anticoagulated with UFH or low-molecular-weight heparin (LMWH) before concurrent warfarin therapy is begun. UFH/LMWH should be continued for at least 48 hours, warfarin has a full therapeutic effect.

Inherited deficiency of protein S has similarly been implicated in warfarin-induced skin necrosis. Protein S deficiency is commonly acquired in acute illness. Protein S circulates in a free form and is bound by complement 4b (C4b)-binding protein; only free protein S is active as a cofactor for protein C. Because C4b-binding protein is an acute phase reactant, its increase with severe illness can decrease the level of free protein S. A similar effect is seen in normal pregnancy.

Short-term therapy for homozygous protein C deficiency or for doubly heterozygous protein C or S deficiency, especially in the setting of neonatal purpura fulminans, has included plasma or protein C concentrate with full-dose UFH anticoagulation. Functional and antigenic levels of antithrombin, protein S, and protein C can be assessed to define whether functional deficiency is caused by a dysfunctional protein or by diminished synthesis. As with AT deficiency, initial heparin therapy followed by long-term treatment with warfarin has been successful in heterozygous protein C or S deficiency. As expected, both protein C and protein S levels are decreased during warfarin therapy; therefore, for adequate evaluation of protein C and S, the patient must not be taking warfarin when tested.

Venous Thrombosis: Acquired Risk Factors

Surgery and Medical Hospitalization

Medical and surgical illnesses convey increased thrombotic risk; these *acquired* risk factors are well accepted, even though the pathophysiologic features favoring thrombosis may be uncertain (Table 53.3). Stasis of blood flow is a clear risk factor for thrombus formation (e.g., VTE in immobilized inpatients). Other high-risk situations, including surgery (especially orthopedic) and trauma, are similarly associated with immobilization and stasis of lower extremity blood flow. When evidence of thrombosis is thoroughly sought, both surgery and trauma can be shown to be associated with extremely high (>50%) incidences

TABLE 53.3 Acquired Risk Factors for Thrombosis

Medical and Surgical Illnesses

Antiphospholipid antibody, lupus anticoagulant
 Artificial heart valves
 Atrial fibrillation (nonvalvular)
 Congestive heart failure

 Malignancy
 Myeloproliferative disorders with thrombocytosis
 Nephrotic syndrome
 Orthopedic procedures
 Pregnancy
 Trauma, fat embolism

Medications

Heparin-induced thrombocytopenia
 Oral contraceptives, hormone replacement therapy
 Prothrombin complex concentrates

of VTE. Fat embolism and tissue damage may also contribute to the risk for VTE with surgery and trauma, particularly in closed head injuries that result in massive tissue factor release. Prophylactic inferior vena cava (IVC) filters are often placed in trauma patients to protect against PE, especially in high-risk patients for whom anticoagulation is contraindicated because of the increased risk for bleeding, but there remains a high risk for thrombus formation proximal to the filter with subsequent pulmonary embolism. IVC filters should be removed as soon as patients may be safely anticoagulated.

All hospitalized medical patients should be considered for venous thromboprophylaxis with UFH or LMWH. Factors that increase bleeding risk that argue against anticoagulation include thrombocytopenia (typically a platelet count <50,000), coagulopathy (with or without liver disease), and recent hemorrhage. Risk factors that warrant aggressive prophylaxis include malignancy, prior VTE, immobilization, and thrombophilic conditions.

Pregnancy and Fetal Loss

Pregnancy is a hypercoagulable state associated with venous stasis; the risk for VTE during pregnancy and in the postpartum period for women with identified thrombophilia is about 5-fold higher than it is for nonpregnant women. Pregnancy increases procoagulant proteins, including fibrinogen, VWF, and factors VII, VIII, and X, and decreases natural anticoagulants such as protein S and antithrombin as well as fibrinolytic inhibitors such as PAI-1 and thrombin activator fibrinolysis inhibitor (TAFI). VTE can occur at any time during pregnancy or the puerperium. The risk of postpartum VTE is significantly higher in women with any of the following conditions: stillbirth, pre-term delivery, obstetric hemorrhage, caesarean procedure, medical comorbidities, or a pre-pregnancy body mass index greater than 30 kg/m².

Inherited maternal thrombophilia can compound the procoagulant state of pregnancy and predispose to both fetal loss and VTE in the mother. The principal inherited associated risk factors for fetal loss are FVL mutation, the G20210A prothrombin mutation, antithrombin deficiency, and protein C or protein S deficiency. The relative risk for fetal loss is markedly higher in those mothers with a history of prior

VTE, although this particular risk appears to be restricted to the period after 9 weeks' gestation. In fact, inherited thrombophilia may be protective against fetal loss during the first 9 weeks, possibly by limiting oxygen toxicity to the early embryo. Therefore, recommended indications for evaluating the inherited thrombophilia risk in women seeking to become pregnant are a history of VTE or recurrent fetal loss after 9 weeks of gestation when no other specific cause (e.g., antiphospholipid syndrome) can be identified. Both antithrombin deficiency and hyperhomocysteinemia have also been associated with placental abruption.

In the absence of an identified inherited thrombophilia or a diagnosis of antiphospholipid syndrome (discussed later), no role has been identified for prophylactic anticoagulant therapy with recurrent pregnancy loss although prophylactic aspirin is increasingly used in many women with high-risk pregnancy.

Oral Contraceptives and Hormone Replacement

Estrogen-containing oral contraceptive use conveys an increased risk for VTE, and a similar increased risk is seen early after institution of hormone replacement therapy in postmenopausal women. Concomitant heterozygosity for FVL mutation synergistically increases the risk for VTE in women who take estrogen-based oral contraceptives or hormone replacement therapy. Cigarette use in women using oral contraceptives also increases the risk of thrombosis, possibly through increased platelet reactivity mediated by increased thromboxane synthesis. On the arterial side, epidemiologic evidence clearly points to smoking as the main cardiovascular risk factor. Paradoxically, most data suggest a protective role for hormone replacement therapy in cardiovascular disease. As discussed previously, acquired APC resistance and decreases in the levels of both free and functional protein S occur with oral contraceptive use.

VTE in Malignancy

VTE is the second leading cause of death in malignancy. VTE occurs in a wide spectrum of malignancies, including mucin-producing malignancies (i.e., pancreatic, gastric, ovarian), gastrointestinal, lung, breast, lymphoma, and more. Interestingly, the part of the Virchow triad that is most affected can vary; for example, adenocarcinoma is known to increase hypercoagulability, whereas lymphoma can lead to VTE through compression of blood vessels and thus blood flow stasis.

When idiopathic VTE occurs in a cancer-free individual, an intensive work-up to find an occult malignancy is not necessarily warranted and has not been shown to improve subsequent cancer-related morbidity or mortality, as shown in the SOME Trial (2015). However, once a cancer diagnosis is established in patients with prior VTE, they are at increased risk for subsequent VTE events, especially if the FVL or G20210A prothrombin mutation is present. LMWH prophylaxis after malignancy-associated VTE achieves superior prevention compared to warfarin, possibly because of better maintenance of an anticoagulated state. Direct oral anticoagulants (DOACs) are being increasingly used given numerous recent clinical trials (see section "Therapy for VTE in Malignancy").

In the special case of myeloproliferative disorders (e.g., essential thrombocythemia), abnormal platelet physiologic mechanisms causing hyperaggregation are often present and require platelet-specific inhibition (see "Hypercoagulability and Platelet Disorders").

Other Prothrombotic Disease States

As described earlier, thrombosis in nephrotic syndrome is associated with loss of antithrombin through the kidneys. Hemolysis is a general prothrombotic state that appears to be mediated through blood cell destruction, perhaps through increased exposure to procoagulant membrane phospholipids; hemolysis with thromboembolic

complications has been observed in patients who have artificial heart valves, sickle cell disease, and other hemolytic anemias, including Coombs-positive autoimmune hemolytic anemia. In the case of paroxysmal nocturnal hemoglobinuria (PNH), complement activation may directly mediate platelet activation, and therapy with the complement inhibitor eculizumab has significantly decreased the rate of thromboembolic disease in PNH.

Platelet activation and clearance appear to be the primary prothrombotic manifestations of heparin-induced thrombocytopenia (HIT) and thrombotic thrombocytopenic purpura (TTP).

Additionally, chronic disseminated intravascular coagulation (DIC) is classically associated with certain malignancies such as mucinous adenocarcinoma and promyelocytic leukemia. In that setting, known as Trousseau syndrome, there is an increased risk in malignancy for VTE that is not related to DIC.

Antiphospholipid Antibody Syndrome

Another acquired prothrombotic disorder is the antiphospholipid antibody syndrome (APS). APS is a primary disorder, unlike the occasional association of lupus anticoagulant or antiphospholipid antibodies with other autoimmune diseases such as systemic lupus erythematosus (SLE). The etiologic connection with SLE has not been fully defined, but replacement of the host immune system after hematopoietic stem cell transplantation for refractory SLE has the potential to eradicate the lupus anticoagulant and thromboembolic risk. All of the manifestations of APS are related to hypercoagulability, including recurrent venous or arterial thrombosis, thrombocytopenia caused by microcirculatory platelet clearance, and recurrent fetal loss resulting from placental vascular insufficiency. Serologic markers of APS include *anticardiolipin antibodies*, *anti- β_2 -glycoprotein I antibodies*, and *lupus anticoagulants*. The Sydney Consensus Criteria for Antiphospholipid Syndrome (also known as the revised Sapporo criteria) are the current standard for diagnosis of APS. Diagnosis requires both the clinical criterion of radiologically or pathologically confirmed thrombosis or thrombosis-related fetal loss and the laboratory criterion of positive tests on two or more occasions at least 12 weeks apart. Anticardiolipin and anti-glycoprotein antibodies are detected by enzyme-linked immunosorbent assay (ELISA), whereas lupus anticoagulants are defined by correction of prolonged phospholipid-dependent clotting tests (most commonly hexagonal phase partial thromboplastin time [PTT] or Russell viper venom clotting time), with addition of excess phospholipid. Therefore, *lupus anticoagulant* is a misnomer; its presence predisposes the patient to clotting rather than to bleeding, and the risk for thrombosis is highest when a lupus anticoagulant is detectable. Another misleading aspect of this nomenclature is that phospholipid-reactive antibodies are actually directed against phospholipid-binding proteins in plasma (e.g., β_2 -glycoprotein I antibody, annexin V, prothrombin). Anti- β_2 -glycoprotein I antibody is detected by immunoassay, and high titers of this marker are also correlated with thromboembolic risk.

In patients with recurrent pregnancy loss in the context of APS, LMWH during pregnancy can help reduce further miscarriages.

Hypercoagulability and Platelet Disorders

Essential thrombocythemia and polycythemia vera are clonal myeloproliferative disorders commonly associated with somatic mutations in the *JAK2* gene. In essential thrombocythemia, mutations are also found in *CALR* and *MPL* in those negative for *JAK2* mutations. They are wholly (essential thrombocythemia) or partially (polycythemia vera) characterized by thrombocytosis, and patients with these disorders are at increased risk for thrombosis. Platelet aggregometry in these disorders often shows abnormal

responses, especially to epinephrine and ADP; however, the abnormal aggregation does not correspond to either bleeding or thrombosis risk. Patients with polycythemia vera in particular have a high incidence of thrombosis in the mesenteric, portal, and hepatic venous circulation.

Thrombotic complications, both arterial and venous, occur in essential thrombocythemia, even in young patients. The risk of arterial thrombosis in essential thrombocythemia (and probably also in primary myelofibrosis and polycythemia vera) is most increased by a history of previous thrombosis or the presence of the *JAK2* V617F mutation. Therefore, prophylaxis with low-dose aspirin is probably justified in patients with high-risk essential thrombocythemia and other myeloproliferative disorders.

Increased platelet turnover in thrombocytosis is also associated with thromboembolic complications, but this does not necessarily involve high platelet counts, as has been demonstrated by radioactive platelet survival studies and an increase in reticulated (young) platelets in thrombotic essential thrombocytopenia. Moreover, successful treatment of symptomatic patients with aspirin increases platelet survival by decreasing platelet clearance. Concomitant therapy to prevent thrombotic complications of thrombocytosis includes lowering the platelet count with hydroxyurea, pegylated alpha interferon or anagrelide. Evidence suggests that patients with essential thrombocythemia who are at high risk for thrombosis (prior thrombosis or over age 60) are most effectively treated with the combination of hydroxyurea and low-dose aspirin. Patients with reactive (secondary) thrombocytosis resulting from iron deficiency anemia, chronic infection, or rheumatoid arthritis do not generally have increased thrombotic risk and do not require aspirin prophylaxis.

Heparin-Induced Thrombocytopenia

HIT must be distinguished from other drug-induced forms of immune thrombocytopenia because of its potentially catastrophic *thrombotic* complications and its unique pathophysiologic features. Almost 25% of patients who are exposed to UFH develop antibodies (detected by ELISA) that recognize the complex of heparin and platelet factor 4 (PF4), the latter being released from activated platelets, although most will not develop the clinical syndrome of HIT. When such patients receive heparin again, between 5% and 10% develop HIT, most with platelet counts between 50,000 and 100,000/ μ L. HIT rarely occurs in patients who have not been previously exposed to heparin (0.3% incidence).

Surgery is a specific risk factor for HIT; the incidence of HIT in surgical patients is about 2.6%, compared with 1.7% in medical patients. HIT antibodies occur with high frequency in patients undergoing either cardiac surgery with cardiopulmonary bypass or an orthopedic procedure such as hip replacement. The incidence of HIT in patients who have received only LMWH is far lower, only about one tenth the rate seen with UFH. However, the mechanism of thrombocytopenia for both UFH and LMWH appears to be similar: Platelet Fc-receptor binding of the heparin-PF4 antibody complex causes signal transduction and platelet activation with enhanced thrombin generation on the platelet surface.

The diagnosis is predominantly clinical (e.g., using the 4Ts algorithm for scoring HIT—magnitude of thrombocytopenia, timing of platelet fall, thrombotic sequelae, and ruling out other causes of thrombocytopenia), but the rapid ELISA test will detect heparin-PF4 antibodies in serum. The main drawback of ELISA is that it does not indicate whether the antibody complex is a functional activator of platelets; therefore, it is sensitive but not specific for HIT. The serotonin release assay is the functional test for HIT; it

detects platelet activation after exposure to serum antibody in the presence of a therapeutic heparin level. However, a low probability for HIT based on the 4Ts score can be used to exclude the HIT diagnosis.

The thrombin-based procoagulant response in HIT incorporates platelets into microcirculatory clots, leading to thrombocytopenia; about 30% of HIT patients have overt thromboembolic complications, which can be severe or life-threatening. Thromboembolic events can occur before, concurrent with, and after development of thrombocytopenia in HIT, with about equal frequency. Although thrombosis is more frequent in patients with both HIT and concomitant cardiovascular disease and in those receiving full-dose heparin, any heparin dose (even intravenous catheter heparin flushes) can result in thrombosis in HIT. Arterial and venous thromboembolic disease can occur even weeks after heparin has been discontinued, an effect perhaps mediated by EC glycosaminoglycan binding to PF4, which serves as a target for circulating HIT antibodies.

Discontinuation of all heparin is critical; moreover, although the antibody may have been induced by treatment with UFH, more than 80% of these antibodies cross-react with LMWH. Therefore, the preferred therapy for short-term anticoagulation in patients with HIT is a direct thrombin inhibitor (DTI), such as argatroban or bivalirudin, which is not a target for the heparin-PF4 antibodies. Indeed, because the event rate for subsequent thrombosis, limb amputation, and death is increased in patients with HIT even if they do not have thrombosis at presentation, DTI therapy is mandated after discontinuation of heparin. The choice of DTI may be dictated by other clinical conditions; for example, renal insufficiency slows bivalirudin clearance, increasing bleeding risk, whereas argatroban is cleared by hepatic metabolism. For patients who develop HIT after warfarin has already been started, in addition to substituting a DTI, one should administer vitamin K to correct protein C levels. Although it has not been approved by the US Food and Drug Administration (FDA) for this clinical scenario, the synthetic pentasaccharide indirect Xa inhibitor fondaparinux has the advantages of once-daily subcutaneous administration without need for laboratory monitoring and of having no effect on the International Normalized Ratio (INR). DOACs are also an attractive option for treatment with clinical trials ongoing to determine safety and efficacy.

DTI therapy should be continued until the platelet count is higher than 100,000 to 150,000/ μ L. Warfarin can then be added, and the two therapies should overlap for at least 5 days with the INR at a therapeutic level for at least 48 hours. Because DTIs prolong the INR, a therapeutic warfarin level after 5 days may result in a supratherapeutic INR (usually >4); gradual downward titration of the DTI as the INR increases is a logical management strategy. Once DTIs are stopped, it is essential to repeat the INR measurement after 4 to 6 hours to confirm that it remains within the therapeutic range.

If there is no thrombosis with HIT, the total duration of anticoagulation should be at least 4 weeks; if thrombosis is present, anticoagulation should be continued for 3 to 6 months. Warfarin should never be used as initial therapy to treat HIT, and it should not later be instituted without simultaneous DTI coverage because it may induce acquired protein C deficiency leading to venous limb gangrene. One hallmark of protein C depletion in HIT is a sudden rise in the INR (to >3.5) after a single warfarin dose; in that circumstance, warfarin should be discontinued and the patient repleted with vitamin K. Patients with a history of HIT who need surgery requiring cardiopulmonary bypass can be safely reexposed to brief systemic UFH if ELISA testing is negative for the antibody at least 100 days after the previous UFH exposure.

Thrombotic Thrombocytopenic Purpura

Another cause of thrombocytopenia resulting from platelet activation and clearance is TTP. In patients with congenital or familial TTP, mutations in the VWF-cleaving protease, ADAMTS13 (*a disintegrin and metalloproteinase with thrombospondin type 1 motif, member 13*), abrogate its activity. Patients with acquired TTP usually have an antibody that blocks the normal function of VWF-cleaving protease to less than 10% of normal. Ultralarge VWF multimers released by EC normally anchor to EC through P-selectin and form long strings that adhere and aggregate platelets in the microcirculation. ADAMTS13 downregulates the size of these multimers by docking to the A1/A3 VWF domains and cleaving within the A2 site. Deficient cleaving protease function in TTP leads to an increase in the larger, highest-molecular-weight VWF multimers, which are most effective in anchoring and activating platelets. These, in turn, cause increased platelet adhesion and clearance *without* activating the coagulation cascade. Therefore, both the prothrombin time (PT) and the PTT are normal in TTP, unlike the case in DIC.

TTP after chemotherapy (mitomycin C) or in association with pregnancy, stem cell transplantation, lupus, or HIV infection appears to have a similar pathogenic mechanism of thrombosis. Thrombocytopenia (often severe) is accompanied by microangiopathy with schistocytes on smear and increased serum lactate dehydrogenase. Microvascular occlusions in multiple organs cause symptoms, especially in the kidney and brain. The classic pentad (fever, thrombocytopenia, microangiopathic hemolysis, neurologic symptoms, and renal insufficiency) is present in fewer than 5% of patients with TTP. The diagnosis is typically made based on the clinical assessment of thrombocytopenia and microangiopathic hemolytic anemia; assays for ADAMTS13 activity and inhibitor do not have a rapid turnaround time in most laboratories. Clinical prediction scores (e.g., the PLAMIC score) are helpful as an additional piece of clinical information in the decision to initiate treatment for TTP but cannot be used on their own to exclude TTP. In validation studies, some patients ultimately found to have an ADAMTS13 activity level, less than 10% were noted to have low PLAMIC scores.

Treatment of familial TTP is based on replenishment of cleaving protease activity with plasma transfusion; acquired TTP additionally requires removal of the antibody. The latter is accomplished by therapeutic plasma exchange, whereby patient plasma is removed (plasmapheresis) and replaced with fresh-frozen plasma, which often has been made “cryo-poor” to reduce ultralarge VWF multimers in transfused plasma. Corticosteroids are often administered simultaneously, but any added benefit to plasma exchange remains unclear. Platelet transfusions are relatively contraindicated in TTP because of the risk of thrombosis, and they should not be given for thrombocytopenia in the absence of significant bleeding. When plasma exchange fails to remit acquired TTP or when early relapse occurs, immunosuppressive therapy with anti-CD20 may be successful and data suggest that early rituximab will reduce the risk of relapse. The mortality rate associated with severe TTP (defined as undetectable ADAMTS-13 activity) is still significant, almost 10% at 18 months after therapy with plasma exchange. Replacement of ADAMTS-13, which is present in fresh-frozen plasma and in cryoprecipitate, is a potential treatment. Clinical trials have shown the anti-VWF therapy caplacizumab to have benefit in reducing the number of days of plasma exchange needed to achieve a normal platelet count and also reductions in mortality, although with increasing bleeding risk. The ideal subset of patients to receive caplacizumab in conjunction with other therapies for TTP remains to be defined. Caplacizumab does not address the underlying autoantibody causing ADAMTS13

deficiency and use of rituximab for inhibitor eradication is most likely to be beneficial in patients receiving caplacizumab therapy.

The *hemolytic-uremic syndrome* (HUS) is part of the TTP spectrum of disease and also is associated with microvascular platelet thrombi. However, the hemolytic anemia and renal failure of HUS are not usually accompanied by neurologic impairment, and HUS usually does not produce the same degree of thrombocytopenia or microangiopathy as TTP. Moreover, fewer than 3% of HUS cases are associated with any decrease in VWF-cleaving protease activity. Unlike TTP, HUS is usually diagnosed in children (and less commonly in adults) who have hemorrhagic colitis caused by Shiga-like, toxin-producing bacteria, especially the *Escherichia coli* O157:H7 serotype. Atypical HUS (i.e., without diarrhea or Shiga-like toxin) is rarely associated with other bacterial infections or with complement dysregulation due to mutations or polymorphisms in factors H, I, and B. These mutations increase platelet activation through complement (C3) deposition on the platelet surface. Atypical HUS cases are those that are clinically consistent with HUS but are not associated with toxin-producing bacteria. Some HUS cases, particularly atypical forms, may temporarily respond to plasma exchange along with maintenance hemodialysis until renal function recovers. Data support use of the anti-C5a complement therapy eculizumab to prevent the complement-mediated damage associated with this disease. More recently, a modified form of eculizumab with a longer half-life, ravulizumab, has been approved to treat atypical HUS, allowing patients longer intervals between therapeutic infusions.

CLINICAL EVALUATION OF THROMBOSIS

The approach to patients with thromboembolism is defined by the clinical history, results of laboratory studies, and even physical findings. Events that trigger VTE disease include immobilization, orthopedic and other surgical procedures, use of oral contraceptives, and pregnancy. VTE that is recurrent (thrombophilia) may manifest at an early age or at unusual thrombotic sites (e.g., cerebral vessels) and may be accompanied by a family history of VTE, suggesting an inherited disorder. Acquired VTE risk may be associated with systemic disorders such as hemolysis (e.g., PNH, autoimmune hemolytic anemia), collagen vascular disorders (e.g., lupus), or various malignant diseases (e.g., adenocarcinoma). In contrast, arterial thromboembolic disease is more commonly superimposed on ruptured atherosclerotic plaque (e.g., coronary artery disease) or on atheroembolic disorders (e.g., ischemic stroke, peripheral arterial disease). Arterial vascular disease is mainly associated with metabolic risk factors including hypertension, hypercholesterolemia, and diabetes. The clinical approach to thrombotic disease is tailored to the location of the disease (arterial vs. venous and the specific vascular bed) and whether there are abnormalities of the vascular endothelium, platelets, or soluble coagulation factors that predispose the patient to thromboembolic risk.

Laboratory Diagnostics

Recurrent VTE is a strong indication for laboratory testing for causes of thrombophilia, especially in patients younger than 50 years of age, in those with unexplained VTE, and in those with a first-degree family history of VTE. Any risk factors that may predispose these individuals to recurrence must be defined, as well as any inherited disorders that may necessitate family counseling or avoidance of additional environmental risks. The current work-up for VTE thrombophilia includes the following: (1) APC resistance, (2) genotyping for prothrombin G20210A, (3) lupus anticoagulant assay and anticardiolipin and anti- β_2 -glycoprotein I antibody serologies, (4) functional AT and protein C levels, and (5) free protein S (Table 53.4).

TABLE 53.4 Laboratory Evaluation of Venous Thrombosis

Activated protein C resistance, factor V Leiden
Lupus anticoagulant
Anticardiolipin, anti- β_2 -glycoprotein I antibody serology
Homocysteine level: fasting or after methionine load
Prothrombin G20210A mutation
Antithrombin activity
Protein C activity
Free protein S level
Paroxysmal nocturnal hemoglobinuria (select patients)
Myeloproliferative disorders (in select patients)

Genotyping for the FVL mutation can substitute for APC resistance and also determines whether the patient is heterozygous or homozygous, although it may miss rare variants of APC resistance. Patients need to be off of warfarin during these tests and they should not be performed during the acute episode, given the changes in protein levels during these instances.

The utility of laboratory testing in the setting of atherothrombosis and arterial thromboembolism is unclear. In the setting of a myeloproliferative disorder, the use of hydroxyurea and/or aspirin therapy may be justified by platelet count and platelet function testing, but typically risk prediction models based on age and prior thrombosis are used to guide management decisions. In patients with unusual or recurrent arterial disease, other assays can be justified, including testing for t-PA and PAI-1 levels and for dysfibrinogenemia (thrombin time and antigen activity ratio), all of which should be performed in consultation with specialists in hemostasis.

THErapy FOR VENOUS THROMBOEMBOLISM

Once VTE has been diagnosed, immediate therapy is required. In most patients, anticoagulation options include heparin, LMWH, or the newer direct oral anticoagulants (DOACs) (i.e., apixaban, rivaroxaban) initially and then warfarin or DOACs thereafter. The DOACs edoxaban and dabigatran require initial parenteral anticoagulation prior to use of the DOAC, but apixaban and rivaroxaban may be started as initial therapy with higher doses. Thrombolytic therapy is indicated for patients with extensive proximal venous clots or PE. IVC filters are used in patients with contraindications to anticoagulation, complications of anticoagulation (usually active bleeding), or failure of anticoagulation (recurrent PE). IVC filters clearly decrease the incidence of early PE, but their use is also associated with thrombosis at the insertion site and late complications of IVC thrombosis as well as a 10% to 20% incidence of postphlebotic syndrome. In patients who may be safely anticoagulated, IVC filters do not reduce the risk of pulmonary embolism and appear to be associated with a higher risk of PE. Temporary IVC filters are often used in trauma patients and appear to be most efficacious when they are placed for fewer than 7 to 10 days.

UFH is often the anticoagulation therapy of choice for many inpatients because of its short half-life and reversibility, but LMWH is increasingly used for this indication. UFH is begun as a bolus intravenous infusion of 80 U/kg, followed by a continuous infusion of 18 U/kg/hour; UFH doses in excess of 30,000 U/day have been shown to be most efficacious at preventing recurrent VTE. UFH is monitored by the PTT, and the therapeutic PTT range determined by each hospital corresponds to anti-Xa levels of 0.3 to 0.7 U/mL. Many hospitals have established protocols for adjustment of UFH infusion based on the patient's weight and PTT monitoring.

UFH should be continued for at least 5 days (longer in patients with extensive clots) and may be discontinued after the patient has been fully anticoagulated with warfarin (INR ≥ 2 for 2 consecutive days). Some patients receiving large doses of heparin (usually $>40,000$ U/day) do not develop a therapeutic PTT. This heparin resistance can be caused by a variety of mechanisms, including increased heparin-binding proteins, counteracting medications (e.g., protamine), and decreased antithrombin. An *apparent* heparin resistance is often seen in patients with coexistent inflammatory disease with high plasma levels of factor VIII and fibrinogen; direct monitoring of anti-Xa levels is indicated. It is important to remember that the anti-Xa level is a measurement of anticoagulant level in the blood but is not a direct measure of the anticoagulant effect present. Some patients may require a higher anti-Xa level in order to achieve therapeutic anticoagulation.

LMWH is an excellent alternative to UFH in the treatment of thromboembolism and acute coronary events. The small controlled-size elements of LMWH stimulate antithrombin activity that is more restricted to factor Xa compared with UFH, which has effects on thrombin, factor IX, and factor XI, in addition to others. The practical advantages of LMWH over UFH include increased plasma half-life, more predictable dose response allowing for intermittent fixed dosing, a lower *de novo* incidence of HIT (10% to 20% of the rate for UFH), and significantly reduced monitoring requirements. LMWH levels are prolonged in renal failure and in those circumstances may need to be monitored and adjusted based on anti-Xa levels. Peak anti-Xa levels (0.5 to 1 U/mL for twice-daily dosing and 1 to 2 U/mL for once-daily dosing) typically occur between 3 and 5 hours after subcutaneous LMWH injection. As with UFH, switching from LMWH to warfarin for long-term management can be accomplished after therapeutic INR values have been present for at least 2 days.

Supratherapeutic INR levels commonly occur with warfarin therapy, with or without bleeding. In patients with moderately elevated INR values (>5) and little or no bleeding, temporary discontinuation of warfarin and reinstitution of the drug at a lower maintenance dose may be sufficient. Patients with higher INR values (5 to 9) who are without serious bleeding should have warfarin withheld and should receive low doses (1 to 2.5 mg/day) of oral vitamin K to reach therapeutic INR levels; parenteral vitamin K may be given if gastrointestinal function is problematic. If serious active bleeding occurs with high INR values, especially if surgery is required to correct the bleeding, a combination of vitamin K and transfusion of plasma (see [Chapter 52](#)) will rapidly correct the INR. The INR can become elevated as a result of concurrent use of drugs that increase free warfarin levels ([Table 53.5](#)). Whenever bleeding occurs as a complication of anticoagulation, serious consideration must be given to future bleeding risks and to whether the patient requires placement of a filter for prophylaxis.

Recently, DOACs have been used with increased frequency because their efficacy and safety have now been evaluated in many circumstances. For patients with acute DVT, the initial anticoagulation (within the first week or two) options include: oral factor Xa inhibitors rivaroxaban or apixaban (in addition to the previously mentioned LMWH, subcutaneous fondaparinux, or unfractionated heparin). The decision of which agent to use is based on risk of bleeding, clinician comfort, patient comorbidities, and cost. The doses are: rivaroxaban 15 mg twice daily for 21 days then 20 mg daily; apixaban 10 mg twice daily for 7 days then 5 mg twice daily. For long-term, maintenance therapy, the DOACs approved are: direct factor Xa inhibitors (rivaroxaban, apixaban, edoxaban), thrombin inhibitors (dabigatran); as mentioned, warfarin, LMWH and fondaparinux can also be used for

TABLE 53.5 Guidelines for Duration of Prophylactic Anticoagulation After VTE

Condition	Duration of Therapy
Distal or superficial vein thrombus	3-12 wk
First Proximal VTE	
No risk factors	3-6 mo ^a
Correctable risk factor (e.g., surgery, trauma)	3-6 mo
Malignancy	Long-term ^b
Antiphospholipid syndrome	Long-term
Inherited risk factor ^c	>6 mo
Recurrent VTE/PE	Lifelong

PE, Pulmonary embolism; VTE, venous thromboembolism (includes deep vein thrombosis, pulmonary embolism, and sinus or cerebral thrombosis).

^aEvaluation of D-dimer after 3-6 mo may assist in the decision to stop prophylaxis.

^bLong-term therapy must be adjusted individually according to presence of other diseases, risks for bleeding, presence of transient risk factors, and ease of compliance.

^cInherited risk factors include factor V Leiden; prothrombin 20210A; deficiencies of antithrombin, protein C, or protein S.

long-term therapy. Dosing is as follows: dabigatran 150 mg BID (needs renal dose adjustment 75 mg BID if CrCl 15-30), edoxaban (after acute phase parenteral anticoagulation). DOACs are not recommended with severe renal impairment. However, apixaban can be dose adjusted for renal impairment and other variables. If creatinine is greater than 1.5, age older than 80, or weight 60 kg or less, decrease apixaban dosing to 2.5 mg orally twice daily. RE-COVER (2009) demonstrated, in patients with acute VTE, the oral direct thrombin inhibitor, dabigatran, was found to be as effective as warfarin for reducing recurrence risk and is associated with less bleeding. The benefit is that the DOACs have less variability in therapeutic range compared with warfarin and patients do not need to have blood drawn for INR checks when on the DOACs, as they have to do on warfarin.

In summary, based on the most recent American College of Chest Physicians (ACCP) Antithrombotic Therapy for VTE Disease Guidelines (2016), DVT of the leg or PE without cancer, dabigatran, rivaroxaban, apixaban, or edoxaban is preferred over vitamin K antagonist therapies as treatment for the 3 months of maintenance therapy.

The treatment duration varies based on unprovoked or provoked DVT, location of clot, and initial or recurrent DVT. For most patients with a first episode of DVT (provoked and unprovoked, proximal and distal), treatment should be for 3 months. If proximal DVT or PE and low/moderate bleeding risk, this should be extended beyond 3 months. In patients with recurrent VTE, regardless of bleeding risk, the duration should be greater than 3 months and depending on risk factors of bleeding and patient comorbidities, indefinite anticoagulation may be recommended. The duration of therapy greater than 3 months has not been fully specified and will vary on a case-to-case basis. For patients who have received at least 6 to 12 months of anticoagulant therapy and have clinical equipoise to continue anticoagulation, low-dose rivaroxaban (10 mg once daily) or apixaban (2.5 mg twice daily) is safe and effective to reduce VTE risk with little to no increased bleeding risk as shown in the EINSTEIN Choice and AMPLIFY-EXT trials, respectively.

After stopping anticoagulation for unprovoked proximal DVT or PE, guidelines suggest aspirin over no aspirin to prevent recurrent DVT in patients with no contraindication to aspirin but in whom anticoagulant is not continued.

Therapy for VTE in Malignancy

In patients with malignancy, LMWH is preferred to warfarin. Based on the CLOT trial in 2003, dalteparin (LMWH) had a lower recurrent VTE risk without increasing bleeding risks or deaths compared to warfarin. These were confirmed in the 2006 LITE and ONCENOX trials. The Hokusai VTE Cancer Trial (2018) demonstrated that in patients with VTE and malignancy edoxaban was noninferior to dalteparin for recurrent VTE in an open label study but had higher bleeding risk. For specific malignancies, such as gastrointestinal cancer, LMWH is preferred to edoxaban for long-term anticoagulation (see Raskob 2017). Additionally, some studies recommend not using edoxaban if the CrCl is greater than 95, although the data for avoiding this medication in VTE are not clear. The SELECT-D pilot trial compared rivaroxaban to dalteparin in cancer-associated VTE and showed a decreased rate of recurrent VTE in the rivaroxaban group compared to dalteparin but an increased rate of non-major bleeding. There are multiple current trials studying apixaban versus dalteparin for patients with malignancy-associated VTE: the Caravaggio Trial is ongoing, and preliminary results for ADAM-VTE suggest low bleeding risk and low VTE recurrence rates.

In summary, based on the most recent ACCP Antithrombotic Therapy for VTE Guidelines (2016), for patients with cancer-associated VTE, as therapy for the first 3 months, LMWH is recommended over other agents whereas ASCO guidelines suggest DOACs may be used as first-line therapy. As mentioned previously, duration of therapy for VTE depends on cancer type (clotting and bleeding risks) and treatment plan for the malignancy.

Given known interactions and lack of safety data, DOACs should not be prescribed for patients on dual P-glycoprotein and strong CYP3A inhibitors, including medications such as carbamazepine, phenytoin, ketoconazole, ritonavir, rifampin, and more. Certain antibiotics (i.e., erythromycin or clarithromycin) may increase levels of DOACs, especially in individuals with renal dysfunction.

Prophylaxis of VTE

Even with the advent of the DOACs, both warfarin and LMWH are often used for treatment of VTE. Warfarin should be begun during the first 24 hours after presentation with VTE, concurrent with heparin treatment. The PT is prolonged within hours by warfarin because of a rapid decrease in factor VII levels; however, therapeutic warfarin anticoagulation does not occur until other vitamin K-dependent factors (II, IX, and X) also decrease. Therapeutic warfarin anticoagulation is usually achieved within 4 to 5 days with adequate warfarin dosing; UFH or LMWH may be discontinued after the INR has been greater than 2 for at least 2 consecutive days. One long-standing problem with warfarin anticoagulation is the interindividual variability in INR response; at least 50% of this variability in sensitivity to warfarin may be explained by polymorphisms in the *CYP2C9* and *VKORC1* genes. Although these have been incorporated into models for predicting safe and therapeutic warfarin dosing, most clinicians simply begin dosing and adjust therapy as needed based on periodic monitoring.

The therapeutic INR range depends on the condition predisposing the patient to thromboembolism. Prophylaxis after uncomplicated VTE in a patient without known risk factors requires an INR between 2 and 3; in contrast, warfarin prophylaxis for patients with APS and recurrent VTE may require INR values as high as 3 to 4 (Table 53.6).

The duration of warfarin or LMWH prophylaxis varies depending on the circumstances of the VTE, the risk for bleeding, and the potential for recurrence. In general, the longer the period of anticoagulation with warfarin, the less the chance of recurrence. Short-term warfarin (6 weeks) is less effective at preventing recurrence than longer courses (6 months). Patients with definite transient risk factors such

as orthopedic surgery have low recurrence rates, even with short-term therapy; still, prolonged thromboprophylaxis (>21 days) after total hip replacement is more efficacious than shorter therapy (7 to 10 days). It is not clear that oral Xa inhibitors and dabigatran provide any additional benefit over LMWH for thromboprophylaxis after total hip or knee replacement (Table 53.7).

Additionally, DOACs have been studied as thromboprophylaxis in specific patient settings. The MARINER trial evaluated patients who were discharged after medical illness with increased risk of VTE and showed that rivaroxaban 10 mg by mouth daily for 45 days after discharge did not reduce VTE or VTE mortality compared with placebo.

In contrast, patients with “unprovoked” VTE (i.e., outside the setting of trauma, surgery, immobilization, pregnancy, or cancer) have significant recurrence rates, even after 3 to 6 months of warfarin therapy. Because the risk for recurrence in patients with unprovoked proximal VTE or PE is relatively low when D-dimer levels are normal 3 weeks after cessation of anticoagulation, this measure may help providers decide whether anticoagulation past 3 to 6 months is necessary.

Given increased risk of recurrence in patients without reversible risk factors for VTE, extended-duration anticoagulation is sometimes warranted. Two studies evaluated using aspirin 100 mg versus placebo after anticoagulation therapy for unprovoked VTE. ASPIRE 2012 found a nonsignificant trend towards fewer recurrent VTE events and a nonsignificant trend towards higher bleeding risk, whereas WARFASA 2012 found statistically significant demonstration of fewer VTE recurrences without differences in major bleeding. There is thought that the trials differ in outcomes due to ASPIRE’s lack of enrollment for prespecified power, differences in inclusion criteria, and that only two thirds of ASPIRE patients had received 6 or more months of anticoagulation prior to initiation of aspirin.

Furthermore, the EINSTEIN-CHOICE Trial demonstrated that, in patients with VTE who have completed 6 to 12 months of anticoagulation, there was reduced risk of recurrent VTE without significant bleeding when using both 10 or 20 mg/day of rivaroxaban compared to aspirin 100 mg/day. In AMPLIFY-EXT, another oral factor Xa inhibitor, apixaban, was studied for extended anticoagulation at doses of 5 mg (treatment) or 2.5 mg (prophylactic) and was found to have statistically decreased number of recurrent VTE and no increased bleeding risk compared to placebo.

TABLE 53.7 Therapeutic International Normalized Ratio (INR) Ranges for Warfarin

Patient Subgroup	INR Range
Venous Thrombosis	
Treatment	2.0-3.0
Prophylaxis	1.5-2.5
Artificial Heart Valves	
Tissue	2.0-2.5
Mechanical	3.0-4.0
Atrial Fibrillation (Nonvalvular)	
Prophylaxis	1.5-2.5
Lupus Anticoagulant	
Treatment, prophylaxis	2.0-3.0
Refractory thromboembolism	3.0-4.0

Thus, current management for an unprovoked acute VTE includes use of either rivaroxaban or apixaban for the initial 6 months of therapy followed by a dose reduction in either agent. For patients with a provoked VTE, initial anticoagulation practice is the same, but anticoagulation may be stopped 3 months after the provoking risk factor has resolved.

Evidence also indicates that inherited hypercoagulable disorders (e.g., FVL mutation) probably confer a lifelong increased risk for VTE or PE, but whether the index VTE was provoked or unprovoked determines length of therapy. Some studies have shown that the bleeding risks incurred by long-term, low-intensity warfarin use are favorably balanced by the decreased incidence of recurrent thrombosis. Therefore, the presence of inherited thrombophilia may warrant continuation of anticoagulation for a longer period, depending on the patient’s other medical illnesses and whether transient circumstances may have predisposed the patient to VTE. Patients who develop recurrent VTE after discontinuation of anticoagulation should receive long-term anticoagulation regardless of whether they have a defined cause of thrombophilia. Patients with APS and a first episode of VTE are at very high risk for recurrent VTE (up to 50% per year) after anticoagulation is discontinued, clearly supporting the rationale of testing for antiphospholipid. Table 53.8 suggests broad guidelines for the duration of warfarin therapy in specific patient subgroups. Because warfarin is a teratogen, effective contraception should be used concurrently in women of childbearing age.

Prophylaxis for VTE in Orthopedic Surgeries

RECORD1 and RECORD3 (both published 2008) demonstrated improved efficacy of short-course rivaroxaban over short-course enoxaparin in prevention of VTE after hip and knee replacements, respectively, without increased bleeding risk. RECORD2 (2008) demonstrated that extended-course rivaroxaban was more effective in preventing VTE than short-course enoxaparin without increasing bleeding rates following hip replacement.

Prophylactic Anticoagulation in Hospitalized Medically Ill Patients

MEDENOX, PREVENT, and ARTEMIS demonstrated promise of in-hospital thromboprophylaxis with LMWH with a relative risk reduction of 45% to 63% compared to placebo. In acutely medically ill hospitalized patients, MAGELLAN (2013) demonstrated short-course rivaroxaban (10 mg daily for 10 days) is noninferior to short-course

TABLE 53.8 Direct Oral Anticoagulants (DOAC) and Their Indications

DOAC	Indications
Dabigatran	Direct thrombin inhibitor for nonvalvular atrial fibrillation (to prevent stroke and non-CNS embolism); VTE as maintenance therapy (after initial therapy); VTE prophylaxis of VTE after hip replacement
Rivaroxaban	Anti-Xa for nonvalvular atrial fibrillation (to prevent stroke and non-CNS embolism); treatment of VTE and subsequent prophylaxis; and VTE prophylaxis of VTE after hip or knee replacement
Apixaban	Anti-Xa for nonvalvular atrial fibrillation (to prevent stroke and non-CNS embolism); VTE as initial therapy or maintenance therapy; VTE prophylaxis of VTE after hip or knee replacement
Edoxaban	Anti-Xa for prevention of VTE as maintenance therapy (after initial therapy); prevention of embolism in atrial fibrillation; has been studied for treatment of VTE in patients with malignancy and is noninferior to dalteparin (a LMWH) with an increased bleeding risk

CNS, Central nervous system; VTE, venous thromboembolism; Xa, activated factor X.

enoxaparin (40 mg daily for 10 days) in preventing VTE, although it increases risk of bleeding. Extended rivaroxaban (10 mg daily for 35 ± 4 days) was also found to be superior to short-course enoxaparin for prevention of VTE and its complications but also had increased bleeding risk.

The APEX trial studied acutely ill medical patients and showed that extended-duration betrixaban for 35 to 42 days did not reduce the primary end point of asymptomatic proximal clot or symptomatic VTE compared to standard enoxaparin for 6 to 14 days.

Prophylactic Anticoagulation in High-Risk Patients With Malignancy in the Ambulatory Setting

The CASSINI trial evaluated ambulatory cancer patients at high risk for thromboembolism (Khorana score ≥2) and whether low-dose rivaroxaban (10 mg daily) is more effective than placebo in reducing incidence of venous thromboembolism. Rivaroxaban did not result in statistically significant reduction in incident thromboembolism at 180 days when compared to placebo and had a small, not statistically significant increase in bleeding risk; however, when only time on the drug was considered, there was an absolute reduction in VTE with rivaroxaban compared to placebo. On the other hand, the AVERT trial studied apixaban 2.5 mg twice daily versus placebo in ambulatory cancer patients at intermediate-to-high risk for venous thromboembolism (Khorana score ≥2). Prophylactic apixaban reduced the risk of VTE in these patients but increased the risk of major bleeding episodes. Major bleeding was most common in those with GI or GU malignancy. Of note, the trial populations were different, with AVERT having a significant proportion of patients with lymphoma and CASSINI having a higher proportion of pancreatic cancer.

Antithrombotic Therapy During Pregnancy

Heparins, both UFH and LMWH, are the safest therapy for venous thrombosis treatment and prevention during pregnancy. Heparin does not cross the placenta, unlike warfarin, which causes a characteristic fetal embryopathy. Warfarin also causes fetal hemorrhage and placental abruption and should be avoided during pregnancy. VTE or PE during pregnancy should be treated with intravenous UFH for

5 to 10 days, followed by an adjusted-dose regimen of subcutaneous UFH, starting with 20,000 U every 12 hours and adjusted to achieve a PTT higher than 1.5 times baseline at 6 hours after injection. An attractive alternative to UFH during pregnancy is LMWH, which can be given subcutaneously once or twice daily and does not require monitoring. Suprarenal IVC filters have also been used successfully during pregnancy without significant morbidity. In women with APS who become pregnant, therapy is critical to prevent fetal loss; aspirin is combined with prophylactic doses of either subcutaneous UFH (10,000 to 15,000 U/day in divided doses) or LMWH (to achieve an anti-Xa level of 0.1 to 0.3 U/mL). When such women have a history of thromboembolic disease, therapeutic doses of LMWH or UFH plus aspirin are employed.

Heparin should be discontinued at the time of labor and delivery, although the risk for hemorrhage is not high during delivery, especially if anti-Xa levels are less than 0.7 U/mL. One concern with residual anticoagulation at delivery is the risk for spinal hematoma with epidural anesthesia; this concern has been reported with both UFH and LMWH. The anti-Xa level that is safe for an epidural procedure is not known. Protamine sulfate can be used to neutralize UFH if the PTT is prolonged during labor and delivery; however, LMWH is only partially (10%) reversed by protamine.

Anticoagulation during the postpartum period can be carried out with heparin (either UFH or LMWH) or warfarin; neither drug is contraindicated during breast-feeding. Women receiving long-term warfarin therapy (e.g., for valvular heart disease) who wish to become pregnant need to be switched to a fully anticoagulating dose of UFH or LMWH; warfarin treatment may be restarted after delivery.

There is limited evidence to support use of DOACs in pregnancy. There are concerns about a higher incidence of miscarriages and fetal anomalies with DOACs. There is currently not enough data to show safety and suggest use of the DOACs during pregnancy, so they are not recommended.

Perioperative Anticoagulation

A common clinical problem is the management of anticoagulation in patients who require surgery. The principles of care in this situation reflect the need for adequate hemostasis during and immediately after surgical procedures as well as the critical importance of restarting anticoagulation as soon as possible postoperatively, especially because surgery itself represents a relative hypercoagulable state. The perceived risk for thromboembolism in patients with atrial fibrillation clearly affects the management of perioperative anticoagulation; in this clinical situation, the CHADS-2 score (cardiac failure, hypertension, age, diabetes, and stroke) may estimate postoperative stroke risk and thus dictate the need for bridging anticoagulation with UFH/LMWH when stopping vitamin K antagonist. For patients with VTE who are anticoagulated on a short-term basis (<1 month), elective surgical procedures should be postponed; if such patients must undergo urgent surgery, discontinuation of anticoagulation and placement of a temporary IVC filter may be the best option. In most patients receiving long-term anticoagulation for VTE, preoperative heparin is not typically used; vitamin K antagonist should be discontinued for at least 4 days preoperatively to allow the INR to decrease gradually to less than 1.5, a level that is safe for surgery. Postoperatively, intravenous heparin (or subcutaneous LMWH) can be safely used for anticoagulation until therapeutic INR levels are reached after warfarin has been restarted. Increasingly, restarting a DOAC postoperatively at pre-surgery therapeutic dosing is safe and effective to avoid the need for bridging with parenteral therapy. As with all guidelines, individual patient circumstances may dictate changes. For example, institution of heparin immediately after a major surgical procedure may be contraindicated because of the high

risk for hemorrhage, and reinstatement of anticoagulation may need to be delayed for 12 to 24 hours postoperatively.

Risk of postoperative VTE in patients undergoing hip or knee arthroplasty without postoperative anticoagulation is estimated at 6% by Caprini score. Thus, VTE prophylaxis is standard of care. EPCAT II 2018 showed extended thromboprophylaxis with aspirin 81 mg was noninferior to rivaroxaban 10 mg daily for 5 days in preventing symptomatic VTE in low-risk patients after total hip or knee arthroplasty.

Cancer Biology

Andre De Souza, Wafik S. El-Deiry

INTRODUCTION

Cancer is a complex genetic disease that is defined by the transition of a normal cell, governed by processes that control its replication, into a cancer cell that is typified by unrestrained proliferation and dissemination. The underlying landscape of cancer genetics is now fully defined for many cancers, aided by the evolving technologies in gene sequencing. Many therapeutic advances of the last decade have successfully focused on targets identified by the study of genetic mutations. This chapter reviews the essential elements of cancer biology and key underlying genetic alterations driving this biology.

THE GENETICS OF CANCER

Cancer is a genetic disease. Carcinogens are chemical mutagens or physical insults that result in DNA alterations. Each of these insults produce different alterations with distinct outcomes for a cancer cell. These alterations can also be derived from random mutations enabled by failure of DNA repair mechanisms.

The most common gene alterations in cancer are nonsynonymous point mutations. A synonymous point mutation is a single nucleotide exchange (also called single nucleotide polymorphism [SNP] or single nucleotide variant [SNV]) that does not affect the final resultant amino acid and therefore does not affect the function of a protein. By contrast, a nonsynonymous mutation will result in an amino acid change that may be beneficial for the survival of a cancer cell. Dr. Bert Vogelstein described the stepwise acquisition of mutations as drivers of cancer progression. Using the progressive histopathological stages of colorectal cancer as a model, he depicted carcinogenesis as a sequence of alterations in genes such as APC, KRAS, TP53, and SMAD4 (small mothers against decapentaplegic 4). In recognizing TP53 as a tumor suppressor gene and determining its central role in the transformation of a preneoplastic adenoma to colorectal cancer, Dr. Vogelstein linked the most common tumor suppressor gene to one of the most prevalent human malignancies. He further unraveled the role of mutations as “drivers” and “passengers” in the pathogenesis of cancer and its heterogeneity. The genetic changes associated with cancer paved the way for screening tests that could be used for early detection and prevention of cancer development.

Copy number variation or gene amplification denotes the loss or gain of a whole copy of a gene. When a cell has extra copies of genes, it can produce twice or more the amount of proteins. On the other hand, when just parts of a gene are lost (deletions) or anomalous sequences are inserted amid the full gene sequence (insertions), these events are called indels (insertions and deletions). Indels have a knack for activating the immune system. Why? When proteins transcribed from genes with indels are presented in the regular health cellular checkup we call antigen presentation, they look more foreign to immune cells than point mutations. Lastly, mitosis malfunction may be conducive to fusion of distinct segments of

chromosomes. Natural selection can then favor gene fusions from translocational events that stimulate cell survival. Much progress has been made in the past several decades to unravel oncogenic fusions in various leukemias and solid tumors (Fig. 54.1). The classical Philadelphia chromosome in chronic myelogenous leukemia creates a fusion of the *BCR-ABL* genes. Tyrosine kinase inhibitors such as Imatinib block the transforming ability of *BCR-ABL* and have led to prolonged patient survival. The *BCL-2* gene translocated in follicular lymphoma can be therapeutically inhibited by venetoclax, while various NRTK fusions driving cancer can be treated with larotrectinib or entrectinib. Other common translocations in Burkitt’s lymphoma, Ewing’s sarcoma, or prostate cancer are well-known but not yet therapeutically targeted.

THE TUMOR MICROENVIRONMENT

Tissues are made of a myriad of cells, each contributing to a state of homeostasis that controls unchecked growth of individual cells. Our understanding of cancer is evolving from a cellular disease to an infirmity of tissues.

There is a growing body of evidence that bone marrow–derived and stromal–derived cells contribute to the evolution of cancer. Myeloid-derived suppressor cells (MDSCs) have been shown to suppress NK and cytotoxic T cells (CD8⁺) in the tumor microenvironment, whereas cancer-associated fibroblasts (CAFs) synthesize the thick extracellular matrix (desmoplasia) that serves as a scaffold and a shield for drugs targeting stroma-rich tumors such as pancreatic cancer (Fig. 54.2). The tumor microenvironment (TME) is complex and includes multiple immune, stromal, endothelial cells, altered extracellular matrix, proinflammatory, immunosuppressive, and chemoattracting cytokines, and physical changes such as hypoxia, altered tumor metabolism leading to low pH, a dysregulated metabolome. The TME promotes cancer progression and resistance to therapy.

HALLMARKS OF CANCER

The hallmarks of cancer were established by Hanahan and Weinberg and updated in 2011. These hallmarks are products of driver mutations that incapacitate selective pressures restricting tumor growth. The hallmarks include acquisition of immortality, genomic instability, hyperactive proliferative signaling pathways, growth checkpoint disruption, angiogenesis, metabolism reprogramming, invasion and metastasis, and immune escape.

Immortality: Apoptosis Suppression, and Telomerase Activation

Apoptosis or programmed cell death occurs in adult cells when DNA damage or other forms of cellular stress elicit a suicidal program to

Fig. 54.1 Chromosomal translocations and oncogene activation in human cancer. (A) Depicted are several classical translocations associated with different types of cancer and the FDA-approved drugs used to treat them. These include chronic myelogenous leukemia t(9,22)(BCR-ABL), follicular lymphoma t(14,18) (*IgH/BCL2*), and *NTRK* gene fusions that occur in various solid tumors (e.g., *ETV-6/NTRK3*). (B) Major chromosomal translocations associated with Burkitt's lymphoma t(8,14) (*MYC/IgH*), Ewing's and other sarcomas (*EWS/Fli*), and prostate cancer (*TMPRSS2/ERG*). Other translocations are being recognized as they contribute to therapy resistance including *ESR1* whose translocation (not shown) confers resistance to hormonal therapy in breast cancer. Not shown are common translocations in mantle cell lymphoma t(11,14) (Cyclin D, *IgH*) or other *NTRK* genes such as *NTRK1* and *NTRK2*.

Fig. 54.2 The tumor microenvironment promotes cancer progression and impedes cancer therapy. The tumor microenvironment (TME) is composed of different cell types in addition to cancer cells. The TME of a growing tumor typically has hypoxic regions, low pH due to altered metabolism, and low levels of nutrients. Cancer associated fibroblasts (CAF) create a thick connective tissue mesh which acts as a mechanical barrier to drug delivery to cancer cells. This connective tissue shell is also known as desmoplasia, here stylized as *blue concentric curves*. A small molecule or biologic drug is represented as *red circles* crossing through the endothelial lining of a blood vessel. Although some drug does make it to the tumor cell, some bounces off the desmoplastic shell. Once cancer evolves, the body tries to fight it off with an adaptive immune response, which ultimately delivers cytotoxic T cells (TCD8) to kill cancer cells, enabled by chemical mediators such as Interleukin-6 (IL-6) and attenuated by immunosuppressive factors such as transforming growth factor β (TGF- β). Immunosuppressive cells include macrophages and T regulatory cells (T-regs). The cytotoxic T cells are characterized by specific transmembrane receptors, the cluster of differentiation (CD) 8 proteins, and are regulated in part by myeloid-derived suppressor cells (MDSCs), which dampen an overstimulated immune response that otherwise would result in autoimmune disease. MDSCs are generated in the bone marrow and also cross endothelial cell gaps to render TCD8 cells anergic. MDSCs are hijacked by tumors to serve as one of the mechanisms of immune evasion. Some of these concepts have been recently summarized in a review of the physical hallmarks of cancer (Nia HT, Munn LL, Jain RK: *Science* October 2020; 370[546]: 1–11).

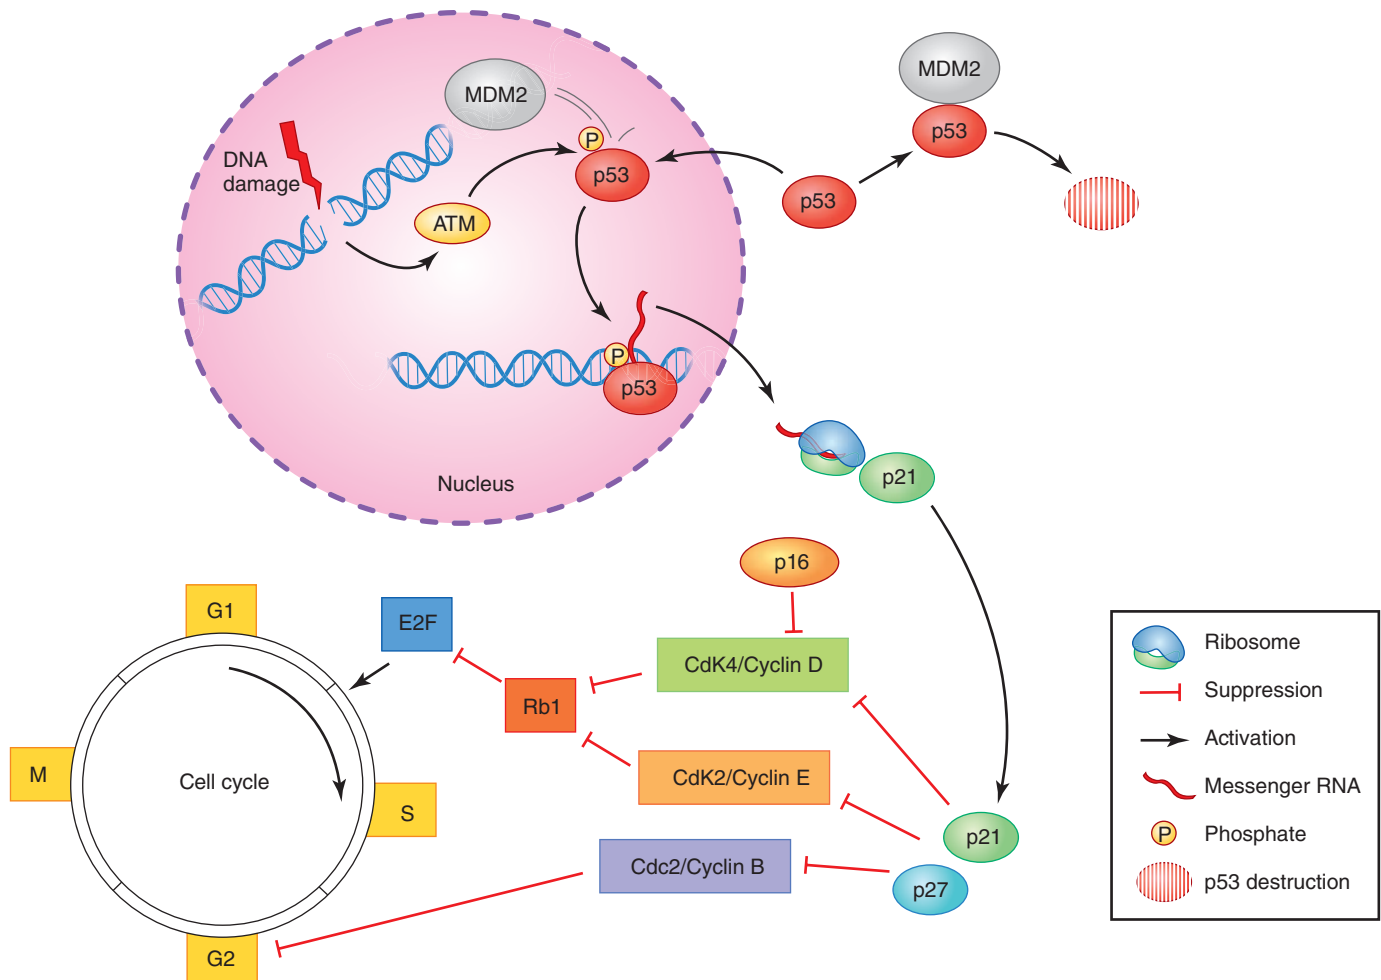

Fig. 54.3 DNA damage stalls the cell cycle. DNA damage, for example after exposure to ionizing radiation, triggers ATM phosphorylation of the p53 protein. Other kinases induced by DNA damage include ATR, Chk1, and Chk2 (not shown). The p53 protein is constitutively tagged to proteasomal destruction by the E3 ligase MDM2; p53 phosphorylation stabilizes the protein by blocking its binding to MDM2. The p53 protein transcriptionally activates the expression of the p21 gene (*CDKN1A*, *WAF1*). The p21 protein is the cell checkpoint of all three CDK and cyclin complexes (CDK4/Cyclin D, CDK2/Cyclin E, CDC2/Cyclin B). Therefore, p53, through p21, arrests the cell cycle to allow repair after DNA damage and thereby prevent cancer. *TP53* is the most commonly mutated gene in human cancer. The p27 protein is another universal inhibitor of CDK complexes. By contrast, the p16 protein, encoded by the *CDKN2A* gene, inhibits CDK4/Cyclin D. Inhibition of CDK4 and CDK2 complexes allows unphosphorylated RB to bind E2F proteins and inhibit entry of cells into S-phase where the DNA is replicated. CDK4 and 6 inhibitors are approved for therapy of estrogen receptor positive breast cancer. MDM2, ATR, ATM, Chk1, and Chk2 inhibitors are currently in clinical trials for cancer therapy. The “p” denotes protein, followed by molecular weight in Kilodaltons, as in p21 and p53. Arrows indicate activation processes in a pathway. Red “T” symbols indicate suppression of a pathway. ATM, Ataxia telangiectasia mutated; CDK, cyclin-dependent kinase; E2F, a family of transcription factors which activate genes required for S-phase; MDM2, mouse double minute 2; RB, retinoblastoma.

save the organism as a whole. This program is actioned by extracellular ligands (extrinsic pathway) or intracellular mediators (intrinsic pathway). The extracellular ligand FASL or TRAIL (in immune cells) or soluble ligands (in the extracellular space) bind to FAS and TRAIL receptors in the cell that undergoes apoptosis. The intrinsic pathway culminates in release of cytochrome c to the cytosol. Caspase activation in response to either the extrinsic or intrinsic cell death pathways results in proteolytic cleavage of thousands of cellular proteins that result in cell detachment, shrinkage, nuclear fragmentation and engulfment by macrophages. Several pro- and anti-apoptotic regulator proteins, such as Bcl-2, are deregulated in cancer (Figs. 54.3–54.5). Telomere shortening is the prime cellular timekeeper process

only avoided by the enzyme telomerase, dormant in most tissues. Telomerase reactivation induces cancer cell immortality and is a key early event in carcinogenesis. However, the telomerase target is yet to be meaningfully exploited in cancer therapy.

Genomic Instability: Impairing DNA Repair Genes

Alterations in DNA repair genes increase tumor mutation burden. It was also observed that some cancer cells had frail chromosomes, prone to breakage. While some tumor cells have chromosomal instability, others have microsatellite instability characterized by mutations including frequently at repetitive DNA sequences. This microsatellite instability (MSI) is a result of mutations in DNA repair

Fig. 54.4 DNA damaging chemotherapy activates p53 leading to tumor cell death through the intrinsic apoptosis pathway. This figure shows the central role of the p53 protein in the intrinsic apoptosis pathway, which culminates in apoptosome activation. Oncogene activation or cytotoxic DNA damaging chemotherapies stabilize and activate the p53 protein. If the damage is repaired, cells survive and do not become transformed. If there is too much damage, cells undergo p53-dependent cell death. When p53 is mutated in cancer, its tumor suppressor function is lost. As part of its normal function after DNA damage, the p53 protein modulates the intrinsic apoptosis pathway by regulating the balance of the proapoptotic proteins PUMA, NOXA, and BAX and the antiapoptotic proteins BCL-XL and BCL-2, resulting in the release of cytochrome c from the mitochondria. When cytochrome c binds to the apoptosome, a multimer of caspase 9 and APAF1, it activates caspases 3 and 6, which promote nuclear membrane destruction by Lamin-A and DNA fragmentation by CAD. The “p” denotes protein, followed by molecular weight in Kilodaltons, as in p53. Arrows indicate activation processes in a pathway. Red “T” symbols indicate suppression of a pathway. *APAF1*, Apoptosis protease activating factor 1; *BAX*, BCL-associated X; *BCL-2*, B-cell lymphoma 2; *BCL-XL*, BCL-extra-large; *CAD*, caspase-activated deoxyribonuclease; *NOXA*, Latin for damage; *PUMA*, p53 upregulated mediator of apoptosis. For a more detailed review of the apoptosis pathway and its exploitation in cancer therapy, see Carneiro BA, El-Deiry WS, *Nat. Rev. Clin. Oncol.* 2020 Jul;17(7):395–417.

genes. When the repair system is defective, the number of mutations increases. The total number of mutations in a cancer cell is called tumor mutation burden. MSI correlates with tumor mutation burden. The processing of the mutant proteins from MSI-high tumor cells in the endoplasmic reticulum and their presentation by the main histocompatibility complex-I (MHC-I) as neo-antigens predicts response to immunotherapy. Furthermore, mutations in components of the FANCD1 complex (including BRCA genes) affect DNA double-strand break repair, resulting in homologous recombination deficiency (HRD) observed in subsets of ovarian, breast, prostate, and pancreatic cancer patients. Some of these cancers use a rescue DNA repair system, the poly-ADP ribose polymerase (PARP) system,

which can be targeted with inhibitors, a concept often named synthetic lethality (specifically in the BRCA-mutated cells). PARP inhibitors are oral medications available in the oncology clinic for patients with HRD. Both MSI and HRD may be acquired through germline (inherited from parents) or somatic (originated in the tumor) mutations.

Oncogenes Unleash Proliferation

Oncogene mutations convert a normal cell into a cancerous cell (Fig 54.6). Oncogenes often activate pathways that are important for cancer. For example, chronic myelogenous leukemia (CML) occurs when the proto-oncogene ABL from chromosome 9 translocates to

Fig. 54.5 The innate immune system, through the extrinsic apoptosis pathway, eliminates transformed cells. Extracellular molecules (TRAIL and FASL) bind to transmembrane receptors (DR4, DR5, and Fas), anchoring the intracellular adaptor protein FADD to the cellular membrane. Then, FADD recruits initiators Pro-caspase 8 and Pro-caspase 10, which are then cleaved to their active forms, caspase 8 and caspase 10. This activation reaction is tightly regulated by c-FLIP. The apoptosome, a multimer of caspase 9 and APAF1, leads to activation of executioner caspases 3 and 6, promoting nuclear membrane destruction by Lamin-A and DNA fragmentation by CAD, respectively. The *TRAIL*, *DR5*, and *FAS* genes are regulated by p53. The “p” denotes protein, followed by molecular weight in Kilodaltons, as in p53. Arrows indicate activation processes in the pathway. “T” symbols indicate suppression of a pathway. *DR*, Death receptor; *FADD*, FAS-associated protein with death domain; *FAS*, FS-7 (a cell line)-associated surface antigen; *FASL*, FAS ligand; *FLIP*, FADD-like interleukin 1 beta-converting enzyme inhibitory protein; *TRAIL*, tumor necrosis factor-related apoptosis inducing ligand. For a more detailed review of the apoptosis pathway and its exploitation in cancer therapy, see Carneiro BA, El-Deiry WS, *Nat. Rev. Clin. Oncol.* 2020 Jul;17(7):395–417.

the *BCR* gene on chromosome 22. The new protein formed by expression of the combined gene *BCR-ABL* sends unchecked growth-promoting signals to the nucleus. An activating mutation in one allele of an oncogene is usually sufficient to promote tumorigenesis (e.g., *KRAS*).

Because oncogenes activate pathways that drive cancer growth, their discovery has led to specifically designed drugs that target the products of these genes and the pathways they control. For example, among patients with breast cancer, HER2 amplification serves as a biomarker that identifies those who will benefit from treatment

with the anti-HER2 monoclonal antibody trastuzumab. Similarly, activating mutations in EGFR serve to identify patients with non-small cell lung cancer who will improve with the use of drugs (erlotinib, gefitinib, afatinib, dacomitinib, osimertinib) that specifically inhibit the mutated form of EGFR. Another example is BRAF mutations in melanoma, which are inhibited by the FDA-approved drugs dabrafenib, vemurafenib, and encorafenib. This paradigm—identify a mutated oncogene, find a specific drug that inhibits the activated mutant protein, and treat patients who have the specific mutation with a drug that affects the mutated protein—has

Fig. 54.6 Principles of intracellular cancer signaling and targeted therapeutics. Ligands are extracellular molecules such as the epidermal growth factor (EGF) which binds to a transmembrane receptor known as the EGF receptor (EGFR), to activate intracellular cancer pathways. Illustrated here are the MAPK (mitogen-activated protein kinase) and the phosphatidylinositol-3 kinase/mammalian target of rapamycin (PI3K/mTOR) pathways. These pathways converge into proliferative genetic programs mediated by transcription factors including myelocytomatosis (Myc), Fos, Jun, hypoxia-inducing factor-1 α (HIF-1 α), and others. These transcription factors turn on genes that promote cell growth and proliferation as well as tumor growth and metastases. The major effect of mTOR signaling is to stimulate protein translation that is required for cell growth and proliferation. Modern cancer therapy has evolved to include therapeutic agents targeting most of these tumor promoting proteins. Examples include trastuzumab (Her2/neu), cetuximab (EGFR), dabrafenib (RAF), trametinib (MEK), copanlisib (PI3K), mTOR (everolimus), and many others. Yellow "p" denotes phosphate. Arrows indicate activation processes in the pathway. Red "T" symbols indicate suppression of a pathway. Activation of Myc, Fos, and Jun by the MAPK pathway and HIF-1 α by mTOR and S6 kinase is indirect. AKT, AK mouse strain transforming retrovirus (AKT is also known as PKB [protein kinase B]); ERK, extracellular signal regulated kinase; Her2/neu, human EGF receptor 2/neural; KRAS, Kirsten rat sarcoma; MEK, MAP (mitogen-activated protein)/ERK kinase; PIP3, phosphatidylinositol (3,4,5)-trisphosphate; PTEN, phosphatase and tensin homolog; RAF, rapidly accelerating fibrosarcoma.

repeatedly been proven to be a successful approach. Recently, targeting of a specific KRAS G12C driver mutation has been achieved through a small molecule that covalently attaches to the cysteine, and this appears efficacious in some patients with non-small cell lung cancer and colon cancer. Other significant advances involved the development and FDA-approval of Ret inhibitors selpercatinib and pralsetinib for multiple tumor types including non-small cell lung cancer. Capmatinib inhibits Met exon-skipping mutant non-small cell lung cancers and sonic hedgehog pathway inhibitors vismodegib and sonidegib are used for the treatment of advanced basal cell carcinoma. Ongoing research aims to target additional oncogenic cancer pathways such as the Wnt/Beta-catenin and Notch pathways (Fig. 54.7).

Tumor Suppressor Genes Disrupt Growth Checkpoints

The inactivation of both alleles of a tumor suppressor gene (e.g., retinoblastoma, *RBI*) results in cancer, most commonly by an inherited mutation in an allele followed by loss of heterozygosity due to epigenetic events or aneuploidy (loss or gain of part of chromosomes). The tumor suppressor gene *TP53* is the most commonly mutated gene in human cancer. The p53 protein is a transcription factor that activates various genes such as p21 (WAF1) and multiple genes that induce cell death (Figs. 54.3–54.5). Mutation of this *TP53* gene can be inherited (Li-Fraumeni syndrome) in families that have higher rates of a variety of leukemia, sarcoma, breast, and brain tumors, or most commonly is acquired during cancer growth. Loss of two copies of a tumor suppressor gene leading

Fig. 54.7 The beta-catenin intracellular cancer signaling pathway is involved in cancer development. The extracellular molecule Wnt engages the transmembrane proteins LDL receptor related protein (LRP) and Frizzled, which activate the intracellular adaptor protein Dishevelled. Then, Dishevelled disassembles the kinase complex composed of the proteins Adenomatous Polyposis Coli (APC), Axin, Glycogen Synthase Kinase-3 β (GSK-3 β), and Casein Kinase-1 α (CK-1 α). This kinase complex usually breaks down beta-catenin by tagging it for destruction through phosphorylation. However, the activation of Dishevelled by Frizzled bound to Wnt promotes kinase complex disassembly, stabilizing beta-catenin. Finally, beta-catenin crosses the nuclear membrane displacing the transcription repressor Groucho, which enables TCF/LEF transcriptional activity that activates target genes such as *MYC* and the Cyclin D gene (*CCND1*). This pathway is deregulated in most colon cancers through *APC* mutation (both sporadic and inherited forms of colon cancer such as Familial Adenomatous Polyposis). In other tumors, β -catenin mutations are more commonly observed. This pathway remains largely untapped for cancer therapeutic development. Inhibitors of GSK-3 β , Wnt, and β -catenin are currently under development. *Arrows* indicate activation processes in a cellular pathway. *TCF/LEF*, T-cell factor/lymphoid enhancer-binding factor; *Wnt*, wingless/integrated.

to cancer was predicted by Knudson's two-hit hypothesis. Tumor suppressor genes can be inactivated by viral genes including Human Papilloma Virus (HPV) E6 and E7 that target p53 and Rb. HPV types 16 and 18 can cause cervical cancer and head and neck cancer, and there is a preventative vaccine.

Hypoxia, Angiogenesis, Invasion, and Metastases

Under hypoxic pressure from the tumor microenvironment, cancer cells shift their metabolism towards aerobic glycolysis. This so-called Warburg effect diverts Krebs cycle intermediate metabolites towards nucleic acid and amino acid production, favoring cell growth. Although mutations affecting enzymes from the Krebs cycle are uncommon in cancer (i.e., fumarate hydratase in certain kidney tumors and succinate dehydrogenase in pheochromocytomas), isocitrate dehydrogenase (IDH) 1 or 2 are commonly mutated in certain brain, bile duct, and acute myelogenous

leukemia and are targeted by the FDA-approved drugs ivosidenib (mutant IDH1 inhibitor) and enasidenib (mutant IDH2 inhibitor). Also, the upregulation of a transcription factor known as hypoxia-inducing factor induces overexpression of the vascular endothelial growth factors (VEGF). VEGF then co-opts endothelial cells to form new aberrant vessels (angiogenesis), allowing the growing mass to survive hypoxia. These ill-walled vessels allow elopement of cancer cells to the bloodstream, priming distant organ colonization (metastasis). The angiogenesis inhibitors include the biologic agents bevacizumab, ramucirumab, and ziv-aflibercept and some small molecules such as sunitinib, sorafenib, regorafenib, lenvatinib, cabozantinib among others. Finally, hypoxia upregulates a series of transcription factors (Snail, Slug, TWIST, ZEB 1 and 2) that coordinate cell-to-cell adhesion dysregulation promoting phenotypic changes (epithelial-mesenchymal transition) that enable cell migration and metastasis. Such is the importance of the hypoxia

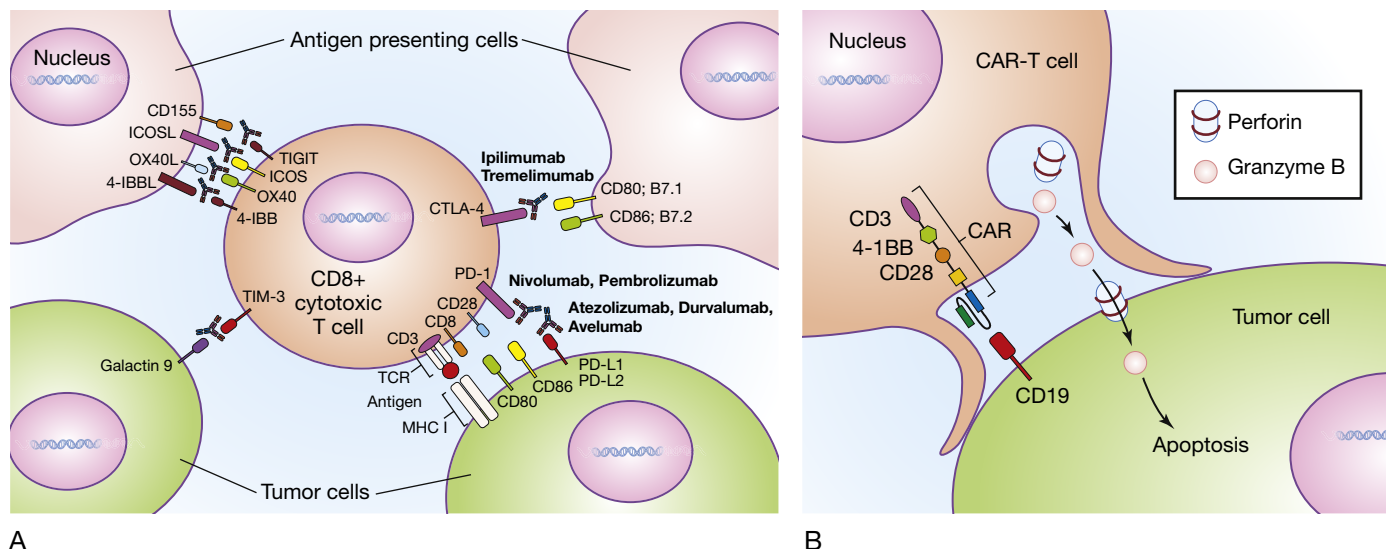

Fig. 54.8 Cancer immunotherapy. (A) Targets for cancer immune checkpoint therapy. Depicted here is a CD8+ cytotoxic T cell, an antigen presenting cell, and a tumor cell. These cell-cell interactions may take place within a primary tumor, draining lymph nodes, or metastatic sites. On the right of the T cell are immune checkpoints that have been successfully targeted in cancer therapy with now FDA-approved antibodies. Examples include ipilimumab and tremelimumab that target CTLA-4, nivolumab and pembrolizumab that target PD-1, and atezolizumab, avelumab, and durvalumab that target PD-L1. These therapeutics are currently being combined with chemotherapy or targeted therapy in the clinic. To the left of the T-cell are a number of checkpoints for which therapeutics are being tested in clinical trials. They include the T cell targets TIGIT, ICOS, OX40, TIM-3, and 4-1BB. (B) Cellular chimeric antigen receptor-T cell (CAR-T) therapy has been developed and is now FDA-approved in the treatment of acute lymphocytic leukemia and diffuse large B cell lymphoma. Shown is an engineered CAR-T cell with an immune synapse, with binding of different receptors, release of granzyme B and perforin, leading to apoptosis of a target tumor cell.

pathways in cancer that the Physiology or Medicine Nobel prize of 2019 was bestowed on William G. Kaelin, Gregg L. Semenza, and Peter J. Ratcliffe.

Immune Escape

The immune system is constantly killing cancer cells. Under pressure of this constant immune vigilance, cancer cells with random mutations that allow re-expression of useful genes that are usually dormant survive. Among the genes involved in this “immune escape,” one of the best studied is *PD-L1* (programmed-death ligand 1). *PD-L1* usually is expressed in the placenta, preventing a mother’s immune system from attacking her fetus, ultimately a foreign body. When tumors express *PD-L1* it binds its receptor PD-1 in cytotoxic T CD8⁺ cells, rendering them ineffective. One of the most revolutionary therapies in oncology is use of monoclonal antibodies to *PD-L1* and other so-called immune checkpoints (Fig. 54.8). They have been so successful that the scientists James Allison and Tasuku Honjo who were responsible to bring them to the clinic were awarded the Nobel Prize in Physiology or Medicine in 2018.

Dr. Steven Rosenberg observed that T cells fighting cancer could be removed from patients, cultured ex-vivo, and used as cancer therapies. This adoptive cell therapy acquired an iteration when Carl June selected patient-derived (autologous) cells through special magnetic beads, introduced genetically engineered antibodies linked to immune checkpoint receptors through viral vectors, and infused it back to the same patients who donated the cells. Chimeric antigenic receptor (CAR)-T cell therapy has been developed to target surface proteins in

various tumors, such as CD19 in acute lymphocytic leukemia, which was approved by the FDA in 2017. The first patient treated in a clinical trial in 2012 is cancer free by 2020. Off-the-shelf CAR-T cells, extracted from allogeneic donors and engineered to avoid rejection by the recipient, are in development. Umbilical cord-derived CAR-natural killer (CAR-NK) cells are also under development.

Cancer Epidemiology

Gary H. Lyman, Nicole M. Kuderer

INTRODUCTION

Globally, more than 18 million individuals are diagnosed with cancer and nearly 10 million die annually from the disease. At the same time, the number of cancer survivors worldwide is increasing dramatically each year. In the United States in 2020, it is estimated that more than 1.8 million individuals will be diagnosed with cancer, for an age-adjusted incidence rate of 448 per 100,000 population. At the same time, more than 600,000 individuals will die from cancer, for an age-adjusted death rate of 158 per 100,000. Cancer has become the leading cause of mortality among both women and men between the ages of 40 and 80 and the second leading cause of death for most other age groups, including children between 1 and 14 years of age.

The leading types of new invasive cancer cases and cancer-specific deaths are shown in [Table 55.1](#). While breast cancer and prostate cancer are the most common noncutaneous forms of cancer in men and women, respectively, lung cancer is the leading cause of cancer-specific mortality accounting for nearly 30% of cancer deaths in both genders. While mortality rates for gastric and cervical cancers have decreased steadily for decades, overall cancer death rates have decreased some 20% since their height in the early 1990s, with the greatest declines for colorectal, prostate, and lung cancers in men and colorectal and breast cancer in women ([Fig. 55.1](#)). Disparities in cancer occurrence and mortality persist despite a reduction in the overall age-adjusted mortality from cancer. Cancer incidence remains highest in the United States among white individuals, likely due to their high rates of lung and female breast cancer. However, black men continue to have the highest gender-specific cancer incidence among men and the highest mortality rates despite considerable reductions in cancer mortality for all genders and races. While white women have the highest cancer incidence among women, black women have the highest gender-specific cancer mortality rate despite gradually falling rates for all races. Cancer mortality rates in developed countries are consistently higher among those from racial and ethnic minority groups, especially African Americans, and among those from lower socioeconomic strata. Greater mortality rates among racial and ethnic minorities are not fully explained by differences in the stage at diagnosis. Socioeconomic factors, access to appropriate treatment, and comorbidities represent additional determinants of greater cancer mortality.

CANCER EPIDEMIOLOGY METHODS

Epidemiologists study disease variation among populations and the factors that influence such variation. The proportion of individuals with disease in the population at a given point in time is the *prevalence* whereas *incidence and mortality rates* represent the number of events in a population over a defined period of time (e.g., cancers per

100,000 per year). To facilitate comparisons of rates between populations, rates are often adjusted for age, sex, race, or other demographic characteristics. The association between a characteristic or exposure with cancer risk is generally assessed in either cohort or case-control studies. *Cohort studies* are generally prospective and evaluate disease experience in exposed and unexposed individuals whereas *case-control studies* assess the exposure experience in individuals with and without disease. The *relative risk (RR)* is a measure of association between exposure and disease with estimates above 1.0 representing an increase in risk. In case-control studies, RR is estimated by the odds ratio because the sizes of the exposed and unexposed populations are often not known. The larger the study population, the more precise the estimate of association is between exposure and disease. However, proper interpretation of the results must explore whether any systematic error or bias has been introduced during the study design or analysis. Confounding factors may obscure or weaken a true association or create a false association because of an association between the factor and both the exposure and disease. Confounding can be evaluated and adjusted for in stratified or multivariate analysis if the potential confounder is recognized and has been properly measured in the data. It is generally not safe to assume that all possible confounding factors have been considered. Therefore, causal inference is seldom justified on the basis of a single study but evolves gradually with study repetition and consideration of other information including animal and other laboratory results, the strength of the association, and a careful consideration of likely confounding factors. Interventions for cancer prevention and screening are generally studied in randomized controlled trials requiring large numbers of participants, close monitoring for adherence in the intervention, long-term follow-up, and appropriate ascertainment of disease and disease-free status.

RISK FACTORS

Genetic

Risk factors for developing cancer can be grouped as either genetic (inherited) or acquired. While important for our understanding of carcinogenesis, only a small proportion of cancers are inherited in a mendelian fashion. Neoplasms inherited in an autosomal dominant manner include retinoblastomas, multiple endocrine neoplasia syndromes, and polyposis coli. Several additional pre-neoplastic conditions demonstrate mendelian inheritance with variable penetrance. Several common malignancies demonstrate familial risk patterns with low penetrance, including breast cancer and colorectal cancer. Genetic testing and potential preventative measures are available for several inherited cancer syndromes ([Table 55.2](#)). Although genetic testing is available for several identified cancer susceptibility genes, care must be

TABLE 55.1 US 2020 Cancer Statistics

ESTIMATED NEW CANCER CASES ^a			
Females (912,930)		Males (893,660)	
Breast	30%	Prostate	21%
Lung and bronchus	12%	Lung and bronchus	13%
Colon and rectum	8%	Colon and rectum	9%
Uterine corpus	7%	Urinary bladder	7%
Thyroid	4%	Melanoma of the skin	7%
Melanoma of the skin	4%	Kidney and renal pelvis	5%
Non-Hodgkin lymphoma	4%	Non-Hodgkin lymphoma	5%
Kidney and renal pelvis	3%	Oral cavity and pharynx	4%
Pancreas	3%	Leukemia	4%
Leukemia	3%	Pancreas	3%
All other sites	22%	All other sites	22%

ESTIMATED CANCER DEATHS			
Females (285,360)		Males (321,160)

Data from Siegel RL, Miller KD, Jemal A: Cancer statistics, 2020. CA: A Cancer Journal for Clinicians. (70)1:7-30, 2020.

^aExcludes basal cell and squamous cell skin cancers and in situ carcinoma except urinary bladder.

utilized in selecting individuals for such testing. Such testing requires a reasonable understanding of cancer genetics as well as the target population along with relevant ethical, economic, and societal issues.

At the same time, acquired somatic mutations are universally identified in malignant cells with some clearly driving the development and progression of cancer. While random genetic mutations occur frequently, proto-oncogenes involved in cell growth and proliferation, tumor suppressor genes involved in regulation of cellular proliferation, and mismatch repair genes associated with chromosomal instability play critical roles in carcinogenesis, tumor growth, progression, invasion, and metastasis. Fortunately, the spontaneous mutation rate is relatively low, and more than one mutational event is usually necessary for complete carcinogenic transformation resulting in a malignancy.

Lifestyle

Acquired risk factors for cancer include lifestyle factors as well as occupational and other environmental exposure to carcinogenic substances. Major lifestyle risk factors include tobacco, alcohol and other dietary factors, as well as lack of physical activity (Table 55.3).

Tobacco

Tobacco products are, by far, the single greatest contributor to cancer incidence and mortality worldwide. Cigarette smokers have a 20-fold or greater risk for developing cancer compared with nonsmokers, with smoking being the single largest cause of lung cancer. Tobacco accounts for one third of all cancers in the United States, contributing to the more than 1 million people annually who are estimated

to die from tobacco-induced cancers globally. The vast majority of lung cancers are attributable to cigarette smoking while exposure to secondhand smoke increases the risk for lung cancer in nonsmokers. Cigarette and cigar smoking and chewing tobacco are major risk factors for head, neck, mouth, and esophageal cancers and are associated with development of stomach, pancreas, kidney, bladder, and cervical cancer as well. While tobacco use has declined in the United States over the past two decades, it continues to be unacceptably high, especially among younger women, and continues to increase in many parts of the developing world.

Nutrition

Diet and body weight appear to play an important role in cancer causation. Excess alcohol use is clearly a significant risk factor for cancers of the liver, head and neck, esophagus, and breast. Obesity and dietary fat intake are associated with colon and breast cancers, but the exact nature of the relationship is still under investigation. Central or visceral adiposity in both men and women is associated with increased incidence and mortality from a number of cancers, including endometrium, breast in postmenopausal women, kidney, gallbladder, pancreas, esophagus, colon, and prostate.

Infection

Several chronic infections, including bacterial, viral, and parasitic, have been associated with an increased risk of different types of cancer. In certain parts of the developing world, infection with *Schistosoma haematobium* is a major cause of squamous cell carcinoma of the bladder.

Fig. 55.1 US cancer mortality rates, 1930-2017. (A) Males. (B) Females. †Includes intrahepatic bile duct, gall bladder, and other biliary. (From Siegel RL, Miller KD, Jemal A: Cancer statistics, 2020, CA: A Cancer Journal for Clinicians [70]1:7-30, 2020.)

Both DNA and RNA viruses have been associated with human cancers. Viruses associated with human malignancies include the Epstein-Barr virus (EBV) (nasopharyngeal cancer and Burkitt lymphoma) and human T-cell leukemia virus type I (HTLV-1). Patients with the acquired immunodeficiency syndrome (AIDS) associated with the human immunodeficiency virus (HIV) are at increased risk of Kaposi's

sarcoma, non-Hodgkin lymphoma, and anogenital squamous cell carcinoma. Chronic hepatitis B and C viral infections have been linked with the development of hepatocellular carcinoma. Human papillomaviruses 16 and 18 have been linked with cervical cancer, with vaccines against these virus strains and those causing genital warts, both on the market.

TABLE 55.2 Genetic Testing for Selected Hereditary Cancer Syndromes

Cancer: Involved Genes	Prevention Measures
Breast <i>BRCA-1, BRCA-2</i> <i>PTEN, STK-11, TP53</i>	Prophylactic mastectomy Selective estrogen receptor modulators Lifestyle measures Increased intensity of screening, including breast MRI
Lobular Breast Cancer and Gastric Cancer <i>CDH-1</i> (E-cadherin)	Prophylactic mastectomy Prophylactic gastrectomy Increased intensity of screening, including breast MRI Selective estrogen receptor modulators
Ovarian <i>BRCA-1, BRCA-2</i>	Prophylactic oophorectomy Oral contraceptives
Colon Familial adenomatous Polyposis (FAP) <i>APC</i> Hereditary nonpolyposis Colon cancer (HNPCC) <i>MLH-1, MSH-2</i> <i>MSH-6, PMS-2</i> MYH-associated polyposis <i>MYH</i>	Prophylactic colectomy Nonsteroidal anti-inflammatory drugs Lifestyle measures Lifestyle measures Nonsteroidal anti-inflammatory drugs Increased surveillance Prophylactic total abdominal hysterectomy and oophorectomy Lifestyle measures Nonsteroidal anti-inflammatory drugs Prophylactic colectomy
Uterine <i>PTEN, MLH-1, MSH-2, MSH-6, PMS-2</i>	Prophylactic hysterectomy Increased surveillance

FAP, Familial adenomatous polyposis; HNPCC, hereditary nonpolyposis colorectal cancer; MRI, magnetic resonance imaging; MYH, mutY homologue.

TABLE 55.3 Cancer Risk Factors

Lifestyle Factor	Associated Cancers
Tobacco	Lung, bronchus, esophagus, head and neck, stomach, pancreas, kidney, bladder, cervix
High alcohol consumption	Liver, rectum, breast, oral cavity, pharynx, larynx, esophagus
Obesity, high dietary fat	Colon, breast, endometrium, kidney, pancreas, esophagus, prostate
Low dietary fiber	Colon
Sedentary lifestyle	Colon, breast
Environmental Exposures	Associated Cancers
Human papillomavirus:16,18	Cervical
Hepatitis B and C viruses	Liver and hepatocellular cancers
Asbestos	Mesothelioma and other types of lung cancer
Radon	Lung
Ultraviolet radiation	Melanoma, basal and squamous cell carcinomas
Ionizing radiation	Leukemia, thyroid, lung, breast

Cancer and the Severe Acute Respiratory Syndrome Coronavirus 2 (SARS-Cov-2)

The 2020 pandemic from SARS-Cov-2 has placed patients with cancer at disproportionately greater risk of contracting COVID-19, as well as greater risk of serious medical complications including hospitalization, need for intensive care and ventilator support, and a greater risk for mortality. The reason for this impact is multifactorial and includes greater exposure to the health care system and infected patients and staff as well as greater risk from the immunosuppression resulting from disease and cancer therapies. Other factors that lead to greater

risk include older age, one or more serious medical comorbidities, and concurrent complications from other infectious agents and a range of demographic and geographic disparities.

Given the sudden and urgent crisis of this global pandemic, much of the epidemiologic information currently available has risen out of crowdsourcing efforts to rapidly and broadly gather as much information as possible on the impact of COVID-19 on patients with cancer and their management. The major driving force has been the need to gather and disseminate this information as quickly as possible for both clinical and public health purposes or containment and mitigation. While the resulting

case experience and cohort studies have provided much important and timely information from across the globe, it has come with analytic challenges and interpretation. Confounding by indication has complicated the rush to evaluate both preventive and therapeutic interventions in these largely uncontrolled and non-randomized studies. In the meantime, large-scale conventional epidemiologic studies are under development that should provide longer-term and more reliable information about the risk of COVID-19 in patients with cancer. Such studies may also provide data about the concurrent factors that impact the most on the risk of infection in the critically ill patient and disease and treatment-related predictors of serious and even fatal outcomes, while we are awaiting the development of effect treatments and vaccines. Nevertheless, the essentially exponential spread of SARS-Cov-2 both globally and in multiple specific sites, and the apparent, albeit limited, success of mitigation measures such as social distancing and masking, have reminded us of epidemiologic and public health measures of the past, which are equally if not more relevant today and critically important for patients with cancer.

Radiation

Non-ionizing radiation. Excess to ultraviolet (UV) radiation is unquestionably associated with an increased risk of skin cancers including basal and squamous cell carcinomas as well as cutaneous melanoma, with observed rates increasing directly with the amount of daily sunlight exposure. Most of the harmful effects from sun exposure are thought to be related to direct DNA damage associated with exposure to intermediate wavelength UV-B. The use of tanning beds and other frequent exposures to sunlight are of particular concern given the rapid increase in rates of melanoma among younger individuals.

Ionizing radiation. Ionizing radiation is arguably the most extensively studied carcinogen and has been unequivocally associated with an increased risk of both hematologic malignancies and various solid tumors in humans. Radiation-induced malignancies including leukemia and solid tumors are most extensively studied in the occupational settings among radiation workers and miners, among survivors of the atomic weapons used in Hiroshima and Nagasaki in World War II, and among those exposed to radiation for various medical indications. Excess cancer risk from radiation exposure can be seen with a latency period ranging from a few years (leukemia) to decades (solid tumors) and correlates with the cumulative exposure dose. As the survivors of the atomic bombing of Japan age, estimates of the associated risk of cancer have continued to increase.

Natural sources account for at least 80% of human exposure to radiation, most notably from radon. It has been estimated that radon exposure is the second leading cause of lung cancer due to widespread low-level exposure in the residential setting. In the occupational setting, there is a strong interaction between smoking and radon such that most radon-induced lung cancers are among smokers. Medical exposure accounts for most of the remaining average annual radiation exposure in the United States. There is increasing evidence that repeated exposure to radiation from multiple imaging studies such as CT scans, especially at a young age, is associated with an increased risk of cancer later in life.

Chemicals

Various pharmacologic agents have been associated with an increased risk for specific cancers. As with radiation, these agents may be used in the occupational setting, for diagnostic or therapeutic medical use, as well as for various purposes in the home setting. Organic and inorganic chemical compounds linked to human cancers including benzene (leukemia), benzidine (bladder), arsenic, soot and coal tars (lung and skin), and wood dusts (nasal). Arguably, asbestos is probably the most common cause of occupational cancer because of its link with the development of mesothelioma and other types of lung cancer. Nearly all mesotheliomas diagnosed in the United States are associated with

prior asbestos exposure. A strong interaction exists between asbestos exposure and cigarette smoking for lung cancer.

A range of medications are associated with an increased risk of cancer, including the alkylating agents, anthracyclines, and other classes of cancer chemotherapy and immunosuppressants. Estrogen use in postmenopausal women increases the risk of endometrial cancer, while the rates drop when combined with progesterone. Synthetic estrogens, such as diethylstilbestrol (DES), administered to mothers during pregnancy increase the risk of vaginal cancer in offspring. Lifestyle exposures to carcinogenic chemicals covered previously include multiple carcinogens in tobacco products and dietary factors including aflatoxins in many part of the world.

CANCER PREVENTION

Cancer prevention strategies can be thought of as primary or secondary based on whether they reduce risk of exposure or detect cancer at an early stage when intervention can change the natural history of the disease. Reasonable primary prevention strategies include reductions in lifestyle risks (smoking cessation; use of sunscreen; adherence to a low-fat, high-fiber diet), avoidance of occupational or environmental risks, and chemoprevention (see [Table 55.3](#)).

Lifestyle Changes

Smoking cessation is unquestionably the most direct and effective cancer prevention strategy available. More than 1 million people die from tobacco-induced cancers globally each year, and tobacco accounts for one third of all cancer diagnoses in the United States. Although tobacco prevention and control programs have resulted in a decline in smoking prevalence in the United States, tobacco use continues to be high and has been increasing in a number of countries. There is also evidence from epidemiologic studies that other lifestyle changes including regular exercise and dietary modification may also reduce the risk of cancer. Central adiposity is associated with increased incidence and mortality from a number of cancers, including breast and endometrium. Sufficient dietary intake of fruits and vegetables appears to reduce the risk for gastric and esophageal cancers. Avoidance of excessive sun exposure and the use of artificial tanning devices also is important to reversing recent upward trends in cutaneous malignancies. Reduction in exposures to known carcinogenic agents is an important goal in both the occupational and domestic setting. Evidence for an association between air pollution and lung cancer incidence illustrates how difficult that may be. However, prudent use of potentially carcinogenic chemicals and radiation in the medical setting will hopefully minimize exposures to settings where the benefit clearly outweighs the potential harms.

Chemoprevention

Chemopreventive agents are drugs, vaccines, or micronutrients (e.g., minerals, vitamins) used to prevent the development of cancer. Both randomized trials and epidemiologic studies have suggested that a number of strategies may be capable of reducing the risk of some common types of cancer. Recent data from multiple studies have provided suggestive evidence that daily aspirin use may reduce the risk of several types of cancer, including colon and melanoma. Evidence suggests that hepatitis B vaccination can reduce the incidence of hepatocellular cancer. The vaccine directed against specific strains of the human papillomavirus (HPV) offers the strong promise of preventing cervical cancer.

CANCER SCREENING

Cancer screening programs should be able to detect premalignant states or early-stage cancer before the onset of symptoms with relatively high sensitivity. Likewise, for cancer screening to be useful there

must be a treatment available that improves the outcome of patients with premalignant or early-stage disease. Such cancer screening programs should also, ideally, be noninvasive, inexpensive, and associated with high specificity (low false-positive rate). Identification of high-risk individuals can be of value to the effective and cost-effective application of genetic counseling and testing as well as cancer screening efforts.

Proper interpretation of the results of cancer screening studies must consider both *lead-time bias* and *length-time bias*. Lead time is the time between detection of disease by screening and the actual appearance of symptomatic disease. Diagnosing the disease earlier with screening may make it appear that the patient lived longer even when the survival of the patient from the onset of disease has not been altered. Length-time bias occurs when subsets of the cancer under study have different growth rates. Screening is more likely to detect cancers that grow slowly because of the greater prevalence of asymptomatic people with slow-growing tumors than with fast-growing tumors. Thus patients with cancer that is detected with screening appear to have longer survival as a result of screening, when in fact the longer course of their disease results from the behavior of the tumor itself. While randomized controlled trials of cancer screening programs require large numbers of participants and take years to complete, such trials are needed to accurately estimate screening performance and to address both lead-time and length-time bias.

It is important to note that screening tests may also be associated with false-negative and false-positive results. *False-negative results* fail to obtain a proper diagnosis and patients, therefore, are not provided the opportunity for effective early treatment. *False-positive results* may also cause harm by leading to unnecessary testing and treatment as well as contributing to patient costs and emotional stress.

A number of cancer screening tests are currently recommended, including clinical examination and mammography to detect breast cancer, Papanicolaou smears and HPV DNA tests to detect cervical dysplasia or cancer, colonoscopy to detect polyps or colon cancer, and digital rectal examination and serum PSA to detect prostate cancer. Low-dose CT scanning for screening appropriate high-risk individuals for lung cancer has recently been recommended based on several large randomized controlled trials.

Principles of Cancer Therapy

Davendra P.S. Sohal, Alok A. Khorana

INTRODUCTION

The treatment of cancer includes a rapidly growing portfolio of modalities and agents: locoregional therapies (surgery, radiation), systemic therapies (chemotherapy, targeted therapies, immunotherapies), and supportive care agents. Surgery and radiation therapy are safe and effective treatments for localized cancers, and techniques continue to be refined. In most settings (particularly advanced stages), however, cancer is a systemic disease and requires systemic treatment. Chemotherapy—the “first generation” of cancer drugs—is the current mainstay of systemic treatment. The explosive increase in our knowledge of cancer biology and genomics has allowed the development of both specific targeted agents and drugs harnessing the immune system to fight cancer. Many new drugs have been approved, and many more are in clinical trials—more than for any other class of medicine. Moreover, cancer treatment incurs many side effects. Symptom control, therefore, is a very important component of cancer therapy. All these modalities make it imperative that patients with cancer be treated by multidisciplinary teams at dedicated cancer centers. This chapter reviews the principles of the various components of cancer therapy.

DIAGNOSIS AND STAGING

Definitive treatment for cancer usually requires histologic diagnosis. This typically involves an invasive biopsy to obtain sufficient material to evaluate the morphology and invasiveness of the tumor and the expression of various molecular markers. Noninvasive tests such as radiologic imaging are seldom substitutes for tissue diagnosis. (There are occasional exceptions, such as an elevated α -fetoprotein level along with imaging evidence in a patient with cirrhosis, which can be used to make a diagnosis of hepatocellular carcinoma.)

Once the diagnosis of cancer has been made, for most solid-organ tumors, the next step is to systematically determine the extent of tumor spread, a process called *staging*. Tumor staging can be clinical or pathologic. *Clinical staging* involves physical examination and imaging studies, including targeted ultrasound (percutaneous or using invasive endoscopy devices), computed tomography scans, magnetic resonance imaging, whole-body positron-emission tomography scans, and radionuclide scans, usually in some combination, depending on the propensity of particular tumors to spread to particular organs. *Pathologic staging* is more definitive and follows the tumor-node-metastasis (TNM) method developed by the American Joint Committee on Cancer and the International Union against Cancer. This system requires a careful evaluation of the primary resection specimen for three measurements: (1) the size and extent of invasion of the primary tumor (the T score), (2) the number and location of histologically involved regional lymph nodes (the N score), and (3) the presence or absence of distant metastases (the M score). The M score is based

on information derived from both clinical and pathologic staging. TNM scores are then grouped into a pathologic stage, typically from I through IV, reflecting an increasing burden of disease. The final TNM stage has both prognostic and therapeutic implications. For instance, a resected colon cancer that invades the muscularis propria, involves 2 of 16 lymph nodes, but shows no evidence of distant metastases is staged as a T2 N1 M0 (stage III) colon cancer. The likelihood of tumor recurrence is 40% to 50%; and patients are recommended 3 to 6 months of chemotherapy after surgery. On the other hand, if no lymph nodes are involved (T2 N0 M0, stage I), the likelihood of recurrence is less than 10%, and chemotherapy is usually not recommended.

Biomarkers provide additional prognostic information, such as the absence of hormone receptors or expression of HER2 in breast cancer, which are indicative of a poor prognosis. Such markers can also be predictive; for instance, overexpression of HER2 in breast cancer predicts response to trastuzumab. Similarly, *KRAS* mutations in colorectal cancer predict lack of response to antibodies (e.g., cetuximab, panitumumab) that are directed against the epidermal growth factor receptor (EGFR) (Fig. 56.1). Both prognostic and predictive biomarkers provide important information in addition to the formal TNM stage. With an increasing array of biomarkers being identified, a panel of them are now usually tested, using next-generation sequencing (NGS) platforms that can sequence hundreds of relevant genes to identify point mutations, translocations, copy number alterations, and expression level changes. All of this information is compiled into a final assessment of whether the cancer is curable or not.

The next step is to evaluate the patient’s overall clinical condition with respect to comorbidities affecting major organ function and the patient’s functional ability, termed *performance status*. Performance status is assessed with the use of various history-based methods, such as the Eastern Cooperative Oncology Group (ECOG) or Karnofsky performance score. Patients with poor performance status or major comorbid conditions may not derive a benefit from cancer-directed therapy and are at greater risk for adverse events. This comprehensive assessment—diagnosis, stage, prognostic and predictive markers, and patient condition—dictates the management plan: either curative or palliative.

PRINCIPLES OF CANCER SURGERY

Surgery can prevent cancer by removal of precancerous lesions or organs that are at high risk for cancer (e.g., bilateral mastectomy in those with hereditary defects that can lead to breast cancer). Surgery can also make the diagnosis of cancer by biopsy; assist in staging by sampling lymph nodes; provide definitive treatment by removing the primary tumor; reconstruct the limb or organ sacrificed; and provide palliative treatment of cancer (e.g., intestinal bypass for obstruction, spinal cord decompression, or orthopedic procedures to prevent or

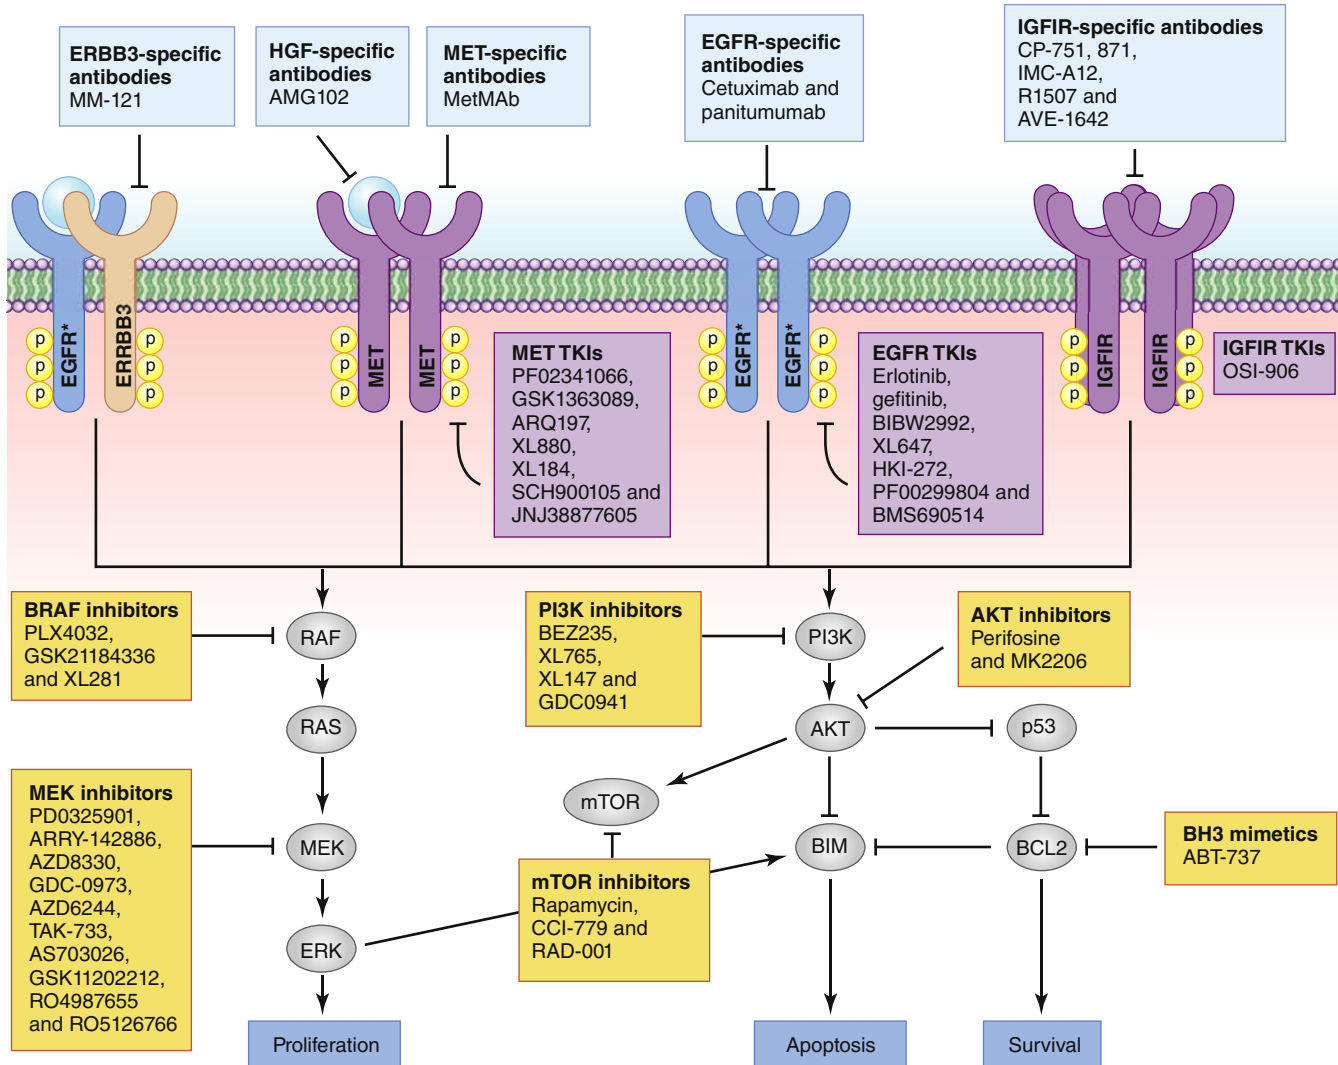

Fig. 56.1 The epidermal growth factor receptor (EGFR) pathway and related therapeutic targets. This figure depicts the transmembrane receptors of the EGFR family and the molecules involved in downstream signal transduction that ultimately lead to control of key proteins affecting cell survival, growth, and proliferation.

treat pathologic fractures). Invasive procedures, such as biopsies and the insertion of various access devices, tubes, stents, catheters, and drains, are also performed by interventional specialists, such as radiologists, gastroenterologists, and pulmonologists.

When a solid organ cancer is localized, surgery is the most effective curative treatment available. The intent is to completely remove the tumor, regional lymph nodes, and adjacent involved tissue, along with a safe margin of normal tissue. At surgery, the tumor is isolated and is almost never opened during the procedure. Refinements in cancer surgery include increasing use of minimally invasive methods in selected cancers and the identification of a sentinel lymph node by injection of a dye during surgery, which avoids a full lymph node dissection if the sentinel node is uninvolved by cancer.

PRINCIPLES OF RADIATION THERAPY

Radiation therapy can sometimes be used as definitive treatment, either alone or in combination with systemic therapy. Unlike surgery, local or regional treatment with radiation can preserve organ structure and function, improving quality of life for patients. For example, use of radiation with chemotherapy for treatment of localized laryngeal

cancer has outcomes similar to those of surgery but allows preservation of the larynx. Radiation therapy is also effective in the palliative setting, where it is used to control various cancer-related problems such as pain, mechanical obstruction of a luminal organ, and bleeding.

Ionizing radiation damages cellular DNA directly or indirectly through free radical intermediates. Cells are most susceptible to radiation during the M and G₂ phases of the cell cycle. The aim of radiation therapy is to deliver the highest dose possible to the tumor with minimal toxicity to adjacent normal tissues. Dividing the total planned radiation dose into small daily fractions takes advantage of the difference in repair capability between normal and malignant tissue and improves the tolerance of normal tissue. The biologic effects of radiation can be modified by numerous factors, including the amount of oxygen in the irradiated tissue and the use of chemotherapy for sensitizing tissue to radiation.

The goal of treatment planning for radiation therapy is to precisely define the dose and volume to be irradiated. The dose of radiation is measured in units of absorbed dose, Gray (Gy), which has replaced the older unit, rad (1 Gy = 100 rad). Conventional radiation treatments deliver 1.8 to 2 Gy/day on 5 days per week, over a period of 5 to 6 weeks. For palliative treatment, higher doses per fraction may be used to deliver an effective dose over a shorter period.

TABLE 56.1 Commonly Used Chemotherapy Agents

Drug	Cancers Treated	Specific Class or Mechanism of Action	Common Side Effects
Cell Cycle–Specific			
5-Fluorouracil	Gastrointestinal, head and neck, breast	Antimetabolite, inhibits thymidylate synthase	Myelosuppression, mucositis, diarrhea
Gemcitabine	Pancreas, lung, breast, bladder	Antimetabolite, deoxycytidine analogue	Myelosuppression, nausea, emesis
Methotrexate	ALL, choriocarcinoma, bladder, lymphoma	Antimetabolite, folic acid antagonist	Myelosuppression, mucositis, acute renal failure
Doxorubicin	Breast, lung, NHL	Anthracycline, intercalates into DNA	Myelosuppression, nausea, emesis, cardiomyopathy
Irinotecan	Colorectal, lung	Camptothecin, topoisomerase I inhibitor	Myelosuppression, diarrhea
Paclitaxel	Breast, lung, Kaposi's sarcoma, ovarian	Plant alkaloid, inhibits microtubule formation	Myelosuppression, hypersensitivity reaction, neuropathy
Vincristine	ALL, lymphomas, myeloma, sarcoma	Plant alkaloid, disrupts microtubule assembly	Peripheral neuropathy, constipation
Cell Cycle–Nonspecific			
Cyclophosphamide	Breast, NHL, CLL, sarcoma	Alkylating agent, cross-links DNA	Myelosuppression, hemorrhagic cystitis, nausea, emesis
Cisplatin	Lung, bladder, ovarian, testicular, head and neck	Alkylating agent, cross-links DNA	Nephrotoxicity, nausea, emesis, ototoxicity, sensory neuropathy

ALL, Acute lymphoblastic leukemia; CLL, chronic lymphocytic leukemia; NHL, non-Hodgkin's lymphoma.

Ionizing radiation can be administered as external-beam therapy with the use of a linear accelerator to generate electrons or high-energy radiographs. Electrons have a limited depth of penetration and are useful for superficial tumors. High-energy radiographs deliver the radiation deep into the body while reducing the dose to the skin as they enter. Brachytherapy uses radioactive sources to deliver ionizing radiation (gamma rays) directly to the tumor. An example is the implantation of iodine-125 seeds into the prostate as definitive therapy for early prostate cancer. Current approaches to improving radiation therapy include the use of advanced technology that allows delivery of a higher dose of radiation to specific areas of the tumor and sparing of normal tissue (conformal and intensity-modulated radiation therapy).

Injury to normal tissue from radiation therapy can be either acute or late. Acute effects occur within days to weeks after irradiation and are seen primarily in rapidly proliferating tissues such as skin and gastrointestinal mucosa. The severity depends on the total dose, but the damage can usually be repaired. Late effects, such as necrosis, fibrosis, or organ failure, appear months or years after irradiation and are dependent on fraction size. Another late complication of radiation therapy is the development of secondary malignancies of organs in the radiation field, sometimes decades after radiation.

PRINCIPLES OF MEDICAL THERAPY

The term *chemotherapy* refers to the use of cytotoxic agents, singly or in combination, for the systemic treatment of cancer. Most such agents are general antiproliferative agents that are more effective against rapidly growing tumors and have significant adverse effects on normal tissues that also divide rapidly, such as bone marrow and digestive tract mucosa. Newer agents, including monoclonal antibodies and signal transduction inhibitors, are directed against targets that are relatively specific to tumor cells and therefore may have less toxicity. These drugs are classified separately from chemotherapy as *targeted therapy* agents. The newest class of anticancer drugs is *immunotherapy*. These drugs stimulate the T cell cytotoxic machinery to allow cancer cell kill by native immunologic mechanisms. Related to these immunotherapy drugs is the use of the T-cell arsenal from a donor (stem cell transplantation) or self (chimeric antigen receptor–T cells).

Mechanisms of Chemotherapy

Chemotherapeutic agents can be cell cycle–specific or cell cycle–non-specific. Cell cycle–non-specific agents have a greater effect on cells traversing the cell cycle but also affect noncycling cells; cell cycle–specific agents affect only cycling cells. Chemotherapy agents are further classified according to their mechanism of action into alkylating agents, antimetabolites, antitumor antibiotics, and mitotic spindle inhibitors (Table 56.1). Most chemotherapy agents suppress the bone marrow, increasing the risk of neutropenic infections, anemia, and exacerbated bleeding. For most drugs, treatment schedules involve successive doses every 2 to 4 weeks. This interval between successive doses, the *cycle* of chemotherapy, allows recovery of blood counts and other side effects before administration of the next dose. The concept of *dose intensity* is also important. Cellular killing with chemotherapy follows first-order kinetics: A given dose of drug kills only a fraction of tumor cells. The dose-response curve for chemotherapy drugs is steep. Therefore, the greater the dose administered, the greater the kill: A 2-fold increase in dose can lead to a 10-fold increase in tumor cell kill. This also means that dose reductions may adversely affect the eventual cure rate. Shortening of the duration of cycles of chemotherapy using growth factor support—a “dose-dense” approach—has been shown to improve survival in selected patients when compared with traditional chemotherapy for breast cancer.

Single chemotherapy agents seldom cure cancer. Combination chemotherapy regimens have therefore been developed for a variety of cancers. Combination therapy provides maximal cell kill and broader coverage of resistant cells; it may also prevent or slow the development of resistant cells. Drugs used in a combination are chosen because they have known efficacy as single agents but have differing mechanisms of action and non-overlapping toxicity profiles. These regimens are commonly referred to by acronyms, such as CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone) for lymphoma or FOLFOX (5-fluorouracil, leucovorin, and oxaliplatin) for colorectal cancer.

Indications for Chemotherapy

Chemotherapy outcomes in general for localized or advanced cancers are summarized in Table 56.2. *Adjuvant* chemotherapy refers to its use after the primary tumor has been resected. Here, chemotherapy is

TABLE 56.2 Efficacy of Medical Therapy in Selected Cancers**Cure Possible Even in Advanced Disease**

Testicular cancer
 Acute leukemia: lymphocytic, promyelocytic, selected myelocytic
 Lymphomas: Hodgkin's lymphoma, selected non-Hodgkin's lymphomas
 Childhood solid tumors: rhabdomyosarcoma, Ewing sarcoma, Wilms tumor
 Choriocarcinoma
 Small cell lung cancer

Cure Likely in Locoregional Disease

Breast cancer
 Colorectal cancer
 Prostate cancer
 Renal cancer
 Head and neck cancer

Long-Term Control Possible in Advanced Disease

Melanoma
 Non-small cell lung cancer
 Chronic myeloid leukemia

directed against presumed systemic micrometastases in patients who are at high risk for recurrence. In the example of stage III colon cancer (described earlier), 3 to 6 months of adjuvant chemotherapy after primary tumor resection can reduce the patient's likelihood of developing recurrent cancer from 50% to 25%. Adjuvant chemotherapy has been shown to increase cure rates in many other cancers.

Neoadjuvant or *preoperative* chemotherapy refers to the use of chemotherapy before surgery, sometimes in combination with radiation therapy. If successful, neoadjuvant therapy can reduce the size of the tumor and consequently permit less removal of normal tissue, such as a lumpectomy instead of a mastectomy in breast cancer or limb-sparing surgery instead of amputation in extremity sarcoma.

Chemotherapy can be curative on its own in cancers such as germ cell tumors, lymphomas, and leukemias. Most often, chemotherapy is employed in the treatment of metastatic disease for which surgery or radiation therapy is ineffective. Even when it is not curative, chemotherapy often extends survival and improves cancer-related symptoms and quality of life.

Limitations of Chemotherapy

Chemotherapy is curative only under certain circumstances, because it is inherently limited by side effects (i.e., the dose ceiling). There are several reasons for the inability of standard doses of chemotherapy to cure cancer. First, tumor cell kinetics naturally protect against chemotherapy. When chemotherapy was initially developed, it was believed that tumors contained a percentage of cells traversing the cell cycle. However, most human tumors display Gompertzian growth kinetics—that is, the rate of tumor cell doubling *slows* progressively as tumor size increases. Therefore, the growth fraction of tumors is greatest when a tumor is clinically undetectable. By the time the patient is symptomatic and has clinically evident disease, the growth fraction of tumors can be less than 5%. Chemotherapy can be successful in the adjuvant setting (when the burden of disease is minimal), but it rarely results in cure in the metastatic setting.

Second, cancer cells can become resistant to chemotherapy. One of the most important forms of resistance is intrinsic and is mediated by an evolutionarily conserved cell membrane efflux pump called *P-glycoprotein*. Resistance can also be acquired after a period

of exposure to chemotherapy agents by a variety of mechanisms; for example, tumor cells can decrease the uptake of methotrexate by decreasing the expression of the folate transporter, or they can amplify expression of the target enzyme thymidylate synthase when treated with 5-fluorouracil.

Third, mutations in the *TP53* gene are common in various cancers. The TP53 protein causes cell-cycle arrest and mediates apoptosis when DNA damage occurs. In the absence of a functioning TP53, cancer cells are protected from chemotherapy-induced apoptosis.

Targeted Therapy

The limitations of chemotherapy, coupled with a greater understanding of cancer cell biology, has led to the development of a new class of drugs directed against targets that are relatively specific to cancer cells: growth factors and signaling molecules that are essential for proliferation of tumor cells; cell-cycle proteins; regulators of apoptosis; and molecules mediating host-tumor interactions such as angiogenesis and tumor immunity. These agents include monoclonal antibodies directed against cell surface antigens or growth factors, specific or multitargeted receptor tyrosine kinase inhibitors, specific pathway signal transduction inhibitors, antisense oligonucleotides, and gene therapies. Additional agents are under development. The usual side effects of chemotherapy, such as myelosuppression, nausea, emesis, diarrhea, and alopecia, are not necessarily observed with these drugs. However, other target-specific toxicities require careful monitoring and management (Table 56.3).

The best-known targeted therapy agent is imatinib, which inhibits both BCR-ABL, the constitutively active fusion product arising from the Philadelphia chromosome of CML, and KIT (c-kit, CD117), which is overexpressed in gastrointestinal stromal tumors (GIST). The daily oral administration of imatinib results in complete hematologic responses in more than 90% of patients in chronic-phase CML and partial responses in more than 50% of patients with metastatic GIST. Ibrutinib is another novel agent, targeting Bruton tyrosine kinase, with excellent efficacy in CLL and Waldenström's macroglobulinemia.

In many other malignancies, there are multiple redundant signaling pathways that are dysregulated. Increasingly, tyrosine kinase inhibitors with multiple (as opposed to specific) targets have been developed to treat such cancers. Sorafenib and sunitinib are two examples of such agents that inhibit various pathways, including vascular endothelial growth factor (VEGF), platelet-derived growth factor (PDGF), and KIT. Studies have shown these drugs to be effective in renal and liver cancers.

Targeted therapy drugs can also increase the efficacy of chemotherapy, through various mechanisms. For instance, the EGFR antagonists cetuximab and panitumumab increase the efficacy of irinotecan-based chemotherapy in colorectal cancer and that of definitive radiation therapy in oropharyngeal cancers. The availability of these agents has increased the number of drug combinations that can be used in particular cancers. As multiple combinations of chemotherapy and targeted therapy have become available for the treatment of advanced colon cancer the median survival time of patients with this disease has more than doubled. Targeted therapy agents are also increasingly being used in the adjuvant setting—imatinib in patients with resected GIST or trastuzumab in patients with resected HER2-positive breast cancer have substantially improved outcomes for these malignancies.

Endocrine Therapy

Cancers originating from organs that are regulated by hormones, such as breast and prostate, may be susceptible to hormonal control mechanisms even when metastatic. Endocrine therapy includes the use of both hormonal and antihormonal agents that work as antagonists or partial agonists.

TABLE 56.3 Examples of Targeted Therapy Agents

Drug	Cancers Treated	Targets	Common Side Effects
Monoclonal Antibodies			
Alemtuzumab	CLL	CD52	Myelosuppression, fever, rash
Bevacizumab	Colorectal, renal, lung	VEGF	Hypertension, proteinuria, bleeding, thromboembolism
Cetuximab	Colorectal	EGFR	Rash
Ipilimumab	Metastatic melanoma	CTLA4	Cytokine release storm
Ofatumumab	CLL	CD20	Rash, diarrhea, respiratory tract infections
Panitumumab	Colorectal	EGFR	Rash
Pertuzumab	Breast	HER2	Rash, diarrhea
Rituximab	NHL	CD20	Infusional reaction, skin reactions
Trastuzumab	Breast	HER2/Neu	Infusional reaction, congestive heart failure
Signal Transduction Inhibitors			
Axitinib	Renal	VEGF, PDGF, KIT	Hypertension, hand-foot syndrome, diarrhea
Crizotinib	Lung	EML4-ALK	Edema, diarrhea
Dasatinib	CML	BCR-ABL	Myelosuppression, pleural effusions
Imatinib	CML, GIST	BCR-ABL	Diarrhea, fluid retention, myelosuppression
Erlotinib	Lung, pancreas	EGFR tyrosine kinase	Rash, diarrhea
Gefitinib	Lung	EGFR tyrosine kinase	Rash, hypertension
Ibrutinib	CLL, Waldenström's macroglobulinemia	Bruton tyrosine kinase	Bacterial infections
Imatinib	CML, GIST	BCR-ABL	Diarrhea, fluid retention, myelosuppression
Lapatinib	Breast	HER2, EGFR	Rash, diarrhea
Regorafenib	GIST, colorectal	VEGF	Hypertension, hepatotoxicity, dysphonia
Sunitinib	Renal, GIST	VEGF, PDGF, KIT	Rash, diarrhea, fatigue
Sorafenib	Liver, renal	VEGF, PDGF, KIT	Hypertension, fatigue, diarrhea, hand-foot syndrome
Vandetanib	Medullary thyroid	VEGF, EGFR, RET	Rash, abdominal pain, diarrhea
Vemurafenib	Melanoma	BRAF	Rash, skin lesions, arthralgia
Others			
All- <i>trans</i> -retinoic-acid	Acute promyelocytic leukemia	Differentiating agent	Vitamin A toxicity, retinoic acid syndrome, hyperlipidemia
Azacitidine	Myelodysplasia	Hypomethylating agent	Myelosuppression, injection site reactions
Bortezomib	Lymphoma, myeloma	Proteasome inhibitor	Rash, nausea, emesis, neuropathy
Everolimus	Renal, breast, neuroendocrine	mTOR inhibitor	Hyperglycemia, diarrhea, fatigue

CLL, Chronic lymphocytic leukemia; CML, chronic myelogenous leukemia; CTLA4, cytotoxic T lymphocyte-associated protein 4; EGFR, epidermal growth factor receptor; GIST, gastrointestinal stromal tumor; mTOR, mammalian target of rapamycin; NHL, non-Hodgkin's lymphoma; VEGF, vascular endothelial growth factor.

Many patients with metastatic breast cancer express hormone receptors (estrogen or progesterone) in tumor cells. Most of these patients respond either to tamoxifen, an estrogen receptor modulator, or to aromatase inhibitors (letrozole, anastrozole, or exemestane), which inhibit adrenal steroid production. Similar responses are observed in men with metastatic prostate cancer treated with the luteinizing hormone-releasing hormone agonists leuprolide or goserelin, which decrease testosterone to castrate levels.

In selected breast and prostate cancer patients, metastatic disease can be controlled for years with only endocrine therapy. Tamoxifen and the aromatase inhibitors are also highly effective adjuvant treatments after breast cancer resection. Furthermore, tamoxifen has been shown to reduce the incidence of breast cancer by 50% in healthy women who are at high risk for developing breast cancer.

Personalized Medicine

These targeted therapies—kinase inhibitors, antibodies, hormones—work only when their specific targets are present in the cancer cells. The paradigm of evaluation of tissue specimens for such targets to allow the use of drugs impinging on those targets is referred to as *precision* or

personalized medicine/oncology. The time and costs involved in analyzing genomic alterations from a patient's tumor are now much reduced. In addition to DNA, transcriptomic (RNA), epigenomic (DNA methylation), and single-nucleotide polymorphism (SNP array) analyses can also be performed. Several cancers have already been sequenced completely. Such work creates "reference libraries" against which a patient's tumor can be tested. Based on findings from such analyses, specific drugs or regimens can be recommended for individual patients. Most of the targeted therapies, and even immunotherapies, have predictive molecular markers: microsatellite instability, tumor mutation burden, *NTRK* and *FGFR* fusions, *KRAS* and *BRAF* mutations, *HER2* and *cMET* overexpression being prominent examples. A prominent success story has been lung cancer, where therapies targeting *EGFR* mutations, *ALK* fusions, *MET* alterations, and others are now front-line treatments with much greater clinical benefit than traditional cytotoxic agents.

Immunotherapy

Immunotherapy agents act by altering the host immune response to the tumor. They either stimulate the cytotoxic T-cell machinery directly

or counter the inhibitory mechanisms keeping these cells quiescent, the result being that T cells get primed to recognize and kill cancer cells. Cancer vaccines, such as the dendritic cell vaccine sipuleucel-T for prostate cancer, exploit the presence of specific tumor antigens that can serve as targets of the stimulated T cells. Their use is so far limited to a handful of scenarios.

More recently, antibodies targeting CTLA4 and PD1, which are inhibitory receptors on the surface of cytotoxic T-cells (or PD-L1, the ligand on tumor cells that corresponds to PD1), have achieved great success in the treatment of various malignancies. These checkpoint inhibitors—so called because they block the molecular “checkpoints” that normally inhibit cytotoxic T-cells—unleash the body’s immune response to recognize cancer cells as “foreign” and kill them. This is akin to the graft-versus-tumor response used in allogeneic hematopoietic stem cell transplantation; only here, the body’s native immune system is primed to achieve the desired effect, with much less toxicity. A major toxicity observed with this approach is the possibility of “autoimmune” reaction whereby uncontrolled T-cell cytotoxicity damages normal cells and tissues. These drugs are now routinely used to treat melanoma, kidney cancer, and lung cancer, and achieve remarkably durable clinical responses.

The ability of these checkpoint inhibitors to work is dependent largely on their ability to see the cancer cells as “different” from the normal cells. Because cancer cells frequently have mutations that lead to the production of abnormal proteins, these neopeptides serve as neoantigens for the T cells, allowing differential identification and targeting of cancer cells. Therefore, the higher the tumor mutation burden, the more likely the efficacy of these drugs. This is clearly evident in high mutational load tumors such as ultraviolet light–associated melanoma, smoking-associated lung cancer, and cancers with high microsatellite instability, which respond very well to these drugs.

Stem Cell Transplantation

The traditional model of using T-cell immunity to counter cancer has been allogeneic stem cell transplantation. By using harvested stem cells (typically from the bone marrow of an HLA-matched donor), the immunologic response mounted by the donor cells, termed *graft-versus-tumor* effect, can lead to durable cures in various leukemias. However, allogeneic transplantations can be offered only to a minority of patients because of the limited availability of matched donors (particularly in ethnic minority populations) and the inability of older patients and those with comorbid illnesses to tolerate this procedure. To increase the availability of donors, umbilical cord blood is being studied as a source of stem cells.

The complications of stem cell transplantation are primarily related to the toxicity of chemotherapy and radiation therapy to vital organs, including lungs and liver. Long-term morbidity and mortality after allogeneic transplantation can result from *graft-versus-host disease* and from complications of immunosuppressive agents used to treat it.

CAR-T Cell Therapy

The newest advance in the field of using T cell cytotoxicity to kill cancer cells is chimeric antigen receptor–T (CAR-T) cells. This involves extracting a cancer patient’s T cells and then modifying them using retroviral, lentiviral, or CRISPR/Cas9 gene editing methods. This editing process attaches a chimeric receptor on the surface of these T cells: the chimeric receptor combines a cancer cell–specific antigen binding site and a T cell activating site. These primed T cells are then infused back into the patient after depleting native T cells using chemotherapy. Extensive cytotoxic T cell activity leads to a “cytokine storm” that requires aggressive supportive care, but eventually, durable clinical responses in leukemias and lymphomas have been achieved. The efficacy of this approach in patients with solid organ malignancies is currently being tested.

EVALUATION OF RESPONSE

The efficacy of cancer-directed therapies is gauged by various methods and has been granted its own vocabulary. In patients with metastatic disease, all known sites of disease are monitored by physical examinations and serial radiologic imaging. Responses are judged according to the internationally accepted Response Evaluation Criteria in Solid Tumors (RECIST) rules. Disappearance of all known lesions is called a *complete response*, whereas a 30% or greater reduction in size is called a *partial response*. Appearance of new lesions or an increase in the size of known lesions by 20% is termed *progression of disease* and implies failure of treatment. A tumor that is neither responding nor progressing is termed *stable disease*.

The percentage of patients who experience a response is called the *response rate* to the agent or agents being administered. New drugs are often evaluated on the basis of response rates. However, a response does not imply cure. Even a drug with a 100% response rate is not curative if all patients relapse. Therefore, the “gold standard” for measuring the efficacy of a drug is considered to be an improvement in *overall survival*, or its surrogate, *disease-free survival*—the time interval during which the patient is alive without disease. The use of effective second-line therapies may minimize the survival differences between two treatments prescribed as initial therapy, and in this context, disease-free survival can serve as an important end point in evaluating new regimens. Increasingly, quality-of-life end points such as use of pain medications or patient-reported outcomes are also being used to assess the efficacy of drugs in palliation.

SUPPORTIVE CARE

Supportive care interventions can improve the safety and tolerability of cancer treatments. Many drugs can mitigate chemotherapy-related side effects. Serotonin receptor antagonists and neurokinin-1 receptor antagonists, in combination with older antiemetic drugs, may control chemotherapy-induced nausea and vomiting. Granulocyte colony-stimulating factor (filgrastim) and granulocyte-macrophage colony-stimulating factor (sargramostim) stimulate the proliferation and differentiation of myeloid progenitor cells and can prevent or minimize the duration of chemotherapy-induced neutropenia and reduce the likelihood of neutropenic fever. These agents are also used to mobilize and collect stem cells for transplantation.

Supportive care is an integral part of the treatment of cancer, particularly in noncurative settings. Palliative aspects of treating cancer address not only physical symptoms in particular pain syndromes but also psychosocial and spiritual concerns. Chemotherapy and radiation therapy are often used with palliative intent and can improve quality of life.

DEFINITION AND EPIDEMIOLOGY

Lung cancer is the second most common cancer in the United States and the leading cause of cancer death. Worldwide, an estimated 1 million people die of lung cancer each year. Despite recent advances in understanding of the biology and genetics of lung cancer and the advent of novel therapeutic agents for its treatment, the 5-year survival rate for patients with lung cancer is below 20%. The relatively poor long-term survival partly stems from the fact that most patients with lung cancer have an advanced stage of the disease at the time of diagnosis.

Historically, lung cancer has been divided into two major types: *small cell lung carcinoma* (SCLC) (E-Fig. 57.1) and *non-small cell lung carcinoma* (NSCLC). It is increasingly important to recognize the subtypes of NSCLC (based on histologic, or genetic differences), and it is essential to do so when selecting drug therapy for stage IV (metastatic) NSCLC. Histologic subtypes of NSCLC include adenocarcinoma (40% of lung cancers) (E-Fig. 57.2), squamous cell carcinoma (30% of lung cancers) (E-Fig. 57.3), large cell carcinoma (10% of lung cancers) (E-Fig. 57.4), and some more poorly differentiated histologic subtypes not otherwise specified (NOS).

A current or prior history of cigarette smoking remains the leading known risk factor for the development of lung cancer. SCLC, in particular, is so causally linked to tobacco smoking that its prevalence (currently <15% of all lung cancers) is falling as smoking prevalence falls. Still, up to 15% of newly diagnosed NSCLCs (usually adenocarcinoma) are seen in never-smokers. In recent years, it has been recognized that lung cancer in smokers is a different disease from lung cancer in never-smokers and impacts prognosis, genetic underpinnings, and response to immune therapy.

The risk for lung cancer is generally proportional to the number of cigarette pack-years smoked (packs per day \times years smoked), and the incidence peaks in the sixth and seventh decades of life. Former-smokers have a persistent risk for lung cancer throughout life. Second-hand smoking is also a risk factor for lung cancer in a portion of nonsmokers who develop the disease. Nonsmokers who live with smokers have a more than 30% increased risk of developing lung cancer than those who live with nonsmokers. Other risk factors for lung cancer include environmental hazards such as asbestos and petroleum exposure. Smoking is considered an important cofactor of lung cancer in the setting of asbestos exposure. Radon exposure also increases the risk for developing lung cancer (see Chapter 55).

An ever-growing list of genetic alterations have been identified in terms of both proto-oncogenes and tumor suppressor genes. Unique molecular-genomic subgroups of lung cancer have been recognized, including those harboring (1) mutated epidermal growth factor receptor (*EGFR/ERBB1*), (2) mutated Kirsten rat sarcoma viral oncogene homolog (*KRAS*), and (3) anaplastic lymphoma kinase (*ALK*) 2p23

chromosomal rearrangement, more commonly known as *EML4-ALK*, a fusion with echinoderm microtubule-associated protein-like 4 (*EML4*). Importantly, these oncogenic alterations inform gene-targeted drug selection in that the cancer is dependent upon a single oncogenic pathway for sustained proliferation and/or survival (oncogene addiction).

Several targeted therapies have been approved by the US Food and Drug Administration (FDA) for the treatment of advanced NSCLCs containing mutated *EGFR* (gefitinib, erlotinib, afatinib, osimertinib) or the *ALK* 2p23 rearrangement (crizotinib, ceritinib, alectinib, brigatinib, lorlatinib). Lung cancers with *EGFR* mutations are more frequently identified in never-smokers or in those with a light smoking history. They are more often of the adenocarcinoma subtype and more commonly found in women and in patients of East Asian descent. *KRAS*-mutated lung cancers are found primarily in patients with a more extensive smoking history. Lung cancers with mutated *EGFR* and those with the *ALK* 2p23 rearrangement are typically seen in younger patient populations, with a median age at diagnosis of approximately 55 years.

PATHOLOGY

Histologic Subgroups

Non-Small Cell Lung Carcinomas

Most lung cancers fall under the major histologic subgroup of NSCLC. Of these, *adenocarcinomas* and *squamous cell carcinomas* are the most common.

Adenocarcinomas. Adenocarcinoma is the most commonly diagnosed subtype of lung cancer, accounting for approximately 40% of lung cancer diagnoses and 65,000 deaths each year in the United States. It is the histologic subtype most commonly diagnosed in never-smokers. Primary lung adenocarcinomas are usually found in the periphery of the lung (75%) (E-Fig. 57.5), in contrast to squamous cell carcinomas that may arise in central airways.

Histologically, adenocarcinomas typically form glandular structures and produce mucin. *EGFR* mutations are more commonly associated with nonmucinous lung adenocarcinoma, whereas the mucinous subtype is more commonly associated with mutated *KRAS*. The tumor cells typically stain positive for cytokeratin 7 (CK7) and thyroid transcription factor 1 (TTF-1) and stain negative for cytokeratin 20 (CK20). *Lepidic adenocarcinomas* (previously known as bronchioloalveolar carcinomas) grow along alveolar spaces and allow air to enter the tumor. These adenocarcinomas manifest as translucent *ground-glass* lung infiltrates on computed tomography (CT) scan. Mucinous adenocarcinomas can cause dense lung consolidation and can be accompanied by copious sputum production, known as *bronchorrhea*.

Squamous cell carcinomas. Squamous cell carcinomas arise from the epithelial layer of the bronchial wall. Normal columnar

E-Fig. 57.1 Small cell lung carcinoma.

E-Fig. 57.4 Large cell undifferentiated carcinoma of the lung.

E-Fig. 57.2 Adenocarcinoma of the lung.

E-Fig. 57.3 Squamous cell carcinoma of the lung.

E-Fig. 57.5 Peripheral tumor of lung cancer (*arrow*). Peripherally located primary lung cancer most commonly occurs with adenocarcinoma of the lung, as shown here.

epithelial cells undergo metaplasia, dysplasia, and then localized carcinoma formation (*carcinoma in situ*), which can then further extend and invade beyond the bronchial mucosa as it acquires a full malignant invasive phenotype. Most squamous cell carcinomas arise within central airways (E-Fig. 57.6). Therefore, the airway lumen may become obstructed, leading to collapse of the lung or postobstructive pneumonia. Although necrosis and cavity formation can occur in any lung tumor, this feature is more common in squamous cell carcinomas. Squamous lung cancers have a lower potential for metastatic spread compared to invasive adenocarcinomas. Histologically, squamous cell carcinomas can be distinguished from other NSCLCs by the presence of keratinization, pearl formation, intercellular bridging, and staining positive for p40 and/or p63.

Adenosquamous carcinomas. Adenosquamous carcinomas constitute between 0.4% and 4% of all lung cancers and have a worse prognosis. They have components of both adenocarcinoma and squamous cell carcinoma, each comprising at least 10% of the tumor. It is important to recognize intratumor heterogeneity and mixed histology NSCLCs, especially when the diagnosis is based on a single needle biopsy. Most molecular pathology guidelines recommend genetic analysis of small biopsy specimens so as not to miss the druggable gene mutations that are more common to adenocarcinoma.

Sarcomatoid carcinomas. Sarcomatoid carcinomas, also known as *giant cell* or *pleiotropic carcinomas*, are high-grade lung cancers with a poor prognosis but that may harbor druggable oncogene drivers (especially MET exon 14 skipping) or may be particularly susceptible to immune checkpoint inhibitors.

NSCLC not otherwise specified. These NSCLCs are poorly differentiated tumors that defy specific classification based on their histology and immunophenotyping profile, but they may still be subtyped based on gene mutation analyses.

Small Cell Lung Carcinoma

SCLC cells are of pulmonary neuroendocrine cell origin and are often associated with paraneoplastic syndromes (Table 57.1). SCLCs typically are perihilar in location. They often originate from the main bronchi and have associated malignant adenopathy (E-Fig. 57.7). These tumors have a high propensity for metastasis, most commonly to the thoracic lymph nodes, bones, liver, adrenal glands, and brain. Most patients are already affected with metastatic disease at the time of presentation. SCLC is an aggressive lung tumor. In fact, without treatment, the median survival time of patients with SCLC is less than

5 months. The overall survival for all patients is 5% at 5 years and has not improved over the past several decades.

Molecular-Genomic Subtypes

Lung cancer is now increasingly regarded as a disease with distinct genetic subgroups (Table 57.2). Many of these molecular-genomic alterations can inform the use of targeted therapeutics and predict responses.

Mutant *EGFR*

EGFR mutation testing and targeted therapy are essential to the care of patients with stage IV (metastatic) NSCLC. Specific somatic *EGFR* activating-sensitizing mutations predict clinical response to *EGFR* tyrosine kinase inhibitors (gefitinib, erlotinib, afatinib, osimertinib). These mutations are usually found in never-smokers with adenocarcinoma. *EGFR* mutations are more prevalent in women and patients of Asian race (30%, compared with 7% to 10% in Caucasians).

ALK 2p23 Rearrangement

The *EML4-ALK* fusion is an oncogenic driver that occurs in 3% to 7% of NSCLCs and is often found in light smokers (<10 pack-years) or never-smokers. In most cases, *EML4-ALK* fusions do not overlap with other oncogenic mutations of *EGFR* or *KRAS*. Patients with *ALK* rearrangements can be treated with *ALK* inhibitors (crizotinib, ceritinib, alectinib, brigatinib, lorlatinib).

ROS-1 Rearrangement

ROS-1 is a receptor tyrosine kinase of the insulin receptor family. *ROS-1* gene rearrangements are found in approximately 2% of NSCLCs. There is protein homology between the *ALK* and *ROS-1* kinase domain, such that the lists of active drugs overlap. FDA-approved drugs for *ROS-1* include crizotinib and entrectinib. Other *ALK*-inhibitors (ceritinib, lorlatinib) are effective against both *ALK* and *ROS-1*.

Mutant *KRAS*

KRAS gene mutations are uncommon in squamous cell carcinomas but are present in 15% to 25% of lung adenocarcinomas. *KRAS* mutations are more commonly seen in former or current cigarette smokers than in never-smokers or light smokers. There is currently no FDA-approved treatment for mutated *KRAS*, but covalent modifiers of the *KRAS* G12C oncoprotein show promise and have moved into phase 2 clinical testing.

TABLE 57.1 Paraneoplastic Syndromes Associated With Lung Cancer

Syndrome	Cell Type	Mechanism
Hypertrophic pulmonary osteoarthropathy and clubbing	All except small cell	Unknown
Hyponatremia	Small cell most common; may be any type	SIADH, ectopic antidiuretic hormone production by tumor
Hypercalcemia	Usually squamous cell	Bone metastases, osteoclast-activating factor, parathyroid hormone–like hormone, prostaglandins
Cushing syndrome	Usually small cell	Ectopic ACTH production
Eaton-Lambert myasthenic syndrome	Usually small cell	Voltage-sensitive calcium-channel antibodies in >75%; affects presynaptic neuronal calcium channel activity
Other neuromyopathic disorders	Small cell most common; may be any type	Antineuronal nuclear antibodies, also known as anti-Hu; others unknown
Thrombophlebitis	All types	Unknown

ACTH, Adrenocorticotropic hormone; SIADH, syndrome of inappropriate secretion of antidiuretic hormone.

E-Fig. 57.6 Central tumor of lung cancer (squamous cell tumor). Examples of centrally located primary lung cancer include squamous cell carcinoma of the lung and small cell lung carcinoma.

E-Fig. 57.7 Malignant adenopathy in primary lung cancer. This patient has a small cell carcinoma with adenopathy and collapse of the left upper lobe.

TABLE 57.2 Selected Molecular-Genomic Subtypes of NSCLC

Oncogene	Class of Molecular-Genomic Alterations	Characteristics
<i>EGFR</i> -mutant	Somatic missense mutations (most common with <i>L858R</i> in exon 21) and exon 19 deletions	More frequent in Asians, females, never-smokers or light smokers; most frequently adenocarcinoma subtype Sensitizing to <i>EGFR</i> inhibitors gefitinib, erlotinib, afatinib, osimertinib <i>T790M</i> mutation in <i>EGFR</i> is resistant to gefitinib, erlotinib, afatinib
<i>EML4-ALK</i>	<i>ALK</i> 2p23 chromosomal translocation	3-7% of NSCLCs More common in light smokers (<10 pack-years) or never-smokers Sensitizing to <i>ALK</i> inhibitors crizotinib, ceritinib, alectinib, brigatinib, lorlatinib
<i>KRAS</i> -mutant	Somatic mutations	Found in 15-25% lung adenocarcinomas More commonly seen in former or current cigarette smokers No effective targeted treatment at present but covalent inhibitors of <i>G12C</i> are in phase 2 development
<i>BRAF</i> -mutant	Somatic mutations	Belong to a family of serine-threonine protein kinases Identified in 1-3% of cases Only <i>BRAF V600E</i> is sensitive to trametinib, dabrafenib
<i>HER2</i> -mutant	Exon 20 insertion	<i>HER2</i> alterations were identified in ≈2-4% of NSCLCs In the selected population of <i>EGFR/KRAS/ALK</i> -mutation–negative patients, <i>HER2</i> mutations can reach up to 6% Predominantly found in females, nonsmokers; predominantly adenocarcinoma subtype May be associated with sensitivity to <i>HER2</i> -targeting drugs (trastuzumab, lapatinib, pertuzumab, and T-DM1)
<i>STK11/LKB1</i>	Inactivating mutations, deletion	A tumor suppressor gene Mutational frequency about 17-35% of NSCLCs, associated with resistance to immune checkpoint inhibition
<i>RET</i> -fusion	Chromosomal translocations	Occur in lung adenocarcinomas (1-2%). Respond to vandetanib, cabozantinib with off-target toxicity. On-target TKIs with fewer side effects are in late-phase development.
<i>ROS-1</i> -fusion	Chromosomal translocations	<i>ROS-1</i> is a receptor tyrosine kinase of the insulin receptor family <i>ROS-1</i> -fusions were identified in ≈2% of NSCLCs More commonly found in younger people, more likely in never-smokers, and Asian patients are overrepresented Similar protein structure to other RTKs leads to overlapping active drug list (crizotinib, entrectinib, ceritinib, lorlatinib)
<i>MET</i>	Alternative spliced variant, mutations, amplification, receptor overexpression	The <i>MET</i> proto-oncogene is a receptor tyrosine kinase that binds to hepatocyte growth factor <i>MET</i> gene amplification can be found in 2-4% of NSCLCs, whereas overexpression of its receptor protein is much more common. May respond to crizotinib. <i>MET</i> exon 14 skipping results in lung cancers that respond to crizotinib. Several more potent <i>MET</i> inhibitors are in late-phase development.
<i>NTRK</i>	Chromosomal translocations	Rare, <1%. The <i>NTRK</i> genes encode the tropomyosin receptor kinases, which are receptors for nerve growth factors. When detected in lung cancer, patients respond to TKIs larotrectinib, entrectinib.

EGFR, Epithelial growth factor receptor; *FDA*, US Food and Drug Administration; *NSCLC*, non–small cell lung cancer; *RTK*, receptor tyrosine kinase.

The Lung Cancer Genome

In the last decade, The Cancer Genome Atlas (TCGA) project has provided a more comprehensive understanding of lung cancer by defining many of its nuances on a genomic level. The TCGA analysis of lung adenocarcinoma identified a relatively high exonic somatic mutation rate (mean, 12.0 events per megabase), similar to the rate found in squamous cell lung carcinoma. Three distinct expression subtypes of lung adenocarcinoma were identified from RNA-sequencing data: bronchioid, magnoid and squamoid. In addition, multiple gene fusions were found to be expressed in lung adenocarcinomas and multiple mechanisms for inactivation of the tumor suppressor gene *CDKN2A* were discovered.

For squamous cell NSCLCs, a most unexpected finding in the TCGA study was the identification of loss-of-function mutations in the *HLA-A* gene, which plays an important role in tumor cell surface

antigen presentation and immune recognition. This is regarded as the first evidence of somatic cancer genome alterations evading the immune system by changing their surface antigens. Potential therapeutic targets were identified in most tumors, offering new therapeutic avenues of investigation for targeted therapy in lung cancer.

CLINICAL PRESENTATION

Initial symptoms of lung cancer are usually nonspecific (cough, dyspnea, sputum production, chest pain, weight loss) and are often attributed to bronchitis or pneumonia. The cancer has often invaded adjacent structures or metastasized when first recognized, causing symptoms that reflect the site of involvement. For example, destruction of blood vessels can cause hemoptysis, and tumor invasion of the pleura or chest wall can cause pleuritic chest pain. Involvement of

the left recurrent laryngeal nerve or esophagus can cause hoarseness or dysphagia, respectively. Pleural effusions can develop either due to direct tumor involvement of the pleura or obstruction of lymph flow from the mediastinal nodes (E-Fig. 57.8). By a similar mechanism, malignant pericardial effusions can form, which can progress to *cardiac tamponade*. Patients might develop focal neurologic deficits due to spinal cord compression or brain metastasis. Superior vena cava obstruction may result in the *superior vena cava syndrome*, with edema of the face and upper extremities due to impaired venous return. Tumors in the apex of the lung (called *Pancoast tumors* or *superior sulcus tumors* [E-Fig. 57.9]) can invade adjacent chest wall structures and compress the brachial plexus, resulting in ipsilateral upper extremity weakness and/or pain. Tumor erosion into the cervical sympathetic chain causes *Horner syndrome*, with ptosis, miosis, and anhidrosis over the face and forehead.

Physical examination can be normal but may reveal changes in the lungs that reflect the impact of the tumor, such as crackles (e.g., postobstructive pneumonia [E-Fig. 57.10]); inspiratory wheezes, suggestive of airway obstruction; dullness to percussion at the lung bases from underlying pleural effusion; and lymph node enlargement in the supraclavicular (E-Fig. 57.11) or cervical and axillary areas. The most common sites of metastases are the lymph nodes, liver (E-Fig. 57.12), brain, adrenal glands, kidneys, and lungs.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Prevention and Screening

The most effective lung cancer prevention strategy is smoking cessation. In addition, the United States Preventive Services Task Force (USPSTF) recommends lung cancer screening by yearly, low-dose, noncontrast CT scan in patients between the ages of 55 and 80 years who are either current smokers or former smokers who quit less than 15 years ago, with a smoking history of 1 pack per day for 30 years (or 30 pack-year equivalent). This recommendation is based on a prospective clinical trial showing a 20% reduction in lung cancer–specific mortality in a CT-screened population of heavy smokers.

Diagnostic and Staging Work-Up

Early diagnosis of lung cancer is essential and can potentially lead to cure in the case of a malignant tumor. Diagnostic evaluation should consider the patient's age, sex, smoking history, family history of lung and other types of cancer, and other relevant risk factors.

When lung cancer is suspected, either incidentally or because of symptoms, a tissue diagnosis is essential unless the patient is not eligible for treatment because of comorbidity. After assessment for metastases, the site of biopsy should be chosen to determine the highest stage of the tumor, if this is feasible. If the apparent tumor is confined to the chest, bronchoscopy is appropriate for central masses and transthoracic needle aspiration for peripheral lesions. Pleural effusion should be sampled to assess for malignant cells, which would indicate stage IV (metastatic) disease.

Contrast-enhanced chest CT, including images of the abdomen, is useful to delineate the location and size of the primary tumor and to examine for mediastinal lymph nodes, pleural disease, and adrenal or liver metastases. CT has limited ability to distinguish benign from malignant lymphadenopathy in the mediastinum. Positron emission tomography (PET) using 18-fluorodeoxyglucose (FDG) is more sensitive and more specific than CT in the detection of mediastinal lymph node metastases and may also detect unexpected metastases elsewhere. In principle, any suspected mediastinal or extrathoracic metastases identified by imaging alone should be confirmed with

tissue sampling before the patient is excluded from being considered an operative candidate. Techniques for invasive staging of the mediastinal lymph nodes include endobronchial ultrasound (EBUS)–guided needle aspiration and/or mediastinoscopy. EBUS is best for ruling in lymph node metastases. Mediastinoscopy can assess mediastinal spread of disease in patients without definite imaging evidence of lymph node involvement and is used to rule out lymph node metastases prior to surgery. PET scanning is limited in its ability to detect brain lesions, and magnetic resonance imaging (MRI) of the brain with intravenous contrast (or CT scanning if MRI cannot be done) should be performed if brain metastases are suspected or prior to surgery for stage IB or higher. Bone scans are useful for suspected symptomatic bony metastases.

Once a diagnosis of lung cancer is established, staging is necessary for prognostication and treatment. Staging of NSCLC determines whether surgical resection for cure, radiation, and/or chemotherapy is indicated. The tumor-node-metastasis (TNM) system is used to stage NSCLCs (Table 57.3). Using the TNM staging system, patients are classified as having stage I to IV disease (Table 57.4). For staging of SCLC, the Veterans Administration Lung Study Group designations of limited-stage (confined to one hemithorax) and extensive-stage (beyond one hemithorax) are used. Combined chemoradiation therapy with curative intent is considered for limited-stage SCLC, whereas extensive-stage SCLC is treated with palliative chemotherapy.

Metastatic NSCLC is subdivided into disease that is confined to the chest (M1a)—malignant pleural/pericardial effusion or separate tumor nodule(s) in the contralateral lung—which has a better prognosis compared to patients with disseminated disease in liver, bone, brain, or adrenal gland (M1b/M1c). Of patients with widely disseminated disease, there is a better prognosis in patients with a single site of metastasis in a single organ (M1b) compared to multiple metastases (M1c).

Solitary Pulmonary Nodule

A *solitary pulmonary nodule* (SPN) is a single, rounded lesion in the lung that is 3 cm in diameter or smaller. Although these lesions are commonly lung cancers in certain patient populations, the differential diagnosis of SPN includes many other malignant and benign processes. In addition to primary lung cancer (adenocarcinoma; see E-Fig. 57.5), other possible causes include bronchial carcinoid tumors and metastases from extrapulmonary malignancies (e.g., malignant melanoma, sarcoma, colon, kidney, breast, and testicular cancers). Benign etiologies include benign tumors of the lung (hamartomas) (E-Fig. 57.13), infectious granulomas (from fungal diseases, including histoplasmosis and coccidioidomycosis, and mycobacterial disease), lung abscess, vascular abnormalities (arteriovenous malformation), rounded atelectasis (E-Fig. 57.14), and pseudotumor (pleural fluid trapped within a fissure).

Radiographic features of an SPN can be helpful diagnostically. Larger lesions are more likely to be malignant. Lesions 4 to 7 mm in diameter in patients without a history of cancer have a 0.9% chance of being malignant; this probability rises to 18% for lesions 8 mm to 2 cm in diameter and 50% for those larger than 2 cm. Benign tumors are more likely to have smooth, discrete borders, whereas malignant tumors often have irregular or spiculated borders. Central, popcorn, diffuse and laminated (onion-skin) calcification patterns are associated with benign tumors. Conversely, lesions with eccentric (asymmetrical) or stippled calcifications are more likely to be malignant (E-Fig. 57.15). It is important to assess the rate of progression of an SPN or its stability by comparing imaging studies with previous scans whenever available. An SPN that has not changed in size for more than 2 years is unlikely to be malignant, with the exception of ground-glass nodules that might represent slowly growing adenocarcinoma in situ.

TABLE 57.3 TNM Staging System for Lung Cancer (2018)**T (Primary Tumor)**

TX	Primary tumor cannot be assessed Or tumor proven by the presence of malignant cells in sputum or bronchial washings but not visualized by imaging or bronchoscopy
T0	No evidence of primary tumor
Tis	Carcinoma in situ
T1	Tumor ≤ 3 cm in greatest dimension, surrounded by lung or visceral pleura, without bronchoscopic evidence of invasion more proximal than the lobar bronchus (i.e., not in the main bronchus)
T1a	Tumor ≤ 1 cm in greatest dimension
T1b	Tumor >1 cm but ≤ 2 cm in greatest dimension
T1c	Tumor >2 cm but ≤ 3 cm in greatest dimension
T2	Tumor >3 cm but ≤ 5 cm or tumor with any of the following features (T2 tumors with these features are classified T2a if ≤ 4 cm): <ul style="list-style-type: none"> • Involves main bronchus • Locally invades visceral pleura • Locally invades the diaphragm • Associated with obstructive atelectasis (either partial or whole lung)
T2a	Tumor >3 cm but ≤ 4 cm in greatest dimension
T2b	Tumor >4 cm but ≤ 5 cm in greatest dimension
T3	Tumor >5 cm or tumor with local invasion to any of the following structures: <ul style="list-style-type: none"> • Chest wall (including superior sulcus tumors) • Phrenic nerve • Parietal pericardium
	OR
	If tumor is associated with a satellite nodule in the same lobe
T4	Tumor of any size that invades any of the following: <ul style="list-style-type: none"> • Mediastinum • Heart or great vessels • Trachea • Recurrent laryngeal nerve • Esophagus • Vertebrae • Carina
	OR
	If tumor is associated with an ipsilateral satellite nodule in a different lobe

N (Regional Lymph Nodes)

NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastases
N1	Metastasis in ipsilateral peribronchial and/or ipsilateral hilar lymph nodes and intrapulmonary nodes, including involvement by direct extension
N2	Metastasis in ipsilateral mediastinal and/or subcarinal lymph node(s)
N3	Metastasis in contralateral mediastinal, contralateral hilar, ipsilateral or contralateral scalene, or supraclavicular lymph node(s)

M (Distant Metastasis)

MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis
M1a	Separate tumor nodule(s) in a contralateral lobe; tumor with pleural nodules or malignant pleural (or pericardial) effusion
M1b	Single extrathoracic metastasis or involvement of single distant lymph node
M1c	Multiple extrathoracic metastases

TABLE 57.4 Staging Using TNM Score (AJCC 8th Edition)

	N0	N1	N2	N3
T1a	Early (Stage I-II)		Locally Advanced (Stage IIIa)	
T1b				
T1c				
T2a			Locally Advanced (Stage IIIb)	
T2b				
T3				
T4				
M1a/b/c	Metastatic (Stage IV)			

TREATMENT**Small Cell Lung Cancer**

SCLCs can occasionally be resected if no evidence of metastasis is found, but most SCLCs are treated with chemotherapy for systemic disease. Limited-stage SCLC is treated with combination chemoradiation with curative intent. Extensive-stage SCLC is treated with chemotherapy alone with palliative intent. Carboplatin plus etoposide has the lowest rate of side effects and best survival, making it the chemotherapy of choice for extensive-stage disease. Recent phase 3 data demonstrate an improvement in overall survival with the addition of the immune checkpoint inhibitor (ICPI), atezolizumab, to first-line carboplatin plus etoposide. Previously treated patients can benefit

E-Fig. 57.15 Patterns of calcification. Benign patterns of calcification: (A) central, (B) popcorn, (C) diffuse, and (D) lamellated; and patterns concerning for malignancy: (E) eccentric and (F) stippled. (From Abbott G.F., Vlahos I. (2019) CT Diagnosis and management of focal lung disease. In: Hodler J., Kubik-Huch R., von Schulthess G. (eds) Diseases of the chest, breast, heart and vessels 2019-2022. IDKD Springer Series. Springer, Cham.)

from re-treatment with carboplatin plus etoposide if they achieve at least 6 months of disease control with initial therapy. Second-line therapies include topotecan or alternative immune checkpoint inhibitors (nivolumab or pembrolizumab) for patients who did not receive first-line atezolizumab. Durable responses to both chemotherapy and radiation therapy and long-term survival are possible. However, relapse with progressive therapeutic resistance is usual despite initial treatment response. Prophylactic cranial irradiation (PCI) improves overall survival in limited-stage disease after completion of chemoradiation. PCI is also favored for patients with extensive-stage disease following good response to primary chemotherapy, but recent evidence allows for active surveillance as a reasonable alternative.

Non–Small Cell Lung Cancer

Early-Stage Disease (Stages I and II)

Surgery is potentially curative for early-stage NSCLC and is indicated for patients with stage I or II disease who are eligible as operative candidates. Anatomic resection (lobectomy or pneumonectomy) is favored to remove the primary tumor as well as its draining lymph nodes (N1 disease). Lesser resections (wedge resections or segmentectomies) are favored to spare lung for clinically N0 peripheral tumors that are 2 cm or smaller, radiographically noninvasive cancers (ground glass), in patients with limited pulmonary function, or for multiple primary lung cancers. Stereotactic body radiation therapy (SBRT) or needle-directed thermal ablation may be used to cure stage I NSCLCs that are not amenable to surgery due to medical comorbidities. Once spread to lymph nodes is suspected, patients unable to tolerate anatomic resection are best treated as locally advanced.

Locally Advanced Disease (Stages IIIA and IIIB)

Stage III NSCLC is a heterogeneous disease and the optimal treatment strategy is unclear. For stage IIIA/N2 disease, “tri-modality” therapy with neoadjuvant chemotherapy or chemoradiation followed by surgery may be offered. Most patients with stage III NSCLC are not surgical candidates and are treated with chemoradiation followed by immune checkpoint blockade.

Advanced Metastatic Disease (Stage IV)

Molecular testing of diagnostic biopsy material is essential for optimal palliative drug selection for patients with stage IV NSCLC. Tumors that do not have any targetable mutations (“wild-type” patients) should be treated with immune checkpoint inhibitor therapy, either alone or in combination with chemotherapy. Prospective, randomized (phase 3) trials have shown that gene-targeted therapy is superior to chemotherapy for stage IV NSCLC with *EGFR* activating-sensitizing mutations or *ALK* gene rearrangement. In addition, single-arm (phase 2) studies have shown durable responses to targeted therapy for patients with *BRAF V600E*, rare *EGFR*, *HER2* mutations, or *ROS-1*, *RET*, *MET* or *NTRK* gene rearrangements with outcomes superior to chemotherapy (E-Fig. 57.16).

These targeted drugs provide durable disease control but do not cure patients. Acquired drug resistance inevitably leads to disease progression and death. A repeat biopsy can be used to determine the molecular mechanism of acquired resistance to targeted therapy, which can be used to inform subsequent drug selection. Patterns of resistance have been used to refine first-line drug selection. For example, the predominant mechanism of gefitinib/erlotinib/afatinib resistance is the emergence of the *EGFR T790M* mutation (located on exon 20), which accounts for about half of all resistant cases. Patients who have progression of disease despite gefitinib/erlotinib/afatinib therapy are routinely tested for *T790M* mutation, and, if present, are candidates for osimertinib therapy. First-line osimertinib proved to be superior to gefitinib/erlotinib in a randomized phase 3 trial.

Acquired genetic changes may occur in “off target” genes, shifting oncogenic signal to so-called “bypass tracts.” These include druggable targets such as *BRAF*, or *HER2* mutations, *RET* rearrangements, and *MET* amplification. Adenocarcinomas may undergo histologic transformation to squamous histology or SCLC. Patterns of primary sensitivity and acquired resistance may guide multiple lines of therapy in patients with *EGFR*, *ALK*, and *ROS-1* genetic changes, keeping their management pathway distinct compared to wild-type patients.

In wild-type patients, the decision whether or not to use chemotherapy is based on measurement of programmed death-ligand 1 (PD-L1) expression. PD-L1 expressed on cancer cells or nearby immune cells binds with the PD-1 receptor on T cells and blocks anticancer immunity. Patients with PD-L1 expression on more than 50% of cancer cells are candidates for single-agent pembrolizumab, an ICPI that is a monoclonal IgG antibody against PD-L1. In a phase 3 trial, pembrolizumab was associated with improved survival and fewer adverse events than chemotherapy in patients with metastatic NSCLC without *EGFR* or *ALK* mutations and high PD-L1 expression.

Cytotoxic chemotherapy plus pembrolizumab is used for wild-type patients with low PD-L1 expression. Cytotoxic drugs include platinum (carboplatin or cisplatin), which cause DNA double-strand breaks, combined with drugs that block DNA synthesis (pemetrexed, gemcitabine) or cellular mitosis (paclitaxel, docetaxel, *nab*-paclitaxel, vinorelbine). Cytotoxic chemotherapy lowers the neutrophil count, which can lead to septicemia. ICPIs cause autoimmune side effects, most commonly dermatitis, colitis, or thyroiditis, but also vital organ inflammation (pneumonitis, hepatitis, nephritis), which requires stopping the ICPI and consideration of corticosteroids. Targeted drug therapy is not without difficult or dangerous side effects, including skin rash, diarrhea, gastrointestinal side effects, and rarely cardiac or lung toxicity.

PROGNOSIS

The most important prognostic factor in lung cancer is the TNM stage of the disease at the time of initial diagnosis. Poor performance status and weight loss are negative prognostic factors for survival of patients with lung cancer.

For a deeper discussion on this topic, please see Chapter 182, “Lung Cancer and Other Pulmonary Neoplasms,” in *Goldman-Cecil Medicine*, 26th Edition.

E-Fig. 57.16 Molecular-genomic classification in lung adenocarcinoma. Various molecular and genomic driver oncogenic alterations have been identified within non-small cell lung cancer, especially adenocarcinoma, through molecular and genomic tumor profiling. Many of these alterations represent “actionable” or “druggable” therapeutic targets. The pie chart presents the affected genes and the proportions of lung adenocarcinomas containing alterations in them. *AKT1*, v-akt murine thymoma viral oncogene homolog 1; *ALK*, anaplastic lymphoma kinase; *BRAF*, B-Raf proto-oncogene, serine/threonine kinase; *EGFR*, epithelial growth factor receptor; *HER2*, v-erb-b2 avian erythroblastic leukemia viral oncogene homolog 2; *KRAS*, Kirsten rat sarcoma viral oncogene homolog; *MEK1*, mitogen-activated protein kinase kinase 1; *MET*, MET proto-oncogene, receptor tyrosine kinase; *NRAS*, neuroblastoma RAS viral (v-ras) oncogene homolog; *PIK3CA*, phosphatidylinositol-4,5-bisphosphate 3-kinase, catalytic subunit alpha; *PTEN*, phosphatase and tensin homolog; *RET*, ret proto-oncogene; *ROS1*, ROS proto-oncogene 1, receptor tyrosine kinase.

Gastrointestinal Cancers

Khaldoun Almhanna

INTRODUCTION

Gastrointestinal (GI) cancers are among the most common cancers worldwide. In the United States, approximately 300,000 new cases of GI cancer were expected in 2018 with an estimated 150,000 deaths. Gastrointestinal cancers are typically epithelial malignancies—carcinomas—with well-defined pathologic patterns of neoplastic transformation. The incidence of GI malignancies is increasing. Screening and early detection have been established for colon cancer and hepatocellular cancer. Asian populations should be screened for gastric and esophageal cancer. Risk factors, presentations, and management of GI malignancies are site specific. Management usually involves advanced diagnostic procedures and multidisciplinary treatment including advanced endoscopy, chemotherapy, radiation, and surgical intervention. Complications of advanced disease including bowel and biliary obstruction, liver failure, bleeding, and impaired nutrition play a significant role in the prognosis and mortality of these diseases. Recent advances in immunotherapy and checkpoint inhibitors, although promising, have not yet significantly improved the overall outcome of these diseases.

ESOPHAGEAL CANCER

Epidemiology

The incidence rates of esophageal cancer vary by geographic region with the highest incidence in Asia and Eastern Africa and the lowest in Western countries. The incidence of squamous cell carcinoma in the United States is decreasing while the incidence of adenocarcinoma, mostly in the gastroesophageal junction, is increasing in part due to obesity, reflux disease, and Barrett esophagus.

Pathology

Squamous cell carcinoma (SCC) is commonly seen in the upper esophagus and is associated with smoking, alcohol use, and dietary intake. Consuming hot beverages in certain areas is thought to be responsible for a higher incidence of SCC (e.g., China, Iran). On the other hand, most adenocarcinomas arise in background of Barrett esophagus. Interestingly, only 50% of patients with Barrett esophagus report a history of chronic reflux. The risk of developing esophageal cancer is increased at least 30-fold in patients with Barrett esophagus and is higher in the presence of high-grade dysplasia.

Clinical Presentation

Progressive dysphagia and weight loss are the most common presenting symptoms in patients with esophageal cancer. Chronic blood loss leading to iron deficiency anemia is not an uncommon presentation as well. History of longstanding reflux disease is not as common as expected. Early stage tumors are usually asymptomatic and are diagnosed as part of GI bleeding work-up or Barrett esophagus follow-up.

Diagnosis and Staging

Upper endoscopy remains the preferred diagnostic test for esophageal cancer. The diagnosis of cancer will require a histologic examination of the primary tumor or, in case of advanced disease, of metastatic lesions. Endoscopic ultrasound (EUS) provides detailed images of the depth of invasion into the esophagus wall (T stage) and peri-esophageal lymphadenopathy (N stage). EUS also visualizes the left lobe of the liver and can identify metastatic lesions (M stage). Bronchoscopy is recommended in patients with tumors located at or above the carina. Contrast-enhanced computed tomography (CT) and 18-fluorodeoxyglucose positron emission tomography (FDG-PET) scans are helpful in detecting occult metastatic disease.

Treatment

Early stage esophageal cancer with negative lymph nodes (T1a: invasion into the mucosa) can be treated with endoscopic mucosal resection. T1b tumors (tumor invades the submucosa) should be treated with upfront surgery. For locally advanced disease, multimodality therapy is recommended. Neoadjuvant concurrent chemotherapy and radiation followed by surgical resection is the standard of care, at least in the United States. Definitive chemotherapy and radiation is an acceptable alternative for patients who are not surgical candidates. The combination of carboplatin and paclitaxel with radiation is currently the most commonly used neoadjuvant (chemotherapy administered before surgery) or definitive therapy. Esophagectomy can be performed with a transthoracic (Ivor-Lewis) or a transhiatal technique, with comparable clinical outcomes.

Advanced (stage IV) esophageal cancer is a highly lethal disease with poor outcome. The goals of treatment are to improve survival and quality of life. Several chemotherapeutic agents have shown benefits in patients with advanced esophageal cancer as a single agent or in combination including 5-fluorouracil (5-FU), platinum agents, irinotecan, and taxanes.

Two targeted agents, trastuzumab, a monoclonal antibody directed against human epidermal growth factor receptor 2 (HER2), and ramucirumab, a monoclonal antibody against vascular endothelial growth factor receptor 2 (VEGFR 2), have shown activity in metastatic esophageal cancer when combined with chemotherapy. Trastuzumab is indicated in patients who overexpress Her-2 neu. The recently developed PD-1/PDL-1 antibodies are showing some promising activity in this setting for patients with metastatic disease who progressed on first-line therapy. Ongoing studies are currently evaluating these agents alone and in combination with chemotherapy and radiation. Supportive care and localized therapy to the primary tumor might be indicated to help with pain, obstruction, bleeding, and other localized symptoms. Nutritional support in this patient population is always challenging and might require parenteral administration of nutrients.

GASTRIC CANCER

Epidemiology

Gastric adenocarcinoma is one of the most common malignancies worldwide. The disease has shown a remarkable decline in incidence and mortality worldwide secondary in part to refrigeration and the decreased use of food preservatives as well as the recognition of *Helicobacter pylori* infection as a risk factor. However, this disease remains common in Asian countries (China, Japan, and Korea), in the Middle East, and in Eastern Europe, placing it among the five most common cancers worldwide.

Pathology

There are two main histologic subtypes of gastric adenocarcinoma: diffuse and intestinal. The diffuse type (undifferentiated) is increasing in incidence and is associated with younger age, signet ring cells, early metastasis, and worse prognosis. The intestinal type (differentiated) is seen in older patients, is differentiated with a background of intestinal metaplasia, and has a declining incidence and a somewhat better prognosis. The main carcinogenic event in diffuse carcinomas is loss of expression of E-cadherin, the protein responsible for intercellular connections and the organization of epithelial tissues.

Clinical Presentation

Weight loss, nausea, and epigastric abdominal pain are the most common symptoms of gastric cancer at initial diagnosis. Early satiety (with the linitis plastica subtype), dysphagia (gastroesophageal junction or cardia tumors), and gastrointestinal bleeding are also commonly seen. Symptoms of distant metastatic disease might be seen at diagnosis. The most common metastatic sites are the liver, peritoneal surfaces (causing ascites), distant lymph nodes, and less commonly, the ovaries (Krukenberg tumor) and lungs.

Diagnosis

Upper gastrointestinal endoscopy is the standard diagnostic test to obtain tissue and localize the tumor. Endoscopic ultrasound will help with the TNM staging in combination with CT scans of the chest, abdomen, and pelvis. The role of PET scans is still evolving. The diagnosis of the linitis plastica subtype can be challenging because overt mucosal lesions are often not evident. Radiologic and endoscopic features can guide the diagnosis as well as deep biopsies. Staging laparoscopy can upstage 20% to 30% of patients with gastric cancer with otherwise negative work-up and will spare the patient unnecessary laparotomy. Screening endoscopy is recommended in high-incidence countries as well as high-risk patients.

Treatment

Surgery remains the cornerstone of treatment for nonmetastatic disease. The most controversial areas in the surgical management of gastric cancer are whether to perform total gastrectomy for tumors in the upper third of the stomach versus partial gastrectomy for tumors in the lower two thirds. Also controversial is the extent of lymph node dissection. Extended D2 dissection to remove the stomach, all surrounding lymph nodes, and the spleen is superior and recommended compared to D1 dissection (refers to a limited dissection of only the perigastric lymph nodes), but it is associated with excess morbidity and mortality and should be performed by an experienced surgeon. For locally advanced disease, in addition to surgery, either perioperative chemotherapy with a platinum-based regimen or postoperative chemoradiation with 5-FU is an acceptable approach. For metastatic disease, first- and second-line palliative chemotherapy can improve outcomes, including survival. Similar to esophageal cancer (mentioned

previously), trastuzumab and ramucirumab have shown activities in metastatic disease when combined with chemotherapy. The role of immune checkpoint inhibitors in gastric cancer is still evolving as with esophageal cancer.

Prognosis

Clinical outcomes depend on the stage at diagnosis. Five-year survival rates are 65%, 40%, 15%, and 5% for stages I, II, III, and IV, respectively. Survival outcomes in Japan and Korea are better than in most Western countries; this disparity may be attributable to routine screening endoscopies or to differences in disease biology.

PANCREATIC CANCER

Epidemiology

Pancreatic cancer is the eighth leading cause of cancer deaths worldwide and is more common in the Western part of the world (see also [Chapter 39](#)). Smoking, obesity and chronic pancreatitis are established clinical risk factors. Pancreatic cancer risk increases with inherited mutations in *BRCA1*, *BRCA2*, and *PALB2* and with familial syndromes. Intraductal papillary mucinous neoplasms of the pancreas (IPMN) are at risk for malignant degeneration and are commonly managed with surveillance.

Pathology

Pancreatic ductal adenocarcinoma is the main histologic type of pancreatic cancer (85% of cases). Adenocarcinoma develops with an accumulation of mutations in the pancreatic duct epithelium. Histologic progression occurs in various stages of pancreatic intraepithelial neoplasia, leading to invasive adenocarcinoma with desmoplastic reaction. Neuroendocrine neoplasms of the pancreas are composed of epithelial neoplastic cells with phenotypic neuroendocrine differentiation. Pancreatic neuroendocrine tumors are uncommon malignancies that originate from the endocrine cells in the pancreas. They may be nonfunctional, or they may secrete hormones such as insulin (insulinoma), gastrin (gastrinoma), glucagon (glucagonoma), or vasoactive intestinal peptide (VIPoma).

Clinical Presentation

Pain, jaundice, and weight loss are the most common presenting symptoms in patients with pancreatic ductal adenocarcinoma. New-onset type 2 diabetes mellitus in an adult older than 50 years of age without overt obesity-related risk factors should raise suspicion for pancreatic cancer. Venous thromboembolism is commonly associated with pancreatic cancer and can rarely be a presenting feature. Pancreatic neuroendocrine tumors are usually diagnosed incidentally or can cause symptoms related to excess hormone production including hypoglycemia (insulinoma), Zollinger-Ellison syndrome (gastrinoma), hyperglycemia (glucagonoma), and diarrhea with electrolyte disturbances (VIPoma).

Diagnosis

Imaging of the abdomen using ultrasound can be utilized as an initial screening test if pancreatic cancer is suspected. CT or magnetic resonance imaging (MRI) can further identify the lesions and their relation to the surrounding vessels as well as metastatic disease. Endoscopic ultrasound and endoscopic retrograde cholangiopancreatography help visualize the lesions better, relieve any obstruction by stent placement, and obtain histologic confirmation by biopsies with fine-needle aspirations or bile duct brushings. Somatostatin-receptor scintigraphy can be helpful in localizing occult neuroendocrine tumors.

Treatment

Pancreatic adenocarcinomas are some of the most difficult cancers to treat. Their anatomic locations make them poor candidates for resection. Only 15% to 20% of patients are candidates for surgical resection at the time of diagnosis because the tumor frequently involves the celiac arterial axis and superior mesenteric artery and vein and even the portal vein. Whipple procedure (pancreatoduodenectomy) and distal pancreatectomy are the standard surgeries; however, the 5-year overall survival rate after pancreatic adenocarcinoma resection is less than 20%.

The role of adjuvant therapy following resection is not well established. Recent studies with multiagent regimens such as a combination of 5-FU, irinotecan, and oxaliplatin (FOLFIRINOX) or combined gemcitabine and nab-paclitaxel have demonstrated improved overall survival for metastatic pancreatic cancer and following resection as well. Observation only or somatostatin analogues are both acceptable first-line treatment for unresectable pancreatic neuroendocrine tumors. Recent studies in neuroendocrine tumors have also shown improvement in outcomes with targeted agents such as everolimus and sunitinib. Palliation of symptoms is a large component of care. Early referral to palliative care should be considered, especially in symptomatic patients with adenocarcinoma. Referrals to nutrition consultants, opioids, celiac nerve plexus block, biliary drainage, as well palliative surgeries can help improve patients' quality of life.

Prognosis

Pancreatic adenocarcinoma carries a very poor prognosis; the 5-year overall survival rate remains less than 10%. Survival has not improved significantly over the last few decades, in contrast to several other cancers. Neuroendocrine tumor carries a better prognosis, depending on the stage and the grade of the tumor, with survival measured in years.

CHOLANGIOCARCINOMA (BILE DUCT CANCERS)

Epidemiology

Cholangiocarcinomas (bile duct cancers) arise from the intrahepatic and extrahepatic biliary epithelium of the bile ducts. Cancer of the gallbladder or the ampulla of Vater are sometimes included with cholangiocarcinomas but have different risk factors and clinical behavior. Although uncommon in the United States, the incidence of cholangiocarcinomas has been on the rise for unclear reasons. Established risk factors include sclerosing cholangitis, cholelithiasis, cholecystitis, chronic liver disease, toxin exposure, metabolic syndrome, and infections. Gallbladder cancer is particularly prevalent in South American countries—especially Chile—as well as southeastern Asian countries.

Pathology

The majority of cholangiocarcinomas are adenocarcinoma. Immunohistochemistry staining might appear similar to other malignancies, in particular pancreatic cancer and upper gastrointestinal malignancies. Imaging and clinical correlation might aid in the differential diagnosis.

Clinical Presentation

Painless jaundice, pruritus, dark urine, and light color stool are usually the presenting symptoms of extrahepatic cholangiocarcinoma and are caused by biliary obstruction. Intrahepatic cholangiocarcinoma usually presents with vague right upper quadrant pain or is found incidentally on imaging. Gallbladder cancer can sometimes be an incidental finding during histologic evaluation after cholecystectomy, which is commonly performed for presumed cholelithiasis or cholecystitis.

Diagnosis

Transabdominal ultrasonography can be used to confirm biliary dilation, but to confirm the diagnosis of cholangiocarcinoma, computed tomography scanning or magnetic resonance imaging with magnetic resonance cholangiopancreatography MRCP should be performed. In some patients, an endoscopic retrograde cholangiopancreatography (ERCP) is used as the first test because it allows direct visualization of the suspected area, helps obtain a tissue diagnosis, and allows for therapeutic intervention to alleviate the obstruction. Endoscopic ultrasound can aid in identifying tumor location and extension as well.

Treatment

A negative margin surgical resection is the only curative treatment for intrahepatic and extrahepatic cholangiocarcinoma. Distal cholangiocarcinomas have the highest rate of complete resection (R0), compared to proximal and intrahepatic cholangiocarcinoma. Adjuvant chemotherapy (with or without radiation), following curative resection, is recommended in general, and based upon meta-analysis. Gemcitabine, platinum and 5-fluorouracil based treatments are usually recommended in the adjuvant setting.

Surgical resection with lymph node dissection is the standard treatment for gallbladder cancer and ampullary cancer as well. The role of adjuvant therapy is less clear in this setting. Gallbladder cancer is treated in a similar fashion to cholangiocarcinoma, while recommendations following ampullary cancer resection are less clear. Many clinicians recommend surveillance-only, given the more favorable prognosis of ampullary cancer as compared with other biliary tract cancers and the lack of data supporting a survival advantage with further therapy. However, some oncologists tend to treat these patients as they would resected pancreatic cancer, even for those with the intestinal histology. Enrollment in clinical trials is always preferred.

Treatment with gemcitabine and cisplatin is the standard treatment for stage IV cholangiocarcinoma and gallbladder cancer. Stage IV ampullary carcinoma is treated like pancreatic cancer. Tumor profiling and the role of targeted therapy is evolving. The overall prognosis is still poor for all of these stage IV malignancies, with median overall survival less than 12 months.

Prognosis

Even following curative resection, cholangiocarcinoma still carries a poor prognosis. Five-year overall survival rate ranges from 30% in patients with negative lymph nodes to 2% in patients with metastatic disease. Enrollment in clinical trials is always recommended. Several new agents and pathways are being evaluated in this patient population.

HEPATOCELLULAR CARCINOMA

Epidemiology

Hepatocellular carcinoma (HCC), or primary liver cancer, is a common disease around the world. It is the second most common cause of cancer-related death in men worldwide.

Pathology

Most HCCs arise in the setting of underlying cirrhosis, with alcohol use, hepatitis B, and hepatitis C being the most common causes of cirrhosis. Other diseases causing cirrhosis such as hemochromatosis, primary biliary cirrhosis, and α_1 -antitrypsin deficiency are also contributory. Cirrhosis involves chronic hepatocyte injury and ensuing cell regeneration, which provides the substrate for cancer development: inflammatory cytokine stress, constant cell cycling, and aberrant cell development and differentiation.

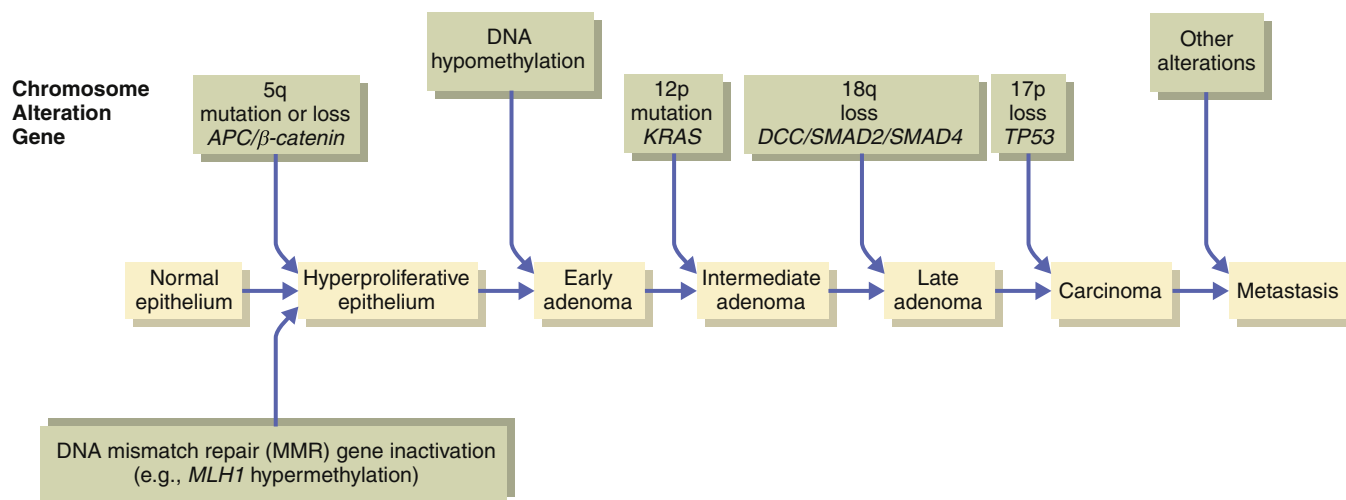

Fig. 58.1 Model of colorectal carcinogenesis. Several genes are involved in the stepwise progression from normal colonic epithelium to adenocarcinoma.

Clinical Presentation

HCC is frequently masked by the underlying liver disease. Abdominal distention from ascites, fatigue, muscle wasting, anorexia, and encephalopathy are features of cirrhosis. Acute hepatic decompensation or right upper quadrant pain may herald the development of HCC. HCC can also be an incidental finding during routine surveillance by screening ultrasound for patients with cirrhosis.

Diagnosis

HCC is one of those rare malignancies for which a diagnosis can be made without histologic confirmation. Nonhistologic criteria for diagnosis include underlying cirrhosis, elevated α -fetoprotein level (>400 ng/mL), and a characteristic appearance on contrast-enhanced CT or MRI (arterial enhancement and rapid washout). In the absence of underlying cirrhosis, however, a tissue diagnosis must be obtained. For patients with cirrhosis, a surveillance program incorporating regular measurements of α -fetoprotein and ultrasound imaging can detect early lesions.

Treatment

For small lesions, surgical resection can be curative. Preoperative assessment of liver function to ensure that the patient is an appropriate candidate for partial liver resection is critical. Liver transplantation is an option that will address HCC as well as the underlying cirrhosis. Strict criteria, such as the Milan criteria (i.e., single tumor ≤ 5 cm, or up to three tumors each <3 cm, and no vascular invasion), are used to determine which patients are eligible for transplantation. For those who are ineligible for surgical approaches, radiofrequency ablation, transarterial chemoembolization, yttrium-90 embolization, and percutaneous ethanol injection can provide local control. Until recently, Sorafenib, a multikinase inhibitor, was the only proven treatment for metastatic HCC. In the last 2 years, two other kinase inhibitors, lenvatinib and cabozantinib, have been approved for the treatment of HCC. Immune check point inhibitors including pembrolizumab and nivolumab are both approved for the second line treatment of HCC after failure of tyrosine kinase inhibitors.

Prognosis

The prognosis in HCC is often determined by the severity of the underlying liver disease. The 5-year survival rate approaches 50% with complete surgical resection or liver transplantation. For advanced HCC, the median overall survival time with therapy is approximately 1 year.

COLORECTAL CANCER

Epidemiology

Colorectal cancer is the third most common cancer as well as the third most common cause of cancer-related death in the United States, with approximately 150,000 new cases diagnosed each year. Worldwide, it is a growing problem and one of the most common cancers. There appears to be an increased association between colon cancer and high dietary fat, red meat consumption, low dietary fiber, obesity, and alcohol use. Conversely, increased physical activity and use of supplemental estrogen, folate, vitamin, aspirin, and nonsteroidal anti-inflammatory drugs appear to be protective. A history of inflammatory bowel disease is a risk factor for colorectal cancer.

Pathology

Adenocarcinoma of the colon progresses from normal epithelium to frank cancer in a stepwise fashion, as illustrated in Fig. 58.1. Most colon cancers arise in polyps. Hamartomatous polyps usually are non-neoplastic but can be part of juvenile polyposis or Peutz-Jeghers polyposis where they can undergo malignant transformation. Serrated polyps 10 mm or greater with dysplasia should be managed as high-risk adenoma. Adenomatous polyps are the most common neoplastic polyps in the colon and can progress to cancer.

Several inherited abnormalities lead to a genetic predisposition to colon cancer. Such syndromes are responsible for 3% to 5% of all colon cancers. They can be divided into syndromes associated with underlying polyps and those without polyps. Classic familial adenomatous polyposis (FAP) is caused by an autosomal dominant mutation in the *APC* gene. The colon is full of polyps—hundreds to thousands—that start forming during adolescence, leading to development of cancer in early adulthood. Patients with attenuated FAP have fewer polyps and later development of malignancy. *MYH*-associated polyposis is caused

by an autosomal recessive mutation in the *MYH* gene, and the phenotype mimics that of attenuated FAP. Peutz-Jeghers syndrome, juvenile polyposis, and Cowden syndrome are other uncommon conditions that are associated with an inherited predisposition to colorectal polyps leading to cancer.

The classic nonpolyposis syndrome is hereditary nonpolyposis colorectal cancer, also called Lynch syndrome. Germline recessive mutations in genes involved in the mismatch repair pathway (*MSH2*, *MSH3*, *MSH6*, *MLH1*, *MLH3*, *PMS1*, *PMS2*) lead to adenocarcinoma. These cases are indistinguishable from sporadic cases associated with defective mismatch repair, except for the family history of colon and other associated cancers in the inherited syndrome (e.g., endometrial ovarian, gastric, and small bowel cancer).

Clinical Presentation

Hematochezia and altered bowel habits are the classic symptoms of colon cancer. Early cases are essentially asymptomatic and are typically identified by screening. Advanced cases can manifest with bowel obstruction or perforation, frank rectal bleeding, weight loss, abdominal pain, and ascites due to hepatic or peritoneal metastases. Cancers associated with the mismatch repair pathway have certain typical features: They are right-sided, more common in women, and occur in younger patients. They are usually poorly differentiated and locally advanced without significant lymph node involvement.

Diagnosis

Screening for colorectal cancer is an important public health tool. Screening methods include fecal occult blood testing, imaging (barium enema, CT-guided colonography), and endoscopy (flexible sigmoidoscopy, colonoscopy). Colonoscopy is the “gold standard” for visual confirmation and histologic diagnosis of colon cancer. Once a cancer diagnosis is established, CT scans of the chest, abdomen, and pelvis are indicated to evaluate for distant disease. MRI of the pelvis or endoscopic ultrasound are used in rectal cancer to determine the exact tumor location and its extent prior to neoadjuvant therapy.

Treatment

For patients with resectable disease, surgical resection is the treatment of choice. Removal of the involved segment of the colon, along with the associated mesentery containing all draining lymph nodes, is recommended. Such procedures are being increasingly performed with the use of laparoscopic techniques, resulting in decreased perioperative morbidity. Decisions regarding chemotherapy after surgery (i.e., adjuvant chemotherapy) are based on the pathologic findings. For stage I disease (T1 or T2, N0), no chemotherapy is recommended. For stage III disease (any T, N+), chemotherapy is strongly recommended. A combination of a fluoropyrimidine (5-FU, capecitabine) with oxaliplatin, administered for 6 months, is the standard of care. For stage II disease (T3 or T4, N0), data are controversial. A careful risk-benefit evaluation for each patient is recommended to determine whether adjuvant chemotherapy is appropriate. Rectal cancer is associated with a high rate of local recurrence that can lead to significant morbidity. To improve outcomes, preoperative chemotherapy and radiation therapy are used, and surgery should include total mesorectal excision.

For metastatic colorectal cancer, treatment options include chemotherapy agents such as fluoropyrimidines, oxaliplatin, and irinotecan. The advent of targeted therapies has improved clinical outcomes. These therapies include anti-angiogenic agents (bevacizumab, ziv-

afibercept, ramucirumab), anti-epidermal growth factor receptor antibodies (cetuximab, panitumumab). The multikinase inhibitors (regorafenib) and trifluridine-tipiracil (Lonsurf) are both approved for patients who progress after first- and second-line chemotherapy but efficacy is only modest. Another option for patients with metastatic colorectal cancer who have MSI-H/dMMR tumors is immunotherapy. The immune checkpoint inhibitor nivolumab, both as a single agent or in combination with ipilimumab, are approved by the FDA for patients who progressed after standard of therapy. Colon cancer is one of the few malignancies in which some cases of metastatic disease can also be cured with aggressive systemic therapy and surgery. Therefore, close surveillance after treatment of the initial cancer is recommended to detect early recurrences. Surveillance should include regular physical evaluation, CT scanning, and measurement of serum levels of carcinoembryonic antigen (CEA), a protein synthesized disproportionately by malignant epithelial cells. Increased physical activity and dietary modifications (reduced red meat and fat; increased fruits, vegetables, and fiber) following treatment have been associated with improved outcomes. Another important component of colorectal cancer care is family risk assessment, because this is a common disease, with up to 7500 cases each year in the United States being attributable to heritable syndromes. Referral for genetic counseling should be made if such a syndrome is suspected.

Prognosis

Among gastrointestinal cancers, colorectal cancer has the best overall prognosis. For nonmetastatic disease, the 5-year survival rate ranges from 50% to 95%, depending on the extent of lymph node involvement. For metastatic disease, newer therapies, given in succession, can achieve a median overall survival time of more than 2 years. The key remains early detection by screening, which can improve outcomes.

ANAL CANCER

Epidemiology

Anal cancer is an uncommon malignancy, with about 7000 cases reported annually in the United States. It is strongly associated with human papillomavirus (HPV) infection. It is also more common in patients with human immunodeficiency virus (HIV) infection and in those who engage in anal-receptive sexual intercourse, most likely because of poor host immunity and increased transmission of HPV, respectively. Condyloma acuminata are precursor lesions for this cancer.

Pathology

The histology is typical of a squamous cell carcinoma, with sheets of hyperproliferative keratinized cells. HPV, especially types 16 and 18, causes inactivation of the tumor suppressor genes *TP53* and *RB1* via the viral proteins E6 and E7, predisposing to eventual development of carcinoma. Chronic local inflammation due to inflammatory bowel disease or recurrent anal fissures and fistulas can also lead to anal cancer.

Clinical Presentation

Local symptoms, such as perianal pruritus or pain, bleeding, discharge, and a masslike sensation, are common presentations. In cases of chronic underlying disease such as Crohn's disease, the presence of a nonhealing anal or perianal lesion despite good disease control elsewhere should raise suspicion for malignancy.

Diagnosis

Physical examination is adequate to identify suspicious lesions. A biopsy should be obtained to confirm the diagnosis. Evaluation for distant spread should include CT scans of the chest, abdomen, and pelvis. Special attention should be paid to examination of inguinal lymph nodes, because they are common sites of early spread.

Treatment

Anal cancer is one of the few solid tumor malignancies that are curable without surgical resection. For very small, early lesions, complete excision may suffice. However, for most cases, combined chemotherapy with 5-FU and mitomycin, together with radiation therapy, is the standard curative modality. This regimen has significant short-term toxicities that should be managed aggressively. This treatment can obviate the need for a large operation that would result in a permanent colostomy.

Prognosis

More than 70% of cases can be cured with chemoradiation. Relapsed disease is usually treated with surgical excision (if local) or systemic chemotherapy (if distant). Widespread vaccination against HPV, anal Pap smears in high-risk populations, and better prevention and treatment of HIV infection should lower the incidence of anal cancer.

RENAL CELL CARCINOMA

Definition and Epidemiology

Renal cell carcinoma (RCC) represents approximately 3% to 5% of all malignancies and 85% of kidney tumors. It is the sixth most common cancer in men and the eighth most common cancer in women, with approximately 74,000 new cases diagnosed in the United States in 2019 that will contribute to 14,770 deaths. Aside from age and male sex, most patients do not have an identifiable risk factor. The median age of diagnosis is about 65 years and the incidence is twice as high in men as in women. Smoking, obesity, and hypertension are well-established risk factors for RCC. Smokers have a relative risk 2-fold greater than that of nonsmokers whereas hypertension is associated with a 70% increased risk. RCC is also more common in patients with end-stage renal failure. A small number (3%) of cases of RCC are inherited. Approximately 65% of cases of RCC are diagnosed as localized disease with an estimated 5-year survival of 92%. The 5-year survival for advanced disease is 12%.

The most recognized inherited RCC is Von Hippel–Lindau (VHL) syndrome, an autosomal dominant disorder that is characterized by the development of multiple vascular tumors including clear cell RCC. The genetic events underlying VHL syndrome (loss of function truncating mutations or deletions of the *VHL* gene) also occur in sporadic (noninherited) clear cell tumors, leading to the remarkable RCC reliance on blood vessels for growth. Research into this syndrome has led to modified treatment options for advanced disease (see later discussion).

Pathology

The histologic subtypes of RCC are characterized by distinct genetic characteristics, histologic features, and clinical phenotypes. Clear cell RCC (75% of all RCCs) is the most common subtype and is characterized by *VHL* gene inactivation. Less common are the papillary, chromophobe, unclassified subtypes, and medullary RCC, which occurs almost exclusively in patients with sickle cell trait. Although these RCC subtypes are biologically distinct, the current surgical approaches are most frequently uninfluenced by subtype. However, the histologic subtype impacts the medical treatment of advanced disease.

Diagnosis and Differential Diagnosis

Masses in the kidney may be benign or malignant, with an increasing likelihood of malignancy with increasing size. Most clear cell RCC tumors are distinguishable based on their contrast enhancement. Other considerations for renal masses include benign tumors (e.g., oncocytoma), metastatic disease from another primary site (rare), angiomyolipoma, a lipid-containing benign tumor (most commonly occurring in young females), and infectious processes. The diagnosis is made on the basis of a biopsy or at the time of nephrectomy, although

the radiographic appearance of each of the differential diagnoses is often characteristic.

Clinical Presentation

RCC is more common in males (2:1), and the median age at presentation is approximately 65 years. Patients diagnosed with RCC below 46 years of age and those presenting with multifocal or bilateral renal masses should be considered for genetic counseling because these features can be associated with hereditary RCC. In the United States, most RCCs are diagnosed as incidental findings on imaging studies (70% of the cases). Classic signs and symptoms include hematuria, flank pain, and a palpable abdominal mass. Systemic symptoms can include pain caused by bone metastases or adenopathy, respiratory symptoms related to involvement of lung parenchyma, or neurologic symptoms when presenting with brain metastases. Symptoms also occur with paraneoplastic syndromes. A renal mass is discovered, usually on computed tomography (CT) scanning, and has an appearance that is characteristic of RCC (i.e., highly vascular). Subsequently, a full staging work-up is performed, including CT scanning of the chest; CT or MRI of the brain is performed if signs or symptoms suggest brain metastases; bone scan is recommended in the presence of bone pain or elevation of alkaline phosphatase. Diagnosis is usually made at the time of nephrectomy, although a biopsy of the renal mass may be indicated, such as in a patient with distant metastases in whom nephrectomy is not pursued or in a patient with a small renal mass that may be initially observed.

Treatment

Renal Masses

Some renal masses (approximately 20%) are not cancerous, and the likelihood of malignancy increases with size, so a diagnostic biopsy should be considered for lesions smaller than 4 cm to confirm diagnosis and guide local treatment or surveillance strategies. If the mass has a radiographic appearance suggestive of RCC, biopsy is often not necessary before surgery, and larger masses are more likely to have such features. The differential diagnosis for enhancing renal masses includes non-RCC malignancies (e.g., upper tract urothelial carcinoma), metastases, and benign tumors. One option for small renal masses, even if proven to be RCC, is initial observation. Retrospective series have defined this approach for renal masses smaller than 4 cm in a select group of patients with significant comorbidities or limited life expectancy. The growth rate is approximately 3 mm/year, and the reported incidence of development of metastases is very low. If surgery is pursued, then removal of either part of the kidney (partial nephrectomy or nephron-sparing surgery) or the entire kidney (radical nephrectomy) is the standard of care, depending on factors such as the extent and anatomy of the tumor, native renal function, and surgical skill. Cancer outcomes are equivalent, although renal

TABLE 59.1 Therapeutic Approaches in Metastatic RCC

Agent	Objective Response Rate	PFS (mo)	Comments
Hormonal therapy	2%	N/A	Limited, palliative role in the treatment of metastatic RCC
Chemotherapy	5-6%	N/A	Not generally used
Interleukin-2	≈20-25% (high dose)	3.1	Durable complete response rate of 7-8%
Interferon-α	10-15%	4.7	Modest improvement in overall survival compared with inactive therapy
VEGF inhibitors ^a	≈30%	9-11	Common toxicity includes fatigue, mucositis, hand-foot syndrome, diarrhea, hypertension, and hypothyroidism
Checkpoint inhibitors ^b	25-42%	4.6-11	Adverse effects include fatigue, pruritus and immune-related hypothyroidism, colitis, adrenal insufficiency. Complete response rates of 9% were observed with the combination of nivolumab (anti-PD-1) and ipilimumab (anti-CTLA4).
mTOR inhibitors ^c	2% (treatment refractory) to 9% (treatment naive)	4	Increased overall survival of temsirolimus monotherapy vs. IFN monotherapy in poor-risk patients Toxicity includes fatigue, mucositis, rash, and hypertriglyceridemia/hyperglycemia/hypercholesterolemia
mTOR inhibitor (everolimus) + lenvatinib	41%	14.6	Combination of everolimus with lenvatinib improved the outcomes compared to everolimus monotherapy

IFN, Interferon; mTOR, mammalian target of rapamycin; N/A, not applicable; PFS, progression-free survival; RCC, renal cell carcinoma; VEGF, vascular endothelial growth factor.

^aVEGF inhibitors: sorafenib, sunitinib, pazopanib, axitinib.

^bAnti-PD-1 agents such as pembrolizumab and avelumab have also been combined with axitinib.

^cmTOR inhibitors: temsirolimus, everolimus.

function is better preserved with partial nephrectomy. Another management option for renal masses is exposure to temperature extremes: freezing (cryotherapy) or burning (radiofrequency ablation). This approach is usually pursued in patients with contraindications to surgery, significant comorbidities, and/or small tumors (<3 cm). Although metastasis-free survival and cancer-specific survival rates for partial nephrectomy and ablation techniques are comparable, local recurrence rates can be higher with ablation. Biopsy of kidney mass is recommended prior to ablation to confirm diagnosis and guide subsequent surveillance strategies.

Surgery in Metastatic RCC

Removal of the primary renal tumor in the face of metastatic disease (i.e., debulking or cytoreductive nephrectomy) has been pursued in patients with good performance status, limited extrarenal disease, and low comorbidities based on results from patients receiving systemic treatment with interferon-α (INF-α) in the 1990s. However, results of a randomized clinical trial showed that systemic treatment alone with contemporary tyrosine kinase inhibitor (TKI) sunitinib had comparable overall survival to nephrectomy followed by sunitinib in patients with intermediate- or poor-risk disease, but the study did not address cytoreductive nephrectomy in patients with good-risk disease. In addition, surgical removal of solitary metastatic sites is associated with disease control in up to 30% of highly selected patients.

One randomized clinical trial demonstrated that 1 year of treatment with sunitinib administered following nephrectomy (i.e., adjuvant treatment) improved the disease-free survival of patients at high risk for recurrence, but no difference in overall survival or quality of life was reported. Patient selection and shared decision making are critical in light of treatment toxicities, lack of demonstrated overall survival benefit, and negative results of other clinical trials. To date, no clinical trial evidence has demonstrated improvement in patient outcome with systemic therapy administered before nephrectomy (i.e., neoadjuvant treatment).

Systemic Therapy for Metastatic RCC

The initial treatments for metastatic RCC—hormone therapy and chemotherapy—produced only minimal benefits (Table 59.1). Immunotherapy with cytokines interleukin-2 (IL-2) and INF-α has yielded modest benefits, the majority of benefit realized in highly selected patients who have a durable complete response to high-dose IL-2. The discovery of clear cell RCC reliance on stimulation of the vascular endothelial growth factor (VEGF) pathway, which results from *VHL* gene inactivation, led to the clinical development of several VEGF pathway inhibitors that include TKIs and monoclonal antibodies against VEGF (see Table 59.1). In general, 70% to 75% of patients who receive these drugs have some reduction or stabilization of tumor burden. Periods of disease control typically last for months, although they can extend to several years in a small minority of patients. The incorporation of immune checkpoint inhibitors, such as antibodies against cytotoxic T lymphocyte-associated protein 4 (CTLA-4) and programmed death receptor-1 (PD-1) or its ligand (PD-L1), represents another relevant advancement in the treatment of metastatic RCC. These agents promote antitumor immune response by blocking stimulation of PD-1 or CTLA-4 receptors that suppress T cell immune function. These agents have significant antitumor activity both as anti-PD-1 monotherapy (e.g., nivolumab) or in combination with ipilimumab (anti-CTLA4). Anti-PD-1 and PD-L1 antibodies (pembrolizumab and avelumab, respectively) have also shown strong antitumor activity in combination with the multikinase inhibitor axitinib. Inhibitors of mammalian target of rapamycin (mTOR) represent treatment alternatives as monotherapy or in combination with the multikinase inhibitor lenvatinib. The data supporting the use of TKIs and checkpoint inhibitors for RCC are strongest for clear cell RCC; the optimal treatment of non-clear cell RCC is much less well defined. In the context of growing treatment options, advances in biomarkers of treatment response as well as molecular drivers of prognosis will guide optimal sequencing of agents.

Prognosis

The prognosis of localized kidney cancer is determined largely by the stage and grade of the primary tumor. In metastatic disease, established schemas divide patients into prognostic groups based on performance status, time from diagnosis to metastatic disease, and laboratory values (lactate dehydrogenase [LDH], hemoglobin, calcium, neutrophils, and platelets). Good-, intermediate- and poor-risk groups have median survivals of about 43, 22, and 8 months, respectively.

BLADDER CANCER

Definition and Epidemiology

Urothelial carcinoma of the bladder (UCB) represents 4% of all malignancies and about 3% of cancer-related deaths in the United States. It is more common in developed countries and is the fourth most common cancer among men and ninth among women in the Western world. Smoking is an established risk factor for bladder cancer; the incidence rate is four times higher for smokers than for nonsmokers. Occupational exposures from a range of agents that contain aromatic amines, as chlorinated hydrocarbons and polycyclic aromatic hydrocarbons are believed to account for up to 20% of all bladder cancers. Genetic susceptibility is increasingly recognized as an important risk factor. The risk of bladder cancer is doubled in first-degree relatives of patients with bladder cancer. Inherited genetic factors, such as the slow acetylator *N*-acetyltransferase 2 (NAT2) variants and the glutathione *S*-transferase Mu 1 (GSTM1)-null genotypes, are established risk factors.

Pathology

Urothelial carcinoma is the predominant histologic subtype in the United States and Europe, where it accounts for 90% of all bladder cancers. Adenocarcinoma, squamous cell carcinoma, and small cell cancers account for most of the remaining 10%, although there are parts of the world where nonurothelial carcinomas are more common. The bladder wall consists of four layers: urothelium (the innermost epithelial lining), lamina propria, muscularis propria (detrusor muscle), and adventitia (serosa).

Clinical Presentation

UCB is more common in males (3:1), and the median age at presentation is 73 years. Approximately 75% of newly diagnosed cases of UCB are not muscle invasive; the remaining 25% exhibit *de novo* invasion of the muscle wall of the bladder at presentation.

Patients with bladder cancer typically have painless hematuria at presentation, although irritative voiding symptoms (frequency, urgency, and dysuria) can be the initial manifestation. Patients with more advanced disease may have progressive flank or pelvic pain from direct extension of disease or as a consequence of ureteral obstruction.

Diagnosis and Differential Diagnosis

The initial evaluation typically involves an office-based cystoscopic evaluation, with the collection of urine for cytology. Upper urinary tract evaluation with either a CT urogram or retrograde pyelogram is also important. When a bladder tumor is found, patients undergo a transurethral resection of bladder tumor (TURBT) under anesthesia to obtain tissue for histologic diagnosis. Inclusion of muscle in the pathologic specimen is necessary to exclude muscle invasion. For patients with muscle-invasive disease, CT imaging of the chest is indicated, and bone scintigraphy in patients with bone pain. Most new cases of UCB are staged as Ta (involvement of epithelial lining), T1 (invasion of lamina propria), or carcinoma in situ (CIS) (Fig. 59.1); these are

Fig. 59.1 Bladder cancer presentations by depth of invasion.

typically grouped and considered as non-muscle-invasive bladder cancer (NMIBC).

Patients with low-grade, low-stage urothelial carcinoma of the bladder remain at high risk for non-muscle-invasive recurrence but low risk for progression to more advanced stage disease. In contrast, patients with intermediate- or high-grade disease are at increased risk for both recurrence and progression to muscle-invasive and metastatic disease. Secondary involvement of the bladder with other cancers (e.g., lymphoma, sarcoma) is uncommon.

Treatment

Organ-Confined Disease

Low-grade non-muscle-invasive UCBs are typically managed with TURBT and intravesically administered cytotoxic agents. Multifocal, low-grade recurrent disease is managed with intravesically administered bacillus Calmette-Guérin (BCG). High-grade NMIBC (including CIS) is managed with BCG or cystectomy.

Muscle-invasive bladder cancer is optimally managed with radical cystectomy and bilateral pelvic lymphadenectomy. For patients who are deemed poor surgical candidates or who refuse cystectomy, external beam radiotherapy or chemoradiation and TURBT are alternative management options.

Cisplatin-based multiagent chemotherapy administered before cystectomy (i.e., neoadjuvant chemotherapy) has been shown by level I evidence to improve survival. Although it has not been prospectively evaluated in the neoadjuvant setting, the regimen of gemcitabine plus cisplatin (GC) is widely substituted for the older combination of methotrexate, vinblastine, doxorubicin, and cisplatin (M-VAC). Ongoing clinical trials are evaluating the role of perioperative immunotherapy.

Metastatic Disease

Level I evidence from a series of phase III trials provides evidence that cisplatin-based chemotherapy (i.e., M-VAC or GC) in patients with *de novo* metastatic disease leads to median survival times in the range of 14 to 15 months, with 5% to 15% of patients likely to be cured. The latter group is made up primarily of patients with nodal metastatic disease.

Although there have been no completed randomized phase III trials comparing cisplatin-based chemotherapy with carboplatin-based therapy in patients with advanced UCB, multiple randomized phase II trials have reported superior activity with cisplatin-based regimens. However, between 30% and 50% of patients with advanced UCB are ineligible for cisplatin because of concomitant renal insufficiency, typically as a consequence of age-related renal comorbidity or disease-related extrinsic obstruction. Immunotherapy with checkpoint inhibitors, such as pembrolizumab (anti-PD-1) and atezolizumab (anti-PD-L1), is approved for cisplatin-ineligible patients whose tumors have high expression of PD-L1 (the specific PD-L1 expression cutoff is specific to the immune checkpoint inhibitor used) as well as for patients who have already received or who are ineligible for carboplatin.

The management of advanced disease after front-line therapy has evolved with various options beyond single-agent chemotherapy. Novel treatments include PD1 and PD-L1 checkpoint inhibitors and the TKI erdafitinib targeting of fibroblast growth factor receptor 3 (FGFR3) in tumors displaying FGFR3 activating mutations or gene fusions. The best sequencing of agents beyond the front-line treatment remains to be defined. Antibodies targeting cell surface protein and delivering cytotoxic payloads (antibody drug conjugates), such as the Nectin-4 antibody enfortumab that delivers the cytotoxic drug vedotin and the trophoblast cell surface 2 antibody sacituzumab with its topoisomerase inhibitor SN-38 payload, have shown promising antitumor activity in advanced bladder cancer, and ongoing trials are comparing these drugs to standard of care treatments. Enfortumab vedotin was granted accelerated approval in the United States for patients previously treated with or ineligible for platinum-based chemotherapy and an immune checkpoint inhibitor.

Prognosis

Patients with low-grade, low-stage NMIBC typically do not progress to muscle-invasive disease. Their disease does not alter life expectancy but is associated with morbidity and use of health care resources and requires long-term follow-up. Patients with muscle-invasive disease who undergo cystectomy are at risk for systemic failure based on the T stage and extent of nodal involvement. Patients with organ-confined disease without nodal involvement have cure rates greater than 50%. Patients with metastatic disease have median survival times in the range of 14 to 16 months with systemic therapy, and only a small subset (5% to 15%) are long-term survivors, although immune checkpoint blockers and new targeted therapies may change these metrics in the near future.

PROSTATE CANCER

Definition, Epidemiology, and Screening

Prostate cancer is the most common malignancy among men in the United States; more than 174,000 cases were expected to be diagnosed in 2019 with 31,000 deaths. The lifetime risk of diagnosis and death is roughly 12% and 2.4%, respectively. The incidence has declined since the United States Preventative Service Task Force (USPSTF) recommended against prostate-specific antigen (PSA)-based screening in 2012 (D recommendation). In 2018, the USPSTF revised the recommendation to shared decision making with men age 55 to 69 years (C Recommendation). Evidence from randomized clinical trials reveals that PSA-based screening programs in men aged 55 to 69 years may prevent 1.3 prostate cancer deaths and three cases of metastatic prostate cancer per 1000 men screened. The USPSTF recommends against PSA-based screening in men 70 years and older (D recommendation).

Multiple risk factors, including age, race, dietary factors, and genetic factors, have been linked to prostate cancer. The median age at diagnosis is 65 years, and younger men (<40 years) rarely develop prostate cancer. African American men have a greater risk of developing prostate cancer compared with white men (16% vs. 11% lifetime risk of diagnosis). Although it is possible that screening may offer greater benefit for African American men, there is no conclusive evidence to support race-based screening recommendations. A man with first-degree relatives affected by prostate cancer has a 5-fold to 10-fold increased risk of prostate cancer. Whereas high animal fat intake has been linked to an increased risk of prostate cancer, no foods, vitamins or dietary supplements have been shown to reduce the likelihood of being diagnosed with the disease.

A large chemoprevention trial (SELECT) demonstrated that intake of selenium and vitamin E does not reduce the risk of prostate cancer. Two studies evaluating the 5 α -reductase inhibitors finasteride and dutasteride demonstrated a 23% to 25% reduction in relative risk of prostate cancer. Despite these benefits, the use of these agents remains low. Adverse effects such as erectile dysfunction, loss of libido, and gynecomastia along with concern of a small increase in high-grade tumors have resulted in low acceptance and adoption.

Clinical Presentation

Because prostate cancer can be detected in small subsets even with very low PSA levels (i.e., <1 ng/mL) there is no “normal” PSA value below which there is no risk of prostate cancer. PSA values can be affected by rectal examination, ejaculation, infection, bicycle riding, and urinary obstruction.

Most men with early disease have no symptoms; however, urinary frequency, urgency, nocturia, and hesitancy do occur. The presence of hematuria or hematospermia should prompt consideration of prostate cancer. An abnormal rectal examination result (asymmetric mass/nodule) is also suggestive of cancer.

Men with advanced, metastatic prostate cancer are more frequently symptomatic. Given the proclivity for bone metastasis, skeletal pain is common. Because of the frequency of spine metastases, malignant spinal cord compression and resulting neurologic injury is part of the natural history of prostate cancer. Adenopathy in the abdomen and pelvis is also common, as are deep venous thromboses, and men may thus present with lower extremity edema. Men can also experience urinary obstruction with hydronephrosis due to ureteral obstruction or bladder outlet obstruction. Constitutional symptoms such as weight loss and night sweats have also been described, especially with visceral metastasis.

Diagnosis and Staging

Most patients with prostate cancer are diagnosed with local disease with the use of extended core biopsies (12 cores). Multiparametric magnetic resonance imaging (MRI) is increasingly being utilized in initial assessment of a man with an abnormal PSA. MRI is interpreted using the Prostate Imaging-Reporting and Data System (PI-RADS), a 1-5 scale, with higher numbers indicating a greater likelihood of clinically significant cancer (Gleason score 7-10). In patients with MRI PI-RADS 3 to 5, biopsies can be done with MRI guidance to improve diagnostic accuracy.

After diagnosis, risk stratification based on PSA level, Gleason score, and clinical stage becomes crucial to define management. Bone scans and CT scans are not indicated for men with a new diagnosis of prostate cancer unless they have certain intermediate-risk or high-risk features. In addition to stage, grade, and PSA level, important features determining treatment include age, comorbidities, patient preferences, and life expectancy.

Pathology, Prognosis, and Genetic Mutations

Adenocarcinoma accounts for more than 95% of all prostate cancers. The remaining histologic subtypes include neuroendocrine (small cell carcinoma), squamous, and basal cell neoplasms.

The Gleason scoring system is pivotal in the management of prostate cancer, but its interpretation requires expertise in pathology. The score is based on growth pattern and degree of differentiation and ranges from 3 to 5 (5 being the least differentiated). The composite Gleason score is derived by adding together the numerical values for the two most prevalent differentiation patterns. For instance, if a specimen comprises primarily a grade 3 pattern and secondarily a grade 4 pattern, the score is reported as 7 (3 + 4). In 2016 the World

TABLE 59.2 WHO/ISUP Prostate Cancer Histologic Grading System

Grade Group 1	Gleason 3 + 3 = 6
Grade Group 2	Gleason 3 + 4 = 7
Grade Group 3	Gleason 4 + 3 = 7
Grade Group 4	Gleason 4 + 4 = 8, 3 + 5 = 8, 5 + 3 = 8
Grade Group 5	Gleason 4 + 5 = 9, 5 + 4 = 9, 5 + 5 = 10

Health Organization (WHO) defined a new prostate grading system to improve prognostic strata. The WHO histologic grading system includes five grade groups as defined in Table 59.2.

Prognosis and primary management of localized prostate cancer depends on tumor (T) stage, PSA level, tumor grade, and number of positive biopsies. Risk stratification includes very low, low, favorable intermediate, unfavorable intermediate, high, and very high risk prostate cancer.

Genes in the DNA repair pathway, such as *BRCA1/2*, *ATM*, and *CHEK2*, have been found to be pathologically mutated in approximately 20% of metastatic castrate-resistant prostate cancer (mCRPC) and 8% to 12% of localized prostate cancer. *BRCA2* mutations have been associated with more aggressive prostate cancers with higher recurrence and mortality. Recommendations for genetic counseling in men with prostate cancer include presenting with de novo metastatic prostate cancer, significant family history of prostate, breast, pancreatic cancer, and Gleason 8 to 10 disease, and Ashkenazi Jewish heritage.

Treatment

Available treatment options for localized prostate cancer include radical prostatectomy, radiation therapy (either external beam radiation or brachytherapy), and active surveillance. Consensus recommendation favors active surveillance over primary treatment for very-low-risk and low-risk prostate cancer (Gleason score 6, PSA <10 ng/mL, low tumor burden). The selection between radical prostatectomy and radiation therapy is based on risk stratification and patient preferences. Surgery carries risks of urinary incontinence and erectile dysfunction. Radiation therapy has lower rates of urinary incontinence but also causes erectile dysfunction. Late complications from radiation therapy include radiation cystitis and proctitis. There is a small increased risk of second malignancies after radiation therapy, especially bladder cancer in smokers. Primary radiation therapy for intermediate- and high-risk patients is often given in combination with androgen deprivation therapy leading to additional adverse effects.

Once patients have developed advanced disease, androgen deprivation therapy (chemical or surgical castration) is widely used. Intermittent androgen deprivation therapy is an effective alternative for patients whose only sign of recurrence is a rising PSA level. In men with metastatic disease, continuous therapy with luteinizing hormone releasing hormone (LHRH) agonist or antagonist is used. Androgen deprivation therapy also has major side effects, including night sweats, hot flashes, erectile dysfunction, weight gain, loss of muscle mass, fatigue, bone loss, and metabolic syndrome. In men with metastatic prostate cancer, randomized controlled trials have reported longer overall survival when androgen deprivation therapy was combined with any of the four following medications: abiraterone (a novel CYP17A1 inhibitor), docetaxel chemotherapy, or the androgen receptor antagonists enzalutamide and apalutamide.

Bone health is a significant problem in men with prostate cancer. Osteoporosis due to androgen deprivation therapy and skeletal-related events from metastases are both common. Two agents are available to prevent these complications: zoledronic acid, a bisphosphonate, and

denosumab, a RANK-ligand inhibitor. Their benefit is primarily in men with mCRPC and skeletal metastasis. All men on ADT should be counseled on osteoporosis screening and prevention and lower-dose bisphosphonate or denosumab can be used if significant bone loss develops.

All patients with metastatic prostate cancer eventually develop castrate-resistant prostate cancer (CRPC), defined by serologic, clinical, or objective progression in the setting of a castrate testosterone level. Although the mechanism of CRPC is not well understood, several treatment options are now available. Sipuleucel-T, an autologous antigen-presenting cell product shown to prolong survival in a randomized trial, is sometimes used in the prechemotherapy setting, but its use has been limited by the fact that it is not associated with a reduction in PSA, and there is thus no way to measure whether it is controlling the cancer. If not used in the castrate-sensitive setting, either abiraterone or one of the new androgen receptor antagonists (enzalutamide, apalutamide, or darolutamide) can be prescribed. Radium 223 improves survival outcomes and reduces skeletal events in men with symptomatic skeletal metastasis and without visceral or bulky, soft tissue metastasis. Two chemotherapy agents, docetaxel and cabazitaxel, are therapeutic options. Finally, the poly ADP-ribose polymerase (PARP) inhibitors are beneficial in men with mCRPC and a documented DNA repair defect.

TESTICULAR CANCER

Definition and Epidemiology

It is estimated that 9,610 new cases of testicular cancer will be diagnosed in men in the United States in 2020 and 440 men are predicted to die from the disease. It accounts for 1% of all cancers in men. The incidence of testis cancer varies widely among racial groups and geographic regions. In the United States, it is the most common cancer diagnosed in men aged 20 to 40 years of age, but it is rarely diagnosed before age 15 or after age 55. It is four times more common in white than in Black individuals. The incidence has increased by more than 50% since 1975. Risk factors include cryptorchidism, a personal or family history of testis cancer, gonadal dysgenesis, and Klinefelter's syndrome. Cryptorchidism increases risk in the undescended testicle and the normally descended contralateral testicle. Orchiopexy for cryptorchidism before puberty reduces the risk of testis cancer.

Pathology

Approximately 98% of testis cancers are germ cell tumors; the others are lymphomas, sex-cord stromal tumors, and adenocarcinomas of the rete testis. Germ cell tumors are divided into two broad categories: seminomas and nonseminomas (i.e., nonseminomatous germ cell tumors, or NSGCTs). Seminomas by definition are 100% seminoma, whereas most NSGCTs are a mixture of two or more of the five types of germ cell tumors: seminoma, embryonal carcinoma, teratoma, yolk sac tumor, and choriocarcinoma. A tumor that contains any elements of embryonal carcinoma, teratoma, yolk sac tumor, or choriocarcinoma is considered to be an NSGCT even if most of the tumor is seminoma. Because seminomas do not produce α -fetoprotein (AFP), patients who have a significantly elevated AFP level have an NSGCT regardless of the histopathology.

Diagnosis and Differential Diagnosis

Whenever a testis tumor is suspected, transscrotal ultrasound should be performed; if a mass suspicious for cancer is seen, the standard diagnostic procedure is an inguinal orchiectomy. Transscrotal orchiectomy or biopsy is contraindicated because of the risk of seeding the tumor in the scrotum and altering the pattern of spread. Differential diagnosis

includes testicular lymphoma, torsion, epididymitis, orchitis, and other benign scrotal lesions.

Clinical Presentation

Testis cancer most often manifests as testicular enlargement, mass, or induration. It may or may not be painful or tender, and the presence of pain does not exclude a diagnosis of cancer. Testicular atrophy, gynecomastia, back pain, and thromboembolic disease can also occur.

Staging the cancer requires measuring postorchectomy levels of serum AFP, human chorionic gonadotropin (β -HCG), and LDH as well as assessing for nodal and organ metastases, which should be done with a CT scan of the abdomen and pelvis and either chest CT or a chest radiography. The testes drain to the retroperitoneal lymph nodes, and retroperitoneal nodal spread constitutes stage II disease. In practice, testis cancer is divided into three categories: stage I (localized), with no evidence of spread to lymph nodes or beyond; stage II (regional), with enlarged retroperitoneal lymph nodes but no distant metastases; and disseminated disease. Disseminated disease includes stage I or II disease in which serum AFP and/or β -HCG levels are persistently elevated after orchectomy, bulky stage II disease, and all stage III disease. Metastases to other organs or to pelvic or other non-retroperitoneal lymph nodes represent stage III disease, as does spread to retroperitoneal nodes in the setting of highly elevated serum tumor markers. Disseminated disease is divided into three categories: good-risk, intermediate-risk, and poor-risk disease; treatment differs for the different risk groups.

Treatment

Stage I seminomas and NSGCTs are usually managed with surveillance after surgery. The risk of relapse is about 18% for seminomas and 30% for NSGCTs. For pure seminomas, larger tumor size and lymphovascular invasion are each associated with a higher risk of recurrence. For nonseminomas, lymphovascular invasion has been most strongly associated with risk of relapse and tumors that are pure or predominantly embryonal carcinoma are also at higher risk. Alternatives to surveillance are single-agent carboplatin chemotherapy or radiation therapy for seminomas and bleomycin and etoposide and cisplatin (BEP) chemotherapy or retroperitoneal lymph node dissection (RPLND) for NSGCTs. Long-term disease-specific survival for stage I disease is 99% regardless of which of these approaches is used.

Stage II seminomas are usually treated with radiation therapy or chemotherapy (with BEP or etoposide plus cisplatin [EP]). Chemotherapy is preferred when the disease bulk is greater than 5 cm and sometimes for less bulky tumors. Management of stage II NSGCTs depends on the disease bulk and the levels of serum AFP and β -HCG. If either marker is elevated, then chemotherapy is preferred regardless of disease bulk. If no nodes are bigger than 2 cm and there are fewer than six enlarged nodes, then RPLND or chemotherapy can be considered. For bulkier disease, chemotherapy is preferred.

Treatment of stage III disease depends on the sites of metastases and the levels of serum tumor markers. For good-risk disease, the treatment is three cycles of BEP or four cycles of EP chemotherapy. For intermediate- and poor-risk disease, the treatment is four cycles of BEP chemotherapy (or etoposide, ifosfamide, and cisplatin [VIP] chemotherapy). In NSGCT, all residual masses should be resected after chemotherapy if feasible. In cases of seminoma, residual masses are typically observed unless they grow. Sometimes, post-chemotherapy residual masses greater than 3 cm in patients with pure seminoma are evaluated with an FDG-PET/CT, but the value of that approach is limited by the incidence of false-positive results. Patients with pure seminomas and residual masses after chemotherapy are the only testis cancer patients who should be considered for PET scans.

Relapsed disease after chemotherapy is treated with salvage chemotherapy given either at standard doses or at high doses with hematopoietic stem cell support.

Prognosis

Overall, the long-term disease-specific survival rate for testis cancer is 96%. By stage, the survival rates are 99% for stage I, 96% for stage II, and 73% for stage III. By disseminated disease risk category, survival is about 90% for good-risk disease, about 80% for intermediate-risk disease, and about 50% for poor-risk disease.

Breast Cancer

Mary Anne Fenton, Rochelle Strenger

EPIDEMIOLOGY

Worldwide and in the United States, breast cancer is the number one malignancy in women. In 2019 in the United States approximately 271,270 new cases were diagnosed including 268,600 in females and 2670 in males. Breast cancer is the second leading cause of female cancer deaths in the United States. Projected 2019 breast cancer mortality is estimated to be 42,260 (41,760 female, 500 male breast cancer patients). A woman has a 12.4% lifetime risk of breast cancer, and her risk increases with age (Table 60.1). The mortality risk from breast cancer in the United States declined by 39% between 1989 and 2015 due to early detection and more effective treatment; the current 5-year survival rate is 90%. For most solid tumors 5-year survival is predictive of a cure. Unfortunately, however, for the ER+ breast cancer subtype systemic recurrences continue to occur beyond 20 years.

Not all women share equally in improved breast cancer outcomes. Socioeconomic barriers may limit access to early detection and effective therapies. In addition, there are significant ethnic differences in breast cancer incidence and outcome. While breast cancer is less common in African American women, they are more likely to present at a later stage, have a higher incidence of the more aggressive triple-negative subtype and have a higher breast cancer specific mortality rate. The difference in mortality rate is in part related to tumor biology comorbidities, access and adherence to care.

RISK FACTORS

A women's risk of breast cancer increases with age (see Table 60.1) with a lifetime risk of 12%. To put it another way, 1 in 8 women in the United States will develop breast cancer during the course of their lifetime. Reproductive factors such as early onset of menses, late onset of menopause, first live birth after age 35 or nulliparity correlate with a mild increased risk of breast cancer. A positive personal history of dense breasts, findings on a breast biopsy of atypical ductal hyperplasia (ADH) or lobular carcinoma in situ (LCIS) increase breast cancer risk 4-fold.

The risk of breast cancer is increased when there is family history of breast cancer and other cancers such as ovarian, high-risk pancreatic, and prostate. When there is one family member with breast cancer the risk is increased 2-fold. The presence of a familial breast cancer predisposition to gene mutation *BRCA1/2* increases breast cancer risk over 4 fold (Table 60.2).

Breast Cancer Genetics

Approximately 10% of breast cancers are associated with inheritable genetic mutations. The first high-penetrance genes, *BRCA1* and *BRCA2*, were identified by screening families with early-onset breast cancer. Mutations in the tumor suppressor genes *BRCA1/2* are also

associated with ovarian cancer and other malignancies. Screening recommendations and guidelines for genetic testing and counseling from organizations such as Medicare and the National Comprehensive Cancer Network (NCCN) Guidelines focus on individuals with first-, second-, and third-generation maternal and paternal family histories of cancer, including age of onset.

NCCN guidelines from 2019 recommend referral for genetic counseling for patients diagnosed with breast cancer below the age of 50, or triple-negative (ER/PR, HER2-negative) disease below the age of 60, two breast primaries in an individual, family member with diagnosis of breast cancer below age of 50, family member with ovarian cancer, patient or relative with male breast cancer, and individuals of Eastern European Jewish ancestry who may be at risk for founder mutations. Unfortunately, many individuals are unaware of their family history of cancer including site of cancer and age of onset (Table 60.3).

The identification of a high-penetrant mutation in a family member without breast cancer will afford them the opportunity to consider preventative and early detection strategies. Prior to 2012, breast cancer genetic testing focused on *BRCA1/2* testing and was performed by the Sanger method of sequencing a single DNA fragment at a time, a sequencing technique known to miss large deletions. Next-generation sequencing (NGS) allows for testing of multiple genes, and the number of "clinically actionable mutations" has increased beyond *BRCA1/2*. Patients with *BRCA1/2* testing with negative results prior to 2012 should be referred for genetic counseling and updated testing. In the metastatic setting, patients with germline *BRCA1/2* (g*BRCA1/2*) mutations may be candidates for PARP inhibitor therapy (see metastatic breast cancer section).

CLINICAL PRESENTATION AND DIAGNOSIS

In the United States, over 50% of breast cancers are detected on a screening mammogram, and 33% of cases will present with a self-detected or clinically detected breast mass. In the majority of mammogram and ultrasound detected masses, calcifications and clinically palpable lesions are amenable to core needle biopsy in order to establish a diagnosis, determine breast cancer histology, assess tumor grade, and assess ER, PR, and HER2 expression by immunohistochemistry. The presence or absence of estrogen receptor (ER), progesterone receptor (PR), and human epidermal growth factor receptor 2/neu (HER2) are prognostic for survival and predict response to systemic therapies for breast cancer. Patients presenting with a palpable mass should be referred for diagnostic mammogram and ultrasound and biopsy. If imaging and biopsy are not concordant with the patient's presentation and clinical examination the patient should be referred to a breast surgeon.

TABLE 60.1 Age-Specific Probabilities of Developing Invasive Breast Cancer for US Women

Age	10-Year Probability	Or 1 in
20	0.1%	1567
30	0.5%	220
40	1.5%	68
50	2.3%	43
60	3.4%	29
70	3.9%	25
Lifetime	12.4%	8

Note: Probability is among those free of cancer at the beginning of each age interval based on cases diagnosed 2012-2014 American Cancer Society, Inc. Surveillance Report 2017.

TABLE 60.2 Risk Factors for Breast Cancer

		Relative Risk
Family history of breast cancer	First-degree relative	2
	More than one first degree relative	3-4
	<i>BRCA1/2</i> mutation carrier	>4
Age over 65		>4.0
Early menses	age < 12	1.1-2
Nulliparous		1.1-2
First birth	>35 years	1.1-2
Late menopause	>55 years	1.1-2
Never breast fed		1.1-2
Postmenopausal obesity (BMI greater than or equal to 30)		1.1-2
Mammographically dense breasts		4
Proliferative breast lesions	Atypical ductal hyperplasia	4
	Lobular carcinoma in situ	
High-dose radiation to the chest	Hodgkin's lymphoma age 10-30	2.1-4

Data from American Cancer Society. Breast Cancer Facts and Figures 2017-2018 Atlanta, GA; American Cancer Society, 2017.

Traditionally, breast cancer histology and anatomic stage have driven patient stage, prognosis, and decision making for surgery, radiation, and medical oncology care. In current practice, and as delineated in the latest American Joint Commission (AJCC) 8th edition *Staging Manual*, ER, PR, HER2 status, tumor grade, and genomics impact breast cancer prognosis in the prognostic breast cancer stage.

Histology

Breast cancer arises from the epidermal cells of the terminal ductal lobular unit and progresses in a continuum from intraductal hyperplasia, atypia, ductal carcinoma in situ, to invasion through the basement membrane of the duct.

Ductal Carcinoma in Situ

Ductal carcinoma in situ (DCIS) is a clonal disorder of cancer cells contained within the milk duct basement membrane with the potential to

TABLE 60.3 NCCN Guideline on Referral for Genetic Counseling 2019

No history of breast cancer	Personal history of ovarian cancer Family history of pancreatic cancer Family history of metastatic prostate cancer Eastern European Jewish ancestry and personal history of breast cancer or high-grade Gleason 7 or greater prostate cancer in family member
Patient with breast cancer	Age under 50 Triple-negative breast cancer under the age of 60 Ovarian cancer Two breast primaries Male breast cancer Pancreatic cancer Greater than or equal to two family members with breast cancer Family member with ovarian cancer Gleason 7 or greater or metastatic prostate cancer

Data from National Comprehensive Cancer Network Genetic/familial high-risk assessment: breast/ovarian version 3.2019 http://www.nccn.org/professionals/physician_gls/pdf/breast.pdf. Accessed September 25, 2019.

progress to invasive ductal carcinoma (Fig. 60.1). Twenty-five percent of breast cancers diagnosed each year in the United States are classified as DCIS (Tis, Stage 0). Fifteen to fifty percent of DCIS will progress to invasive cancer. Treatment for DCIS is excision to 2-mm negative margins and local breast radiation. Low-grade DCIS less than 2.5 mm considered “low risk” DCIS may be treated with excision alone. The option of “watchful waiting” is being investigated in ongoing studies on molecular features of DCIS. Patients with DCIS are not at risk for systemic spread unless it progresses or recurs as invasive disease.

DCIS treated with mastectomy has a local regional recurrence rate less than 1%. Lumpectomy and radiation recurrence rate is 6% to 16%, of which 50% of recurrences are invasive. There is no difference in survival for mastectomy versus lumpectomy/radiation therapy. For ER-positive DCIS, tamoxifen or anastrozole (reserved for postmenopausal patients) reduces local recurrence by 32% and contralateral breast cancer by 50%.

Lobular Carcinoma in Situ

LCIS is a spectrum of lobular cells with varying potential for invasion. A patient with LCIS and/or atypical ductal hyperplasia has an increased risk of bilateral breast cancer. Patients with DCIS, LCIS, and atypical hyperplasia are candidates for risk reduction with selective estrogen receptor modulators (SERMS) such as tamoxifen and raloxifene or aromatase inhibitors.

Invasive Breast Cancer

Breast cancer is classified histologically by morphology and grade based on nuclear pleomorphism, gland formation, and mitotic index. The most commonly used grading system is Bloom Richardson or Nottingham, with grade 1 less aggressive and grade 3 more aggressive and with higher invasion potential.

Infiltrating ductal carcinoma (IDC) (49% to 75%), is the most common histology, seen as a density on mammography and gross pathology assessment. The clinical behavior of IDC is dependent on grade and ER, PR and HER2 expression. **Invasive lobular carcinoma (ILC)** comprises 5% to 15% of invasive breast cancer, has a slight increased risk of bilateral

Fig. 60.1 (A-D) Four cases of invasive ductal carcinoma. (Korourian S: Infiltrating carcinomas of the breast: not one disease. In: Bland K, editor. *The Breast: Comprehensive Management of Benign and Malignant Diseases*, 145-155.e4, 64, 2018, Elsevier Press.).

breast cancer and slight propensity for abdominal mesenteric dissemination. ILC is characterized by single cell tissue infiltration, loss of heterozygosity or 16q chromosome, and absence of epithelial e-cadherin. **Medullary carcinoma** (3% to 9%) is associated with *BRCA1* germline mutations and higher grade. The histologic appearance is described as “pushing borders” rather than single cell invasion. **Mucinous and tubular breast cancer** subtypes, 1% to 2% and 1% to 3% respectively, are less common and present a lower risk for systemic metastasis.

BREAST CANCER STAGING

Approximately 90% of breast cancer at presentation is confined to the breast and axilla. Clinical evaluation includes history, including careful review of systems; screening for signs or symptoms of metastasis such as headache, weight loss, and bone pain; clinical examination; and laboratory evaluation including CBC, liver tests, and alkaline phosphatase. Clinical breast cancer staging is based on clinical breast exam including breast inspection for nipple discharge or retraction, skin dimpling, ulceration, erythema, edema, and palpable masses, and palpation of supraclavicular, axillary, and cervical lymph nodes.

Inflammatory breast cancer (Fig. 60.2) is an aggressive subtype of breast cancer with tumor invasion of the dermal lymphatics presenting with rapid skin changes of edema, erythema, and *peau d'orange* change,

involving greater than one third of the breast. Patients with breast cancer considered clinical stage III or signs or symptoms concerning for distant metastasis should be referred for systemic staging with bone scan and CT scan and in select cases PET scan. If a suspicious site is noted on staging, biopsy should be performed to confirm distant spread of breast cancer.

Breast cancer staging is based on the AJCC of anatomic cancer staging using tumor size (T in centimeters), regional node metastasis (N), and distant metastasis (M). The TNM system has prognostic significance. In the AJCC 8th edition *Staging Manual*, released in 2019, clinical stage (c) and pathologic stage (p) are supplemented with an additional pathologic prognostic stage incorporating grade and ER, PR, and HER2 gene overexpression. As an example, patients with T2 (2 to 5 cm) node-negative (N0) ER-positive HER2-negative tumors with gene expression profiles such as an Oncotype® Recurrence Score less than 11 have an excellent 5-year prognosis. This is reflected in the patient's AJCC 8th edition pathological prognostic stage of 1A (previously, by the AJCC 7th edition system, the patient would have been staged as IIA).

TREATMENT

Breast cancer is a story of the old and the new. Tamoxifen, the first cancer targeted therapy, was approved for ER-positive metastatic breast

Fig. 60.2 (A and B) Inflammatory breast cancer with erythema and edema occupying the majority of the breast. (Somlo G, Jones V: Inflammatory breast cancer. In: Bland K, editor. *The Breast: Comprehensive Management of Benign and Malignant Diseases*, 2018, Elsevier Press.).

cancer in 1977. In the adjuvant setting for the most common type of breast cancer, tamoxifen has proven to reduce systemic recurrence by 50%. Scientific discoveries of pathways of tamoxifen resistance have led to additional therapeutic strategies for ER-positive breast cancer including aromatase inhibition to decrease estrogen production in postmenopausal patients, ovarian suppression of estrogen production in the premenopausal setting, and estrogen receptor downregulation with fulvestrant. Recent discoveries have led to FDA approval of cell cycle inhibitors of cyclin D 4/6 in combination with endocrine therapy with improved overall survival of ER-positive metastatic breast cancer.

By gene expression profiling, ER-positive breast cancer is further subdivided into luminal A, with a low cell proliferation signature and high endocrine therapy response, and luminal B, with a high cell proliferation signature and higher recurrence rate indicating relative endocrine insensitivity and relatively higher chemotherapy sensitivity. In the current era of personalized medicine, gene expression profiles such as Oncotype Recurrence Score testing of ER-positive node-negative breast cancer can identify patients who can forgo chemotherapy.

Other applications of personalized medicine for metastatic breast cancer include screening tumor samples with genomic sequencing for actionable mutations with specific targeted agents. PIK3CA-mutant ER-positive stage IV breast cancer patients have improved progression-free survival (PFS) with the PIK3CA inhibitor alpelisib. Approximately 10% of patients with breast cancer harbor somatic mutations in specific tumor suppressor genes such as *BRCA1* and *BRCA2*. These patients are at higher risk of breast cancer and other malignancies with early age of onset. Some patients who harbor these genes are candidates for more intense screening and prevention strategies. Patients with stage IV disease who are *BRCA1/2* mutation carriers may benefit from PARP inhibitor therapy.

Early-Stage Breast Cancer

Local Therapy

Stage I and II breast cancer clinical trials demonstrate equivalent outcomes of overall survival with breast preservation surgery with lumpectomy or segmental mastectomy to achieve negative surgical margins and breast external beam radiation compared to modified radical

mastectomy and axillary dissection. Patients age 70 and older with ER+ stage 1 disease willing to take 5 years of endocrine therapy have an equivalent overall survival with or without radiation and can safely omit radiation.

Unfortunately, not all breast cancer patients are candidates for breast preservation. Patients with multicentric disease (more than one breast quadrant), extensive malignant appearing calcifications, surgical inability to achieve negative margins, prior breast radiation, connective tissue disorder or who are unable to access a radiation facility treatment center are candidates for mastectomy. Patients with inflammatory breast cancer need neoadjuvant chemotherapy, prior to surgery, to eradicate dermal lymphatic cancer metastasis from the skin. In addition, patients with large unresectable tumors or large tumor-to-breast ratio may be candidates for neoadjuvant chemotherapy or endocrine therapy to downstage the tumor and allow for breast preservation.

For patients with no palpable lymph nodes on clinical exam, sentinel lymph node staging with removal and examination of the first draining lymph node accurately reflects the status of axillary metastases. Based on the ACOSZ-0011 trial of patients with clinically negative axillary lymph nodes staged with sentinel lymph nodes (with up to two positive lymph nodes), radiation and systemic therapy provide adequate local control.

Systemic Therapy

Prognosis estimation of systemic recurrence. The indication for breast cancer staging is to estimate the risk of systemic metastasis and help direct therapy. Historically, the most accurate indicators are tumor size, axillary metastasis, tumor grade, and ER, PR, and HER2 neu expression. ER, PR, and HER2 gene expression are detected by immunohistochemistry (IHC). Equivocal HER2 IHC testing is further evaluated by *HER2* gene duplication detected by invitro hybridization (ISH).

Another chapter in breast cancer care is systemic therapy to reduce the risk of recurrence by elimination of micro-metastatic disease. Effective systemic therapy for breast cancer is the result of patient participation in well-designed randomized sequential clinical trials and identification of effective systemic therapies to decrease recurrence. The use of genomic signatures for personalized medicine allows us to

move beyond “chemo for all” to an understanding of which breast cancers are chemotherapy sensitive or require chemotherapy. Tools such as PREDICT.NHS.UK calculate risk of mortality based on a patient’s age, anatomic stage, and prognostic factors and assist clinicians and patients in estimating risk of recurrence and mortality reduction from chemotherapy, endocrine therapy, and validated genomic assays.

Therapy for HR+ Breast Cancer

Hormone receptor positive (HR+) breast cancer is the most common form of breast cancer and HR positivity is prognostic for a better 5-year disease-free survival compared to HR-negative breast tumors. HR+ also predicts those who will respond to antiestrogen directed therapies, although the risk of local and systemic recurrence extends past 10 years and is estimated to occur at a rate of 2% per year.

Tamoxifen was the first “targeted therapy” and ER expression the first biomarker for response to therapy. The Early Breast Cancer Trialists Group (EBCTCG) published series of breast cancer trial meta-analyses. EBCTCG trials of tamoxifen for HR+ breast cancer showed decreases in systemic recurrence by 50% and mortality by 25%; reduction in recurrence continues after 5 years. Further incremental improvement for subsets of patients include ovarian suppression for high-risk HR+ premenopausal patients and addition of aromatase inhibitors for postmenopausal patients. Based on the persistent risk of late recurrences in HR+ disease, trials of extended endocrine therapy with tamoxifen or aromatase inhibitors have shown further decrease in disease recurrence. Extended therapies and ovarian suppression come at a cost of increase in side effects and symptoms including hot flashes, decreased bone density, and for tamoxifen, increase in vaginal bleeding and risk of endometrial cancer.

A subset of HR+ patients is less responsive to endocrine therapy. In the current era of personalized medicine, gene expression profiles such as Oncotype Recurrence Score for HR+ node-negative breast cancer evaluates 16 genes including ER, proliferation, and invasion genes and predicts for risk of recurrence with endocrine therapy as well as a response to chemotherapy. Luminal A patients have low Oncotype Recurrence Scores and can forgo chemotherapy, and luminal B patients may derive benefit from addition of chemotherapy to endocrine therapy. Results of these assays can be used by clinicians for risk-benefit discussions with patients.

Approximately 20% of breast cancers are HER2 positive. *HER2* gene overexpression is a marker of a more aggressive phenotype. Targeted therapy with trastuzumab, a humanized monoclonal antibody to HER2 in combination with chemotherapy reduces systemic recurrence by 40%. Since the identification of trastuzumab, additional HER2-directed monoclonal antibodies have been developed and documented to have clinical utility. Pertuzumab, a monoclonal antibody directed to HER2 that prevents HER2 heterodimerization and cell activation added to trastuzumab and chemotherapy clinically improves the pathologic response rate. Future directions with HER2-directed therapies may be the ability to tailor therapy based on response and potentially to deescalate chemotherapy for HER2-positive patients.

Triple-negative breast cancer, defined as the absence of ER, PR and HER2 expression, is an aggressive breast cancer phenotype and comprises 10% to 15% of all breast cancers. Gene array analysis has identified six subtypes. Triple-negative breast cancer has a high systemic recurrence rate that typically occurs within the first 5 years of diagnosis. Due to high recurrence rates and shortened life expectancy after triple-negative breast cancer recurrence, systemic chemotherapy should be considered for a triple-negative breast cancer greater than 0.5 cm. Neoadjuvant chemotherapy may be considered if tumor size is over 2 centimeters.

Metastatic Breast Cancer

Metastatic breast cancer is “treatable not curable,” and while the goal of therapy is palliative, many patients will live months to years on

systemic therapy. The most frequent sites of breast cancer systemic recurrence are bone, lung, liver, and for lobular cancer, abdominal recurrences including ovaries and mesentery. Patients presenting with clinical or radiographic evidence of systemic recurrence should have a biopsy to confirm diagnosis including evaluation of ER, PR, and HER2 expression of metastatic cells. Results from a small series indicate receptor status on metastasis may change from the original breast cancer approximately 10% of the time. Next-generation sequencing of tumor metastasis screening for actionable mutations may direct cancer therapies in patients demonstrating PIK3CA-mutant ER-positive stage IV, to include alpelisib and fulvestrant. For triple-negative breast cancers, testing for programmed death ligand 1 (PD-L1) expression predicts response to checkpoint inhibitor therapy with atezolizumab. Single-agent chemotherapy for stage IV breast cancer is as effective as combination chemotherapy. Combination chemotherapy is reserved for patients at risk for a visceral crisis.

ER-Positive HER2-Negative Metastatic Breast Cancer

Bone only metastatic disease may have a long disease-free interval and patients may live many months to years with treatment as a chronic disease. Recurrence of ER-positive breast cancer within 6 months of initiation of antiestrogen therapy may indicate primary endocrine therapy resistance. Although chemotherapy response rate is more rapid, in the absence of impending visceral crisis there is no advantage in survival to chemotherapy over initial endocrine therapy.

Triple-Negative Breast Cancer

Unfortunately, systemic recurrence of triple-negative breast cancer (TNBC) frequently occurs in first 2 years after diagnosis. Chemotherapy options for stage IV ER-positive breast cancer resistant to endocrine therapy or TNBC include anthracyclines, taxanes, eribulin, carboplatin, and other single agents.

Targeted therapies for TNBC subtypes have expanded therapeutic options for selected patients. Patients with *BRCA1/2* germline mutations may benefit from disease control with an oral polyadenosine diphosphate-ribose polymerase (PARP) inhibitor. Olaparib and talazoparib are FDA approved for *BRCA*-associated *HER2*-negative breast cancer based on improved progression free survival. Immune checkpoint inhibition is one of many pathways for cancer to evade the immune system. Tumors expressing PD-L1 may activate PD-1 on tumor infiltrating immune cells resulting in immune cell apoptosis. In the Impassion130 trial of checkpoint inhibitor therapy, tumor-infiltrating immune cells with expression of 1% or greater PD-L1 expression derive increase in progression free survival with nab-paclitaxel and atezolizumab.

Special Circumstances

Bone Metastasis

Osteoclast inhibitors zoledronic acid bisphosphonates or denosumab, a RANK ligand inhibitor, prolong the time to skeletal related events such as pathologic fractures or need for surgery or radiation for bone metastases. Risks include renal dysfunction, hypocalcemia, and osteonecrosis.

Survivorship

A cancer patient becomes a cancer survivor on the day of diagnosis, regardless of whether they are currently without evidence of disease or are living with advanced or metastatic breast cancer. There are 15 million cancer survivors in the United States. Forty-four percent are breast cancer survivors. The Institute of Medicine report on cancer survivorship notes the transition of patients from active treatment to cancer survivor. The concern for patients “lost in transition” led the American College of Surgeons Commission on Cancer and the American Society

of Clinical Oncology (ASCO) to recommend the creation of a survivorship plan for patient and primary care practitioner and follow-up care as quality standards.

Endocrine Therapy Compliance

It is estimated that 50% of ER-positive breast cancer patients do not complete adjuvant endocrine therapy due to side effects or barriers such as cost. Side effects that may affect quality of life and compliance include hot flashes from chemotherapy-induced menopause, tamoxifen or aromatase inhibitors. A recent study showed improvement in hot flashes and sleep quality with the use of cognitive behavioral therapy. Arthralgias from aromatase inhibitors may be attenuated by rotation through drug regimens and/or acupuncture, duloxetine or yoga.

Sexual Dysfunction

Unfortunately, sexual dysfunction is a common side effect following a breast cancer diagnosis secondary to surgery, radiation, chemotherapy, and adjuvant endocrine therapy. Practitioners should use open-ended questions about intimacy issues to normalize patients' concerns. Patients note change in self-image, decrease in sexual drive, vaginal dryness, and dyspareunia. Effective interventions can include use of vaginal moisturizers and lubricants, gabapentin and venlafaxine for hot flashes, topical lidocaine for tender vestibule, and referral to a sexual health expert.

Fertility Preservation

Pregnancy following a breast cancer diagnosis does not appear to increase risk for breast cancer recurrence, based on case control studies. Fertility may be compromised by chemotherapy, and fertility preservation options include egg retrieval and invitro fertilization. A general rule is to avoid pregnancy for 2 years after diagnosis, because this time period is a high-risk time for cancer recurrence. The PROMISE trial will follow a cohort of women following breast cancer diagnosis and treatment for breast cancer outcomes who chose to stop adjuvant endocrine therapy for pregnancy.

Lymphedema

Breast and arm lymphedema can be a complication from surgery and may be exacerbated by radiation. Physical therapy, manual massage, and compression bras and sleeves may attenuate this side effect.

Male Breast Cancer

Male breast cancer represents 1% of all breast cancers in the United States. Approximately 2500 men are diagnosed with breast cancer yearly and 500 men will die each year from male breast cancer. Risk factors for male breast cancer include *gBRCA2* mutations, Klinefelter's syndrome, undescended testes or testicular injury, and environmental radiation exposure, as documented in atomic bomb survivors. Male breast cancer patients are not represented in clinical trials. Available data on male breast cancer are primarily from small cohort studies. Mirroring women, incidence increases with age, but unlike women it is slightly higher in black men than in non-Hispanic white men. Presentation is with a palpable breast mass. Initial evaluation includes diagnostic mammogram, ultrasound, and core needle biopsy. On histologic diagnosis, 90% are ER-positive, HER2-positive. Surgical options and systemic therapy are similar to those of female counterparts. Tamoxifen reduces the risk of systemic disease in male breast cancer, with similar side effects as seen in women. The utility of aromatase inhibitor therapy is unknown in the adjuvant or metastatic setting.

Breast Cancer in Older Women

Breast cancer risk increases with age (see Table 60.1). In the United States a woman has a 1 in 8 risk of breast cancer diagnosis. The majority of patients diagnosed with breast cancer are ER-positive and over 65 years old. Patients age 70 and older with ER-positive stage 1 disease willing to take 5 years of endocrine therapy have an equivalent overall survival with or without radiation therapy and can therefore safely omit radiation. For women over 70 years of age with more aggressive or higher stage breast cancer, estimation of risk of recurrence, life expectancy, comorbidities, and toxicities of therapies are necessary to tailor therapy. Tools such as "ePrognosis" can be used for life-expectancy estimates based on comorbidities and PREDICT.NHS.UK for estimation of mortality based on tumor stage and prognostic features.

SCREENING

One outcome of advances in breast imaging techniques has been earlier detection of invasive and noninvasive breast cancers. Multiple guidelines have attempted to address screening of women without symptoms of breast cancer. In 2019, The American College of Physicians issued an updated guidance statement that addresses the use of screening mammography in women aged 50 to 74.

These guidelines do not address high-risk patients such as those with a personal history of breast cancer, prior abnormal mammogram or who carry a genetic mutation known to predispose to an increased risk of breast cancer.

CONCLUSION AND FUTURE DIRECTIONS

Breast cancer 5-year survival overall is 90% due to early detection and effective therapies such as chemotherapy and endocrine therapy. Unfortunately, chemotherapy and endocrine therapy have short- and long-term side effects of fatigue, cardiac toxicity, neuropathy, hot flashes, and sexual dysfunction. In an era of personalized medicine, ER-positive, node-negative breast cancer gene expression profile has identified a large proportion of patients who do not benefit from chemotherapy. Ongoing prospective trials will aid in decision making for ER-positive node-positive patients. For stage IV ER-positive patients, CDK 4/6 inhibitors and PIK3CA inhibitors appear to prolong time to progression. Triple-negative breast cancer continues to have a high proportion of patients who relapse and die within a few years of diagnosis; novel therapies are currently in phase 3 trials.

OVARIAN CANCER

Epidemiology

Ovarian cancer is the most difficult gynecologic cancer to cure, because over 70% of cases present with metastatic disease, and over 80% of cases will recur despite treatment. Ovarian cancer is the seventh most common cancer affecting women worldwide. In North America, Europe, Australia, and New Zealand it is the most common cause of death from a gynecologic malignancy.

A woman's lifetime risk of developing ovarian cancer is 1.4%. Most ovarian cancers are sporadic; however, a family history of ovarian cancer is the strongest risk factor for developing disease due to inherited genetic mutations. For example, inherited BRCA1 and BRCA2 mutations carry a 40% to 60% and a 15% to 20% risk of developing ovarian cancer, respectively. Lynch syndrome, the result of inherited mutations in mismatch repair genes, portends a 12% risk of ovarian cancer.

Currently, guidelines recommend that all women with ovarian carcinoma receive genetic counseling. Multigene panel testing is available to detect mutations that may confer a greater risk of developing the disease and can help guide targeted treatment recommendations. Furthermore, genetic screening enables identification of family members at risk who may benefit from prophylactic removal of the ovaries and fallopian tubes, as well as specialized screening programs for other cancers. (Please see [Chapter 55](#).)

Other significant risk factors for ovarian cancer include reproductive factors associated with increased ovulation such as early menarche, late menopause, and nulliparity. Protective factors against ovarian cancer include pregnancy, breast-feeding, and use of oral contraceptives. Talcum powder has been associated with asbestos contamination, and its use on the perineum has been studied for a potential link to ovarian cancer, with conflicting results.

Pathology

Ovarian carcinoma refers to a family of tumors arising from the epithelial lining of the ovary, fallopian tube, and peritoneum. More recently, it is thought that the majority of ovarian cancers originate in the fallopian tube due to the frequent concurrent finding of premalignant serous tubal intraepithelial carcinoma (STIC). The most common cell type is serous carcinoma. Other histologies include endometrioid, mucinous, and clear cell patterns.

Borderline ovarian neoplasms are an unusual category of ovarian neoplasm with a favorable prognosis that can spread and recur but do not exhibit invasion of tissue. Treatment is surgical because these tumors do not respond to chemotherapy.

Nonepithelial ovarian cancers account for less than 5% of ovarian cancers and originate from sex-cord cells, stromal cells, and germ cells of the ovary. These rare tumors often occur in adolescent

females, and pathologic classification determines treatment and prognosis.

Clinical Presentation

Ovarian cancer is often called the cancer that “whispers” because symptoms are subtle and nonspecific. Bloating, abdominal pain, gastrointestinal disturbance, and bladder symptoms may present once diffuse carcinomatosis develops with nodules of cancer and ascites throughout the abdomen and pelvis. Cancer is often detected during imaging for work-up of sudden GI or GU symptoms. Common sites of metastasis include the omentum, peritoneal surfaces, lymph nodes in the pelvis and abdomen, and pleural effusions. Distant metastases to the lungs, liver, bone and brain are less common. Over 70% of patients are diagnosed with disease beyond the pelvis considered stage IIIC or IV.

Diagnosis and Staging

Ovarian cancer is diagnosed with histologic confirmation of a pelvic mass or abnormal tissue typically identified on ultrasound, computed tomography (CT), or magnetic resonance imaging (MRI). Advanced ovarian cancer is suspected on imaging with the presence of an adnexal mass accompanied by ascites, peritoneal carcinomatosis or enlarged pelvic and para-aortic lymph nodes. Patients with an enlarged complex ovarian mass and no evidence of metastatic disease should have surgery for resection of the mass with effort made to avoid disrupting the integrity of the neoplasm, because rupture may spread cancer if present. If widespread disease is seen on imaging, a clinician may recommend an image-guided biopsy of solid tumor, drainage of ascites or surgical resection to obtain tumor for tissue diagnosis.

The tumor biomarker carbohydrate antigen 125 (CA 125) is a mucin-type glycoprotein secreted into the bloodstream by cancer cells and can be useful in the initial work-up and for monitoring response to treatment, but the test should not be used for diagnostic purposes alone as the marker is nonspecific. CA 125 may be elevated in noncancer conditions such as menstruation, benign ovarian tumors, endometriosis, fibroids, pelvic infection, congestive heart failure, and pleural effusions.

Ovarian cancer stage is assigned by review of clinical, pathologic, and radiologic evaluation. Early disease is isolated to the ovaries or fallopian tubes (FIGO [International Federation of Gynecology and Obstetrics] stage I) or to the true pelvis (stage II). Diffuse carcinomatosis or abdominal/pelvic adenopathy (FIGO stage III) and distant metastases to sites including liver parenchyma, lungs, bone and brain (FIGO stage IV) comprise advanced stage disease.

Treatment

The treatment for presumed early stage ovarian carcinoma is surgical resection and staging to evaluate for metastatic disease. Because

TABLE 61.1 Addition of Maintenance Bevacizumab to Front-Line Therapy for Ovarian Cancer Shows Improved Progression-Free Survival (PFS) in Two Studies

Study	Randomization	N	Median PFS	Hazard Ratio	P-value	Survival Advantage
GOG-218	C/P + placebo	625	10.3 mo	0.91	0.16	No

ICON7	C/P	764	17.3	0.81	0.004	Yes (for those at high risk for PD)
	C/P + bev →7 bev-M	764	19.0			

Data from Burger RA, et al. NEJM 2011; 365:2473-83; Perren TJ, et al. NEJM 2011; 365:2484-96; Tewari, et al. J Clin Oncol. 2019;37:2317-2328. bev, Bevacizumab; bev-M, bev maintenance; C/P, cisplatin + paclitaxel; PD, progression of disease.

ovarian cancer may spread through peritoneal shedding of cells, lymphatically or through the bloodstream, staging includes removing the ovaries, fallopian tubes, uterus, omentum, lymph nodes, and peritoneal biopsies. High-grade cancers isolated to the ovary, or cancer with any sign of spread beyond the ovary, is treated with adjuvant chemotherapy. The standard of care calls for the administration of intravenous carboplatin and paclitaxel every 3 weeks. For early stage ovarian carcinoma, there is no consensus on whether three or six cycles should be administered; one study that looked at the impact of histology on outcomes following chemotherapy suggested that compared to three cycles, six cycles was associated with a significantly lower risk of recurrence for women with serous cancers (HR 0.33, 95% CI 0.14-0.77) but not for those with nonserous cancers (HR 0.94, 95% CI 0.60-1.49). We continue to recommend six cycles for women with early stage ovarian cancer, though have a lower threshold to discontinue treatment after three cycles for women with nonserous cancers, if they opt to stop or if side effects intervene.

In advanced stage disease, the care team must decide whether to begin treatment with a primary “debulking” surgery or neoadjuvant chemotherapy (NACT). Debulking is favored when imaging suggests all visible tumor may be resected at the time of surgery. NACT is favored with a low likelihood of achieving cytoreduction to no visible disease or in patients with major perioperative risk factors related to comorbidities and frailty, which is consistent with the ASCO/SGO Clinical Guidelines in this population. After three to four cycles of NACT, patients are assessed for an interval debulking surgery (IDS) followed by additional chemotherapy. One randomized trial showed a survival advantage in favor of heated intraperitoneal chemotherapy for patients undergoing an IDS; confirmatory trials are underway. In either case, adjuvant therapy is indicated, and we suggest patients receive up to three cycles following surgery to complete at least six cycles total of chemotherapy. Finally, data show that bevacizumab confers a progression-free survival advantage, though this did not translate into an overall survival benefit in the American trial, GOG 218 (Table 61.1).

Following first-line chemotherapy, women with newly diagnosed ovarian cancer should be offered maintenance treatment using a poly-ADP-ribose polymerase (PARP) inhibitor. Multiple trials have shown that treatment is associated with significant improvement in disease-free survival, particularly in those with a mutation in BRCA (mBRCA, germline or somatic), with one trial also supporting its use in combination with bevacizumab in those without a mutation but with evidence of homologous recombination deficiency (HRD). While niraparib was associated with a survival advantage in women without mBRCA or HRD, the benefit was much smaller than in other groups. As such, while we offer PARP inhibition as maintenance treatment to all patients after completion of adjuvant therapy, we strongly recommend it for women with mBRCA or evidence of HRD.

Recurrent ovarian cancer can be treated with additional chemotherapy and surgery can be considered if there are resectable sites of limited disease. If the recurrence occurs more than 6 months after completing primary platinum-based treatment, the tumor is considered “platinum sensitive” and retreatment with a platinum combination is preferred. In these patients, evidence supports the use of PARP inhibitors in the maintenance setting, regardless of whether patients have mBRCA or HRD. When recurrence occurs in less than 6 months, the cancer is considered “platinum resistant,” and an alternative agent is chosen. Patients with recurrent ovarian cancer do not have curable disease; therefore, clinical trials should be offered whenever possible.

Prognosis

Early ovarian cancer is often curable with surgery and chemotherapy. Stage I disease has an 80% to 90% 5-year survival, and stage II disease portends a 60% to 70% 5-year survival. Unfortunately, patients with advanced stage disease usually recur and develop treatment resistance. Eventually treatment turns to best supportive care. Bowel obstruction from massive carcinomatosis is a common terminal event for women with ovarian cancer. Five-year survival for women with stage III to IV disease ranges from 18% to 50% depending on the pattern of disease.

UTERINE CANCER

Epidemiology

Endometrial cancer is the most common gynecologic cancer in North America and in Northern and Eastern Europe. Worldwide, it is the sixth most common malignancy affecting women, and it ranks as the fourteenth cause of cancer death.

Increased circulating estrogen without progesterone to balance stimulation of the endometrial lining is associated with endometrial cancer development. Obesity is a strong risk factor due to high levels of circulating estrogen via conversion of androgens to estrogen by aromatase within adipose cells. Other increased estrogen-related risk factors include anovulatory menstrual cycles, nulliparity, early menarche, late menopause, estrogen producing ovarian neoplasms (benign thecomas and malignant dysgerminomas), and estrogen replacement without the use of protective progesterone. Breast cancer treatment with tamoxifen blocks estrogen action in the breast but has pro-estrogen effects on the endometrium resulting in a 2- to 5-fold increased risk of endometrial cancer after 5 years of use.

Women with hereditary Lynch syndrome (see section on epidemiology of ovarian cancer) have a 60% lifetime risk of developing endometrial cancer and require screening with annual endometrial biopsy, and when childbearing is complete, a hysterectomy with bilateral salpingo-oophorectomy is recommended. Diabetes and hypertension are associated with increased risk of endometrial cancer. Smoking is

associated with a decreased rate of endometrial cancer, likely due to the association with low circulating estrogen.

Pathology

Endometrial cancer traditionally has been divided into two categories: type 1 and type 2. Type 1 endometrial cancers are hormone-induced, arising from the hyperplastic precursor endometrioid intraepithelial neoplasia (EIN). These low-grade endometrioid type cancers are usually limited to the uterus and have a good prognosis. Type 2 endometrial cancer is the more aggressive form of cancer, more likely to metastasize, and carries a worse prognosis. Type 2 histologies include high-grade endometrioid, serous, clear cell, and carcinosarcoma. More recently, genomic analysis has been used to stratify endometrial cancer into four groups: (1) *POLE* gene ultramutated; (2) tumors with microsatellite instability hypermutated; (3) copy number low; and (4) copy number high (serous tumors and one quarter of high-grade endometrioid tumors). Data suggest that the groups confer prognostic information in terms of progression-free survival with *POLE*-type tumors having the best prognosis and those with high copy number having the worst prognosis.

Mesenchymal cancers of the uterus are rare and include cancers, such as sarcoma, arising from the myometrial wall of the uterus and cancers arising from the endometrial stromal cells.

Clinical Presentation

Studies show that 70% to 90% of women with endometrial cancer present with postmenopausal bleeding. In premenopausal women, irregular or heavy vaginal bleeding is the most common symptom. An abnormal Papanicolaou (Pap) smear, or abnormal imaging of the uterus, may also lead to a diagnosis of endometrial cancer. Mesenchymal cancers may present with abnormal uterine bleeding or pain.

Diagnosis and Staging

Postmenopausal women with any uterine bleeding, even spotting, should be evaluated for endometrial cancer. The work-up includes a full gynecologic exam with endometrial sampling and imaging to evaluate the appearance of the endometrium (normal endometrial thickness measures ≤ 4 mm after menopause). Endometrial biopsy may be performed as an office procedure and has a high sensitivity when the endometrial lining measures 11 mm or less. A thicker lining may require further evaluation with a dilatation and curettage of the uterus to definitively rule out malignancy. Premenopausal women with persistent bleeding between menses should also be evaluated with endometrial sampling and radiographic imaging, especially those presenting with known risk factors for endometrial cancer.

If a high-grade cancer is identified on endometrial sampling, then CT of the abdomen and pelvis is recommended to assess for the presence of metastatic disease.

Staging of endometrial cancer is surgical. FIGO stage I disease is cancer limited to the uterus, whereas stage II involves the cervical stroma. Stage III includes disease involving the ovaries, tubes, and regional lymph nodes. Stage IV is defined as peritoneal carcinomatosis, liver metastases, or other metastases beyond the abdomen and pelvis.

Treatment

Unless widespread metastatic disease is identified on preoperative imaging, standard treatment for endometrial cancer is a simple hysterectomy (Fig. 61.1) with bilateral salpingo-oophorectomy and assessment for lymph node metastases. If the uterus is small, this procedure may be performed with a laparoscopic or robot-assisted laparoscopic technique. Laparotomy may be indicated for a large uterus that cannot be extracted vaginally. Sentinel nodal evaluation has largely replaced complete pelvic and para-aortic lymphadenectomy. This procedure

- **Simple hysterectomy**
removes uterine fundus and cervix only
- **Radical hysterectomy**
includes parametrial tissue surrounding cervix and upper vagina

Fig. 61.1 Simple hysterectomy involves removal of uterus including fundus and cervix. Radical hysterectomy extends the surgical margin with removal of surrounding parametrial tissue and upper vagina.

involves injecting the cervix with dye and removing lymph nodes that collect the dye. The advantages of sentinel node dissection include a limited, more targeted surgery, with less risk of surgical complications including lower extremity lymphedema.

Early stage endometrial cancer with low grade histology that invades less than 50% of the myometrium has an excellent prognosis for cure with surgery alone. The protocols for administering adjuvant therapy for endometrial cancer after surgical staging are complex. A careful review of pathologic risk factors by a multidisciplinary team that considers the patient's comorbidities is important in the treatment planning process. Recommendations may include vaginal cuff brachytherapy, pelvic radiation, and/or chemotherapy. Stage I tumors that invade more than 50% of the myometrium are typically treated with vaginal radiation to prevent local recurrence of cancer. Tumors with cervical stromal involvement are treated with additional whole pelvic radiation. If lymph node metastases or other disease beyond the uterus is identified, then chemotherapy with intravenous carboplatin and paclitaxel with or without radiation is typically recommended. Some patients with high grade cancer such as the serous subtype may also benefit from chemotherapy even if cancer is isolated to the uterus.

Treatment for recurrent endometrial cancer is tailored to the site of recurrence. A vaginal recurrence is typically treated with localized radiation. Distant recurrences often require platinum-based chemotherapy; however, a low-grade metastatic endometrial cancer may respond to antiestrogen hormonal therapy alone. For those who progress on first-line chemotherapy, clinical trials should be pursued. To date, there are no FDA-approved agents in the second- or later-line setting for these patients.

A subset of women with early endometrial cancer may opt to forego standard hysterectomy. This includes young women wishing to preserve fertility and elderly, or frail women, who have a high surgical risk. These women may be treated with high-dose progesterone therapy using a progesterone secreting intrauterine device or oral tablets. Success rates greater than 80% are reported for women with low-grade cancers without evidence of myometrial invasion on pretreatment

MRI imaging. Ongoing surveillance or hysterectomy when childbearing is complete is recommended for young patients. For frail patients, progesterone therapy is continued indefinitely.

Prognosis

Endometrial cancer isolated to the uterus is curable in 80% to 90% of cases. Rates of cure for more advanced disease are lower, while advanced stage IV disease remains incurable. Sadly, for women with endometrial cancer presenting with carcinomatosis, the 5-year survival rate is less than 25%.

CERVICAL CANCER

Epidemiology

Cervical cancer is the most preventable gynecologic cancer. Unfortunately, it remains the most common malignancy of the female reproductive tract worldwide and is a leading cause of cancer-related death in developing countries. In the United States, it is the third most common gynecologic cancer. The primary risk factor for developing cervical cancer is infection with a high-risk subtype of the human papillomavirus (HPV). As nearly all cancers of the cervix are the result of HPV-associated cytopathologic changes, infection with the virus is considered a necessary cause in disease development. The incidence and mortality of cervical cancer are influenced by access to screening programs. Thus, resource poor settings with limited access to Pap screening have higher rates of cervical cancer morbidity and mortality. Other risk factors for cervical cancer include smoking, immunosuppression, and diethylstilbestrol (DES) exposure.

HPV infects the female genital tract via sexual transmission. Subtypes are termed high-risk (HR) when they are associated with preinvasive and invasive cervical disease. There are 15 primary HRHPV subtypes associated with the development of cervical cancer; however, HPV-16 and -18 are responsible for 50% and 20% of cervical cancer cases, respectively. While many individuals will clear the HPV virus, persistence of HPV infection is associated with an increased risk for developing preinvasive neoplasia or invasive cervical cancer. Due to the causal relationship of HPV and cervical cancer, vaccines have been developed targeting HRHPV subtypes to prevent the development of HPV associated cervical pathology. In 2006, the FDA approved use of the Gardasil quadrivalent vaccine for the prevention of anogenital lesions, which covered six HRHPV subtypes for females aged 9 to 26 years old. Currently, the only FDA-approved vaccine in the US is Gardasil 9, covering HPV types 6, 11, 16, 18, 31, 33, 45, 52, and 58 for females and males ages 9 to 45 years old.

Pathology

The outer cellular layer of the cervix that lies within the vagina is comprised of squamous epithelium. The endocervical canal is comprised of columnar epithelium. The region where endocervical columnar epithelium is replaced by squamous epithelium—the transformation zone—serves as the primary site of HPV-related preinvasive and invasive lesions of the cervix. The majority of cervical cancers are squamous carcinomas (75%) and adenocarcinomas (25%). Other extremely rare types of cervical cancer include neuroendocrine, adenosquamous, clear cell, and undifferentiated carcinoma.

Clinical Presentation

In early stage disease, patients do not typically experience symptoms. If symptoms are present, they often include abnormal vaginal bleeding, bleeding with intercourse, discharge, or pelvic discomfort.

Cervical cancer spreads by local extension to surrounding tissues, followed by nodal metastasis and then hematologic dissemination.

Patients with advanced stage disease may have symptoms related to involvement of surrounding structures. Local tumor infiltration may result in significant vaginal bleeding and pelvic pain or urinary or bowel complaints. These patients are often noted to have a large cervical mass on physical examination or imaging.

Diagnosis and Staging

The majority of cervical cancers are diagnosed through cervical biopsies performed as a result of a screening Pap that identifies abnormal cervical cytology or persistent HRHPV. In patients who have not undergone routine Pap screening, cervical cancer is diagnosed through biopsies of grossly abnormal appearing cervical tissue or masses. Regardless of PAP smear cytology, patients with persistent HRHPV subtypes should have a diagnostic biopsy for the presence of cervical pathology.

Cervical cancer is clinically and radiographically staged FIGO I through IV. Subcategories within each stage are based on the extent of disease. Cervical cancer is categorized into early stage disease (stages IA-IB1), locally advanced disease (stages IB2-IVA), and metastatic disease (stage IVB). Early stage cancers are small tumors limited to the cervix. Locally advanced disease refers to larger tumors and tumors that have invaded beyond the uterus and extend into nearby pelvic structures, including the bladder and rectum. Metastatic disease refers to cancer that has spread beyond the pelvic organs to distant sites. A complete physical examination and thorough pelvic examination is important in evaluating both localized and distant spread of disease.

Helpful imaging modalities in assessing the extent of disease in cervical cancer include CT of the chest, abdomen, and pelvis; positron emission tomography-computed tomography (PET/CT), which is often helpful in evaluation of nodal involvement or smaller metastasis; and MRI, which can aid in assessment of local spread to soft tissues and adjacent pelvic structures. If imaging identifies sites of metastatic disease, image-guided biopsy should be performed for confirmation of stage.

Treatment

Treatment for cervical cancer is dependent on whether the disease is early, locally advanced or has distant metastases. Both early stage tumors and locally advanced tumors are treated with curative intent. Early stage disease is managed surgically with simple hysterectomy or radical hysterectomy (see Fig. 61.1). Pelvic lymph node dissection is performed as part of the procedure, with the exception of smaller tumors (<3 mm depth of invasion) and no evidence for lymphovascular space invasion. In reproductive age patients with early stage disease who would like to maintain fertility, options include cone excisional procedures or trachelectomy (surgical removal of only the cervix), and the uterus is left intact for future childbearing.

For larger cervical tumors (>4 cm) and locally advanced disease, concurrent chemotherapy and radiation are the mainstays of treatment. The addition of chemotherapy (cisplatin or cisplatin and 5-fluorouracil) to radiation is utilized as a radiosensitizer to increase the effectiveness of radiation. Chemoradiation in locally advanced disease is associated with improved survival and reduction in recurrence rates. Surgical management is not favored for larger cervical tumors and locally advanced disease, because the goal of surgery is to obtain negative margins. With surgery, large tumors and locally advanced disease have higher rates of recurrence, decreased survival, and a high likelihood for requiring post-operative radiation, which is associated with increased complication rates when compared with radiation without prior surgery.

Unfortunately, widely metastatic cervical cancer is not considered curable and treatment is aimed at controlling the spread of disease and palliating bothersome symptoms. Treatment involves combination platinum-based chemotherapy with the addition of bevacizumab to improve survival outcomes. Pelvic radiation in these patients is

reserved for palliative treatment intended to decrease symptomatic pelvic disease burden or to control vaginal bleeding. For those who experience recurrence despite first-line chemotherapy, testing for PD-L1 is recommended because the FDA has approved the immune checkpoint inhibitor pembrolizumab for use in these patients if their tumors are positive.

For patients with recurrent disease localized to the central pelvis and no evidence of distant metastatic spread, pelvic exenterative procedures that remove remaining pelvic structures with urinary and stool diversion may be curative but are associated with high rates of perioperative morbidity. For patients with recurrent disease who are not candidates for operative management or radiation therapy, chemotherapy such as cisplatin with paclitaxel or gemcitabine can help control disease.

New advances in the treatment of cervical cancer are now examining the role of HPV vaccination for active disease, as well as the utilization of immunotherapy as part of systemic treatment.

Prognosis

Outcomes in cervical cancer depend on stage at diagnosis. Patients with nodal disease have higher rates of relapse and poorer prognosis. Five-year survival rates are roughly 92%, 56%, and 17% for localized, regional, and distant disease, respectively.

VULVAR CANCER

Epidemiology

Vulvar cancer is the most frequently overlooked gynecologic cancer and is the fourth most common gynecologic cancer in the United States. A woman's lifetime risk of developing vulvar cancer is roughly 0.3%. Most vulvar cancers arise from either oncogenic HPV-associated preinvasive vulvar intraepithelial neoplasia (VIN) or through autoimmune or inflammatory related changes, such as lichen sclerosus, leading to differentiated VIN (dVIN). While vulvar cancer most commonly occurs in women over the age of 60, HPV-related vulvar cancer occurs more commonly in younger women. Atypical moles of vulva are associated with an increased risk for the development of vulvar melanomas. Other risk factors for developing vulvar cancer include advanced age, smoking, HIV, and a personal history of cervical cancer or preinvasive cervical lesions.

Pathology

The vulva includes the clitoris, mons, labia majora and minora, vestibule, and the perineal body. Squamous cell carcinoma (SCC) accounts for more than 80% of all vulvar cancers. Melanomas are the second most common type accounting for 10%, followed by basal cell carcinomas (2% to 4%), verrucous carcinomas—an indolent variant of SCC—and sarcomas (1% to 2%). Paget's disease of the vulva is a glandular-like intraepithelial neoplasm that can develop into or harbor underlying adenocarcinoma. Bartholin gland carcinomas account for 0.1% to 5% of vulvar cancers and are typically adenocarcinomas. Other rarer types of vulvar cancers include germ cell tumors, urothelial/transitional cell carcinoma, and neuroendocrine tumors.

Clinical Presentation

Vulvar cancers typically present as an irritated or pruritic solitary vulvar lesion that may be flat, raised, indurated, cauliflower, ulcerated or discolored. Occasionally the lesions can be multifocal or may be associated with vulvar bleeding or dysuria. Vulvar cancers metastasize by local extension, lymphatic drainage to the inguinofemoral nodes, and hematogenous spread to distant sites. Patients with more advanced stage disease may present with evidence of a large ulcerated

or verrucous (wartlike) mass extending to surrounding tissues or involving large areas of the vulva, vagina, or the anal verge. Often, enlarged groin lymph nodes can be palpated. Other signs related to local extension may include profound vulvar pain, urinary outlet obstruction or dysuria. As the development of vulvar cancer generally has an indolent growth rate, most patients presenting with locally advanced or advanced stage disease are elderly women who are disconnected from routine gynecologic care, or women with limited access to gynecologic care.

Diagnosis and Staging

Vulvar cancer is pathologically diagnosed and staged. Both patients and providers frequently ignore symptoms of perineal itching and discomfort that are typical for the cancer. Patients who present with a suspicious or bothersome lesion on the vulva should undergo a biopsy to evaluate for the presence of vulvar cancer. In addition to biopsy of the gross lesion for histologic confirmation, a complete pelvic examination should be performed including visual inspection of the entire vulva, vagina, cervix, and anus. The groin nodes are palpated to assess for inguinofemoral adenopathy. Enlarged lymph nodes should be biopsied to confirm the presence of disease versus reactive nodes.

After histologic confirmation, the next step is determining the extent of disease. Vulvar cancer is staged with a combination of clinical examination, pathologic confirmation, and radiographic findings. Helpful imaging modalities include CT of the chest, abdomen, and pelvis, or PET/CT. MRI can often be helpful in ambiguous cases to better characterize local extension of disease into surrounding soft tissues and can aid in operative decision making.

Vulvar cancers spread by local extension, and by lymphatic channels to inguinofemoral nodes then pelvic nodes. FIGO stage I disease defines tumor confined to the vulva. Stage II disease involves cancer extending to the adjacent perineal structures including the urethra, anus, and lower one third of the vagina. Stage III disease is comprised of tumor involving the inguinofemoral lymph nodes and stage IV tumor involves the upper two thirds of the urethra and vagina or any distant structures. Roughly 60% of vulvar cancers are localized to the primary site at diagnosis, approximately one third are diagnosed with regional spread, and roughly 6% present with distant metastasis.

Treatment

Treatment of vulvar cancer depends on the histologic subtype and stage of the disease. Treatment courses for vulvar cancer should be individualized because many affected patients are elderly or medically frail.

For patients with apparent early stage disease, treatment includes a radical wide local excision of the lesion with at least a 2-cm lateral margin. Because inguinofemoral node status is the most important prognostic factor, groin nodal evaluation should be assessed for tumors having more than 1 mm depth of invasion. Sentinel lymph node dissection to diagnose nodal involvement has largely replaced full groin nodal dissection because it is associated with less perioperative morbidity. Bilateral groin nodes are evaluated for midline tumors and tumors larger than 4 cm. Postoperative radiation therapy is typically recommended if two or more lymph nodes are involved or nodal extracapsular spread is present and is associated with improved survival outcomes.

For vulvar cancers that have spread beyond the vulva, treatment is highly individualized with careful consideration of goals of care and patient functional status. These tumors are typically not amenable to surgical management and treatment options include primary chemoradiation, radiation alone, palliative radiation to burdensome disease sites or

systemic chemotherapy. Chemoradiation with sensitizing cisplatin chemotherapy is considered superior to radiation alone for locally advanced disease. Radiation fields typically include the primary tumor site, inguinofemoral nodes, and pelvic lymph nodes. If there is residual primary tumor after radiation, resection, if technically feasible, may improve survival or alleviate symptoms. A palliative care approach to provide supportive care is important for patients with advanced stage disease because they often have a high symptom burden pre- and postradiation.

Patients who present with distant metastasis are treated with systemic chemotherapy such as carboplatin and paclitaxel, and radiation can be offered in palliative doses to highly symptomatic disease sites. Recurrent vulvar cancer is treated with surgical excision if localized to the vulva. Systemic carboplatin/paclitaxel is administered for recurrent vulvar cancer at distant sites.

Prognosis

The most important prognostic factor in vulvar cancer is inguinofemoral nodal involvement. Estimated 5-year survival rates for localized, regional, and distant disease are 86%, 53%, and 19%, respectively. Risk factors for recurrent disease include inguinofemoral nodal involvement, close postoperative surgical margins (<5 mm), and higher stage of disease at diagnosis. Patients with HPV-associated vulvar cancers have improved outcomes with radiation treatment relative to non-HPV-associated vulvar cancers.

VAGINAL CANCER

Epidemiology

Primary vaginal cancer is the rarest gynecologic cancer, accounting for only 1% to 2% of gynecologic malignancies. Extension of primary cancers of the uterus, cervix, and vulva, or metastasis from another primary site, should be ruled out to confirm vaginal origin. Vaginal cancer is typically diagnosed in patients older than 60 years. Risk factors include HRHPV, in utero DES exposure, HIV, history of pre-cancers or cancers of the cervix, and the presence of high-grade vaginal intraepithelial neoplasia.

Pathology

The main histopathologic subtype of vaginal cancer is squamous cell carcinoma (90%). Less common types include adenocarcinomas such as clear cells (8% to 14%), melanomas, sarcomas, lymphomas, neuroendocrine, and yolk sac tumors.

Clinical Presentation

Most patients with vaginal cancer present with vaginal bleeding or abnormal vaginal discharge. Alternatively, asymptomatic patients are diagnosed via biopsy of a grossly abnormal appearing lesion at time of routine annual pelvic examination or colposcopic directed biopsy after abnormal cervical or vaginal cytology is detected. Lesions have a variety of appearances and can be soft, friable, nodular, raised, papillary, flat, erythematous, hyper- or hypopigmented. Lesions are most commonly found in the upper one third of the vagina, but distal lesions can be seen as well. Primary vaginal cancers spread by direct extension, the lymphatics, and hematologically to distant sites. The lymphatic drainage of the upper vagina involves the internal iliac lymph nodes and the lower vagina drains to the inguinal lymph nodes. Patients with more advanced disease may present with symptoms related to local extension such as painful urination or defecation; pelvic, vulvar or vaginal pain; hematochezia or hematuria.

Diagnosis and Staging

The diagnosis of vaginal cancer is made by histologic confirmation via biopsy of visible tumor. Because most vaginal cancers are the result of

metastasis from another primary site, it is important to rule out other primary gynecologic cancers of the cervix, uterus, ovaries, or vulva as well as nongynecologic cancers that may have vaginal extension such as colorectal or urethral/bladder cancers.

FIGO stage I vaginal cancer includes small tumors limited to the vagina. Stage II disease has extended through the vaginal walls. Stage III tumors invade into the pelvic wall or lower one third of the vagina and may obstruct urinary outflow or cause hydronephrosis. Stage IV tumors include nodal metastasis and spread to the rectum, bladder or distant sites.

Vaginal cancer is the only gynecologic cancer that remains clinically staged (physical examination, cystoscopy, proctoscopy, chest radiograph); however, more advanced imaging modalities such as pelvic MRI, PET/CT or CT chest, abdomen, and pelvis can be used to help assess the full extent of disease not detected by clinical examination alone. While these studies help to guide treatment, they are not currently used to assign the stage of disease.

Treatment

Treatment for vaginal cancer is based on location of tumor and stage of the disease. Aside from stage I disease confined to the mucosa, vaginal cancer is typically treated with a combination of primary chemotherapy and radiation.

An important consideration for surgical resection in vaginal cancer is location (upper vagina or lower vagina) and size of the lesion, as the goal is to achieve negative resection margins. Candidates for primary operative management of vaginal cancers include stage I disease limited to the upper or lower vagina. These lesions are best treated surgically when superficial and smaller than 2 cm. Surgery has become the mainstay of treatment for such lesions, with survival rates ranging from 75% to 100%. If the vaginal tumor includes the upper vagina, a radical hysterectomy with a radical upper vaginectomy and pelvic lymph node dissection may be performed. For stage I disease in the lower vagina, a radical vaginectomy and potentially a vulvovaginectomy may be performed with an inguinofemoral nodal dissection.

For stage II to IV tumors, primary chemoradiation is the mainstay of treatment because it is associated with improved disease control and reduction in locoregional recurrence rates. Due to the rarity of vaginal cancer, studies are few and treatment approaches are often derived from favorable outcomes demonstrated in cervical cancers utilizing a combination of chemotherapy and radiation. For a central pelvic recurrence of vaginal cancer after radiation treatment, total pelvic exenteration may be curative in approximately 50% of correctly selected cases.

Prognosis

Outcomes in vaginal cancer vary by stage at diagnosis, reflecting the size of the tumor and spread of disease. Stage I disease has the most favorable prognosis with survival rates ranging from 70% to 90%, and treatment at this early stage can be curative. Overall, 5-year relative survival rates in vaginal cancer are 67%, 52%, and 19% for localized, regional, and distant disease, respectively. Vaginal melanoma has an extremely poor prognosis with 5-year survival of 15%.

GESTATIONAL TROPHOBLASTIC DISEASE AND GESTATIONAL TROPHOBLASTIC NEOPLASIA

Epidemiology

Gestational trophoblastic disease (GTD) and gestational trophoblastic neoplasia (GTN) are unusual gynecologic conditions as they arise from fetal tissue. GTD is a benign growth of placental tissue arising from an

Fig. 61.2 Complete molar pregnancy versus partial molar pregnancy. (Adapted from Ning F, et al. *F1000Research* 2019;8:428.)

abnormal pregnancy. The frequency is 1:1000 to 1:1500 pregnancies in the United States and 1:125 pregnancies in Asia. Proposed reasons for the regional variation include heredity and dietary differences such as low vitamin A and low animal fat diet in the East. While GTD is considered benign, it may be a precursor to GTN, which is a neoplastic process associated with pregnancy. GTN includes invasive molar pregnancy, choriocarcinoma, placental site trophoblastic tumor (PSTT), and epithelioid trophoblastic tumors (ETT).

Pathology

The term “complete mole” refers to an abnormal pregnancy that contains only paternal DNA. For example, an egg devoid of maternal DNA may be fertilized by one sperm that duplicates or two sperm (most commonly XX or XY, with all paternal DNA). A “partial” mole refers to an egg with maternal DNA that has been fertilized by two sperm (69 XXX, 69 XXY or 69XYY) (Fig. 61.2). An invasive mole is a molar pregnancy that has grown into myometrial tissue. Choriocarcinoma is an aggressive form of cancer that can occur following a normal pregnancy, abortion, or complete molar pregnancy, and is comprised of cytotrophoblast and syncytiotrophoblast. It may be associated with local extension beyond the uterus and metastatic disease. PSTT arises in the placental bed of an antecedent pregnancy and has the pathologic appearance of sheets of intermediate trophoblast invading the myometrial wall of the uterus. ETT is composed of neoplastic chorionic-type intermediate trophoblast. Choriocarcinoma, PSTT, and ETT may occur after molar and non-molar pregnancies.

Clinical Presentation

The majority of molar pregnancies present with symptoms of bleeding, pain, hyperemesis, and uterine size too large for suspected dates. The pregnancy hormone, human chorionic gonadotropin (hCG), is abnormally elevated in cases of complete molar pregnancy. Pelvic ultrasound usually shows globular vesicles that are pathognomonic for the disease (Fig. 61.3). Other rarer symptoms may include ovarian theca lutein cysts and hyperthyroidism caused by the alpha subunit of hCG mimicking the effects of thyroid stimulating hormone.

Invasive moles typically present with bleeding due to uterine or vaginal disease. GTN may also present with symptoms of hemoptysis (lung disease), abdominal complaints (abdominal disease), or neurologic symptoms (brain disease). Choriocarcinoma often presents with high hCG levels and bleeding metastatic sites. PSTT and ETT can present years after a prior pregnancy and typically have low elevations in hCG levels and a uterine mass on imaging.

Fig. 61.3 Ultrasound showing classic snowstorm pattern of a complete mole at 24 weeks' gestation. (From *J Ultrasound Med* 2020;39:597-613.)

Diagnosis and Staging

When clinical presentation and imaging suggest a molar pregnancy, pathologic evaluation of products of conception obtained at time of D&C confirm the diagnosis. Although most patients with molar pregnancy are cured with D&C alone, 20% of patients will have a plateau, increase, or persistence of hCG over time not explained by other causes, which confirms the diagnosis of GTN. When this occurs, a metastatic work-up should be performed including physical exam for vaginal metastasis, chest radiograph, CT imaging of abdomen and pelvis or chest, and consideration of head CT or MRI. Biopsy of GTN is hazardous because these lesions are prone to excessive bleeding; therefore, tissue sampling is not required for diagnosis.

The most commonly used staging systems for GTN are the FIGO staging system, which reflects sites of metastases, and the WHO prognostic scoring system, which takes into account a number of prognostic factors including the patient's age, type and timing of antecedent pregnancy, pretreatment hCG level, tumor size, sites and number of metastases, and chemotherapy treatment. Low-risk metastases include disease in lungs and vagina, while high-risk metastases involve other organs including the brain and liver.

Treatment

The primary treatment of a molar pregnancy is a D&C, followed by weekly monitoring of hCG levels until undetectable. For an invasive mole isolated to the uterus, hysterectomy can be a curative treatment for women who do not wish to preserve fertility. Otherwise GTN is treated with chemotherapy, and regimens are determined by stratifying patients into low-risk and high-risk categories. If no evidence of metastatic disease is identified (low risk), then single agent chemotherapy is administered using methotrexate or dactinomycin. If high-risk metastatic disease is identified, or if disease persists despite single agent treatment, then patients are treated with an aggressive regimen such as

the combination of etoposide, methotrexate, dactinomycin, calcium leucovorin, cyclophosphamide, and vincristine (EMA-CO). PSTT and ETT differ in that they are less chemoresponsive and thus are typically treated with hysterectomy and surgical removal of metastatic sites. The use of chemotherapy for PSTT and ETT is controversial.

Prognosis

For patients with low-risk GTN, the cure rate with single agent chemotherapy is nearly 100%. Cure rates with metastatic disease depend on the site of disease. Survival rates for lung, brain, and liver metastases are greater than 90%, 70% to 90%, and 40% to 50%, respectively. Prognosis is poor if metastatic PSTT or ETT is identified.

Other Solid Tumors (Head and Neck, Sarcomas, Melanoma, Unknown Primary)

Christopher G. Azzoli, Ariel E. Birnbaum, Maria Constantinou, Thomas A. Ollila

INTRODUCTION

Head and neck cancer, melanoma, sarcoma, and carcinoma of unknown primary site (CUP) are distinct malignancies each with its own epidemiology, pathology, treatment, and prognosis. Head and neck cancers and melanoma are more common, and sarcomas and CUP are relatively rare. Recent advances in understanding of the molecular biology of cancer and immune therapies have refined diagnosis and improved treatment for each of these diseases.

HEAD AND NECK CANCER

Definition and Epidemiology

Head and neck cancers are squamous cell carcinomas that arise from the mucosal lining of the oral cavity, oropharynx, hypopharynx, and larynx. Other cancers arising from the head and neck include salivary gland cancers and thyroid cancers. These differ in regard to biology, presentation, natural history, pathology, and therapy.

Head and neck cancer accounts for 4% of new cancer diagnoses in the United States. In 2019, it was estimated that 53,000 patients would be diagnosed with, and 10,860 Americans would die of, head and neck cancer. Historically, tobacco and alcohol have been the strongest risk factors for developing this disease. Over the last 20 years, human papilloma virus (HPV) has been responsible for an increase in the incidence of oropharyngeal squamous cell carcinoma. Patients with HPV-associated oropharyngeal cancer are typically younger than patients with HPV-negative disease, and often have minimal tobacco or alcohol use. Nasopharyngeal squamous cell carcinoma is uncommon in the United States and is distinct from other head and neck cancers given its association with Epstein-Barr virus (EBV).

Pathology

Approximately 95% of all cancers arising from the squamous epithelium of the head and neck are squamous cell carcinomas. Other cancers include mucosal melanoma, adenocarcinomas, and neuroendocrine cancers. Poorly differentiated cancers have a worse prognosis.

The increasingly common HPV-associated oropharyngeal cancers differ in molecular profile from HPV-negative cancers. HPV-negative cancers are associated with mutations in the tumor suppressor gene TP53 and decreased expression of the cell cycle regulatory protein p16-INK4a. HPV-positive cancers display a wild-type TP53 with increased expression of p16-INK4a. P16 expression by immunohistochemistry staining of greater than 70% establishes the diagnosis of HPV-positive disease. Most but not all nasopharyngeal carcinomas are non-keratinizing and associated with EBV infection, which is detected by immunohistochemistry for Epstein-Barr–encoding RNAs (EBER).

Clinical Presentation

The presenting symptoms of head and neck cancer depend on the location of the primary cancer and extent of local disease. Tumors of the nasopharynx can present with a blocked eustachian tube or epistaxis. Oral cavity cancers present with a painful ulcerative lesion. HPV-associated oropharyngeal cancers present with enlarged cervical lymph nodes, often larger than the primary lesion. Laryngeal and hypopharyngeal cancers present with dysphagia and hoarseness.

Diagnosis and Staging

The diagnosis of a squamous cell carcinoma requires a biopsy. A direct laryngoscopy and biopsy is recommended to find the site of origin. Patients who have cervical lymphadenopathy and no apparent primary site require random biopsies of the tongue base and the surrounding tissues and often a tonsillectomy. CT scan, MRI, and positron emission tomography (PET) are used to detect nodal involvement and metastatic disease.

Treatment and Prognosis

Prognosis of head and neck cancer depends on tumor stage. The American Joint Committee of Cancer (AJCC) TNM, 8th edition, incorporates HPV status into its staging system, specifically for the base of tongue and tonsil. Patients with early-stage disease (no cervical lymphadenopathy) have an excellent prognosis. The majority of cancers are diagnosed at the locally advanced stage that has spread to the cervical lymph nodes. Average 5-year survival for all patients is approximately 50%.

Prognosis for HPV-associated disease is usually better. Both biology of disease and comorbidities impact prognosis. HPV-negative patients are at higher risk for developing second primary cancers of the lung and esophagus.

Surgery and radiation therapy are potentially curative treatments for head and neck cancer. Stage IV head and neck cancer may still be cured if all disease can be encompassed by treatment. Chemotherapy by itself is not curative. The combination of chemotherapy and radiation therapy improves rates of cure. The combination is also more toxic than radiation by itself. Choice of treatment is determined by location of the cancer and extent of disease. Locally advanced cancers usually require a combination of surgery, radiation therapy, and chemotherapy. Radiation treatment may be used instead of surgery to preserve organ function. In laryngeal cancer, chemoradiation therapy can be used without the need to remove the larynx. Chemoradiation therapy may permit organ preservation, but it has both acute and chronic toxicity.

Disease that has spread through the blood to distant sites is not curable. Chemotherapy may be used to control the disease and extend life.

A major advance in medical therapy for metastatic head and neck cancer are anti-PD1 immune checkpoint inhibitors (pembrolizumab and nivolumab) that can provide immune-mediated and durable control for a subset of patients. As with other metastatic cancers, enrollment in clinical trials and early integration of palliative care consultants is recommended for optimal patient care.

MELANOMA

Definition and Epidemiology

Melanoma is an aggressive form of skin cancer that originates from melanocytes, a pigment-producing cell found in the basal layer of the epidermis. Melanoma accounts for 1% of all skin cancers but it represents the fifth most common cancer in men and women.

The incidence of melanoma has been rising rapidly over the past five decades. An estimated 96,480 cases of melanoma were diagnosed in the United States in 2019 with approximately 7230 deaths. Melanoma is more common among people aged 65 to 74. Ultraviolet (UV) sun exposure is the main risk factor for development of melanoma.

Individuals with high recreational/intermittent sun exposure, history of blistering sunburns in childhood or adolescence, and exposure to artificial UV radiation from use of tanning beds have a higher risk for developing melanoma. In addition, family history of melanoma and certain phenotypic traits such as fair skin, red/blonde hair, light eyes, the presence of multiple nevi, and atypical or congenital nevi appear to also increase the risk.

Pathology

Melanoma can be classified based on four major histopathologic subtypes: superficial spreading melanoma (SSM), nodular melanoma (NM), lentigo maligna melanoma (LMM), and acral lentiginous melanoma (ALM).

SSM is the most common subtype, representing 70% of all melanomas. It typically affects individuals between the ages of 30 and 50 years. These melanomas spread in a radial growth pattern and develop in intermittently sun-exposed skin, often in a preexisting nevus. It commonly appears on the trunk in males and legs in females. It clinically presents as a flat lesion with irregular borders.

NM accounts for 10% to 15% of all melanomas. It has a vertical growth phase and is usually associated with dermal invasion at the time of diagnosis, hence a worse prognosis. It clinically presents as a deeply pigmented nodule, typically blue-black or polypoid, but 5% of nodular melanomas may be amelanotic (no pigment). It usually develops de novo on the trunk, head, and neck of middle-aged individuals.

LMM accounts for 5% of all melanomas. It affects older individuals with peak incidence in the seventh to eighth decade of life. It originates from a large brown patch on chronically sun-damaged skin (lentigo). Lentigo maligna is associated with slow progression and may evolve for decades before invading into the dermis.

ALM is uncommon and represents less than 5% of all melanomas. It is the most common type seen among Asians and African Americans. The median age of diagnosis is 65. ALM arises on palmar, plantar, and subungual surfaces, the nail matrix being the most common site, and it is not associated with sun exposure. Clinically, it appears as a dark brown to black patch on the palms, soles or under the nails.

Pathologic features that have prognostic relevance include the depth of invasion (Breslow thickness) and the presence of ulceration. Breslow thickness represents the depth of melanoma invasion from the upper epidermal layer. It is measured in mm and it defines the T stage. It is one of the most important prognostic and predictive factors for lymph node involvement. The risk of nodal spread increases with the depth of invasion. The presence of lymph node metastases

in melanomas with Breslow thickness less than 0.8 mm is less than 5% and increases to 40% in patients with primary melanomas with Breslow thickness greater than 4 mm.

Another adverse predictor for the development of melanoma metastasis is the presence of microscopic ulceration within the primary site. Patients with ulcerated localized melanoma have a significant decrease in 5 year survival, from 80 to 55%.

Clinical Presentation

Most patients with cutaneous melanoma present with disease confined to the primary site.

Approximately 10% of patients have disease spread to regional lymph nodes, and 4% have distant metastasis at the time of diagnosis. A number of benign lesions share morphologic features with melanoma, making the diagnosis challenging. A lesion that is changing in shape, size, or color should be considered suspicious. Melanomas commonly arise within a preexisting nevus in sun-exposed areas such as the face, upper back, and extremities.

The ABCDE criteria encompass several features that increase the accuracy of skin examination for detection of melanoma: asymmetry (A), border irregularity (B), color change (C), diameter greater than 6 mm (D), and evolution or change (E).

Melanoma can metastasize to regional sites such as the nearby skin, subcutaneous tissue, and lymph nodes or distant sites such as skin, lung, liver, brain, and bone. Regional skin and nodal examination should be performed regularly. Symptoms of advanced disease are highly variable.

Diagnosis and Differential Diagnosis

Pathologic examination with an excisional biopsy is the “gold standard” for diagnosis of melanoma. Such approach allows sufficient depth assessment to ensure that the lesion is not transected at the base of the biopsy. The depth of invasion guides surgical decision making regarding the need for a sentinel lymph node biopsy (sampling the first lymph node that cancer cells are likely to spread to) and the optimal size of resection margin with subsequent excision. If an excisional biopsy cannot be performed, a full-thickness punch biopsy is recommended. Shave biopsies may lead to inadequate sampling and underestimation of the depth of the lesion. The histologic diagnosis is based on characteristic morphology and on immunohistochemical staining for markers such as S100, HMB45, and MART1/Melan A.

In general, imaging investigations for staging purposes are not required for patients with thin (<1 mm) or intermediate-thickness melanoma (1-4 mm). The likelihood of demonstrating metastatic disease is low. Patients with thick melanomas (>4 mm) or lymph node metastasis detected on clinical examination or by sentinel lymph node biopsy are at high risk for disease dissemination and need radiographic staging by CT of the chest, abdomen, and pelvis. Metastasis to the brain is observed in 10% to 40% of melanoma patients and imaging with a brain MRI is warranted for any patient with neurologic symptoms.

Treatment and Prognosis

The prognosis of melanoma can be accurately estimated using the AJCC TNM staging system. Overall survival depends on the thickness of the primary tumor and the presence and number of regional lymph node metastases. Tumor ulceration and high mitotic rate are associated with a poor prognosis. Metastatic disease is incurable, and the clinical course depends on the pattern and extent of dissemination. An elevated serum lactate dehydrogenase (LDH) level is an independent poor prognostic factor for patients with metastases.

Surgery with wide margins is the cornerstone of curative therapy for nonmetastatic disease. The optimal margin depends on the depth of

invasion and the location of the primary lesion but is typically between 1 and 2 cm. Biopsy of the sentinel lymph node (first lymph node to which cancer cells are likely to spread) is recommended for all patients with intermediate-thickness melanoma (1-4 mm) and should also be considered in patients with T1b melanomas 0.8 to 1.0 mm or less than 0.8 mm with ulceration. Despite adequate surgical resection of the primary melanoma, 15% to 36% of patients with early-stage melanoma with no lymph node involvement will develop disease recurrence or metastasis.

Patients who are found to have micrometastatic disease to the sentinel node may choose careful observation with routine nodal ultrasonography or immediate complete lymph node dissection. However, studies have shown that immediate completion of lymph node dissection has not shown to improve melanoma-specific survival in this group of patients. All patients with enlarged lymph nodes that test positive for melanoma, in the absence of distant metastasis, should undergo complete lymph node dissection.

Anti-programmed death (PD-1) agents nivolumab and pembrolizumab have recently gained regulatory approval for treating patients with a high risk of recurrence after complete resection—that is, those with lymph node involvement. These monoclonal antibodies are immune checkpoint inhibitors that block negative regulators of T cell immune function, leading to immune system activation. A year of therapy is associated with significantly longer relapse-free survival.

Approximately 50% of cutaneous melanomas have activating mutations of the proto-oncogene *BRAF*, a component of the mitogen-activated protein kinase (MAPK) signaling pathway. The MAPK pathway plays an important role in cell proliferation, differentiation, and apoptosis. *BRAF*-MEK inhibition with combination dabrafenib plus trametinib therapy is associated with improved clinical benefit and is an alternative adjuvant option for patients whose tumor contains a *BRAF* V600 mutation.

Immunotherapy and kinase inhibitors are the backbone of systemic therapy for patients with metastatic melanoma. Anti-PD1 antibodies and anti-CTLA4 antibodies (ipilimumab) have shown durable responses with improvement in survival. In *BRAF* V600-mutant melanoma, the use of *BRAF* inhibitors with MEK inhibitors has led to high response rates (70%) and a rapid response to induction and symptom control, with a progression-free survival of approximately 12 months.

Cytotoxic chemotherapy is generally not effective for treatment of metastatic melanoma. Radiation therapy is often used for management of brain metastases or central nervous system symptoms, pain associated with bone metastases, spinal cord compression, and superficial skin and subcutaneous metastases.

SARCOMA

Definition and Epidemiology

Sarcomas are heterogeneous solid tumors of mesenchymal origin, with over 70 different clinicopathologic subtypes. These tumors are broadly categorized as sarcomas of bone or sarcomas of soft tissue. There were expected to be 12,750 new diagnoses of soft tissue sarcoma and 3500 new diagnoses of bone sarcoma in the United States in 2019, causing nearly 7000 deaths. Overall, sarcomas account for fewer than 1% of all new cancer diagnoses in adults; however, they are relatively common in children and represent 15% of all pediatric malignancies.

Most sarcomas are sporadic, but risk factors include prior radiation exposure, chemical carcinogens, and genetic predisposition (familial adenomatous polyposis [FAP] and Li-Fraumeni syndrome). Human herpesvirus 8 (HHV-8) infection is associated with the development of Kaposi's sarcoma. Most genetic abnormalities that define sarcomas are sporadic and not inherited.

Soft tissue sarcomas can be classified by their anatomic site of origin: head and neck, visceral, retroperitoneal, intra-abdominal, and extremity. This categorization is useful for staging, assessing prognosis, and establishing a therapeutic approach. The most common soft tissue sarcomas are gastrointestinal stromal tumors (GISTs), pleomorphic sarcoma, liposarcoma, leiomyosarcoma, and synovial sarcoma. The most commonly encountered sarcomas of bone are the Ewing family of sarcomas, chondrosarcomas, and osteosarcomas.

Clinical Presentation

Given the heterogeneity of this group of diseases, including differences in tumor biology and in anatomic site of origin, the clinical presentation is highly variable. Soft tissue sarcomas of the extremities and of the head and neck usually manifest as a progressively enlarging, often painless, mass. Visceral and intra-abdominal sarcomas including GISTs are often found incidentally and are not symptomatic until they are locally advanced. Symptoms are often nonspecific but may include early satiety, abdominal fullness, bloating, or discomfort. Bone sarcomas, such as Ewing sarcoma and osteosarcoma, typically manifest with pain. The most frequently involved locations are the femur, tibia, and humerus. The physical examination may reveal a palpable mass, which is often tender to palpation. Symptoms may be present for several months before diagnosis. Most patients have locally confined disease at diagnosis. The lungs and bone are the most common sites of metastatic spread.

Diagnosis and Differential Diagnosis

The diagnosis of sarcoma can only be established by histologic confirmation, which requires a tissue biopsy. Large biopsy specimens are often necessary to accurately identify and subclassify sarcoma. Sarcoma must be distinguished from more common malignancies such as lymphoma, melanoma, and poorly differentiated carcinoma. The diagnosis of sarcoma is based on characteristic morphology but may be aided by the use of immunohistochemical and molecular studies.

For example, Ewing sarcoma is often associated with a characteristic reciprocal translocation between chromosomes 11 and 22, t(11:22), resulting in gene rearrangements between the *EWS* and *ETS* family of genes. Synovial sarcoma is characterized by a reciprocal t(X;18) translocation resulting in a chimeric *SS18-SSX* fusion protein. Dozens of other gene rearrangements have been identified such that routine molecular pathology testing is often required to establish a specific diagnosis.

For bone sarcomas, plain films often demonstrate a mixture of lytic and blastic components with associated soft tissue edema. For osteosarcoma, the periosteal reaction produces a “sunburst” appearance as new bone forms at right angles to the tumor, as opposed to the “onion peel” appearance caused by layering of reactive bone, which is more commonly associated with Ewing sarcoma.

Treatment and Prognosis

Surgery is the primary therapy for locally confined disease. Radiotherapy before or after surgery may decrease the likelihood of local recurrence. Chemotherapy may be used in resectable sarcoma for certain histologic subtypes (primarily Ewing sarcoma and osteosarcoma) to improve local control and decrease the risk of distant recurrences; however, whether drugs improve overall survival in resectable sarcoma remains uncertain.

Patients with metastatic sarcoma may occasionally benefit from surgical removal of their disease. However, once metastatic dissemination has been detected, the intent of therapy is primarily to control the disease and not to cure. Chemotherapy can reduce the overall tumor burden and minimize cancer-related symptoms.

Historically, the most active drugs for sarcoma were cytotoxic drugs like doxorubicin, ifosfamide, and gemcitabine. These drugs damage or block production of DNA and inhibit cell division. Newer drugs also block cell division. Trabectedin is a DNA damaging agent used as salvage treatment of metastatic liposarcoma, or leiomyosarcoma. Eribulin is a nontaxane inhibitor of microtubules, which blocks cell division and is used for previously treated liposarcoma.

Other new drugs have diverse mechanisms of action and reflect the diverse biology of sarcoma. Imatinib is a small-molecule tyrosine kinase inhibitor (TKI) that blocks the activity of KIT and is highly active in patients with GISTs, which are commonly driven by KIT mutations. Imatinib is used to control metastatic GIST and also improves survival when combined with surgery in patients with resectable GIST. Pazopanib and regorafenib are multitargeted TKIs that have been tested in patients with soft tissue sarcomas (excluding GIST and liposarcoma). The activity of these drugs is limited, and they provide only a few more months of disease control compared to placebo. Other multitargeted TKIs have limited activity against chondrosarcoma, chordoma, osteosarcoma, and desmoid tumors. A small percentage of sarcomas (less than 1%) have a mutation in the neurotrophic receptor tyrosine kinase (NTRK) gene that responds to TRK inhibitors (larotrectinib, entrectinib).

Currently available immune therapies have only limited activity in the treatment of sarcoma. Single-agent anti-PD1 therapy is rarely effective, except in the 1% of sarcomas that are microsatellite instability-high (MSI-H) or mismatch repair deficient (dMMR). A combination of anti-PD1 and anti-CTLA4 drugs is being developed for unselected patients. There is activity of chimeric antigen receptor (CAR) T cells for the treatment of synovial sarcoma on research protocols, making it one of the first solid tumors to be targeted with cellular immune therapy.

CANCER OF UNKNOWN PRIMARY SITE

Definition and Epidemiology

CUPs occur when a malignancy is identified, but no primary site can be identified following pathology review, complete diagnostic imaging or invasive procedures. Once accounting for 5% to 10% of malignancies, improvements in histopathologic techniques have lessened the frequency of CUPs to 3% to 5% of all malignancies. Patients with CUP tend to be older, with median age 65 to 90 years. CUPs are heterogeneous, with adenocarcinoma, squamous cell carcinoma, neuroendocrine tumors, and poorly differentiated carcinoma all fulfilling criteria. Debate exists as to whether CUPs are simply malignancies where the primary is not found, or if they are truly a separate entity.

Treatment typically includes platinum-based chemotherapy unless a high clinical suspicion for a primary site provides a more specific guide. Molecular profiling suggests that CUP is frequently a result of occult lung, kidney, bladder, or pancreaticobiliary cancer.

Clinical Presentation

Many patients with CUP present with advanced disease. Symptoms can be based upon location of metastatic disease or general nonspecific complaints including fatigue, fevers, anorexia or weight loss. Examples of presenting signs and symptoms can include neurologic deficit from brain or spinal cord metastatic disease, ascites, or general malignancy-associated symptoms such as increased risk for thrombotic events, hypercalcemia, paraneoplastic syndrome or pain. Some patients with CUP present earlier with only mild symptoms, such as an enlarged

lymph node or skin lesion. Also, some are found incidentally on imaging performed for another indication.

Diagnosis and Pathology

When considering the origin of a metastatic cancer, it is important to do a thorough history and physical exam, including breast, GU/pelvic, and rectal exam; review of prior malignancies; and available imaging (CT scan of the chest/abdomen/pelvis, which should include neck if there is disease in axillary or supraclavicular lymph nodes). Careful pathologic review of biopsy material is essential. The first step in pathologic evaluation is through immunohistochemistry. Adenocarcinoma constitutes around 70% of CUPs, followed by poorly differentiated carcinoma at 20%, squamous cell carcinoma around 5%, and neuroendocrine carcinoma and other rare subtypes at under 1%. Caution must be used in evaluation of the poorly differentiated carcinomas, because choice of treatment for a specific disease could be radically different. For example, melanoma is typically treated with targeted or immune-based therapy rather than chemotherapy as would be the case for a CUP.

Immunohistochemistry may disclose the site of origin. For example, in the case of poorly differentiated tumors, the presence of S100 and HMB45 supports a diagnosis of melanoma, whereas CD45 supports a diagnosis of lymphoma. Chromogranin and synaptophysin suggest neuroendocrine differentiation. Cytokeratin 5 (CK5) and CK6 are strongly expressed by squamous cell carcinomas, whereas the expression pattern of CK7 and CK20 can limit the differential diagnosis of adenocarcinomas.

Multiple groups have attempted to define genetic and molecular features of CUPs. The success of gene expression profiling to determine the origin of CUP varies widely in published reports, from 33% to nearly 100%, depending on the technique and patient population studied. Gene expression profiling points to biliary tract, urothelial, colorectal, and lung as common sites.

Treatment and Prognosis

Outcomes in CUP remain poor with a median survival of 8 to 12 months. Despite advances in many cancers, survival of CUP patients has not improved in greater than 30 years. Because CUP is typically widespread at time of presentation, treatment is usually palliative rather than curative in intent. There are situations where the histology suggests a favorable type, for example a germ cell tumor and lymphoma, and cure might still be possible. Occasionally CUPs are identified as localized disease, in which case an attempt should be made at definitive treatment.

For example, a woman presenting with adenocarcinoma isolated to unilateral axillary lymph nodes should be evaluated and treated as for a locally advanced breast cancer, even if imaging does not demonstrate a primary breast malignancy. Likewise, a patient with squamous cell carcinoma isolated to cervical lymph nodes at presentation should receive therapy for locally advanced head and neck cancer, again even if a primary lesion is not identified. In both of these circumstances, therapy may prove curative. Another clinical scenario for which specific therapy is beneficial is that of a young man with a poorly differentiated midline chest tumor, in which case a favorable response to a chemotherapy regimen for germ cell cancers may lead to long-term survival.

Whether or not gene expression profiling and next-generation sequencing can improve outcomes remains to be seen. A multicenter phase II trial of 130 patients with gene expression-guided treatment versus empiric carboplatin and paclitaxel in CUP found non-statistically significant inferior outcomes with 1-year survival at 44% in the guided group versus 55% for the empiric group. Despite these results,

hope exists that with further study gene expression profiling can offer guidance to improve outcomes.

Complications of Cancer and Cancer Treatment

Pamela Egan, Ari Pelcovits, John Reagan

INTRODUCTION

The complications of cancer and its associated treatments are myriad. Although many of these complications require the expert management of hematologists and oncologists, all physicians who may encounter these patients should be prepared to recognize their manifestations and understand both their basic management and indications for specialist referral.

Cancer complications can be localized or systemic (Table 63.1). Cancer treatments, which can include radiation, chemotherapy, and hormonal therapy, have potentially significant side effects and complications. Most are temporary, but some, such as peripheral neuropathy, can become permanent (Table 63.2). Complications from cancer-directed therapy can affect not just quality of life for cancer patients, but can also result in treatment delays or discontinuation, hospitalization, and even death. The management of cancer- and treatment-related complications often requires a multidisciplinary approach. This chapter highlights some important complications of cancer and its treatment.

CANCER-ASSOCIATED THROMBOSIS

Epidemiology

Venous thromboembolism (VTE) is a common complication of cancer and is often its initial presenting event. Approximately 15% of patients with cancer develop VTEs during their illness, and it is a major cause of mortality among cancer patients.

Pathology

The primary drivers of the hypercoagulable state in cancer patients are the procoagulant factors associated with the tumor cells. Other contributing factors include immobilization due to illness, venous compression from tumor and resultant vascular stasis, chemotherapies such as platinum compounds and vascular endothelial growth factor (VEGF) inhibitors, hormonal therapies, and central venous catheters placed for treatment or in the setting of critical illness. Gastric, brain, and pancreas cancers pose the highest risk for development of VTE, but any tumor type can trigger a hypercoagulable state, including blood cancers.

Clinical Presentation

Symptoms and signs that should prompt a work-up for VTE include dyspnea, chest pain, tachycardia, unexplained low-grade fever, calf pain, and swelling of either the upper or lower extremities. Patients may present in either the inpatient or outpatient setting, and even those who are already anticoagulated may still thrombose. VTE may be discovered incidentally on staging scans; these should typically be treated even if asymptomatic.

The Khorana score is a widely used validated risk assessment tool that calculates the risk of developing VTE in cancer patients and may be used to guide consideration of prophylactic anticoagulation in these patients.

Treatment

Treatment of cancer-associated VTE with low-molecular-weight heparin (LMWH) has long been the “gold standard.” In a pivotal trial, LMWH was shown to reduce VTE recurrence rate in cancer patients when compared with warfarin. More recently, the direct oral anticoagulants (DOACs) apixaban, edoxaban, and rivaroxaban have been studied in comparison with LMWH in cancer patients. Edoxaban was demonstrated to be noninferior to LMWH in reducing VTE recurrence risk, while apixaban and rivaroxaban were demonstrated to be superior with respect to this outcome. Some DOACs may have more bleeding complications in certain subsets of cancer patients, and the decision to use these agents should be made in consultation with a hematologist. Drug-drug interactions, including certain chemotherapeutic agents, may also preclude the use of DOACs. The duration of anticoagulation depends on the clinical scenario and requires a more nuanced approach than can be detailed here. In general, inferior vena cava (IVC) filters should only be placed if patients have a strong indication for anticoagulation that is contemporaneous with a strong contraindication.

SPINAL CORD COMPRESSION

Epidemiology

Approximately 3% of cancer patients will develop spinal cord compression as a result of their disease. Spinal cord compression is most prevalent in patients with lung and prostate cancers, as well as multiple myeloma.

Pathology

Most cases occur at the level of the thoracic spine, followed by the lumbar, then cervical spine. Spinal cord compression commonly develops when tumor extends from the bone into the epidural space, or as the result of a pathologic fracture. Compression of the spinal cord obstructs venous flow and results in vasogenic edema. When epidural disease occurs below the level of L1-L2 (where the conus medullaris terminates), cauda equina syndrome develops.

Clinical Presentation

The first symptom of spinal cord compression is typically pain. Patients will describe pain that is aggravated in the supine position or during a Valsalva maneuver, and may interfere with sleep. Motor weakness

Skin toxicity
Stomatitis
Tumor lysis syndrome

and sensory deficits, specifically saddle anesthesia, can be present at diagnosis. These symptoms, however, typically herald advanced cord compression and are associated with a lower likelihood of functional recovery. Patients may also present with urinary retention (early) or bowel and bladder incontinence (later).

Diagnosis

A high clinical suspicion for spinal cord compression should develop when patients with known cancer present with any new back pain, and rapidly investigated with spinal imaging. Though plain radiographs of the vertebrae can certainly reveal abnormalities such as lytic lesions or vertebral fractures, time should not be wasted obtaining these studies because negative results in the setting of high clinical suspicion will not rule out spinal cord compression. Magnetic resonance imaging (MRI) is the preferred diagnostic imaging modality and should be obtained unless there is a contraindication to MRI, in which case computed tomography myelography should be performed. Imaging of the full spine is recommended even with localized symptoms because frequently multiple vertebral levels are affected.

Treatment

Dexamethasone and narcotic analgesia are the cornerstones of immediate treatment for cord compression. The optimal dose of corticosteroid is controversial. The most widely accepted dosing of dexamethasone is 10 mg IV followed by 4 to 6 mg IV every 6 hours, although some providers advocate an initial dose as high as 96 mg. This large dose, however, has been demonstrated to result in significant toxicity with questionable benefit.

Surgery and radiation therapy (RT) are the cornerstones of definitive therapy for spinal cord compression. Large randomized studies have demonstrated conflicting evidence about the benefits of surgery followed by RT versus RT alone. Though the presence of neurologic deficits is typically considered to be a clear indication for surgical intervention, goals

of care, patient and tumor characteristics, and other comorbidities factor in to decision making regarding the most appropriate course of therapy.

SUPERIOR VENA CAVA SYNDROME

Definition

Superior vena cava (SVC) syndrome in malignancy is the result of flow obstruction by either external compression or intravascular thrombosis. The superior vena cava is thin walled and therefore easily compressed. The most common malignant causes are lung cancer and lymphoma.

Clinical Presentation

The presenting symptoms and signs of SVC syndrome depend on the rate of vessel obstruction. Slow compression allows for the development of collaterals from the azygos, internal mammary, paraspinal, lateral thoracic, and esophageal venous systems. Of these collateral tributaries the azygos vein is the most important because obstruction below its level is not well tolerated. Symptoms can be sudden or insidious. Most patients experience dyspnea (60% to 70%) and facial or neck swelling (50%). Cough, pain, arm swelling, and dysphagia are less common. Symptoms are frequently positional and exacerbated by leaning forward or lying down. Physical findings may include venous distention of neck and chest wall, facial edema, plethora, cyanosis, and upper extremity edema.

Diagnosis

Plain chest radiographs are usually abnormal; mediastinal widening (64%) and pleural effusion (26%) are the most common findings. The diagnosis is best established with contrast-enhanced computed tomographic scanning of the chest. It demonstrates the location and size of masses, the presence of intravascular thrombosis, and collateral venous drainage. When SVC syndrome is the initial manifestation of malignancy, pathologic diagnosis is the first step in establishing the proper initial treatment modality.

Treatment

The goals of treatment are to alleviate symptoms urgently and to treat the underlying malignancy. General supportive measures include head elevation and administration of glucocorticoids and diuretics. It is essential not to start radiation or glucocorticoids before obtaining a biopsy because these therapies can cloud the pathologic diagnosis. Specific management depends on the underlying pathology. Chemotherapy is the preferred first line of therapy for chemosensitive malignancies such as lymphoma, small cell lung cancer, or germ cell tumors. For non-small cell lung cancers and other less chemosensitive tumors, initial radiation therapy may be preferred.

Symptomatic relief can occur within 2 weeks but is often temporary; therefore, systemic management should be initiated as soon as possible with either chemotherapy, chemoradiation, or surgical resection. Persistent symptoms not relieved by chemotherapy or irradiation and those severe enough to warrant intervention before diagnosis can be successfully managed with endovascular stent placement with or without balloon angioplasty. The treatment of catheter-related SVC syndrome from thrombosis is anticoagulation. The decision regarding catheter removal is case dependent. Typically, catheters may remain in place provided they continue to function without evidence for clot propagation.

HYPERCALCEMIA

Epidemiology

Hypercalcemia complicates cancer in up to 10% of cases, occurring in both hematologic and solid malignancies. The most common etiologies are multiple myeloma, breast cancer, and squamous cell carcinoma.

Pathology

Mechanisms leading to hypercalcemia include osteolysis due to bony involvement or tumor production of parathyroid hormone–related protein (PTHrP), calcitriol, or cytokines. Primary hyperparathyroidism should always be ruled out even in cancer patients. Because most cancer patients also have hypoalbuminemia, calcium levels should either be corrected or ionized calcium levels should be obtained.

Clinical Presentation

Early symptoms of hypercalcemia include altered mental status, constipation, polydipsia, polyuria, nausea, vomiting, and bradycardia. Many patients also have hypovolemia because of the polyuria. The severity of symptoms depends on the time course over which hypercalcemia has developed rather than the absolute calcium level.

Treatment

First and foremost, all calcium supplements, vitamin D, and diuretics should be stopped. Initial aggressive fluid resuscitation with normal saline at 200 to 300 mL/hour should be started to maintain a high urine output. This should be done carefully in patients with compromised cardiac or renal function while loop diuretics can be considered to maintain urine output in all patients who show signs of volume overload.

More definitive treatment for almost all cases of hypercalcemia in cancer patients is centered on bisphosphonates, which inhibit osteoclast activity and bone resorption. Intravenous pamidronate and zoledronic acid are the two most commonly used bisphosphonates. In a pooled analysis, zoledronic acid was associated with a higher rate of calcium normalization and longer control. Calcium response to bisphosphonates can take a few days, so if a rapid reduction in calcium is required then subcutaneous calcitonin (4 units/kg) can be given two to four times daily. Tachyphylaxis occurs with calcitonin so its use should be limited to 48 hours. Calcitonin works by increasing calcium renal excretion and reducing bone resorption. Ultimately, management should eventually include control of the underlying disease, which in the case of myeloma and lymphoma, includes glucocorticoids. Frequently new or recurring hypercalcemia indicates disease progression or treatment resistance and should be addressed with systemic therapy.

FEBRILE NEUTROPENIA

Definition

Febrile neutropenia is another common complication of chemotherapy and is defined as a temperature of 100.4° F sustained over 1 hour, or a one-time reading of 101.0° F in the setting of a neutrophil count lower than 1000/ μ L. The risk of febrile neutropenia increases with the intensity of the chemotherapy regimen and the severity and duration of neutropenia. It can lead to treatment delays or interruptions, prolonged hospitalizations, decreased quality of life, and increased morbidity and mortality. Febrile neutropenia is a medical emergency and delays in assessment and treatment should be avoided.

Treatment

Although most cases are managed in the hospital, low-risk patients may occasionally be successfully managed as outpatients. The American Society of Clinical Oncology (ASCO) has published guidelines for outpatient management that are based on a risk-stratified scoring system, including the Multinational Association for Supportive Care in Cancer (MASCC) and Clinical Index of Stable Febrile Neutropenia (CISNE) scores. All patients should have a history and physical examination to identify possible focal sources of infection. Attention should be given to the presence of mucositis and to swelling or induration and

erythema around indwelling catheters as possible sources of infection. The initial work-up should include a full chemistry profile, complete blood count with differential, two sets of blood cultures, urinalysis, and chest radiography. ASCO guidelines allow for institutional variation in whether one set of blood cultures should be drawn from central venous access devices.

Prompt initiation of broad-spectrum antibiotics as soon as febrile neutropenia is identified is critical. Empirical antimicrobial therapy should consist of an antipseudomonal β -lactam such as cefepime or piperacillin-tazobactam for patients who require inpatient treatment and a fluoroquinolone for those whose risk profile allows for outpatient therapy. Patients with risk factors for antimicrobial resistance should have their regimens tailored accordingly; for example, vancomycin should be added if the clinical picture is consistent with pneumonia or there is hemodynamic instability. Often, no source is identified; in this case, antibiotics are continued until the neutrophil count exceeds 500 (provided that the fever resolves). When a source has been identified, antibiotic duration is dictated by the standard course for that particular type of infection. Certain high-risk chemotherapeutic regimens include the use of prophylactic myeloid growth factors such as filgrastim or pegfilgrastim to shorten the duration of neutropenia, and with that, the risk of developing febrile neutropenia. Routine use of growth factor support is not recommended in the management of febrile neutropenia in the absence of critical illness because there is little evidence to support its use in this clinical scenario.

CHEMOTHERAPY-INDUCED NAUSEA AND VOMITING

Definition

Nausea and vomiting are common adverse effects of chemotherapy, but prevention and management of this toxicity has evolved significantly in the last 2 decades. Nausea and emesis are typically categorized as acute, delayed, or anticipatory. Acute nausea and vomiting occur during the first 24 hours of treatment, whereas delayed nausea occurs 2 to 5 days after treatment initiation. Patients with high levels of anxiety or prior poor control of nausea may also suffer symptoms in anticipation of starting treatment. The risk of chemotherapy-induced nausea and vomiting is greater in younger patients, women, and those with a history of motion sickness.

Pathology

The mechanism by which chemotherapy induces nausea is complex. Proposed mechanisms involve the transmission of signals from neurotransmitter receptors in the gut to the nucleus tract solitarius, the area postrema, and the central pattern generator (in the brainstem) and involve the neurotransmitters dopamine, serotonin, and substance P.

Treatment

The best approach for treatment is prevention. The prophylactic antiemetic protocol depends on the chemotherapy regimen and emetic risk (Table 63.3). Randomized clinical trials have established that the combination of a neurokinin 1 (NK1) receptor antagonist (aprepitant or fosaprepitant), a 5HT₃ serotonin receptor antagonist (ondansetron), olanzapine, and dexamethasone is the regimen of choice for highly emetogenic chemotherapy. For moderately emetogenic chemotherapy, a three-drug regimen of an NK1 receptor antagonist, 5HT₃ antagonist with dexamethasone is recommended, although for some regimens just a 5HT₃ receptor antagonist and dexamethasone alone may be adequate. All patients should be given a dopamine receptor antagonist such as prochlorperazine or a 5HT₃ receptor antagonist

TABLE 63.3 Nausea and Vomiting Risk With Cancer Therapy

Emetic Risk	Percentage of Patients Affected	Representative Agents	Recommended Preventive Antiemetic
High	>90	Cisplatin, high-dose cyclophosphamide	NK1 antagonist + 5HT3 antagonist + olanzapine + dexamethasone
Moderate	30-90	Oxaliplatin, doxorubicin, irinotecan	NK1 antagonist + 5HT3 antagonist + dexamethasone
Low	10-30	Paclitaxel, etoposide, gemcitabine	5HT3 antagonist OR dexamethasone
Minimal	<10	Vincristine, bleomycin	No routine prophylaxis

5HT3, Serotonin receptor; NK1, neurokinin 1.

such as ondansetron as rescue therapy for intermittent nausea, and the addition of olanzapine for breakthrough nausea and vomiting is appropriate in some circumstances.

Dexamethasone is the preferred treatment for delayed nausea and vomiting in highly and moderately emetogenic chemotherapy. Anticipatory nausea or vomiting is best treated with proper control of symptoms in the initial cycles. When it occurs, it is best treated with behavioral therapy, and benzodiazepines can be useful as adjunctive therapy.

DERMATOLOGIC TOXICITY

Many chemotherapeutic and targeted agents are associated with dermatologic toxicity, which can lead to patient morbidity, alter quality of life, and affect therapeutic dosing.

Clinical Presentation

Acneiform eruptions are observed with agents targeted against epidermal growth factor receptor (EGFR) in 70% to 80% of patients. The rash is usually erythematous with pustulopapular eruptions over the face, scalp, and upper trunk.

Palmar-plantar erythema, or so-called hand-foot syndrome, is seen with chemotherapeutic agents such as 5-fluorouracil and capecitabine or with tyrosine kinase inhibitors such as sorafenib, sunitinib, and regorafenib. Manifestations can differ slightly between classes of drugs, but they usually involve symmetrical redness of the palms or soles. Tingling and pain may accompany erythema. With progression, painful blistering or skin peeling may occur. Symptoms are frequently observed at pressure areas, such as on the soles of the feet after prolonged standing or running.

Treatment

Treatment of skin rash associated with anti-EGFR therapies is tailored to the severity of the rash and may include topical steroids, oral antibiotics (minocycline or doxycycline), and dose modification or cessation. Sunscreens, reduced sun exposure, and lotions for dry skin should be used for prevention. For hand-foot syndrome, preventive measures such as sunscreens and routine application of lotion to hands and feet are helpful. The most effective treatment is a brief treatment break (typically for several days, until complete resolution occurs), followed by resumption but with a reduced dose of the inciting agent.

TUMOR LYSIS SYNDROME

Definition

Tumor lysis syndrome (TLS) occurs when tumor cells break up and release toxic contents into the blood stream. It most commonly occurs in hematologic malignancies such as acute leukemias and non-Hodgkin's lymphoma, but can occur in almost any malignancy.

It is typically triggered by the initiation of therapy in aggressive malignancies but can occur spontaneously, especially when there is a high tumor burden.

Pathology

Lysis of tumor cells causes the release of intracellular contents, including nucleic acids, potassium, and phosphate, into the bloodstream. The breakdown of nucleic acids results in high levels of uric acid, which can precipitate in the renal tubules and cause acute kidney injury (AKI). High levels of phosphate result in precipitation of calcium phosphate, which can cause symptomatic hypocalcemia, renal tubular injury and cardiac arrhythmias. High levels of potassium can also result in life-threatening cardiac arrhythmias.

Diagnosis

The recognition of patients who are at high risk for TLS should begin before therapy, and most patients in this category are given prophylactic allopurinol before initiation of treatment. The formal diagnosis of TLS is guided by the Cairo-Bishop criteria, which involves identifying both laboratory abnormalities suggestive of TLS (hyperkalemia, hypocalcemia, hyperphosphatemia, and hyperuricemia) and clinical criteria (AKI, cardiac arrhythmia, and seizure). The prompt diagnosis of TLS is critical to treatment and prevention of life-threatening electrolyte disturbances.

Treatment

Treatment involves aggressive hydration and meticulous management of electrolyte abnormalities. Patients are given 2 to 3 L of normal saline over 24 hours, which is sometimes augmented with loop diuretics to increase urine output. Allopurinol, if not given as a preventative measure, is given at a dose of 300 mg daily. If uric acid rises above 8, or is rapidly rising, rasburicase is given for a reduction in serum uric acid levels, although the magnitude of benefit with respect to preservation of renal function has not been solidly established. Most patients with a diagnosis of TLS require close monitoring, with laboratory checks three to four times a day and telemetry monitoring for cardiac arrhythmias, and sometimes require ICU level of care.

IMMUNE CHECKPOINT INHIBITOR TOXICITY

Definition

The use of recently discovered checkpoint inhibitors (e.g., pembrolizumab, nivolumab) is radically changing prognosis and treatment for several malignancies. With these new drugs, however, has also come new immunotherapy-induced toxicity. These are almost all related to an autoimmune-like response induced by these medications, resulting in inflammation of various organ systems. These include colitis, hepatitis, pneumonitis, dermatitis, encephalitis, and hypophysitis (panhypopituitarism).

Pathophysiology

Immune checkpoint inhibitors work by “releasing the brakes” on the immune system imposed by cancer cells. Co-stimulatory cell surface antigens such as PD-1/PDL-1 and CTLA-4, needed for activation of the immune system, are often downregulated by tumor cell surface markers. Immunotherapy reactivates the immune system, removing the tumor blockades and allowing the body’s own immune system to attack the tumor cells. In doing so, the immune system may be mobilized indiscriminately, resulting in its activation not only against the cancer but also against the patient’s own healthy tissue.

Diagnosis

Immune-mediated toxicity should be considered in all patients on immunotherapy presenting with symptoms consistent with immune-mediated phenomena. These include diarrhea (colitis), shortness of breath or cough (pneumonitis), rash (dermatitis), or altered mentation (encephalitis). In addition, patients are also monitored for laboratory evidence of hepatitis and hypophysitis (most specifically hypothyroidism). These signs and symptoms can be mild and treated symptomatically, but on rare occasions can be life-threatening.

Treatment

Patients with mild signs and symptoms can often be treated symptomatically while remaining on the medication, or with a brief interruption in treatment, which can be restarted once signs and symptoms have resolved. Patients with findings of hypothyroidism can be started on thyroid hormone replacement without need for immune checkpoint discontinuation. In more severe cases, such as with new oxygen requirement, severe diarrhea, or significant elevations in liver function

tests (LFTs), the immunotherapy needs to be discontinued and patients should be started on corticosteroids to try to decrease the inflammatory response, typically at doses of 1 to 2 mg/kg of methylprednisolone (or its equivalent) per day. In rare cases of severe toxicity, immunomodulatory medication such as mycophenolate mofetil or infliximab is utilized in addition to corticosteroids. In most cases, expert consultation should be obtained to guide the management of these toxicities.

For a deeper discussion on this topic, please see Chapter 73, “Thrombotic Disorders: Hypercoagulable States,” Chapter 232, “The Parathyroid Glands, Hypercalcemia, and Hypocalcemia,” and Chapter 372, “Mechanical and Other Lesions of the Spine, Nerve Roots, and Spinal Cord,” in *Goldman-Cecil Medicine*, 26th Edition.

Hypothalamic-Pituitary Axis

Diana Maas, Jenna Sarvaideo

ANATOMY AND PHYSIOLOGY

The pituitary gland sits in the skull base in a bony structure called the sella turcica. It weighs approximately 600 mg and is composed of three lobes, the adenohypophysis (anterior lobe), the neurohypophysis (posterior lobe), and the intermediate lobe. The intermediate lobe regresses in humans at about 15 weeks' gestation and is absent in the adult normal pituitary gland. The infundibular stalk, which contains the portal plexus circulation, connects the hypothalamus to the pituitary gland. The pituitary gland is surrounded by important structures that can be compromised by its enlargement, including the optic chiasm, located superior to the gland, and the cavernous sinuses, located on both sides of the gland. The cavernous sinuses each contain the internal carotid artery and cranial nerves III, IV, V1, V2, and VI (Fig. 64.1).

The anterior pituitary gland produces six hormones that are produced by specific cell types within the gland: adrenocorticotropic hormone (ACTH), follicle-stimulating hormone (FSH), luteinizing hormone (LH), growth hormone (GH), prolactin (PRL), and thyroid-stimulating hormone (TSH or thyrotropin). These hormones are regulated by stimulatory and inhibitory peptides produced within the hypothalamus and are transported to the anterior pituitary gland by the infundibular portal system. The posterior pituitary gland makes up about 20% of the total pituitary mass and stores and secretes two major peptide hormones: vasopressin (AVP or antidiuretic hormone) and oxytocin. These neurohypophyseal hormones are synthesized by the supraoptic and paraventricular nuclei of the hypothalamus and transported to the posterior lobe in neurosecretory granules along the supraopticohypophyseal tract (Table 64.1).

On imaging studies, the normal adult pituitary gland has a flat superior border and a vertical height of approximately 8 to 10 mm. The anterior pituitary is homogeneous in signal on magnetic resonance imaging (MRI), the preferred imaging method, and enhances homogeneously after intravenous administration of a contrast agent (see Fig. 64.1). The posterior pituitary lobe is distinguished from the anterior lobe on T1-weighted MRI as a bright spot in the posterior aspect of the gland, best seen on a sagittal view. The bright appearance is thought to result from the presence of AVP and/or phospholipid vesicles within the normal neurohypophysis.

PITUITARY TUMORS

Pituitary tumors account for approximately 10% to 15% of intracranial tumors. They are the most common tumors in the sella, accounting for more than 90% of masses that develop in that area, and they are usually benign. Their true incidence is difficult to determine because they are often asymptomatic, but the prevalence is about 10% to 20% in radiologic studies. Most pituitary tumors are slow growing, but some have high growth rates and can be invasive. Pituitary carcinomas are very

rare and are defined by the presence of a metastasis that is noncontiguous with the original tumor, or cerebrospinal fluid dissemination.

Pituitary tumors are classified by size and secretory capacity. Tumors that are smaller than 10 mm in diameter are called *microadenomas*, whereas lesions 10 mm or larger are called *macroadenomas*. Hormone-producing tumors are called *secretory adenomas*, and those that do not secrete a hormone are known as *nonsecretory adenomas*. Pituitary tumors may be composed of any of the anterior pituitary cell types, with multiple cell types forming plurihormonal tumors. Prolactin-secreting pituitary tumors are the most common type. Table 64.2 reviews the prevalence of the various pituitary tumors, and Table 64.3 describes the screening tests used to determine the secretory status of a new pituitary tumor.

The clinical manifestations of pituitary tumors are usually signs and symptoms caused by hormone overproduction or underproduction or mass effect. Common clinical features of pituitary mass effect include headaches, visual field defects, and cranial nerve palsies. Superior extension of a tumor compresses the optic chiasm, causing bitemporal hemianopsia; lateral extension into the cavernous sinuses results in ophthalmoplegia, diplopia, or ptosis due to compression of cranial nerves III, IV, or VI or facial pain due to compression of V1 or V2. Compromise of normal pituitary tissue by a tumor can cause hormone loss or hypopituitarism. Screening tests for and causes of pituitary hormone deficiency are shown in Tables 64.3 and 64.4, respectively.

DISORDERS OF ANTERIOR PITUITARY HORMONES

Prolactin

Definition and Epidemiology

The mature prolactin polypeptide contains 199 amino acids and is formed after a 28-amino-acid signal peptide is proteolytically cleaved from the prolactin prohormone (pre-prolactin). Prolactin synthesis and secretion by pituitary lactotrophs is under tonic inhibitory control by hypothalamic-derived dopamine, which keeps prolactin at its basal levels. Factors stimulating prolactin synthesis and secretion, in addition to reduced dopamine availability to the lactotrophs, include thyrotropin-releasing hormone (TRH), estrogen, vasoactive intestinal polypeptide (VIP), AVP, oxytocin, and epidermal growth factor.

Prolactin levels physiologically increase during pregnancy. After delivery, prolactin induces and maintains lactation of the breast. Hyperprolactinemia, regardless of the etiology, can cause hypogonadism through its inhibitory effect on gonadotropin release, infertility, galactorrhea, and/or bone loss from the hypogonadism.

Prolactinomas and hyperprolactinemia are more common in women, with a peak prevalence between 25 and 35 years of age. The mean prevalence of patients medically treated for hyperprolactinemia is approximately 20 per 100,000 in men and approximately 90 per 100,000 in women. Prolactinomas are rare in childhood or adolescence.

Fig. 64.1 Coronal section and corresponding magnetic resonance imaging scan of the pituitary gland and surrounding structures, including cranial nerves III (oculomotor), IV (trochlear), V1 (trigeminal, ophthalmic branch), V2 (trigeminal, maxillary branch), and VI (abducens). CC, Carotid artery (intracavernous); CS, cavernous sinus (left); IC, internal carotid artery; OC, optic chiasm; Pit, pituitary gland; SS, sphenoid sinus. (From Jesurasa A, Kailaya-Vasan A, Sinha S: Surgery for pituitary tumors, Surgery 29:428-433, 2011, Figure 1.)

Clinical Presentation

The clinical presentation of a prolactinoma varies with the age and gender of the patient. Typically, the patient is a young woman with menstrual irregularities, galactorrhea, and infertility. Galactorrhea occurs in 50% to 80% of affected women. Men may report a decrease in libido and erectile dysfunction as a result of hypogonadism caused by reduced secretion of LH and FSH. Typically, however, their tumors are diagnosed after symptoms of tumor compression appear, including headache, neurologic deficits, and vision changes. Galactorrhea and gynecomastia are rare in men. Because of the early presentation of menstrual irregularities in women, microprolactinomas are more common in women; macroprolactinomas are more frequent in men and in postmenopausal women.

Diagnosis and Differential Diagnosis

Hyperprolactinemia is diagnosed by a serum prolactin above the upper limit of normal. This can be drawn at any time of day. For prolactinomas, serum prolactin levels typically parallel tumor size. A prolactin level greater than 250 ng/mL is usually diagnostic of a prolactinoma,

but smaller prolactinomas may have lower levels. Dynamic testing is not needed to diagnose hyperprolactinemia.

Two types of artifacts can occur during the standard measurement of prolactin: the presence of macroprolactin and the hook effect. When a patient with mild hyperprolactinemia does not have the expected clinical features of hyperprolactinemia (e.g., galactorrhea, menstrual disturbance, infertility), one should consider the presence of macroprolactin. Macroprolactin is a polymeric form of prolactin that is biologically inactive. Most commercially available prolactin assays do not detect macroprolactin, but it can be detected inexpensively in the serum by polyethylene glycol precipitation. The estimated incidence of macroprolactin accounting for a significant proportion of hyperprolactinemia is 10% to 20%. The hook effect should be considered in a patient who has a very large pituitary mass and only a mild elevation in prolactin. The hook effect is an assay artifact that occurs when very high serum prolactin concentrations saturate antibodies in the standard two-site immunoradiometric assay, resulting in falsely low levels. This artifact can be overcome by repeating the prolactin measurement on a 1:100 serum sample dilution.

Physiologic increases in prolactin occur with pregnancy, physical or emotional stress, exercise, and chest wall stimulation. Mild to moderate hyperprolactinemia (25 to 200 ng/mL) in the presence of a larger pituitary mass is more likely to be caused by a non-prolactin-secreting tumor with infundibular stalk compression and inhibition of dopamine transport to the lactotroph. Other common causes for hyperprolactinemia are shown in Table 64.5. Some drugs such as metoclopramide and risperidone can increase prolactin to greater than 200 ng/mL.

Treatment and Prognosis

Medical management with a dopamine agonist—bromocriptine or cabergoline—is the recommended treatment. The dopamine agonists normalize prolactin, decrease tumor size, and restore gonadal function in more than 80% of patients with prolactinomas. Because of the rapidity and efficacy of the dopamine agonists in treating these tumors, they are also the initial treatment for macroprolactinomas that have caused compromise in vision, neurologic deficits, or pituitary dysfunction.

Cabergoline, the newer agent, is preferred to other dopamine agonists because it has higher efficacy in normalizing prolactin levels and shrinking tumor size and has fewer side effects. The most common side effects seen with dopamine agonists are nausea, vomiting, orthostatic lightheadedness, dizziness, and nasal congestion. Because of the concern for cabergoline-related cardiac valvulopathy that was reported in patients who had Parkinson's disease treated with higher doses of cabergoline than used in prolactinomas, baseline echocardiogram and regular cardiac auscultation is recommended in patients taking greater than 2 mg weekly. Transsphenoidal resection of the tumor is indicated for patients who cannot tolerate the dopamine agonists or who do not respond to medical treatment. No treatment is required for patients who have microprolactinomas that are asymptomatic.

Studies have shown that dopamine agonists may be safely withdrawn in patients who have maintained normal prolactin levels for 2 years and who have no visible tumor on low doses of dopamine agonist. Once the dopamine agonist is discontinued, prolactin levels should be checked every 3 months for 1 year and then annually. An MRI should be obtained only if the prolactin level becomes elevated again. Recurrence risk after drug withdrawal ranges from 26% to 69% and is predicted by the initial prolactin level and tumor size.

TABLE 64.1 Pituitary–Target Organ Hormone Axis

Hypothalamic Hormone	Pituitary Target Cell	Pituitary Hormone Affected	Peripheral Target Gland	Peripheral Hormone Affected
Stimulatory				
Anterior Lobe of Pituitary Gland				
Thyrotropin-releasing hormone (TRH)	Thyrotroph	Thyroid-stimulating hormone (TSH)	Thyroid gland	Thyroxine (T ₄) Triiodothyronine (T ₃)

Dopamine	Lactotroph	Prolactin (PRL)	Breast	

TABLE 64.2 Prevalence of Pituitary Tumors

Tumor	Prevalence (%)
Prolactin-secreting adenomas	40-45
Gonadotropin-secreting adenomas	20
Growth hormone-secreting adenomas	10-15
Adrenocorticotrophic hormone-secreting adenomas	10-15
Null cell adenomas	5-10
Thyroid-stimulating hormone-secreting adenomas	1-2

Growth Hormone

Definition

GH is a single-chain polypeptide hormone consisting of 191 amino acids that is synthesized, stored, and secreted by the anterior pituitary somatotrophs. GH secretion is regulated by two factors derived from the hypothalamus: growth hormone-releasing hormone (GHRH) and somatostatin. GHRH stimulates somatotroph GH release, and somatostatin inhibits it. GH stimulates secretion of insulin-like growth factor-I (IGF-I) by the liver. IGF-I circulates in the blood attached to binding proteins; although there are six binding proteins in serum, more than 80% of IGF-I is bound to a protein called IGFBP3. Postnatally and through puberty, GH and IGF-I are critical in determining longitudinal skeletal growth, skeletal maturation, and bone mass. In adulthood, they are instrumental in the maintenance of skeletal architecture and bone mass. GH also has effects on the metabolism of carbohydrates, lipids, and proteins by antagonizing insulin action, increasing lipolysis and free fatty acid production, and increasing protein synthesis.

Growth Hormone Deficiency

Epidemiology. Childhood-onset GH deficiency is most commonly idiopathic, but it may be genetic or associated with congenital anatomic malformations in the brain or sellar region. The most common cause of GH deficiency in adults is a pituitary macroadenoma and its treatment;

TABLE 64.3 Biochemical Tests for Pituitary Disorders

Disorder	Tests
Pituitary Tumor	
GH-secreting adenomas	IGF-I OGTT: measure blood sugar and GH (0, 60, 120 min)
PRL-secreting adenomas	Basal serum prolactin
ACTH-secreting adenomas	24-hr urine-free cortisol and creatinine level 1-mg overnight dexamethasone suppression test 11 PM salivary cortisol Serum ACTH
TSH-secreting adenomas	Serum TSH, Free T ₄ , Free T ₃ , alpha subunit
Gonadotropin-secreting adenomas	FSH, LH, alpha subunit estradiol (women), testosterone (men)
Hypopituitarism	
GH deficiency	IGF-I Glucagon stimulation test Arginine-GHRH (GHRH not available in the United States) Arginine-L-DOPA ITT
Gonadotropin deficiency	Women: basal estradiol, LH, FSH Men: 8 AM fasting testosterone (total; free), LH, FSH
TSH deficiency	Serum TSH, free T ₄
ACTH deficiency	8 AM fasting ACTH and cortisol Cosyntropin-stimulation test (1 µg and 250 µg)

ACTH, Adrenocorticotrophic hormone; CRH, corticotropin-releasing hormone; FSH, follicle-stimulating hormone; GH, growth hormone; GHRH, growth hormone-releasing hormone; IGF-I, insulin-like growth factor-I; ITT, insulin tolerance test; LH, luteinizing hormone; OGTT, oral glucose tolerance test; PRL, prolactin; T₄, thyroxine; TFT, thyroid function test; TSH, thyroid-stimulating hormone.

TABLE 64.4 Causes of Pituitary Hormone Deficiency

Causes	Examples
Sellar masses	Pituitary macroadenomas, craniopharyngiomas
Treatment of sellar, parasellar, and hypothalamic tumors	Pituitary/hypothalamic surgery, radiotherapy, radiosurgery (gamma knife)
Infiltrative diseases	Lymphocytic hypophysitis, hemochromatosis, sarcoidosis
Trauma	Head injury, perinatal trauma
Vascular	Sheehan syndrome, pituitary apoplexy
Medications	Opiates, glucocorticoids
Infections	Fungal, tuberculosis
Genetic	Combined or isolated pituitary hormone deficiencies
Developmental	Pituitary hypoplasia or aplasia, midline cerebral and cranial malformations
Empty sella	

TABLE 64.5 Causes of Hyperprolactinemia

Causes	Examples
Medications	Methyldopa, estrogens, metoclopramide, domperidone, neuroleptics and antipsychotics
Hypothalamic-infundibular stalk damage	Infiltrative disorders (sarcoidosis), brain irradiation, trauma, surgery, tumors
Pituitary	Prolactinomas, non-PRL-secreting pituitary macroadenomas with stalk compression
Medical	Renal failure, primary hypothyroidism

deficiency of one or more pituitary hormones occurs in 30% to 60% of such cases. The incidence of hypopituitarism 10 years after irradiation of the sellar region is approximately 50%.

Clinical presentation. Children with GH deficiency exhibit growth retardation, short stature, and fasting hypoglycemia. Manifestations of adult GH deficiency include reduced bone density, decreased muscle strength and exercise performance, decreased lean body mass with increase in fat mass and abdominal adiposity, glucose intolerance and insulin resistance, abnormal lipid profile including elevated low-density lipoprotein (LDL) and triglyceride levels with decreased high-density lipoprotein (HDL), depressed mood, and impaired psychosocial well-being.

Diagnosis and differential diagnosis. Because of the pulsatile nature of pituitary GH secretion, a single random measurement of serum GH is not helpful to diagnose GH deficiency. In adults with GH deficiency due to a pituitary tumor and concomitant hypopituitarism involving any three other pituitary hormones, a low IGF-I level is sufficient to diagnose GH deficiency, and provocative testing is not warranted. Falsely low IGF-I levels are seen in malnutrition, acute illness, celiac disease, poorly controlled diabetes mellitus, and liver disease. In children, there tends to be greater variation in IGF-I levels that do not correspond to the true GH status, so provocative testing is required.

The historical “gold standard” stimulatory test is insulin-induced hypoglycemia (insulin tolerance test or ITT). Symptomatic hypoglycemia with a serum glucose level lower than 45 mg/dL is a potent stimulus for GH secretion; the normal GH response is greater than 10 ng/mL in children and greater than 5 ng/mL in adults. Because of the unavailability in the United States of GHRH, which is as sensitive and specific as the ITT in stimulating GH secretion, glucagon stimulation is being used, especially in adults with ischemic heart disease or seizures. A normal adult response with the glucagon stimulation test is defined

as a GH peak greater than 3 ng/mL for those with normal weight, but in obese patients, a cutoff of 1 ng/mL is used.

Treatment and prognosis. The US Food and Drug Administration (FDA) has approved recombinant human growth hormone (hGH) in both the adult and pediatric populations. It is used in conditions involving complete absence of GH associated with severe growth retardation or partial GH deficiency resulting in short stature. Short stature is defined as height more than 2.5 standard deviations below the mean for age-matched normal children, growth velocity less than the 25th percentile, delayed bone age, and predicted adult height less than the mean parental height. Other conditions approved by the FDA to use hGH include Turner syndrome, Prader-Willi syndrome, chronic kidney disease, AIDS-associated muscle wasting, *SHOX* gene deficiency, Noonan syndrome, and children born small for gestational age. Combined clinical evaluations, along with an inadequate pituitary GH response to provocative testing, are used in the assessment of childhood GH deficiency. Higher doses of GH are recommended for children without GH deficiency disorders or with partial GH deficiency.

In adults, hGH is administered as a daily subcutaneous injection starting at 0.1 to 0.3 mg, with dose increases at 6-week intervals based on clinical response, side effects, and IGF-I levels. Absolute contraindications to hGH therapy in adults include active neoplasm, intracranial hypertension, and proliferative diabetic retinopathy; uncontrolled diabetes and untreated thyroid disease are relative contraindications. Side effects of hGH therapy are usually transient and include arthralgias, fluid retention, carpal tunnel syndrome, and glucose intolerance. Additional side effects in children include slipped capital femoral epiphysis and hydrocephalus.

Acromegaly or Growth Hormone Hypersecretion

Definition and epidemiology. Acromegaly is literally translated as abnormal enlargement of the extremities of the skeleton. It is caused by hypersecretion of GH in adulthood. In children, excessive GH secretion before closure of the epiphyseal growth plate leads to gigantism. In both cases, the cause is almost always a GH-secreting pituitary tumor. Approximately 30% of GH-secreting pituitary adenomas are bihormonal and also secrete prolactin. The incidence of acromegaly is about 2 to 4 per million population, and the mean age at diagnosis is 40 to 50 years. GH-secreting tumors are caused by a clonal expansion of pure somatotrophs or mixed somatomammotrophs. A variety of genetic abnormalities can be found in GH-secreting pituitary adenomas including McCune-Albright syndrome, multiple endocrine neoplasia type 1 and 4, Carney complex, and familial isolated pituitary adenoma.

TABLE 64.6 Clinical Features of Acromegaly

Change	Manifestations
Somatic Changes	
Acral changes	Enlarged hands and feet
Musculoskeletal changes	Arthralgias Prognathism Malocclusion Carpal tunnel syndrome
Skin changes	Sweating Skin tags Nevi
Colon changes	Polyps Carcinoma
Cardiovascular symptoms	Cardiomegaly Hypertension
Visceromegaly	Tongue Thyroid Liver
Endocrine-Metabolic Changes	
Reproduction	Menstrual abnormalities Galactorrhea Decreased libido
Carbohydrate metabolism	Impaired glucose tolerance Diabetes mellitus Insulin resistance
Lipids	Hypertriglyceridemia

Clinical presentation. Acromegaly is a rare disease, and the rate of change of symptoms and signs is slow and insidious. The usual period from earliest onset of symptoms and signs to diagnosis is 8 to 10 years, during which time many patients undergo medical and surgical treatments for many of the metabolic abnormalities and morbidities caused by GH excess. Characteristic clinical findings of this disease include physical changes of the bone and soft tissue and multiple endocrine and metabolic abnormalities (Table 64.6).

Diagnosis and differential diagnosis. Measurement of serum IGF-I can be used to diagnose excess GH in most patients with acromegaly. An alternative is an oral glucose tolerance test using a 75 g glucose load. Normally, glucose suppresses GH levels to less than 1 ng/mL after 2 hours; in patients with acromegaly, GH levels may paradoxically increase, remain unchanged, or decrease but not below 1 ng/mL. Most acromegalic patients have GH-secreting pituitary tumors, and approximately 70% of cases of acromegaly present with pituitary macroadenomas. Rarely, GH hypersecretion is caused by ectopic GHRH-secreting tumors, including hypothalamic hamartomas and gangliocytomas, pancreatic islet cell tumors, small cell carcinoma of the lung, carcinoid, adrenal adenomas, and pheochromocytomas. Ectopic GH secretion has also been reported in pancreatic, lung, and breast cancers.

Treatment and prognosis. Treatment of acromegaly requires both treatment of the tumor and normalization of GH and IGF-I levels, along with management of the comorbidities and metabolic abnormalities caused by the excess GH. Treatment often requires the use of multiple modalities to achieve adequate control of the disease. Primary therapy is almost always transsphenoidal surgery, with the cure rate being directly proportional to tumor size. Patients with intrasellar microadenomas have a 75% to 95% cure rate with surgery.

In patients with noninvasive macroadenomas, surgical removal results in normalization of GH and IGF-I in 40% to 68% of patients.

Approximately 40% to 60% of tumors are not controlled with surgery alone because of cavernous sinus invasion or intracapsular intra-arachnoid invasion. Additional treatment options include primary medical therapy or primary surgical debulking of the tumor followed by medical therapy for hormonal control and/or radiation therapy for treatment of residual tumor. Conventional radiotherapy can normalize GH and IGF-I levels in more than 60% of patients, but the maximum response takes 10 to 15 years to achieve. Focused single-dose gamma knife radiotherapy has a 5-year remission rate of 29% to 60%. Hypopituitarism is seen in more than 50% of patients within 5 to 10 years after radiotherapy.

Currently, three drug classes are used to treat acromegaly: dopamine agonists, somatostatin receptor ligands (SRLs) such as octreotide, lanreotide, and pasireotide, and GH receptor antagonists. SRLs work mainly through the somatostatin receptor subtypes 2 and 5 (except pasireotide works through receptor subtypes 1, 2, 3, and 5), causing a decrease in tumor GH secretion. In acromegaly, SRLs are indicated for first-line treatment when there is low probability of surgical cure, after a failed surgical cure of GH hypersecretion, and to provide GH and IGF-I control while waiting for radiotherapy to achieve its maximum effect. SRLs reduce GH and IGF-I levels to normal in 40% to 65% of patients and shrink tumor size in approximately 50% of cases. Side effects of SRLs include diarrhea, abdominal cramping, flatulence, and cholelithiasis (15%).

Pegvisomant is the only GH receptor antagonist available. It works by blocking the peripheral action of GH through blockade of the GH receptors located on the liver. Pegvisomant is indicated for patients who have persistent elevation in IGF-I even with maximum doses of SRLs. This drug is highly effective in the treatment of acromegaly and normalizes IGF-I levels in 97% of patients; transient elevation in liver function enzymes is seen in 25% of those treated and tumor growth in fewer than 2%. After starting pegvisomant, GH levels are often elevated and are no longer helpful in guiding treatment.

Cabergoline is the most efficacious of the dopamine agonists for treatment of acromegaly, but it is effective in fewer than 10% of patients, working best in bihormonal PRL and GH-secreting tumors.

Thyroid-Stimulating Hormone

Definition

TSH is a glycoprotein secreted from the thyrotroph cells of the anterior pituitary. It is composed of alpha and beta subunits with the beta subunit giving its specific biological activity. Its release is regulated by TRH (stimulatory) and somatostatin (inhibitory). In addition, it is subject to the negative feedback of thyroid hormones released from the thyroid gland. Assessment of the pituitary-thyroid axis requires checking levels of TSH as well as thyroid hormones released by the thyroid gland (i.e., thyroxine [T₄] and triiodothyronine [T₃]).

Deficiency of TSH

Definition and epidemiology. Deficiency of TSH leads to secondary hypothyroidism. The diminished secretion of TSH from the pituitary provides inadequate stimulation to the thyroid gland for thyroid hormone release. The estimated prevalence of TSH deficiency is about 1 in 80,000 to 120,000 individuals. The more common causes of TSH deficiency are found in Table 64.4, listing causes of hypopituitarism.

Clinical presentation. The usual signs and symptoms of hypothyroidism are weight gain, fatigue, cold intolerance, and constipation. If the condition is caused by an underlying sellar tumor, symptoms of mass effect may also be present, depending on the size of the tumor.

Diagnosis and differential diagnosis. Secondary hypothyroidism is characterized by low levels of free T_4 along with low or inappropriately normal TSH. The differential diagnosis includes euthyroid sick syndrome, which is often seen in the setting of an acute illness. This syndrome does not require any intervention, and the laboratory results normalize on repeat testing after resolution of the acute illness.

Treatment and prognosis. Management focuses on replacement of the thyroid hormones, as in primary hypothyroidism. However, measurement of free T_4 , rather than TSH, is used as a guide to adjust therapy. Underlying adrenal insufficiency should always be excluded and treated before treatment of secondary hypothyroidism to avoid precipitating an adrenal crisis.

TSH-Secreting Pituitary Tumors

Definition and epidemiology. TSH-secreting pituitary tumors are rare and are characterized by inappropriate release of TSH that is refractory to the negative feedback mechanism of the thyroid hormones released by the thyroid gland. The prevalence of TSH-secreting pituitary adenomas is 1 to 2 cases per million in the general population. The pathogenesis of TSH-secreting pituitary tumors is unknown.

Clinical presentation. The most common age of presentation is in the early fifth decade, and there is no gender predilection. Presenting symptoms can be the result of a mass effect of the tumor or, most commonly, there are symptoms and signs of hyperthyroidism, including weight loss, tremors, heat intolerance, and diarrhea. Diffuse goiter is observed in up to 80% of patients. Many times, these tumors are initially misdiagnosed as primary hyperthyroidism and patients are mistakenly treated with radioactive iodine. Sometimes, the TSH produced by these tumors is biologically inactive and the tumors are diagnosed as an incidental finding on imaging studies.

Diagnosis and differential diagnosis. The diagnosis is made in the setting of elevated or inappropriately normal TSH and alpha subunit along with elevated levels of thyroid hormones (free and total T_4 and T_3). The differential diagnosis includes genetic resistance to thyroid hormone and euthyroid hyperthyroxinemia, which is characterized by normal TSH, high total T_4 , normal free T_4 , and elevated thyroxine-binding globulin levels. Imaging studies (MRI) should be done only after biochemical confirmation because of the high incidence of incidental pituitary tumors.

Treatment and prognosis. Surgery (transsphenoidal resection) is the first-line treatment. Radiotherapy can be used if surgery is declined or contraindicated, but normalization of thyroid hormones can take years. Medical therapy with somatostatin analogues (e.g., octreotide, lanreotide) is used for first-line drug treatment for persistent hyperthyroidism after surgery. Most patients on SRLs achieve control of symptoms of thyrotoxicosis through normalization of thyroid function as well as reduction in tumor burden.

Adrenocorticotrophic Hormone

ACTH is a 39-amino-acid peptide hormone that is formed from a precursor molecule, pro-opiomelanocortin (POMC) and is synthesized and secreted by corticotrophs in the anterior pituitary. It is stimulated by hypothalamic corticotropin-releasing hormone (CRH). ACTH, in turn, stimulates release of glucocorticoids and androgens from the adrenal cortex.

ACTH Deficiency

Definition. ACTH deficiency causes secondary adrenal insufficiency leading to decreased cortisol and adrenal androgens. Aldosterone secretion from the adrenal glands is not impaired because it is maintained via the renin-angiotensin axis. Causes of ACTH deficiency

can be found in Table 64.4. Central (secondary and tertiary) adrenal insufficiency is most commonly iatrogenic, caused by the use of steroids for other disease processes.

Clinical presentation. Both primary and central adrenal insufficiency are characterized by weight loss, fatigue, muscle weakness, orthostatic symptoms, nausea, vomiting, diarrhea, and abdominal pain. Biochemical abnormalities include hyponatremia, hypoglycemia, eosinophilia, and anemia. Importantly, hyperpigmentation of the skin and hyperkalemia are seen only with primary adrenal insufficiency, not with ACTH deficiency.

Diagnosis and differential diagnosis. Typically, an 8 AM fasting serum cortisol greater than 10 mcg/dL suggests against adrenal insufficiency whereas a value less than 3 mcg/dL is strongly suggestive of adrenal insufficiency. An inappropriately low morning cortisol and ACTH likely suggests secondary adrenal insufficiency. Many times, it is appropriate to perform an ACTH stimulation test. This test measures the cortisol response to synthetic ACTH or cosyntropin. ACTH and cortisol levels are measured at baseline, followed by cortisol levels at 30 and 60 minutes. A peak plasma cortisol level higher than 14 mcg/dL by liquid chromatography tandem mass spectrometry (LC-MS/MS) is considered a normal response. It is important to keep in mind that if secondary adrenal insufficiency is recent, the adrenal glands may initially respond appropriately to cosyntropin because they have not had time to atrophy.

Treatment. Glucocorticoid therapy in the form of hydrocortisone (10 mg in AM and 5 mg in PM) or prednisone (5 to 7.5 mg/day) should be initiated for replacement. Patient education regarding stress dosing of steroids is important. Mineralocorticoids are usually not needed in patients with central secondary adrenal insufficiency.

ACTH-Secreting Pituitary Tumors (Cushing's Disease)

Definition and epidemiology. ACTH-secreting pituitary tumors (by definition, Cushing's disease) account for about 80% of the cases of Cushing's syndrome; they are usually microadenomas. Cushing's syndrome includes any condition of hypercortisolism regardless of the cause. There is a female preponderance (female-to-male ratio, about 3:1). The chronic stimulation by excessive ACTH causes simple diffuse hyperplasia of the bilateral adrenal glands or sometimes multinodular hyperplasia, both leading to excessive cortisol production.

Clinical presentation. Signs and symptoms of Cushing's disease are related to the hypercortisolism and include central obesity, hirsutism, facial plethora, violaceous striae, supraclavicular and dorsocervical fat pads, and proximal muscle weakness (Fig. 64.2). Additional manifestations of Cushing's disease are type 2 diabetes mellitus, hypertension, dyslipidemia, premature coronary artery disease, osteoporosis, and hypogonadism.

Diagnosis and differential diagnosis. Three different tests are performed in combination to assess for endogenous hypercortisolism. A 24-hour urine collection may show an elevated cortisol level, but this test is not reliable in patients with renal dysfunction. A second test, the 1-mg dexamethasone suppression test, measures an 8 AM fasting cortisol level after a dose of 1 mg dexamethasone given at 11 PM the night before. Cortisol suppression to less than 1.8 $\mu\text{g/dL}$ is considered a normal response. Another diagnostic test is the late-night salivary cortisol measurement, using saliva collected at 11 PM on two consecutive nights. The test relies on a normal sleep cycle. Individuals who are using inhaled or topical steroids are not good candidates because of a high rate of false-positive results. A single positive finding is not sufficient to make this diagnosis and must be repeated and confirmed by doing additional tests. Because of the potential of cyclic ACTH overproduction by these tumors, repeat testing is recommended for individuals with high clinical suspicion but negative initial testing.

Fig. 64.2 Clinical features of Cushing's syndrome. (A) Centripetal and some generalized obesity and dorsal kyphosis in a 30-year-old woman with Cushing's disease. (B) Moon facies, plethora, hirsutism, and enlarged supraclavicular fat pads in the same woman as in A. (C) Facial rounding, hirsutism, and acne in a 14-year-old girl with Cushing's disease. (D) Central and generalized obesity and moon facies in a 14-year-old boy with Cushing's disease. Typical centripetal obesity with livid abdominal striae in a 41-year-old woman (E) and a 40-year-old man (F) with Cushing's disease. (G) Striae in a 24-year-old patient with congenital adrenal hyperplasia treated with excessive doses of dexamethasone as replacement therapy. (H) Typical bruising and thin skin of a patient with Cushing's disease. In this case, the bruising has occurred without obvious injury. (From Larsen PR, Kronenberg H, Melmed S, et al: *Williams Textbook of Endocrinology*, ed 10, Philadelphia, 2003, Saunders.)

Pathologic hypercortisolism should be differentiated from physiologic activation of the hypothalamic-pituitary-adrenal axis or pseudo-Cushing's syndrome, which can be observed in conditions such as critical illness, eating disorders, alcoholism, pregnancy, severe neuropsychiatric illness, and poorly controlled diabetes. The desmopressin (DDAVP) stimulation test may be useful to distinguish patients with Cushing's disease from those with pseudo-Cushing's syndrome. Further, pathologic hypercortisolism can be ACTH dependent or independent. Once the diagnosis of ACTH-dependent hypercortisolism is established, a pituitary MRI should be performed looking for a corticotroph adenoma; however, 40% to 45% of ACTH-secreting pituitary tumors are not seen on MRI. In those cases with no or small pituitary tumors and ACTH-dependent Cushing's syndrome, inferior petrosal sinus sampling (IPSS) for ACTH with CRH stimulation differentiates between pituitary and ectopic ACTH overproduction by demonstrating a pituitary-to-peripheral ACTH gradient.

Treatment and prognosis. The treatment involves removal of the pituitary tumor by an experienced neurosurgeon. Options after a failed resection include reoperation, bilateral adrenalectomy, radiotherapy, or pharmacotherapy. Pharmacotherapeutic agents include ketoconazole, metyrapone, mitotane, cabergoline, pasireotide, and mifepristone. In severe cases, intravenous etomidate may be used to stabilize patients for surgery. Long-term remission after resection of a pituitary microadenoma ranges from 69% to 98%, with a recurrence rate of 3% to 19%.

Gonadotropins

Definition

The two gonadotropins, LH and FSH, are glycoprotein hormones that are synthesized and secreted by gonadotrophs in the anterior pituitary. They are both composed of an alpha and a beta subunit, the latter of which gives each its specific biologic function. These hormones bind to the receptors in the gonads (ovaries and testes) and modulate gonadal function. Secretion is regulated both by gonadotropin-releasing hormone (GnRH) from the hypothalamus and by feedback from circulating sex steroids (estrogen and testosterone).

Gonadotropin Deficiency (Hypogonadotropic Hypogonadism)

Definition. Hypogonadotropic hypogonadism is characterized by low levels of sex steroids (estrogen or testosterone) along with low or inappropriately normal FSH and LH.

Clinical presentation. Signs and symptoms depend on the time of onset and the extent of gonadotropin deficiency. If deficiency occurs during fetal life, it can cause ambiguous genitalia. If deficiency occurs after birth but before puberty, it can cause delayed or absent sexual development. Onset after puberty causes menstrual disturbances in women and sexual dysfunction and gynecomastia in men. Osteoporosis and infertility can be present in both sexes.

Diagnosis and differential diagnosis. The diagnosis is made by the presence of low or inappropriately normal FSH and LH levels along with low sex steroids (estrogen or testosterone). Causes of gonadotropin deficiency can be congenital (Kallman syndrome,

Prader-Willi syndrome, septo-optic dysplasia) or acquired, as in hemochromatosis, hyperprolactinemia, sellar tumors, cranial irradiation, and inflammatory and infiltrative disorders.

Treatment and prognosis. For women, replacement therapy in the form of oral or transdermal estrogen should be continued until the age of natural menopause. Progesterone is essential in women with an intact uterus to prevent endometrial hyperplasia. For men, testosterone replacement is available in multiple forms, including injections, implantable pellets, several gels, and a patch. Exogenous testosterone does not restore fertility and in fact inhibits spermatogenesis. For both men and women, fertility treatment requires the use of gonadotropin therapy.

Gonadotropin-Secreting Pituitary Tumors

Definition and epidemiology. Gonadotropin-secreting pituitary tumors are considered nonfunctional. They are usually large and known as the most common macroadenoma. These tumors can secrete FSH, LH, and/or alpha subunit. Nonfunctioning pituitary adenomas are the second most common pituitary adenoma after prolactinomas. They have a prevalence of 7 to 22 per 100,000 population.

Diagnosis and differential diagnosis. Gonadotropin-secreting pituitary tumors typically manifest with signs and symptoms of mass effect. Patients can also have symptoms of pituitary hormone deficiencies. Hormonal evaluation reveals elevated FSH, LH, and/or alpha subunit in the absence of low estrogen or testosterone. Immunoperoxidase staining on tumor tissue is also needed to establish the diagnosis, especially as seen in postmenopausal women when gonadotropins are appropriately elevated.

Treatment and prognosis. Primary treatment is transsphenoidal surgical removal, which is generally successful. Radiation therapy may be used as an adjunct treatment because of the larger size of these tumors at diagnosis. Medical therapy is not used because no effective therapy exists.

DISORDERS OF POSTERIOR PITUITARY HORMONES

AVP and oxytocin are the two hormones that are produced in the hypothalamus and stored in and released from the posterior pituitary.

Diabetes Insipidus

Definition

Diabetes insipidus (DI) is characterized by AVP deficiency and excretion of large volumes of dilute urine. Central DI (posterior pituitary in origin) can be familial due to an autosomal dominant mutation in the vasopressin gene that affects the functioning of the AVP-producing neurons. It can also be acquired secondary to intrasellar and suprasellar tumors, infiltration of the hypothalamus and posterior pituitary, infection, trauma or surgery, or as part of an autoimmune condition. [Table 64.7](#) gives a more extensive list of causes of diabetes insipidus.

Clinical Presentation

Polyuria (defined as excretion of more than 3 L of urine per day) and polydipsia are the clinical hallmarks of DI.

Diagnosis and Differential Diagnosis

DI can be central, caused by AVP deficiency, or nephrogenic, caused by resistance to AVP. As long as access to free water is maintained and the thirst mechanism is intact, patients with DI are usually able to maintain normal serum sodium levels and osmolality. The water deprivation test is the primary test used to make the

diagnosis and to differentiate the cause of DI. In patients with DI, the serum sodium level and osmolality increase in response to water deprivation. The response to a synthetic analogue of vasopressin is analyzed if the normal rise in urine osmolality and decrease in urine volume are not seen. Patients with central DI respond to the synthetic analogue by increasing urine osmolality and decreasing urine volume. In contrast, patients with nephrogenic DI do not respond to the synthetic vasopressin. Patients with partial central DI may have a limited response. Primary polydipsia is characterized by increased water intake without a deficiency or resistance to AVP. Patients with primary polydipsia concentrate their urine without the need for synthetic vasopressin. Copeptin, also derived from arginine vasopressin prohormone, is recently being studied as an arginine vasopressin surrogate to differentiate central and nephrogenic DI and primary polydipsia, using a direct measurement of hypertonic saline-stimulated plasma copeptin rather than the indirect water deprivation test.

Treatment

Replacement therapy with DDAVP, an analogue of AVP, is available in oral (desmopressin), parenteral, and intranasal forms. Aqueous vasopressin is a shorter-acting analogue of AVP that can be given subcutaneously in the immediate postoperative period. Because of the transient nature of DI and a possible shift to a transient syndrome of inappropriate secretion of antidiuretic hormone (SIADH) phase in the patient who has undergone pituitary surgery, AVP is given cautiously and not as a scheduled medication in order to avoid hyponatremia.

Syndrome of Inappropriate Secretion of Antidiuretic Hormone

SIADH is covered in the discussion of hyponatremia in [Chapter 25](#).

Thyroid Gland

Theodore C. Friedman

INTRODUCTION

The thyroid gland secretes thyroxine (T_4) and triiodothyronine (T_3), both of which modulate energy utilization and heat production and facilitate growth. The gland consists of two lateral lobes joined by an isthmus (E-Fig. 65.1). The weight of the adult gland is 10 to 20 g. Microscopically, the thyroid is composed of several follicles that contain colloid surrounded by a single layer of thyroid epithelium. The follicular cells synthesize thyroglobulin, which is stored as colloid. Biosynthesis of T_4 and T_3 occurs by iodination of tyrosine molecules in thyroglobulin.

THYROID HORMONE PHYSIOLOGY

Thyroid Hormone Synthesis

Dietary iodine is essential for the synthesis of thyroid hormones. Iodine, after conversion to iodide in the stomach, is rapidly absorbed from the gastrointestinal tract. After active transport from the bloodstream across the follicular cell basement membrane, iodide is enzymatically oxidized by thyroid peroxidase, which also mediates the iodination of the tyrosine residues in thyroglobulin, to form monoiodotyrosine and diiodotyrosine. The iodotyrosine molecules couple to form T_4 (3,5,3',5'-tetraiodothyronine) or T_3 (3,5,3'-triiodothyronine). Once iodinated, thyroglobulin containing newly formed T_4 and T_3 is stored in the follicles. Secretion of free T_4 and T_3 into the circulation occurs after proteolytic digestion of thyroglobulin, which is stimulated by thyroid-stimulating hormone (TSH). Deiodination of monoiodotyrosine and diiodotyrosine by iodotyrosine deiodinase releases iodine, which then reenters the thyroid iodine pool (E-Fig. 65.2).

Thyroid Hormone Transport

T_4 and T_3 are tightly bound to the serum carrier proteins thyroxine-binding globulin (TBG), thyroxine-binding prealbumin, and albumin. The unbound or free fractions are the biologically active fractions; they represent only 0.04% of the total T_4 and 0.4% of the total T_3 .

Peripheral Metabolism of Thyroid Hormones

The normal thyroid gland secretes T_4 , T_3 , and reverse T_3 , a biologically inactive form of T_3 . Most of the circulating T_3 is derived from deiodination of circulating T_4 in the peripheral tissues. Deiodination of T_4 can occur at the outer ring (5'-deiodination), producing T_3 (3,5,3'-triiodothyronine), or at the inner ring (5-deiodination), producing reverse T_3 (3,3,5'-triiodothyronine).

Control of Thyroid Function

Hypothalamic thyrotropin-releasing hormone (TRH) is transported through the hypothalamic-hypophyseal portal system to the thyrotrophs of the anterior pituitary gland, stimulating synthesis and release

of TSH (Fig. 65.1). TSH, in turn, increases thyroidal iodide uptake and iodination of thyroglobulin, releases T_3 and T_4 from the thyroid gland by increasing hydrolysis of thyroglobulin, and stimulates thyroid cell growth. Hypersecretion of TSH results in thyroid enlargement (goiter). Circulating T_3 exerts negative feedback inhibition of TRH and TSH release.

Physiologic Effects of Thyroid Hormones

Thyroid hormones increase the basal metabolic rate by increasing oxygen consumption and heat production in several body tissues. Thyroid hormones also have specific effects on several organ systems (Table 65.1). These effects are exaggerated in hyperthyroidism and reduced in hypothyroidism, accounting for the well-recognized signs and symptoms of these two disorders.

THYROID EVALUATION

A careful thyroid examination is essential in evaluating a patient with thyroid disease (Video 65.1). Thyroid gland function and structure can be evaluated by (1) determining serum thyroid hormone levels, (2) imaging thyroid gland size and architecture, (3) measuring thyroid autoantibodies, and (4) performing a thyroid gland biopsy by fine-needle aspiration (FNA).

Tests of Serum Thyroid Hormone Levels

Measurements of total serum T_4 and total T_3 indicate the total amount of hormone bound to thyroid-binding proteins by radioimmunoassay. Total T_4 and T_3 levels are elevated in hyperthyroidism and low in hypothyroidism. Increased production of TBG (as with pregnancy or estrogen

Thyroglobulin is a precursor for the thyroid hormones. *DIT*, Diiodotyrosine; *ER*, endoplasmic reticulum; *MIT*, monoiodotyrosine; *NIS*, sodium/iodide symporter; *RT₃*, reverse triiodothyronine; *T₃*, triiodothyronine; *T₄*, thyroxine; *Tg*, thyroglobulin. (From Hall JE: Thyroid metabolic hormones. In Hall JE, editor: Guyton and Hall Textbook of Medical Physiology, ed 12, Philadelphia, 2011, Saunders, Figure 76-2.)

therapy) increases the total T_4 and T_3 levels without actual hyperthyroidism. Similarly, total T_4 and T_3 are low despite euthyroidism in conditions associated with low levels of thyroid-binding proteins (e.g., congenital decrease, protein-losing enteropathy, cirrhosis, nephrotic syndrome). Therefore, further tests to assess the free hormone levels, which reflect biologic activity, must be performed. Free T_4 and free T_3 levels can be measured directly or by dialysis or ultrafiltration and have, at most institutions, replaced measuring total T_4 and T_3 levels.

Serum TSH is measured by a third-generation immunometric assay that accurately discriminates between normal TSH levels and levels below the normal range. Thus, the TSH assay can diagnose clinical hyperthyroidism (elevated free T_4 and free T_3 and suppressed TSH) and subclinical hyperthyroidism (normal free T_4 and free T_3 and suppressed TSH). In hyperthyroidism, the free T_3 may be elevated in the presence of a normal free T_4 . In primary (thyroidal) hypothyroidism, serum TSH is supranormal because of diminished feedback inhibition. The TSH is usually low but may be normal in secondary (pituitary) or tertiary (hypothalamic) hypothyroidism.

Serum thyroglobulin measurements are useful in the follow-up of patients with papillary or follicular carcinoma. After thyroidectomy and iodine-131 (^{131}I) ablation therapy, thyroglobulin levels should be less than 0.5 ng/mL while the patient is on suppressive levothyroxine treatment. Levels in excess of this value indicate the possibility of persistent or metastatic disease.

Calcitonin is produced by the C cells of the thyroid and has a minor role in calcium homeostasis. Calcitonin measurements are invaluable in the diagnosis of medullary carcinoma of the thyroid and for monitoring the effects of therapy for this entity.

Thyroid Imaging

Technetium-99m ($^{99\text{m}}\text{Tc}$) pertechnetate is concentrated in the thyroid gland and can be scanned with a gamma camera, yielding information about the size and shape of the gland and the location of the functional activity in the gland (thyroid scan). The thyroid scan is often performed in conjunction with a quantitative assessment of radioactive iodine (^{123}I) uptake by the thyroid. Functioning thyroid nodules are called *warm* or *hot* nodules; *cold* nodules are nonfunctioning.

Malignancy is usually associated with a cold nodule; 16% of surgically removed cold nodules are malignant.

Thyroid ultrasound evaluation is useful in the differentiation of solid nodules from cystic nodules and to determine which patients should undergo an FNA. The use of thyroid ultrasounds in patients with thyroid nodules is discussed later.

Thyroid Antibodies

Autoantibodies to several different antigenic components in the thyroid gland, including thyroglobulin (TgAb), thyroid peroxidase (TPO Ab, formerly called *antimicrosomal antibodies*), and the TSH receptor, can be measured in the serum. A strongly positive test for TPO Ab indicates autoimmune thyroid disease. Elevated TSH receptor antibody occurs in Graves' disease (see later discussion).

Thyroid Biopsy

FNA of a nodule (E-Fig. 65.3) to obtain thyroid cells for cytologic evaluation is the best way to differentiate benign from malignant disease. FNA requires adequate tissue samples and interpretation by an experienced cytologist.

HYPERTHYROIDISM

Thyrotoxicosis is the clinical syndrome that results from elevated levels of circulating thyroid hormones. Clinical manifestations of thyrotoxicosis result from the direct physiologic effects of the thyroid hormones as well as the increased sensitivity to catecholamines. Tachycardia, tremor, stare, sweating, and lid lag are all caused by catecholamine hypersensitivity.

Signs and Symptoms

Table 65.2 lists the signs and symptoms of hyperthyroidism. Thyrotoxic crisis, or *thyroid storm*, is a life-threatening complication of hyperthyroidism that can be precipitated by surgery, radioactive iodine therapy, or severe stress (e.g., uncontrolled diabetes mellitus, myocardial infarction, acute infection). Patients develop fever, flushing, sweating, significant tachycardia, atrial fibrillation, and cardiac failure. Significant agitation, restlessness, delirium, and coma frequently

TABLE 65.1 Physiologic Effects of Thyroid Hormone

System	Effects
Cardiovascular	Increased heart rate and cardiac output
Gastrointestinal	Increased gut motility
Skeletal	Increased bone turnover and resorption
Pulmonary	Maintenance of normal hypoxic and hypercapnic drive in the respiratory center
Neuromuscular	Increased muscle protein turnover and increased speed of muscle contraction and relaxation
Metabolism of lipids and carbohydrates	Increased hepatic gluconeogenesis and glycogenolysis, as well as intestinal glucose absorption Increased cholesterol synthesis and degradation Increased lipolysis
Sympathetic nervous system	Increased numbers of β -adrenergic receptors in the heart, skeletal muscle, lymphocytes, and adipose cells Decreased cardiac α -adrenergic receptors Increased catecholamine sensitivity
Hematopoietic	Increased red blood cell 2,3-diphosphoglycerate, facilitating oxygen dissociation from hemoglobin with increased oxygen available to tissues

(B) Longitudinal image of a benign thyroid nodule in a different patient shows an incomplete, delicate thin rim of calcification at the inferior pole of a nodule proven to represent a benign hemorrhagic cyst. (From Desser TS, Kamaya A: Ultrasound of thyroid nodules, *Neuroimaging Clin N Am* 18:463-478, 2008.)

occur. Gastrointestinal manifestations may include nausea, vomiting, and diarrhea. Hyperpyrexia out of proportion to other clinical findings is the hallmark of thyroid storm.

Differential Diagnosis

Thyrotoxicosis usually reflects excess secretion of thyroid hormones resulting from Graves' disease, toxic adenoma, multinodular goiter, or thyroiditis (Table 65.3 and Fig. 65.2). However, it may be the result of excessive ingestion of thyroid hormone or, rarely, thyroid hormone production from an ectopic site (as in struma ovarii).

Graves' Disease

Graves' disease, the most common cause of thyrotoxicosis, is an autoimmune disease that is more common in women, with a peak incidence between 20 and 50 years of age. One or more of the following features are present: (1) goiter; (2) thyrotoxicosis; (3) eye disease ranging from tearing to proptosis, extraocular muscle paralysis, and loss of sight as a result of optic nerve involvement; and (4) thyroid dermopathy, usually observed as significant skin thickening without pitting in a pretibial distribution (*pretibial myxedema*). (Do not confuse this use of myxedema with that described below under the discussion of the clinical features of *hypothyroidism*.)

Pathogenesis. Thyrotoxicosis in Graves' disease is caused by overproduction of an antibody that binds to the TSH receptor. These thyroid-stimulating immunoglobulins increase thyroid cell growth and thyroid hormone secretion. Ophthalmopathy results from inflammatory infiltration of the extraocular eye muscles by lymphocytes with mucopolysaccharide deposition. The inflammatory reaction that contributes to the eye signs in Graves' disease may be caused by sensitization of lymphocytes to antigens that are common to the orbital muscles and the thyroid.

Clinical presentation. The common manifestations of thyrotoxicosis (see Table 65.2) are characteristic features of younger patients with Graves' disease. In addition, patients may exhibit a diffuse goiter or the eye signs characteristic of Graves' disease. Older patients often do not have the florid clinical features of thyrotoxicosis, and the condition termed *apathetic hyperthyroidism* is exhibited as flat affect, emotional lability, weight loss, muscle weakness, congestive heart failure, and atrial fibrillation resistant to standard therapy.

TABLE 65.3 Causes of Thyrotoxicosis

Common Causes

Graves' disease
Toxic adenoma (solitary)
Toxic multinodular goiter

Less Common Causes

Subacute thyroiditis (de Quervain or granulomatous thyroiditis)
Hashimoto thyroiditis with transient hyperthyroid phase
Thyrotoxicosis factitia
Postpartum thyroiditis (probably variant of silent thyroiditis)

Rare Causes

Struma ovarii
Metastatic thyroid carcinoma
Hydatidiform mole
TSH-secreting pituitary tumor

TSH, Thyroid-stimulating hormone.

Eye signs associated with Graves' disease may also occur as a non-specific manifestation of hyperthyroidism from any cause (e.g., thyroid stare). In Graves' disease, a specific inflammatory infiltrate of the orbital tissues leads to periorbital edema, conjunctival congestion and swelling, proptosis, extraocular muscle weakness, or optic nerve damage with visual impairment (E-Fig. 65.4).

Pretibial myxedema (thyroid dermopathy) (E-Fig. 65.5) occurs in 2% to 3% of patients with Graves' disease and results in a thickening of the skin over the lower tibia without pitting. Onycholysis, characterized by separation of the fingernails from their beds, often occurs in patients with Graves' disease. Thyroid acropachy, or clubbing, may also occur.

Diagnosis. Elevated total or free T_4 or T_3 (or both) and a suppressed TSH confirm the clinical diagnosis of thyrotoxicosis. TSH receptor antibody is usually elevated, and its measurement may be useful in patients with eye signs who do not have other characteristic clinical features. Increased uptake of ^{123}I differentiates Graves' disease from early subacute or Hashimoto thyroiditis, in which uptake is low in the presence of hyperthyroidism. Magnetic resonance imaging or ultrasonography of the orbit usually shows orbital muscle enlargement, whether or not clinical signs of ophthalmopathy are observed.

Treatment. Three treatment modalities are used to control the hyperthyroidism of Graves' disease: antithyroid drugs, radioactive iodine therapy, and surgery. In Europe, Latin America, and Japan, antithyroid drugs are the favored therapy while in the United States, radioactive iodine is the main therapy. However, more recently antithyroid drugs are becoming the mainstay of treatment for Graves' disease worldwide.

Antithyroid drugs. The thiocarbamide drugs propylthiouracil, methimazole, and carbimazole block thyroid hormone synthesis

by inhibiting thyroid peroxidase. Propylthiouracil also partially inhibits peripheral conversion of T_4 to T_3 . Medical therapy is usually administered for a prolonged period (1 to 3 years), with the dose gradually reduced until spontaneous remission occurs. Many patients can remain on low doses of thiocarbamide drugs for long periods of time without significant side effects. One approach is to gradually decrease the dose while maintaining T_4 and T_3 in the normal range, leaving patients on low doses of thiocarbamide drugs if T_4 and T_3 remain high after a gradual taper. After cessation of medication, 40% to 60% of patients remain in remission. Those who experience relapse can either resume therapy with thiocarbamide drugs or undergo definitive surgery or radioactive iodine treatment. Side effects of the thiocarbamide regimen include pruritus and rash (in about 5% of patients), elevated liver function enzymes, cholestatic jaundice, acute arthralgias, and, rarely, agranulocytosis (<0.5% of patients).

Methimazole was found to be more effective at normalizing thyroid hormone levels and led to a lower rate of transaminase elevation and leukopenia than propylthiouracil; it has now become the preferred medical treatment for hyperthyroidism. Methimazole can be given once a day as long as the total dose is 30 mg or less, leading to better compliance, whereas PTU is usually given two to three times a day. At the onset of treatment during the acute phase of thyrotoxicosis, β -adrenergic receptor blockers can be used to help alleviate tachycardia, hypertension, and atrial fibrillation in symptomatic patients. As the thyroid hormone levels return to normal, the treatment with β -blockers is tapered off.

Radioactive iodine. Radioactive iodine (^{131}I) can be used for treating adults with Graves' disease. However, 80% to 90% of patients become hypothyroid after radiotherapy and require lifelong thyroid hormone replacement. As discussed later, a percentage of patients treated with levothyroxine for hypothyroidism continue to have hypothyroid symptoms despite normalization of TSH; this has caused a shift in the paradigm that radioactive iodine is the preferred treatment of hyperthyroidism, with a greater emphasis on using thiocarbamide drugs. ^{131}I has been found to increase the incidence of cancer mortality. ^{131}I is contraindicated in women who are pregnant, but it does not increase the risk of birth defects in offspring conceived after ^{131}I therapy. Patients with severe thyrotoxicosis, very large glands, or underlying heart disease should be rendered euthyroid with antithyroid medication before receiving radioactive iodine, because ^{131}I treatment can cause a release of preformed thyroid hormone from the thyroid gland that could precipitate cardiac arrhythmias and exacerbate symptoms of thyrotoxicosis.

After administration of radioactive iodine, the thyroid gland shrinks; patients become euthyroid and later hypothyroid over a period of 6 weeks to 3 months. Serum free T_4 and TSH levels should be monitored, and replacement with levothyroxine should be instituted when hypothyroidism occurs. Hypothyroidism always occurs after surgical total thyroidectomy, frequently after subtotal thyroidectomy or administration of radioactive iodine, and in a smaller percentage of patients after antithyroid medication; therefore, lifelong monitoring of all patients with Graves' disease is mandated.

Surgery. Either subtotal or total thyroidectomy is the treatment of choice for patients with very large glands and obstructive symptoms, those with multinodular glands, and sometimes in those who desire pregnancy within the next year. It is essential that the surgeon be experienced in thyroid surgery. Preoperatively, patients receive 6 weeks of treatment with antithyroid drugs to ensure that they are euthyroid at the time of surgery. Two weeks before surgery, oral saturated solution of potassium iodide is administered daily to decrease the vascularity of the gland. Permanent hypoparathyroidism and recurrent laryngeal nerve paralysis occur postoperatively in fewer

than 2% of patients, although the rate of transient postoperative hypocalcemia is higher.

Graves' orbitopathy can be treated with glucocorticoids, orbital radiotherapy, or surgery. It was recently found that selenium is effective for Graves' orbitopathy.

Toxic Adenoma

Solitary toxic nodules, which are usually benign, occur more frequently in older patients. The clinical manifestations are those of thyrotoxicosis. Physical examination shows a distinct solitary nodule. Laboratory investigation shows suppressed TSH and significantly elevated T_3 levels, often with only moderately elevated T_4 . Thyroid scan shows a hot nodule in the affected lobe with partial or complete suppression of the unaffected lobe. Solitary toxic nodules are usually treated with radioactive iodine. Euthyroidism results if the unaffected lobe has suppressed uptake on a thyroid scan, and often hypothyroidism occurs if the unaffected lobe does not have suppressed uptake. For large nodules, unilateral lobectomy after the administration of antithyroid drugs to render the patient euthyroid may be required.

Toxic Multinodular Goiter

Toxic multinodular goiter occurs in older patients with long-standing multinodular goiter, especially in patients from iodine-deficient regions when they are exposed to increased dietary iodine or iodine-containing radiocontrast dyes. The presenting clinical features are frequently tachycardia, heart failure, and arrhythmias. Physical examination shows a multinodular goiter. The diagnosis is confirmed by laboratory features of suppressed TSH, elevated T_3 and T_4 , and a thyroid scan showing multiple functioning nodules. The treatment of choice is often ^{131}I ablation. It is especially effective in patients with small glands and a high degree of radioactive uptake. Larger glands may require surgery.

Subclinical Hyperthyroidism

In subclinical hyperthyroidism, total or free T_4 and T_3 levels are normal and TSH is suppressed. The causes of this condition include early presentation of any form of hyperthyroidism (e.g., Graves' disease, toxic adenoma, toxic multinodular goiter). Because these patients, especially those who are older, are at an increased risk for cardiac dysrhythmias, many patients with a persistently suppressed TSH should be treated with thiocarbamide drugs, β -blockers or, less commonly, radioactive iodine. A decreased bone mineral density is another indication for treatment.

Thyroiditis

Thyroiditis may be classified as acute, subacute, or chronic. Although thyroiditis may eventually result in clinical hypothyroidism, the initial presentation is often that of hyperthyroidism as a result of acute release of T_4 and T_3 . Hyperthyroidism caused by thyroiditis can be readily differentiated from other causes of hyperthyroidism by suppressed uptake of radioactive iodine in the thyroid gland, reflecting decreased hormone production by damaged cells.

A rare disorder, acute suppurative thyroiditis, is caused by an infection, usually bacterial. Patients exhibit high fever, redness of the overlying skin, and thyroid gland tenderness; the condition may be confused with subacute thyroiditis. If blood cultures are negative, FNA should identify the organism. Intensive antibiotic treatment and, occasionally, incision and drainage are required.

Subacute Thyroiditis

Subacute thyroiditis (also known as de Quervain thyroiditis or granulomatous thyroiditis) is an acute inflammatory disorder of the thyroid gland that is probably caused by a viral infection and resolves

completely in 90% of cases. Patients with subacute thyroiditis complain of fever and anterior neck pain. The patient may have symptoms and signs of hyperthyroidism. The classic feature on physical examination is an exquisitely tender thyroid gland. Laboratory findings vary with the course of the disease. Initially, the patient may be symptomatically thyrotoxic with elevated serum T_4 , depressed serum TSH and low radioactive iodine uptake on the thyroid scan. Subsequently, the thyroid status fluctuates through euthyroid and hypothyroid phases and may return to euthyroidism. An increase in radioactive iodine uptake on the scan reflects recovery of the gland. Treatment usually includes high-dose aspirin or other nonsteroidal anti-inflammatory drugs, but a short course of prednisone may be required if pain and fever are severe. During the hypothyroid phase, replacement therapy with levothyroxine may be indicated.

Postpartum thyroiditis resembles subacute thyroiditis in its clinical course. It usually occurs within the first 6 months after delivery and goes through the triphasic course of hyperthyroidism, hypothyroidism, and then euthyroidism, though it may develop with only hypothyroidism. Some patients have underlying chronic thyroiditis.

Chronic Thyroiditis

Chronic thyroiditis (Hashimoto or lymphocytic thyroiditis), caused by destruction of the normal thyroidal architecture by lymphocytic infiltration, results in hypothyroidism and goiter. Riedel struma is probably a variant of Hashimoto thyroiditis; it is characterized by extensive thyroid fibrosis resulting in a rock-hard thyroid mass. Hashimoto thyroiditis is more common in women and is the most common cause of goiter and hypothyroidism in the United States. Occasionally, patients with Hashimoto thyroiditis have transient hyperthyroidism with low radioactive iodine uptake owing to the release of T_4 and T_3 into the circulation. Chronic thyroiditis can be differentiated from subacute thyroiditis in that in the former, the gland is nontender to palpation and antithyroid antibodies are present in high titer. TPO Ab is usually present early and typically remains present for years. The presence of TgAb does not reflect Hashimoto thyroiditis and does not provide additional information beyond the TPO Ab finding. Serum T_3 and T_4 levels are either normal or low; when they are low, the TSH is elevated. FNA of the thyroid shows lymphocytes and Hürthle cells (enlarged basophilic follicular cells). Hypothyroidism and significant glandular enlargement (goiter) are indications for levothyroxine therapy. Adequate doses of levothyroxine are administered to normalize TSH levels and shrink the goiter. Recent evidence that symptoms of profound fatigue, poor sleep quality, and muscle joint pain persist despite levothyroxine supplementation leading to euthyroidism suggests that symptoms may be related to the autoimmune disease per se rather than hypothyroidism.

Thyrotoxicosis Factitia

Patients with thyrotoxicosis factitia ingest excessive amounts of thyroxine, often in an attempt to lose weight, and exhibit typical features of thyrotoxicosis. Serum T_3 and T_4 levels are elevated and TSH is suppressed, as is the serum thyroglobulin concentration. Radioactive iodine uptake is absent. Patients may require psychotherapy.

Rare Causes of Thyrotoxicosis

Struma ovarii occurs when an ovarian teratoma contains thyroid tissue that secretes thyroid hormone. A body scan confirms the diagnosis by demonstrating uptake of radioactive iodine in the pelvis.

Hydatidiform mole is caused by proliferation and swelling of the trophoblast during pregnancy, with excess production of chorionic gonadotropin, which has intrinsic TSH-like activity. The

hyperthyroidism remits with surgical and medical treatment of the molar pregnancy.

HYPOTHYROIDISM

Hypothyroidism is a clinical syndrome caused by deficiency of thyroid hormones. In infants and children, hypothyroidism causes retardation of growth and development and may result in permanent motor and mental retardation. Congenital causes of hypothyroidism include agenesis (complete absence of thyroid tissue), dysgenesis (ectopic or lingual thyroid gland), hypoplastic thyroid, thyroid dysmorphogenesis, and congenital pituitary diseases. Adult-onset hypothyroidism results in a slowing of metabolic processes and is reversible with treatment. Hypothyroidism is usually primary (thyroid failure), but it may be secondary (hypothalamic or pituitary deficiency) or rarely the result of resistance at the thyroid hormone receptor (Table 65.4).

In adults, autoimmune thyroiditis (Hashimoto thyroiditis) is the most common cause of hypothyroidism. This condition may be

isolated, or it may be part of polyglandular failure syndrome type II (Schmidt syndrome), which also includes insulin-dependent diabetes mellitus, adrenal insufficiency, pernicious anemia, vitiligo, gonadal failure, hypophysitis, celiac disease, myasthenia gravis, and primary biliary cirrhosis. Iatrogenic causes of hypothyroidism include ^{131}I therapy, thyroidectomy, and treatment with lithium, amiodarone, opioids, and glucocorticoids, as well as CTLA-4 and PD-1 inhibitors (cancer immunotherapy agents), with the last two drug classes causing painless thyroiditis and transient hyperthyroidism followed by hypothyroidism. Iodine deficiency or excess can also cause hypothyroidism.

Clinical Presentation

The clinical presentation of hypothyroidism (Table 65.5) depends on the age at onset and the severity of the thyroid deficiency. Infants with congenital hypothyroidism (also called *cretinism*) may exhibit feeding problems, hypotonia, inactivity, an open posterior fontanelle, and edematous face and hands. Mental retardation, short stature, and delayed puberty occur if treatment is delayed.

Hypothyroidism in adults usually develops insidiously. Patients often complain of fatigue, lethargy, and gradual weight gain for years before the diagnosis is established. A delayed relaxation phase of deep tendon reflexes (*hung-up* reflexes) is a valuable clinical sign that is characteristic of severe hypothyroidism. Subcutaneous infiltration by mucopolysaccharides, which bind water, causes the edema; this condition, termed *myxedema*, is responsible for the thickened features and puffy appearance of patients with severe hypothyroidism.

Severe untreated hypothyroidism can result in *myxedema coma*, which is characterized by hypothermia, extreme weakness, stupor, hypoventilation, hypoglycemia, and hyponatremia and is often precipitated by cold exposure, infection, or psychoactive drugs. (Do not confuse the uses of myxedema here with *pretibial myxedema* seen in Graves' disease, where it refers to thyroid dermopathy—skin thickening without pitting.)

Diagnosis

Because the initial manifestations of hypothyroidism are subtle, early diagnosis demands a high index of suspicion in patients with one or more of the signs and symptoms (see Table 65.5), though hypothyroidism is often picked up in patients who have a TSH measured as

part of routine laboratories. Early symptoms that are often overlooked include menstrual irregularities (usually menorrhagia), arthralgias, and myalgias.

Laboratory abnormalities in patients with primary hypothyroidism include elevated serum TSH and low total and free T_4 . A low or low-normal morning serum TSH level in the setting of hypothalamic or pituitary dysfunction characterizes secondary hypothyroidism. Often, the serum total and free T_4 levels are at the lower limits of normal.

Hypothyroidism is often associated with hypercholesterolemia and elevated creatine phosphokinase skeletal muscle (MM) fraction (the fraction representative of skeletal muscle). Anemia is usually normocytic and normochromic but may be macrocytic (with vitamin B_{12} deficiency resulting from associated pernicious anemia) or microcytic (caused by nutritional deficiencies or menstrual blood loss in women). Because TPO Ab is usually positive in Hashimoto thyroiditis, the major cause of hypothyroidism in adults, its measurement is helpful in deciding whether levothyroxine treatment is appropriate in patients with subclinical hypothyroidism (discussed later).

Treatment

Hypothyroidism should be treated initially with synthetic levothyroxine (T_4). Administration of levothyroxine results in physiologic levels of bioavailable T_3 and T_4 . Levothyroxine has a half-life of 8 days; consequently, it needs to be given only once a day. The average replacement dose of levothyroxine for adults is 75 to 150 $\mu\text{g}/\text{day}$. In healthy adults, 1.6 $\mu\text{g}/\text{kg}/\text{day}$ is an appropriate starting dose. In some older patients and patients with cardiac disease, levothyroxine should be increased gradually, starting at 25 $\mu\text{g}/\text{day}$ and increasing the dose by 25 μg every 2 weeks; however, most patients can safely be started on a full replacement dose. The therapeutic response to levothyroxine therapy should be monitored clinically and with measurement of serum TSH levels 6 to 8 weeks after a dose adjustment. TSH levels between 0.5 and 2 mU/L are considered optimal. Because TSH measurements are not a useful guide in patients with secondary hypothyroidism (pituitary or hypothalamic dysfunction), these patients should be given levothyroxine until their free T_4 is in the mid- to upper-normal range.

Recent studies have suggested that a percentage of patients treated with levothyroxine for hypothyroidism continue to have hypothyroid symptoms despite normalization of TSH. Furthermore, a large study found that more than 20% of athyreotic patients (those who have absence or functional deficiency of the thyroid gland) treated with levothyroxine replacement did not maintain free T_3 or free T_4 values in the normal range despite normal TSH levels. This reflects the inadequacy of peripheral deiodination to compensate for the absent T_3 secretion. Because of these studies, there is renewed interest (accompanied by a large amount of controversy) in treating hypothyroid patients who have not had an adequate clinical response to levothyroxine replacement with a combination of levothyroxine and liothyronine (a manufactured form of T_3) or with desiccated thyroid preparations that contain levothyroxine and liothyronine.

In patients with myxedema coma, 500 to 800 μg of levothyroxine is administered intravenously as a loading dose, followed by 100 $\mu\text{g}/\text{day}$ of levothyroxine, hydrocortisone (100 mg IV intravenously three times daily), and intravenous fluids. Corticosteroids should be given before thyroxine in autoimmune conditions. The underlying precipitating event should be corrected. Respiratory assistance and treatment of hypothermia with warming blankets may be required. Although myxedema coma carries a high mortality rate despite appropriate treatment, many patients improve in 1 to 3 days.

Arthralgias, myalgias

Subclinical Hypothyroidism

In subclinical hypothyroidism, free or total T_4 and T_3 levels are normal or low-normal, and TSH is mildly elevated. Some of these patients develop overt hypothyroidism. The decision as to when to treat patients who have a mildly elevated TSH level is controversial. It is frequently recommended that patients should be treated with levothyroxine if they have a TSH level greater than 5 mU/L on two occasions and either positive anti-TPO Ab test results or a goiter. If the patient does not have an appreciable goiter and has negative anti-TPO Ab test results, many experts suggest that levothyroxine should be given only if the TSH level is greater than 10 mU/L on two occasions. Other experts suggest treatment at lower TSH levels depending on the presence of TPO antibody.

GOITER

Enlargement of the thyroid gland is called a *goiter*. Patients with goiters may be euthyroid (simple goiter), hyperthyroid (toxic nodular goiter or Graves' disease), or hypothyroid (nontoxic goiter or Hashimoto thyroiditis). Thyroid enlargement (often focal) may also be the result of a thyroid adenoma or carcinoma. In nontoxic goiter, inadequate thyroid hormone synthesis leads to TSH stimulation with resultant enlargement of the thyroid gland. Iodine deficiency (endemic goiter) was once the most common cause of nontoxic goiter. Since the widespread availability of iodized salt, endemic goiter is less common in North America.

Goitrogens are agents that can cause a goiter, and iodine and lithium are the two chemicals or drugs that frequently cause a goiter. Natural goitrogens include thioglucosides found in vegetables such as cabbage, broccoli, Brussels sprouts, turnips, cauliflower, kale, and other greens. Other foods that are goitrogens include soybeans and soybean products, peanuts, spinach, sweet potatoes, and some fruits (e.g., strawberries, pears, and peaches). Thyroid hormone biosynthetic defects can cause goiter associated with hypothyroidism (or, with adequate compensation, euthyroidism).

A careful thyroid examination coupled with thyroid hormone tests can reveal the cause of the goiter. A smooth, symmetrical gland, often with a bruit, and hyperthyroidism are suggestive of Graves' disease. A nodular thyroid gland with hypothyroidism and positive antithyroid antibodies is consistent with Hashimoto thyroiditis. A diffuse, smooth goiter with hypothyroidism and negative antithyroid antibodies may be indicative of iodine deficiency or a biosynthetic defect. Goiters can become very large, extending substernally and causing dysphagia, respiratory distress, or hoarseness. An ultrasound evaluation or radioactive iodine scan delineates the thyroid gland, and measurement of the TSH level determines the functional activity of the goiter.

Hypothyroid goiters are treated with thyroid hormone at a dose that normalizes TSH. Previously, euthyroid goiters were treated with levothyroxine therapy; however, regression with levothyroxine therapy is unlikely and is no longer recommended. Surgery is indicated for nontoxic goiter only if obstructive symptoms develop or substantial substernal extension is present.

SOLITARY THYROID NODULES

Thyroid nodules are common. They can be detected clinically in about 4% of the population and are found in about 50% of the population at autopsy. Benign thyroid nodules are usually follicular adenomas, colloid nodules, benign cysts, or nodular thyroiditis. Patients may have one prominent nodule on clinical examination, but thyroid ultrasound evaluation may reveal multiple nodules. Although most nodules are

benign, a small percentage are malignant. Fortunately, most thyroid cancers are low-grade malignancies.

The major etiologic factor for thyroid cancer is childhood or adolescent exposure to head and neck radiation. Previously, radiation was used to treat an enlarged thymus, tonsillar disease, hemangioma, or acne. Exposure to radiation from nuclear plants (e.g., Chernobyl, Ukraine; Fukushima Daiichi, Japan) contributes to an increased incidence of thyroid cancer. Patients with a history of irradiation should have a baseline thyroid ultrasound study, then a repeat study every 5 years.

All patients with a thyroid nodule noticed by the patient or during physical examination by a clinician should undergo a thyroid ultrasound. Patients who are found to have asymptomatic, incidental, non-suspicious thyroid nodules on imaging performed for other reasons should be referred for diagnostic thyroid ultrasound only if they meet the following criteria: (1) younger than 35 years of age with normal life expectancy and nodule 1 cm or greater, or (2) 35 years of age or older with normal life expectancy and nodule 1.5 cm or greater. Radiologists have a standard report and score on thyroid ultrasounds called TI-RADS that ranges from 1 (looks very benign) to 5 (looks like it might be malignant) (Fig. 65.3). Thus, the TI-RADS helps to distinguish which patient with a thyroid nodule should get a biopsy. If the TI-RADS score is 3 and the nodule is larger than 2.5 cm, if the score is 4 and the nodule is larger than 1.5 cm, or if the score is 5 and the nodule is larger than 1 cm, then an FNA is recommended. If the TI-RADS score is lower and the nodule is smaller, a repeat ultrasound in 1 year is recommended, and for even smaller, more benign looking nodules, no follow-up is needed. FNA should be done under ultrasound guidance if possible.

The Bethesda system for reporting thyroid cytopathology (Table 65.6) is used to report FNA results. Molecular testing can now be performed on FNA specimens to help determine whether follicular lesions have molecular characteristics of malignancy and should be removed.

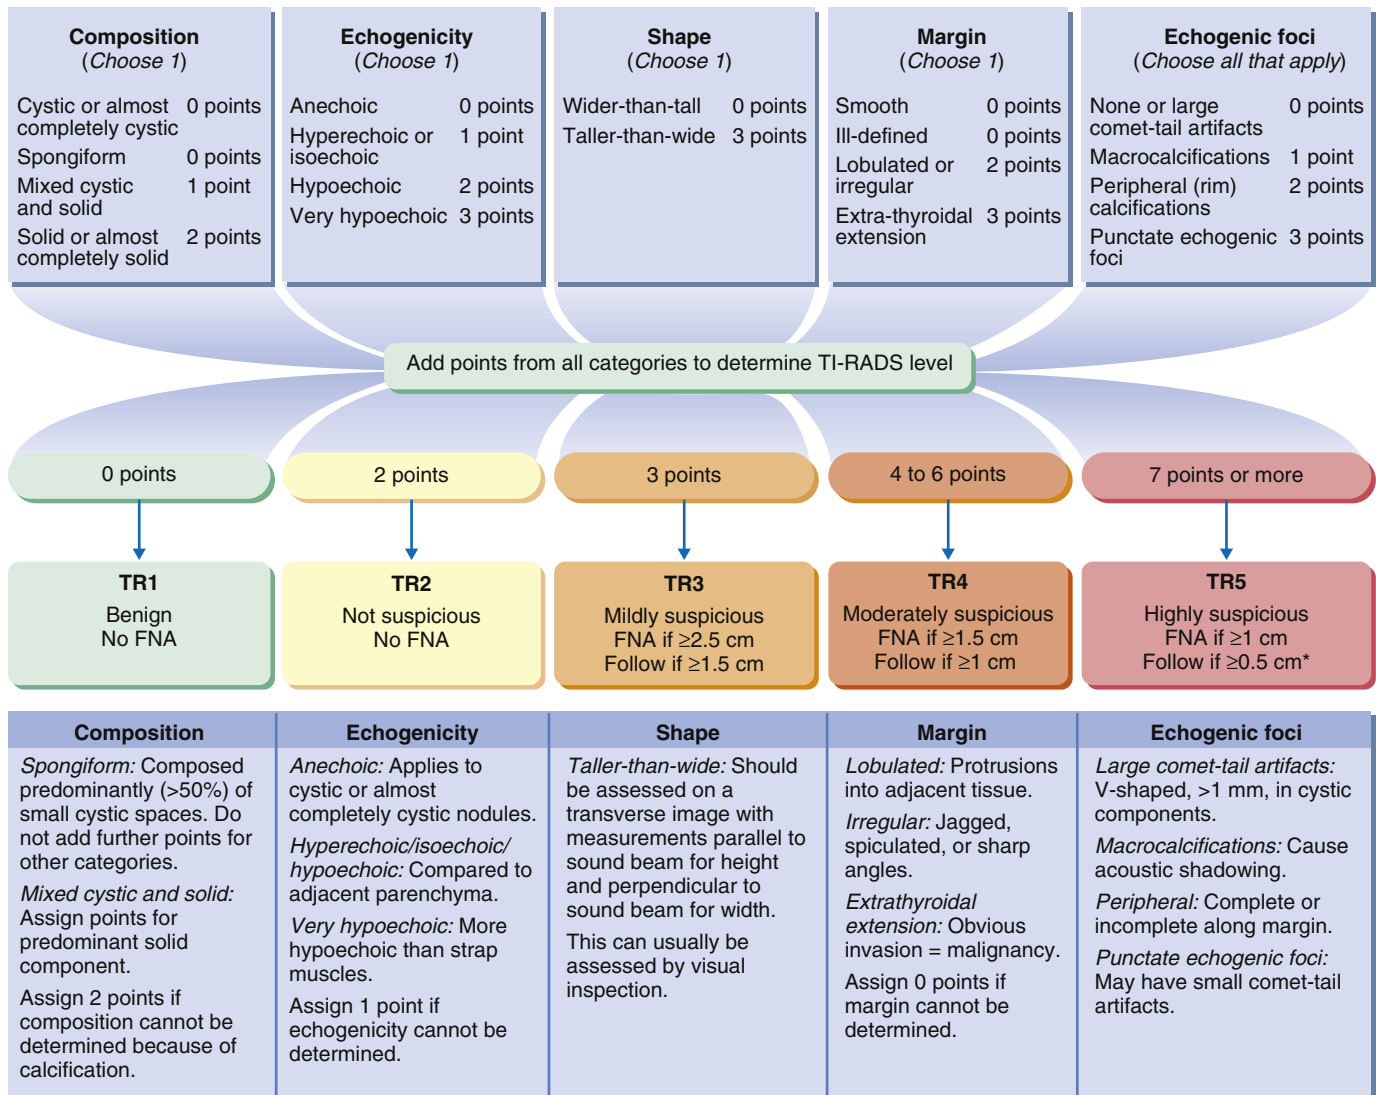

Although in the past benign thyroid nodules were treated with levothyroxine suppression, this is no longer recommended because it is uncommon for thyroid nodules to shrink substantially with levothyroxine.

THYROID CARCINOMA

The types and characteristics of thyroid carcinomas are presented in Table 65.7. Papillary carcinoma is associated with local invasion and lymph node spread. Indicators of poor prognosis include thyroid capsule invasion, size greater than 2.5 cm, age at onset older than 45 years, tall cell or Hürthle cell variant, and lymph node involvement. Follicular carcinoma is slightly more aggressive than papillary carcinoma and can spread by local invasion of lymph nodes or hematogenously to bone, brain, or lung. Many tumors show both papillary and follicular cell types. Patients may exhibit metastases before diagnosis of the primary thyroid lesion. Anaplastic carcinoma tends to occur in older individuals, is very aggressive, and rapidly causes pain, dysphagia, and hoarseness.

Medullary thyroid carcinoma is derived from calcitonin-producing parafollicular cells and is more malignant than papillary or follicular carcinoma. It is multifocal and spreads both locally and distally. It may be either sporadic or familial. When familial, it is inherited in an autosomal dominant pattern and is part of multiple endocrine neoplasia type IIA (medullary carcinoma of the thyroid, pheochromocytoma, and hyperparathyroidism) or multiple endocrine neoplasia type IIB (medullary carcinoma of the thyroid, mucosal neuromas, intestinal ganglioneuromas, marfanoid habitus, and pheochromocytoma). Elevated basal serum calcitonin levels confirm the diagnosis. Evaluation for *RET* proto-oncogene mutations should be performed

ACR TI-RADS

*Refer to discussion of papillary microcarcinomas for 5–9 mm TR5 nodules.

Fig. 65.3 Chart showing five categories on the basis of the ACR Thyroid Imaging, Reporting and Data System (TI-RADS) lexicon, TR levels, and criteria for fine-needle aspiration or follow-up ultrasound. Explanatory notes appear at the bottom.

in patients with medullary carcinoma; if mutations are present, all first-degree relatives should be examined.

Treatment

Lobectomy may be performed for low-risk patients. This includes papillary nodules less than 2.5 cm, TI-RADS score less than 4, absence of neck lymph nodes seen on neck ultrasound, and most follicular tumors. Nodules less than 1 cm with papillary carcinoma can be observed. However, higher risk patients with larger tumors (>3 cm) and/or positive lymph nodes should have a total thyroidectomy. Routine central neck dissection is not needed unless lymph nodes are seen on preoperative imaging or if the surgeon discovers nodes during examination during surgery.

Patients with a lobectomy usually do not need thyroid hormone replacement but should have their TSH monitored. If the TSH goes above range, the patient should be started on levothyroxine. They should have thyroglobulin measured and a thyroid ultrasound every 6 months for the first 2 years and then yearly. A thyroglobulin greater

than 30 ng/mL and/or enlarging nodule on the contralateral lobe or lymph nodes draw concern for recurrent disease and should be evaluated for completion of the thyroidectomy.

After total thyroidectomy, patients with low-risk, small carcinomas may be administered doses of levothyroxine sufficient to keep the TSH level in the low-normal or slightly suppressed range and monitored with serum thyroglobulin determinations and yearly neck ultrasound examinations. In the presence of a stable serum TSH level, one should follow the trend in thyroglobulin values with a rising value being concerning. Ideally the thyroglobulin should be less than 0.5 ng/mL, although values less than 2.5 ng/mL may not require an intervention if the thyroid ultrasound does not show detectable thyroid tissue. Patients with large lesions and those at high risk for persistence or metastatic disease should be treated with radioactive iodine with sufficient levothyroxine administration to suppress serum TSH to subnormal levels for about 5 years after thyroidectomy; after that, normal TSH levels can be targeted if no sign of tumor recurrence is seen.

TABLE 65.6 Bethesda System for Reporting Thyroid Cytopathology

Bethesda Category	Diagnosis	Disposition	Notes
I	Nondiagnostic/Unsatisfactory	Repeat FNA (under ultrasound guidance)	
II	Benign	Clinical follow-up and a repeat ultrasound and a possible repeat biopsy needed if the patient or provider notices the nodule is growing.	
III	Atypia of Undetermined Significance (AUS) or Follicular Lesion of Undetermined Significance (FLUS)	If pathologist determines a FLUS/AUS reading, one additional biopsy should be performed 3-6 months after the initial biopsy. The repeat FNA should include a sample for molecular testing and if the pathology still shows FLUS/AUS, then the sample should be sent out for molecular testing with the results guiding further treatment. If it is still unclear if surgery is needed, ultrasound should be performed to determine if the nodule grows or changes characteristics (higher TI-RADS score). If it does not grow or change characteristics, the nodule could be watched.	A TPO antibody should also be obtained because FLUS/AUS may occur in the context of a Hashimoto gland and its measurement may assist the pathologist. Molecular testing can be used to determine likelihood of malignancy.
IV	Follicular Neoplasm (FN) or Suspicious for a Follicular Neoplasm (SFN)	If initial biopsy shows FN/SFN, a repeat biopsy should be performed 3-6 months later and include a sample for molecular testing with the results guiding further treatment.	Follicular carcinomas cannot be diagnosed on FNA because definitive diagnosis requires identification of capsular/vascular invasion. Molecular testing can be used to determine likelihood of malignancy.
V	Suspicious for Malignancy	As for malignant	
VI	Malignant	Referral to surgery if nodule is >1 cm. Nodules with papillary carcinoma less than 1 cm may not need to be removed and the option of serial ultrasounds (every 6-12 months) should be discussed with the patient. If the patient feels more comfortable with surgery, that can also be an option.	The most common malignancies of the thyroid are well-differentiated malignancies with a favorable prognosis. Of these, the most common is papillary thyroid carcinoma. Other malignancies include medullary thyroid carcinoma, poorly differentiated thyroid carcinoma, undifferentiated (anaplastic) thyroid carcinoma, squamous cell carcinoma, and malignant lymphoma. Metastases to the thyroid from other malignancies can occur as well

TABLE 65.7 Characteristics of Thyroid Cancers

Type of Cancer	Percentage of Thyroid Cancers	Age at Onset (Yr)	Treatment	Prognosis
Papillary	85	40-80	Lobectomy or thyroidectomy, aggressive cases should receive radioactive iodine ablation	Good
Follicular	10	45-80	Lobectomy or thyroidectomy in aggressive cases	Fair to good
Medullary	3	20-50	Thyroidectomy and central compartment lymph node dissection	Fair
Anaplastic	1	50-80	Isthmusectomy followed by palliative radiograph treatment	Poor
Lymphoma	1	25-70	Radiograph therapy or chemotherapy or both	Fair

A rise in serum thyroglobulin levels suggests recurrence of thyroid cancer and should prompt testing for recurrence and/or metastases. These are evaluated by ^{131}I whole body scans carried out under conditions of TSH stimulation, which increases ^{131}I uptake by the thyroid tissue. Elevated TSH levels can be achieved by withdrawal of thyroxine supplementation for 6 weeks or by treatment with recombinant human TSH administered while the patient maintains therapy with thyroid hormone replacement. The latter avoids symptomatic hypothyroidism. Local or metastatic lesions that take up ^{131}I on whole body scanning can be treated with radioactive iodine after the patient has stopped thyroid hormone replacement, whereas those that do not take up ^{131}I can be treated with surgical excision or local radiograph therapy. Conventional chemotherapy has limited efficacy in the treatment of differentiated thyroid cancer, but newer biologic agents targeting the molecular pathogenesis of these tumors appear promising.

Medullary carcinoma of the thyroid requires total thyroidectomy with removal of the central lymph nodes in the neck. Completeness of the procedure and monitoring for recurrence are determined by measurements of serum calcitonin.

Anaplastic carcinoma is treated with isthmusectomy to confirm the diagnosis and to prevent tracheal compression, followed by palliative radiograph treatment. Thyroid lymphomas are also treated with radiograph therapy, chemotherapy, or both.

The prognosis for well-differentiated thyroid carcinomas is good. The patient's age at the time of diagnosis and sex are the most important prognostic factors. Men older than 40 years of age and women

older than 50 years of age have higher recurrence and death rates than do younger patients. The 5-year survival rate for invasive medullary carcinoma is 50%, whereas the mean survival time for anaplastic carcinoma is 6 months.

For a deeper discussion on this topic, please see Chapter 213, "Thyroid," in *Goldman-Cecil Medicine*, 26th Edition. ❖

Adrenal Gland

Theodore C. Friedman

PHYSIOLOGY

The adrenal glands (Fig. 66.1) lie at the superior pole of each kidney and are composed of two distinct regions: the cortex and the medulla. The adrenal cortex comprises three anatomic zones: the outer *zona glomerulosa*, which secretes the mineralocorticoid aldosterone; the intermediate *zona fasciculata*, which secretes cortisol; and the inner *zona reticularis*, which secretes adrenal androgens. The adrenal medulla, lying in the center of the adrenal gland, is functionally related to the sympathetic nervous system and secretes the catecholamines epinephrine and norepinephrine in response to stress.

The synthesis of all steroid hormones begins with cholesterol and is catalyzed by a series of regulated, enzyme-mediated reactions (Fig. 66.2). Glucocorticoids affect metabolism, cardiovascular function, behavior, and the inflammatory and immune responses (Table 66.1). Cortisol, the natural human glucocorticoid, is secreted by the adrenal glands in response to adrenocorticotropic hormone (ACTH), a 39-amino-acid neuropeptide that is regulated by corticotropin-releasing hormone (CRH) and vasopressin (AVP) produced in the hypothalamus (see Chapter 64). Glucocorticoids exert negative feedback on CRH and ACTH secretion. The brain hypothalamic-pituitary-adrenal (HPA) axis (Fig. 66.3) interacts with and influences the functions of the reproductive, growth, and thyroid axes at many levels, with major participation of glucocorticoids at all levels.

The renin-angiotensin-aldosterone system (Fig. 66.4) is the major regulator of aldosterone secretion. Renal juxtaglomerular cells secrete renin in response to a decrease in circulating volume, a reduction in renal perfusion pressure or both. Renin is the rate-limiting enzyme that cleaves the 60-kD angiotensinogen molecule, synthesized by the liver, to produce the bioinactive decapeptide angiotensin I. Angiotensin I is rapidly converted to the octapeptide angiotensin II by angiotensin-converting enzyme in the lungs and other tissues. Angiotensin II is a potent vasopressor; it stimulates aldosterone production but does not stimulate cortisol production. Angiotensin II is the predominant regulator of aldosterone secretion, but plasma potassium concentration, plasma volume, and ACTH level also influence aldosterone secretion. ACTH also mediates the circadian rhythm of aldosterone, and as a result, the plasma concentration of aldosterone is highest in the morning. Aldosterone binds to the type I mineralocorticoid receptor. In contrast, cortisol binds to both the type I mineralocorticoid and type II glucocorticoid receptors. The intracellular enzyme 11 β -hydroxysteroid dehydrogenase (11 β -HSD) type II, which catabolizes cortisol to inactive cortisone, limits the functional binding to the former receptor. The availability of cortisol to bind to the glucocorticoid receptor is modulated by 11 β -HSD type I, which interconverts cortisol and cortisone. Binding of aldosterone to the cytosol mineralocorticoid receptor leads to sodium (Na⁺) absorption and potassium (K⁺) and hydrogen (H⁺) secretion by the renal tubules. The resultant increase in plasma

Na⁺ and decrease in plasma K⁺ provide a feedback mechanism for suppressing renin and, subsequently, aldosterone secretion.

Adrenal androgen precursors include dehydroepiandrosterone (DHEA) and its sulfate and androstenedione. These are synthesized in the zona reticularis under the influence of ACTH and other adrenal androgen-stimulating factors. Although they have minimal intrinsic androgenic activity, they contribute to androgenicity by their peripheral conversion to testosterone and dihydrotestosterone. In adult men, excessive levels of adrenal androgens have negligible clinical consequences, but in women they result in acne, hirsutism, and virilization. Because of gonadal production of androgens and estrogens and the secretion of norepinephrine by sympathetic ganglia, deficiencies of adrenal androgens and catecholamines are not clinically recognized.

SYNDROMES OF ADRENOCORTICAL HYPOFUNCTION

Adrenal Insufficiency

Glucocorticoid insufficiency can be primary, resulting from destruction or dysfunction of the adrenal cortex, or secondary, resulting from ACTH hyposecretion (Table 66.2). Medications and supplements affecting cortisol levels are shown in Table 66.3. Autoimmune destruction of the adrenal glands (Addison's disease) is the most common cause of primary adrenal insufficiency in the industrialized world, accounting for about 65% of cases. Usually, both glucocorticoid and mineralocorticoid secretions are diminished in this condition that, if left untreated, can be fatal. Isolated glucocorticoid or mineralocorticoid deficiency may also occur, and it is becoming apparent that mild adrenal insufficiency (similar to subclinical hypothyroidism, discussed in Chapter 65) should also be diagnosed and, in some cases, treated. Adrenal medulla function is usually spared. About 80% of patients with Addison's disease have antiadrenal antibodies directed at 21 α -hydroxylase (CYP21A2), though in clinical practice this may be lower due to poor quality of commercial autoantibody testing.

Tuberculosis used to be the most common cause of adrenal insufficiency. However, its incidence in the industrialized world has decreased since the 1960s, and it now accounts for only 15% to 20% of patients with adrenal insufficiency; calcified adrenal glands can be observed in 50% of these patients. Rare causes of adrenal insufficiency are listed in Table 66.2. Many patients with human immunodeficiency virus (HIV) infection have decreased adrenal reserve without overt adrenal insufficiency.

Addison's disease may be part of two distinct autoimmune polyglandular syndromes. The triad of hypoparathyroidism, adrenal insufficiency, and mucocutaneous candidiasis characterizes *type I polyglandular autoimmune syndrome*, also called autoimmune polyendocrinopathy 1 (APECED), which usually manifests in childhood. Other, less common manifestations include hypothyroidism, gonadal failure,

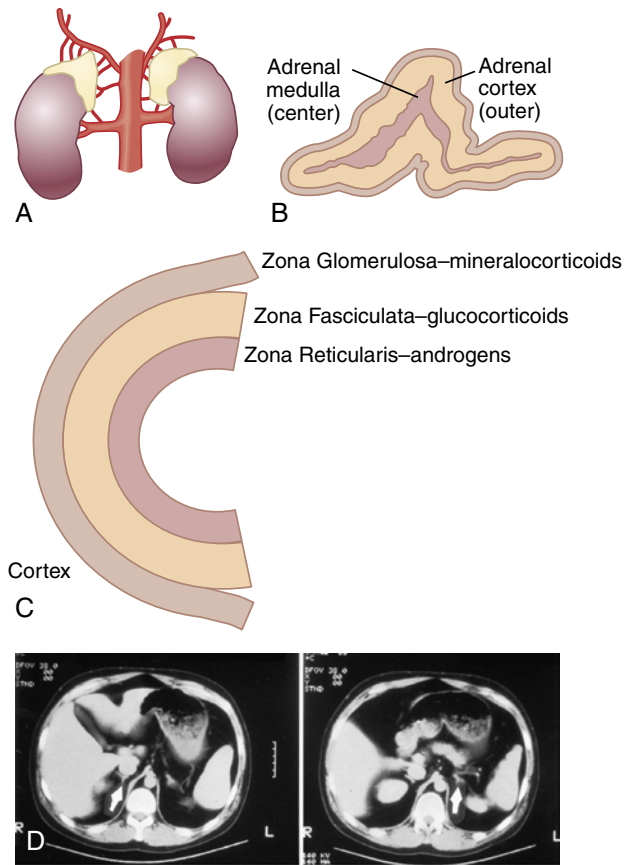

Fig. 66.1 (A) Anatomic location of the adrenal glands. (B) Distribution of adrenal cortex and medulla. (C) Zones of the adrenal cortex. (D) Magnetic resonance images of the abdomen showing the position and relative size of the normal adrenal glands (arrows). (D, From Nieman LK: Adrenal cortex. In Goldman L, Schafer AI, editors: Goldman-Cecil medicine, ed 24, Philadelphia, 2012, Saunders, Figure 234-1.)

gastrointestinal malabsorption, insulin-dependent diabetes mellitus, alopecia areata and totalis, pernicious anemia, vitiligo, chronic active hepatitis, keratopathy, hypoplasia of dental enamel and nails, hypophysitis, asplenism, and cholelithiasis. *Type II polyglandular autoimmune syndrome*, also called *Schmidt syndrome*, is characterized by Addison's disease, autoimmune thyroid disease (Graves' disease or Hashimoto thyroiditis), and insulin-dependent diabetes mellitus. Other associated diseases include pernicious anemia, vitiligo, gonadal failure, hypophysitis, celiac disease, myasthenia gravis, primary biliary cirrhosis, Sjögren's syndrome, lupus erythematosus, and Parkinson's disease. This syndrome usually develops in adults.

Common manifestations of adrenal insufficiency are anorexia, weight loss, increasing fatigue, occasional vomiting, diarrhea, and salt craving. Muscle and joint pain, abdominal pain, and postural dizziness may also occur. Signs of increased pigmentation (initially most significant on the extensor surfaces, palmar creases, and buccal mucosa) often occur secondary to the increased production of ACTH and other related peptides by the pituitary gland (E-Fig. 66.1). Laboratory abnormalities may include hyponatremia, hyperkalemia, mild metabolic acidosis, azotemia, hypercalcemia, anemia, lymphocytosis, and eosinophilia. Hypoglycemia may also occur, especially in children.

Acute adrenal insufficiency is a medical emergency, and treatment should not be delayed pending laboratory results. In a critically ill patient with hypovolemia, a plasma sample for cortisol, ACTH, aldosterone, and renin should be obtained, and then treatment with

hydrocortisone (100 mg IV bolus) and parenteral saline administration should be initiated. Sepsis-induced adrenal insufficiency is recognized by a basal cortisol level lower than 10 $\mu\text{g}/\text{dL}$ or a change in cortisol of less than 9 $\mu\text{g}/\text{dL}$ after administration of 0.25 mg ACTH (1-24) (cosyntropin). In severe illness, albumin and cortisol-binding globulin (CBG) are low, resulting in a low level of total cortisol but not free cortisol; therefore, a low total cortisol level may not be diagnostic of adrenal insufficiency in this setting.

In a patient with chronic symptoms suggestive of adrenal insufficiency described previously, a basal early morning plasma cortisol measurement, a 1-hour cosyntropin test, or both, should be performed. These tests are not recommended in patients without symptoms of adrenal insufficiency. In the latter test, 0.25 mg of cosyntropin is given intravenously or intramuscularly, and plasma cortisol is measured after 0, 30, and 60 minutes. A normal response is a plasma cortisol concentration higher than 18 $\mu\text{g}/\text{dL}$ at any time during the test. A patient with a basal morning plasma cortisol concentration lower than 5 $\mu\text{g}/\text{dL}$ and a stimulated cortisol concentration lower than 18 $\mu\text{g}/\text{dL}$ probably has adrenal insufficiency and should receive treatment. A basal plasma morning cortisol concentration between 10 and 18 $\mu\text{g}/\text{dL}$ in association with a stimulated cortisol concentration lower than 18 $\mu\text{g}/\text{dL}$ probably indicates impaired adrenal reserve and a requirement for receiving cortisol replacement under stress conditions (see later discussion). Birth control pills and oral estrogens increase CBG levels; therefore, a patient on those agents may have a normal basal or cosyntropin-stimulated cortisol level and have a low free cortisol level, making interpretation of the test difficult for these patients.

Once the diagnosis of adrenal insufficiency is made, the distinction between primary and secondary adrenal insufficiency needs to be established. Secondary adrenal insufficiency results from inadequate stimulation of the adrenal cortex by ACTH (see Chapter 64). Hyperpigmentation does not occur. In addition, because mineralocorticoid levels are normal in secondary adrenal insufficiency, symptoms of salt craving, as well as the laboratory abnormalities of hyperkalemia and metabolic acidosis, are not present, although hyponatremia may be observed. Hypothyroidism, hypogonadism, and growth hormone deficiency may also be present. To distinguish primary from secondary adrenal insufficiency, a basal morning plasma ACTH value should be obtained, along with a serum aldosterone level and a measurement of plasma renin activity (PRA). A plasma ACTH value greater than 20 pg/mL (normal, 5 to 30 pg/mL) is consistent with primary adrenal insufficiency, whereas a value lower than 20 pg/mL probably represents secondary adrenal insufficiency. A PRA value greater than 3 ng/mL/hour in the setting of a suppressed aldosterone level is consistent with primary adrenal insufficiency, whereas a value lower than 3 ng/mL/hour probably represents secondary adrenal insufficiency. The 1-hour cosyntropin test is suppressed in both primary and secondary chronic adrenal insufficiency.

Secondary adrenal insufficiency occurs commonly after the discontinuation of exogenous glucocorticoids. Alternate-day glucocorticoid treatment, if feasible, results in less suppression of the HPA axis than does daily glucocorticoid therapy. Complete recovery of the HPA axis can take 1 year or more, and the rate-limiting step appears to be recovery of the CRH-producing neurons.

Under stress, cortisol secretion is increased. Therefore, the concept of adrenal fatigue, proposed by some alternative providers, has no biologic validity.

After stabilization of acute adrenal insufficiency, patients with Addison's disease require lifelong replacement therapy with both glucocorticoids and mineralocorticoids. Many patients are overtreated with glucocorticoids and undertreated with mineralocorticoids. Because overtreatment with glucocorticoids results in insidious weight

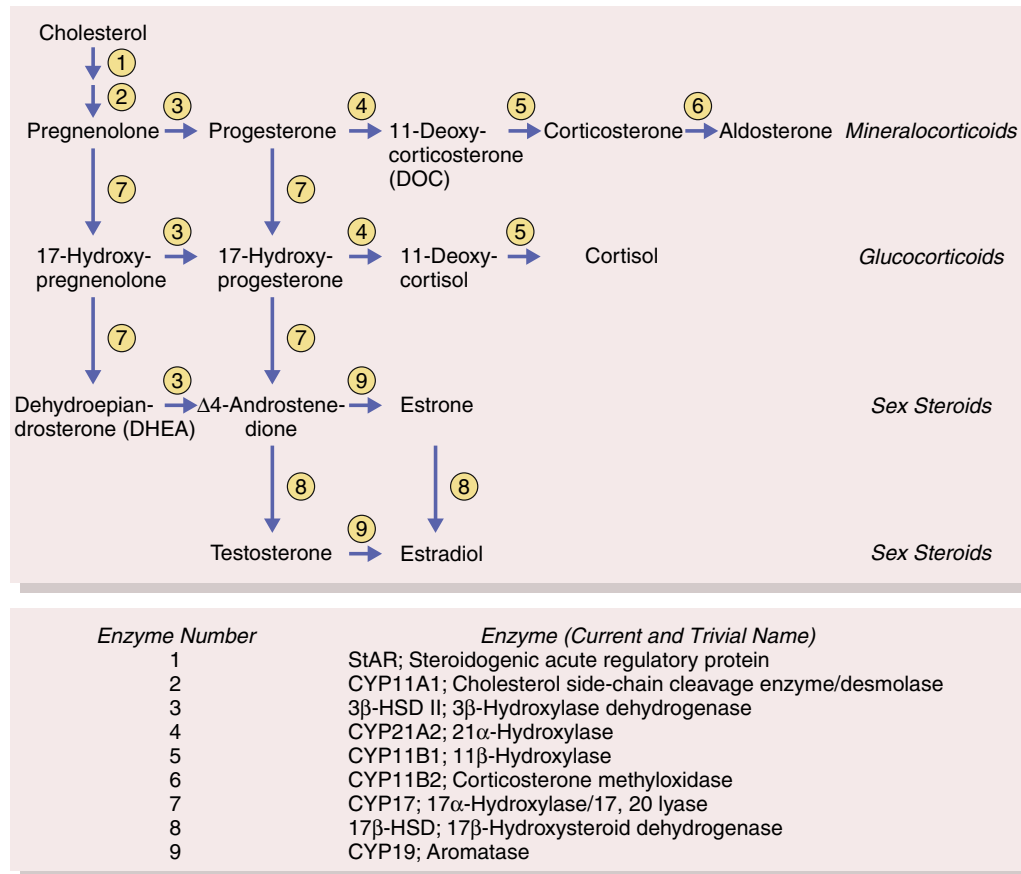

Fig. 66.2 Pathways of steroid biosynthesis.

TABLE 66.1 Actions of Glucocorticoids

Metabolic Homeostasis

Regulate blood glucose level (permissive effects on gluconeogenesis)
 Increase glycogen synthesis
 Raise insulin levels (permissive effects on lipolytic hormones)
 Increase catabolism, decrease anabolism (except fat), inhibit growth hormone axis
 Inhibit reproductive axis
 Stimulate mineralocorticoid receptor by cortisol

Connective Tissues

Cause loss of collagen and connective tissue

Calcium Homeostasis

Stimulate osteoclasts, inhibit osteoblasts
 Reduce intestinal calcium absorption, stimulate parathyroid hormone release, increase urinary calcium excretion, decrease reabsorption of phosphate

Cardiovascular Function

Increase cardiac output
 Increase vascular tone (permissive effects on pressor hormones)
 Increase sodium retention

Behavior and Cognitive Function

Daytime fatigue
 Nocturnal hyperarousal
 Decreased short-term memory
 Decreased cognition

Euphoria or Depression**Immune System**

Increase intravascular leukocyte concentration
 Decrease migration of inflammatory cells to sites of injury
 Suppress immune system (thymolysis; suppression of cytokines, prostanoids, kinins, serotonin, histamine, collagenase, and plasminogen activator)

gain and osteoporosis, the minimal cortisol dose that can be tolerated without symptoms of glucocorticoid insufficiency (usually joint pain, abdominal pain, or diarrhea) is recommended. An initial regimen of 10 to 15 mg hydrocortisone first thing in the morning plus 5 mg hydrocortisone at about 3:00 PM mimics the physiologic dose and is recommended; a third dose is occasionally needed. Whereas glucocorticoid replacement is fairly uniform in most patients, the requirement for mineralocorticoid replacement varies greatly. The initial dose of the synthetic mineralocorticoid fludrocortisone should be 100 $\mu\text{g}/\text{day}$ (often in divided doses), and the dosage should be adjusted to keep the standing PRA value between 1 and 3 ng/mL/hr.

Under the stress of a minor illness (e.g., nausea, vomiting, fever $>100.5^\circ\text{F}$), the hydrocortisone dose should be doubled for as short a period as possible. An inability to ingest hydrocortisone pills may necessitate parenteral hydrocortisone administration. Patients undergoing a major stressful event (e.g., surgery necessitating general anesthesia, major trauma) should receive 150 to 300 mg parenteral hydrocortisone daily (in divided doses) with a rapid taper to normal replacement during recovery. All patients should wear a medical information bracelet and should be instructed in the use of intramuscular emergency hydrocortisone injections or alternatively hydrocortisone suppositories as another option.

Hyporeninemic Hypoaldosteronism

Mineralocorticoid deficiency can result from decreased renin secretion by the kidneys. Resultant hypoangiotensinemia leads to

hypoaldosteronism with hyperkalemia and hyperchloremic metabolic acidosis. The plasma sodium concentration is usually normal, but total plasma volume is often deficient. PRA and aldosterone levels are low and unresponsive to stimuli, including hypokalemia. Diabetes mellitus and chronic tubulointerstitial diseases of the kidney are the most common underlying conditions leading to impairment of the juxtaglomerular apparatus. A subset of hyporeninemic hypoaldosteronism is caused by autonomic insufficiency and is a frequent cause of orthostatic hypotension. Stimuli such as upright posture or volume depletion, mediated by baroreceptors, do not cause a normal renin response. Administration of pharmacologic agents such as nonsteroidal anti-inflammatory agents, angiotensin-converting enzyme inhibitors, and β -adrenergic antagonists can also produce conditions of hypoaldosteronism. Salt administration often with fludrocortisone and the α_1 -receptor agonist midodrine are effective in correcting the orthostatic hypotension and electrolyte abnormalities caused by hypoaldosteronism.

Congenital Adrenal Hyperplasia

Congenital adrenal hyperplasia (CAH) refers to autosomal recessive disorders of adrenal steroid biosynthesis that result in glucocorticoid and mineralocorticoid deficiencies and compensatory increase in ACTH secretion (see Fig. 66.2). Five major types of CAH exist, and the clinical manifestations of each type depend on which steroids are in excess and which are deficient. CYP21A2 deficiency is the most common of these disorders and accounts for about 95% of patients with CAH. In this condition, there is a failure of 21-hydroxylation of 17-hydroxyprogesterone and progesterone to 11-deoxycortisol and 11-deoxycorticosterone, respectively, with deficient cortisol and aldosterone production. Cortisol deficiency leads to increased ACTH release, resulting in adrenal hyperplasia and overproduction of 17-hydroxyprogesterone and progesterone. Increased ACTH production also leads to increased biosynthesis of androstenedione and DHEA, which can be converted to testosterone. Patients with CYP21A2 deficiencies can be divided into two clinical phenotypes: classic 21-hydroxylase deficiency, which usually is diagnosed at birth or during childhood, and late-onset 21-hydroxylase deficiency, which develops during or after puberty. Two thirds of patients with classic CYP21A2 deficiency have various degrees of mineralocorticoid deficiency (salt-losing form); the remaining one third have the non-salt-losing type (simple virilizing form). Both decreased aldosterone production and increased concentrations of precursors that are mineralocorticoid antagonists (progesterone and 17-hydroxyprogesterone) contribute to salt loss.

Late-onset 21-hydroxylase deficiency represents an allelic variant of classic 21-hydroxylase deficiency and is characterized by a mild enzymatic defect. This deficiency is the most common autosomal recessive disorder in humans and is present at high frequency in Ashkenazi Jews. The syndrome usually develops at the time of puberty with signs of virilization (hirsutism and acne) and amenorrhea or oligomenorrhea. This diagnosis should be considered in women who have unexplained hirsutism and menstrual abnormalities or infertility.

The most useful initial measurement for the diagnosis of classic 21-hydroxylase deficiency is that of plasma 17-hydroxyprogesterone. A value greater than 200 ng/dL is consistent with the diagnosis. The diagnosis of late-onset 21-hydroxylase deficiency is based on the finding of an elevated level of plasma 17-hydroxyprogesterone (>1500 ng/dL) 30 minutes after administration of 0.25 mg of synthetic ACTH (1-24).

The aim of treatment for classic 21-hydroxylase deficiency is to replace glucocorticoids and mineralocorticoids, suppress ACTH and androgen overproduction, and allow for normal growth and

sexual maturation in children. A proposed approach to treating classic 21-hydroxylase deficiency recommends physiologic replacement with hydrocortisone and fludrocortisone in all affected patients. Virilizing

effects can be prevented by the use of an antiandrogen (spironolactone or flutamide). Although the traditional treatment for late-onset 21-hydroxylase deficiency is dexamethasone (0.5 mg/day), the use of an antiandrogen such as spironolactone (100 to 200 mg/day) or flutamide (125 mg/day) is probably equally effective and has fewer side effects. Mineralocorticoid replacement is not needed in late-onset 21-hydroxylase deficiency.

11 β -Hydroxylase (CYP11B1) deficiency accounts for about 5% of patients with CAH. In this condition, the conversions of 11-deoxycortisol to cortisol and 11-deoxycorticosterone to corticosterone (the precursor to aldosterone) are blocked. Affected patients usually have hypertension and hypokalemia because of increased amounts of precursors with mineralocorticoid activity. Virilization occurs, as with 21-hydroxylase deficiency, and a late-onset form manifesting as androgen excess also occurs. The diagnosis is made from the finding of elevated plasma 11-deoxycortisol levels, either basally or after ACTH stimulation.

Rare forms of CAH are 3 β -HSD type II deficiency, 17 α -hydroxylase (CYP17) deficiency, and steroidogenic acute regulatory protein (StAR) deficiency. Patients previously diagnosed with 3 β -HSD type II deficiency most likely had polycystic ovarian syndrome (PCOS), which is associated with high DHEAS levels.

SYNDROMES OF ADRENOCORTICAL HYPERFUNCTION

Hypersecretion of the glucocorticoid hormone cortisol results in Cushing's syndrome, a metabolic disorder that affects carbohydrate, protein, and lipid metabolism (see Table 66.1). Hypersecretion of mineralocorticoids such as aldosterone results in a syndrome of hypertension and electrolyte disturbances.

Cushing's Syndrome**Pathophysiology**

Cushing's syndrome refers to any condition of endogenous glucocorticoid excess, while Cushing's disease refers to an ACTH-secreting pituitary tumor leading to glucocorticoid excess. Increased production of cortisol is seen in both physiologic and pathologic states (Table 66.4). Physiologic hypercortisolism occurs with stress, during the last trimester of pregnancy, and in persons who regularly perform strenuous exercise. Pathologic conditions of elevated cortisol levels include exogenous or endogenous Cushing's syndrome and several psychiatric states, such as depression, alcoholism, anorexia nervosa, panic disorder, and alcohol or narcotic withdrawal.

Cushing's syndrome may be caused by exogenous administration of ACTH or glucocorticoid or by endogenous overproduction of these hormones. Endogenous Cushing's syndrome is either ACTH dependent or ACTH independent. ACTH dependency accounts for 85% of patients and includes pituitary sources of ACTH (Cushing's disease) and ectopic sources of ACTH. Pituitary Cushing's disease accounts for 90% of patients with ACTH-dependent Cushing's syndrome. Ectopic secretion of ACTH occurs most commonly in patients with small cell lung carcinoma. These patients are older, usually have a history of smoking, and primarily exhibit signs and symptoms of lung cancer rather than those of Cushing's syndrome. Patients with the clinically apparent ectopic ACTH syndrome, in contrast, have mostly lung, thymic or pancreatic carcinoid tumors. ACTH-independent causes account for 15% of patients with Cushing's syndrome and include adrenal adenomas, adrenal carcinomas, micronodular adrenal disease, and autonomous macronodular adrenal disease. The female-to-male ratio for noncancerous forms of Cushing's syndrome is 4:1.

TABLE 66.3 Medications and Supplements Affecting Cortisol Levels

Type of Drugs	Generic Name	Brand Name	Effect on Cortisol	Comments
Cushing's drugs	Ketoconazole	Nizoral	↓	Decreases cortisol biosynthesis
	Mifepristone	Korlym	↑	Blocks cortisol at the receptor
	Somatostatin analogues (octreotide, lanreotide, pasireotide)	Sandostatin, Somatuline, Signifor	↓	Lowers cortisol mildly
	Metirapone	Metopirone	↓	High rate of adrenal insufficiency
	Etomidate Mitotane	Amidate Lysodren	↓ ↓	Can be given IV Adrenolytic
Antidepressant	Citalopram	Celexa	↑	
	Sertraline	Zoloft	↑	
	Fluoxetine	Prozac	–	
	Imipramine	Tofranil	↓	
	Desipramine	Norpramin	↓	
	Trazodone	Desyrel	↓	
	Mirtazapine	Remeron	↓	
Antipsychotic	Olanzapine	Zyprexa	↓	
	Quetiapine	Seroquel	↓	
Anti-anxiety	Temazepam	Restoril	↓	
	Alprazolam	Xanax	↓	
	Lorazepam	Ativan	↓/–	Anecdotal-lowers cortisol, literature no effect
Dopamine agents	Cabergoline	Dostinex	↓	Variable effect
	Bromocriptine	Parlodel	↓	Variable effect
	Metoclopramide	Reglan	↑	
	Methylphenidate	Ritalin	↑	Found in one study but not another study
Antihypertensives	Clonidine	Catapres	↓	
Opioids/anti-opioids	Loperamide	Imodium	↓	
	Morphine, Methadone, Codeine	Various	↓	
	Buprenorphine	Buprenex	↓	
	Naloxone	Narcan	↑	
	Naltrexone	Revia	↑	Unclear if low-dose naltrexone (LDN) has the same effect
Drugs of abuse	Heroin		↓	
	Cocaine		↑	
	Alcohol		↑	
	Tobacco/nicotine		↑	
Hormones	Progesterone	Provera, Prometrium	↓	Binds to the cortisol receptor, so Cushingoid features could occur, even though cortisol levels are decreased
	Megestrol	Megace	↓	Used for weight gain
	Growth hormone	Various	↓	Increase catabolism of cortisol
	Thyroid hormone	Synthroid, Levoxyl, Cytomel Armour, etc.	↓	Increase catabolism of cortisol
	Raloxifene	Evista	↓	Used for osteoporosis
	Estrogens, birth control pills		–	Raises cortisol-binding protein and raises total cortisol, does not affect free cortisol
	DHEA		↓	
	Desmopressin	DDAVP	↑	
	Oxytocin		↓	Anecdotal reports of lowering cortisol

TABLE 66.3 Medications and Supplements Affecting Cortisol Levels—cont'd

Type of Drugs	Generic Name	Brand Name	Effect on Cortisol	Comments
Diabetes medications	Rosiglitazone	Avandia	↓/–	Initial studies found a reduction in cortisol, not confirmed by additional studies
	Pioglitazone	Actos	↓/–	
Supplements	Phosphatidyl serine	Seriphos	↓	Effective at night, Seriphos and phosphatidyl serine are slightly different
	Ginkgo biloba		↓	
	St. John's wort		↑	
	Rhodiola		↓	

Bold indicates substantial effect.

Clinical Presentation

The clinical signs, symptoms, and common laboratory findings of hypercortisolism observed in patients with Cushing's syndrome are listed in Table 66.5. Patients with Cushing's syndrome often have some, but not all, of the signs and symptoms discussed here. Typically, the obesity is centripetal, with a wasting of the arms and legs, which is distinct from the generalized weight gain observed in idiopathic obesity. Rounding of the face (called *moon facies*) and a dorsocervical fat pad (*buffalo hump*) may occur in obesity not related to Cushing's syndrome, whereas facial plethora and supraclavicular filling are more specific for Cushing's syndrome. Patients with Cushing's syndrome may have proximal muscle weakness; consequently, the inability to stand up from a squat or to comb their own hair can be revealing. Sleep disturbances and insomnia, hyperarousal in the evening and night, mood swings, and other psychological abnormalities are frequently seen. Cognitive dysfunction and severe fatigue are often present. Menstrual irregularities often precede other Cushingoid symptoms in affected women. Patients of both sexes complain of a loss of libido, and affected men frequently complain of erectile dysfunction. Adult-onset acne or hirsutism in women could also suggest Cushing's syndrome. The skin striae observed in patients with Cushing's syndrome are often violaceous (i.e., purple or dark red, from hemorrhage into the striae) depending on the level of hypercortisolism. Thinning of the skin on the top of the hands is a specific sign in younger adults with Cushing's syndrome. Old pictures of patients are extremely helpful for evaluating the progression of the physical stigmata of Cushing's syndrome.

Associated laboratory findings in Cushing's syndrome include elevated plasma alkaline phosphatase levels, granulocytosis, thrombocytosis, hypercholesterolemia, hypertriglyceridemia, and glucose intolerance, and/or diabetes mellitus. Hypokalemia or alkalosis usually occurs in patients with severe hypercortisolism as a result of the ectopic ACTH syndrome.

Diagnosis

If the history and physical examination findings are suggestive of hypercortisolism, then the diagnosis of Cushing's syndrome can usually be established by collecting urine for 24 hours and measuring the urinary free cortisol (UFC). This test is extremely sensitive for diagnosis of Cushing's syndrome because in 90% of affected patients the initial UFC level is greater than 50 $\mu\text{g}/24$ hours (Fig. 66.5).

Cortisol is normally secreted in a diurnal manner: The plasma concentration is highest in the early morning (between 6:00 and 8:00 AM) and lowest around midnight. Most patients with Cushing's syndrome have blunted diurnal variation. Nighttime plasma cortisol values greater than 50% of the morning values are considered to be consistent with Cushing's syndrome. Because of the difficulty

of obtaining nighttime plasma cortisol levels, measurement of late-night salivary cortisol has been developed to assess hypercortisolism. This test has a high degree of sensitivity and specificity for the diagnosis of Cushing's syndrome and is convenient for patients. Multiple measurements of UFC or salivary cortisol may be needed to either diagnose or exclude Cushing's syndrome, especially in subjects with convincing and progressive signs and symptoms of hypercortisolism.

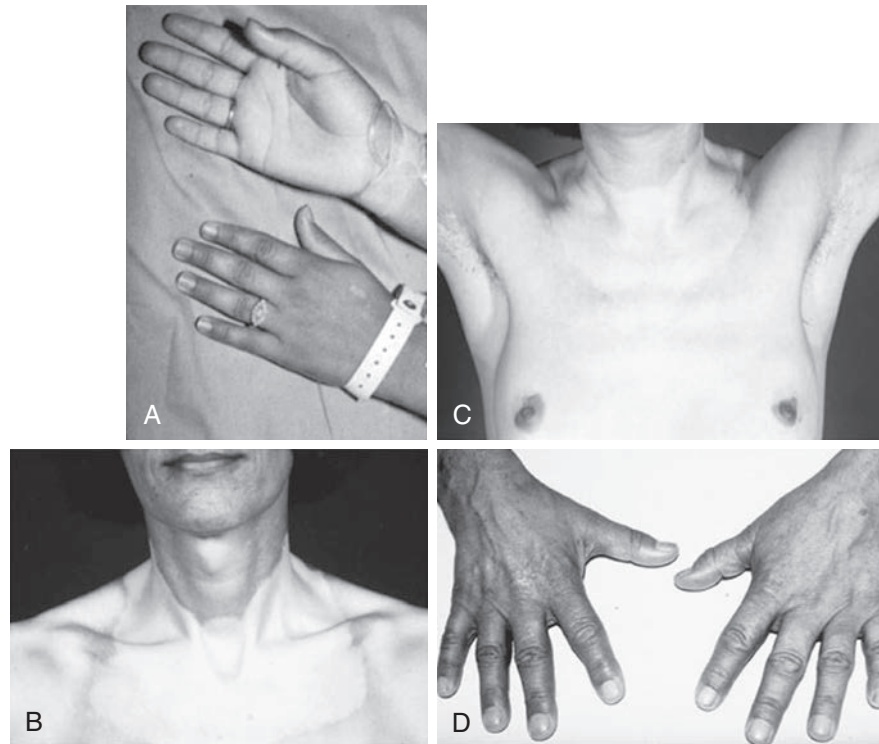

The overnight dexamethasone suppression test has been widely used as a screening tool to evaluate patients who may have hypercortisolism. Dexamethasone, 1 mg, is given orally at 11:00 PM or midnight, and plasma cortisol is measured the following morning at 8:00 AM. A morning plasma cortisol level greater than 1.8 $\mu\text{g}/\text{dL}$ suggests hypercortisolism. This test produces a significant number of both false-positive and false-negative results, but it is recommended in the 2008 Endocrine Society consensus guidelines.

Differential Diagnosis

Once the diagnosis of Cushing's syndrome is established, the cause of the hypercortisolism needs to be ascertained by biochemical studies that evaluate the HPA axis; this should be accompanied by imaging procedures and at times, venous sampling. The initial approach is to measure basal ACTH levels, which are normal or elevated in Cushing's disease and the ectopic ACTH syndrome but are suppressed in primary adrenal Cushing's syndrome. Patients with a suppressed ACTH level can proceed to adrenal imaging studies. To distinguish between Cushing's disease and the ectopic ACTH syndrome, the 2-day dexamethasone suppression test or 8-mg overnight dexamethasone suppression test and bilateral simultaneous inferior petrosal sinus sampling (IPSS) may be used.

In the dexamethasone suppression test (Liddle test), 0.5 mg of dexamethasone is given orally every 6 hours for 2 days (low dose), followed by 2 mg of dexamethasone every 6 hours for another 2 days (high dose). On the second day of high-dose dexamethasone, the UFC level will be suppressed to less than 10% of the baseline collection value in patients with pituitary adenomas but not in patients with the ectopic ACTH syndrome or adrenal cortisol-secreting tumors. The Liddle test has some methodologic drawbacks, and results should be interpreted cautiously; other confirmatory tests should be performed before surgery is recommended.

An overnight high-dose dexamethasone suppression test can be helpful in establishing the cause of Cushing's syndrome. In this test, a baseline cortisol level is measured at 8:00 AM, and then 8 mg of dexamethasone is given orally at 11:00 PM. At 8:00 AM the following morning, a plasma cortisol measurement is obtained. Suppression, which occurs in patients with pituitary Cushing's disease, is defined as a decrease in plasma cortisol to less than 50% of the baseline level.

E-Fig. 66.1 Pigmentation in Addison's disease. (A) Hands of an 18-year-old woman with autoimmune polyendocrine syndrome and Addison's disease. Pigmentation in a patient with Addison's disease before (B) and after (C) treatment with hydrocortisone and fluorocortisone. Notice the additional presence of vitiligo. (D) Similar changes are also seen in a 60-year-old man with tuberculous Addison's disease before and after corticosteroid therapy. (B and C, Courtesy Professor C.R.W. Edwards.  ACTH intake

States of Mineralocorticoid Excess**Primary Aldosteronism**

Aldosterone-secreting adenoma
 Bilateral adrenal hyperplasia
 Aldosterone-secreting carcinoma
 Glucocorticoid-suppressible hyperaldosteronism

Adrenal Enzyme Deficiencies

11 β -Hydroxylase deficiency
 17 α -Hydroxylase deficiency
 11 β -Hydroxysteroid dehydrogenase type II deficiency

Exogenous Mineralocorticoids

Licorice
 Carbenoxolone
 Fludrocortisone

Secondary Hyperaldosteronism

Associated with hypertension
 Accelerated hypertension
 Renovascular hypertension
 Estrogen administration
 Renin-secreting tumors
 Without hypertension
 Bartter syndrome
 Sodium-wasting nephropathy
 Renal tubular acidosis
 Diuretic and laxative abuse
 Edematous states (cirrhosis, nephrosis, congestive heart failure)

ACTH, Adrenocorticotropin hormone; CRH, corticotropin-releasing hormone.

Bilateral IPSS is an accurate and safe procedure for distinguishing pituitary Cushing's disease from the ectopic ACTH syndrome.

Venous blood from the anterior lobe of the pituitary gland empties into the cavernous sinuses and then into the superior and inferior petrosal sinuses. Venous plasma samples for ACTH determination are obtained from both inferior petrosal sinuses, along with a simultaneous peripheral sample, both before and after intravenous bolus administration of ovine corticotropin-releasing hormone (oCRH). Significant gradients at baseline and after oCRH stimulation between petrosal sinus and peripheral samples suggest pituitary Cushing's disease. In baseline measurements, an ACTH concentration gradient of 1.6 or more between a sample from either of the petrosal sinuses and the peripheral sample is strongly suggestive of pituitary Cushing's disease, whereas patients with the ectopic ACTH syndrome or adrenal adenomas have no ACTH gradient between their petrosal and peripheral samples. After oCRH administration, a central-to-peripheral gradient of more than 3.2 is consistent with pituitary Cushing's disease. An ACTH gradient ipsilateral to the side of the tumor is found in 70% to 80% of pituitary Cushing's disease patients sampled. Although this procedure requires a radiologist who is experienced in IPSS, it is available at many tertiary care facilities. The test cannot be done to distinguish patients with Cushing's syndrome from those without the condition, and the test needs to be done when the patient is hypercortisolemic, making it less helpful in those with episodic cortisol secretion.

Magnetic resonance imaging (MRI) with gadolinium is the preferred procedure for localizing a pituitary adenoma. In many centers, a *dynamic* MRI is performed; the pituitary is visualized as the gadolinium enters and leaves the gland. Because about 10% of normal individuals are found to have a nonfunctioning pituitary adenoma on pituitary MRI, pituitary imaging should not be the sole criterion for the diagnosis of pituitary Cushing's disease.

Treatment

The preferred treatment for all forms of Cushing's syndrome is appropriate surgery or, in some cases, radiation therapy (see [Chapter 64](#)). A more appealing option for many patients with Cushing's disease who remain hypercortisolemic after pituitary surgery is bilateral adrenalectomy followed by lifelong glucocorticoid and mineralocorticoid replacement therapy.

In patients with the ectopic ACTH syndrome, the goal is to localize the tumor by appropriate scans so it can be removed surgically. A unilateral adrenalectomy is the treatment of choice in patients with a cortisol-secreting adrenal adenoma. Cortisol-secreting adrenal carcinomas initially should also be managed surgically; however, the prognosis is poor, with only 20% of patients surviving more than 1 year after diagnosis.

Medical treatment for hypercortisolism may be needed to prepare patients who are undergoing or have undergone pituitary irradiation and are awaiting its effects before surgery; it may also be needed for those who are not surgical candidates or elect not to have surgery. Ketoconazole, *o,p*-DDD (mitotane), metyrapone, aminoglutethimide, mifepristone (FDA approved for Cushing's syndrome if accompanied by hypertension or glucose intolerance/diabetes), and trilostane are the most commonly used agents for adrenal blockade and can be used alone or in combination. The somatostatin analogue, pasireotide, which decreases ACTH and may decrease tumor size, is an FDA-approved drug for treating Cushing's disease.

Primary Mineralocorticoid Excess**Pathophysiology**

The causes of primary aldosteronism (see [Table 66.4](#)) are aldosterone-producing adenoma (75%), bilateral adrenal hyperplasia (25%), adrenal carcinoma (1%), and glucocorticoid-remediable hyperaldosteronism (<1%). Adrenal enzyme defects (11 β -HSD type II,

TABLE 66.5 Signs, Symptoms, and Laboratory Abnormalities of Hypercortisolism

Feature	Percentage of Patients
Fat redistribution (dorsocervical and supraclavicular fat pads, temporal wasting, centripetal obesity, weight gain)	95

Cataracts	5

11 β -hydroxylase, and 17 α -hydroxylase deficiencies) and apparent mineralocorticoid excess (from ingestion of licorice or carbenoxolone, which inhibit 11 β -HSD type II, or from a congenital defect in this enzyme) are also states of functional mineralocorticoid overactivity. Secondary aldosteronism (see Table 66.4) results from an overactive renin-angiotensin system.

Primary aldosteronism is usually recognized during evaluation of hypertension or hypokalemia and represents a potentially curable form of hypertension. Up to 5% of patients with hypertension have primary aldosteronism. These patients are usually between the ages of 30 and 50 years, and the female-to-male ratio is 2:1.

Clinical Presentation

Hypertension, hypokalemia, and metabolic alkalosis are the main clinical manifestations of hyperaldosteronism; most of the presenting symptoms are related to hypokalemia. Symptoms in patients with mild hypokalemia are fatigue, muscle weakness, nocturia, lassitude, and headaches. If more severe hypokalemia exists, polydipsia, polyuria, paresthesias, and even intermittent paralysis and tetany can occur. Blood pressure can range from minimally elevated to very high. A positive Trousseau or Chvostek sign may occur as a result of metabolic alkalosis.

Diagnosis and Treatment

Initially, hypokalemia in the presence of hypertension should be documented (Fig. 66.6), although mild cases of hyperaldosteronism without hypokalemia exist. The patient must have adequate salt intake and discontinue diuretics before potassium measurement. A morning plasma aldosterone level (measured in ng/dL) and a PRA value (in ng/mL/hour) should be obtained. A ratio of serum aldosterone to PRA greater than 20 with a serum aldosterone level greater than 15 ng/dL suggests the diagnosis of hyperaldosteronism.

Confirmatory tests for hyperaldosteronism should be performed, such as oral sodium loading, saline infusion, fludrocortisone suppression, or captopril challenge.

Once the diagnosis of primary aldosteronism has been demonstrated, it is important to distinguish between an aldosterone-producing adenoma and bilateral hyperplasia, because the former is treated with surgery and the latter is treated medically. A computed tomography (CT) scan of the adrenal glands should be performed to localize the tumor. Prior to surgery, imaging should be confirmed with adrenal venous sampling for cortisol due to the high degree of adrenal incidentalomas. The patient should undergo unilateral adrenalectomy if a discrete adenoma is observed in one adrenal gland, the contralateral gland is normal, and the adrenal venous sampling lateralizes to the side of the adenoma. Patients in whom biochemical and localization study findings are consistent with bilateral hyperplasia should be treated medically with a potassium-sparing diuretic, usually eplerenone or spironolactone. Hyperaldosteronism and hypertension secondary to activation of the renin-angiotensin system can occur in patients with accelerated hypertension, in those with renovascular hypertension, in those receiving estrogen therapies, and, rarely, in patients with renin-secreting tumors. Hyperaldosteronism without hypertension occurs in patients with Bartter syndrome, sodium-wasting nephropathy, or renal tubular acidosis, as well as those who abuse diuretics or laxatives.

ADRENAL MEDULLARY HYPERFUNCTION

The adrenal medulla synthesizes the catecholamines norepinephrine, epinephrine, and dopamine from the amino acid tyrosine. Norepinephrine, the major catecholamine produced by the adrenal medulla, has predominantly α -agonist actions, causing vasoconstriction. Epinephrine acts primarily on the β -receptors, having positive

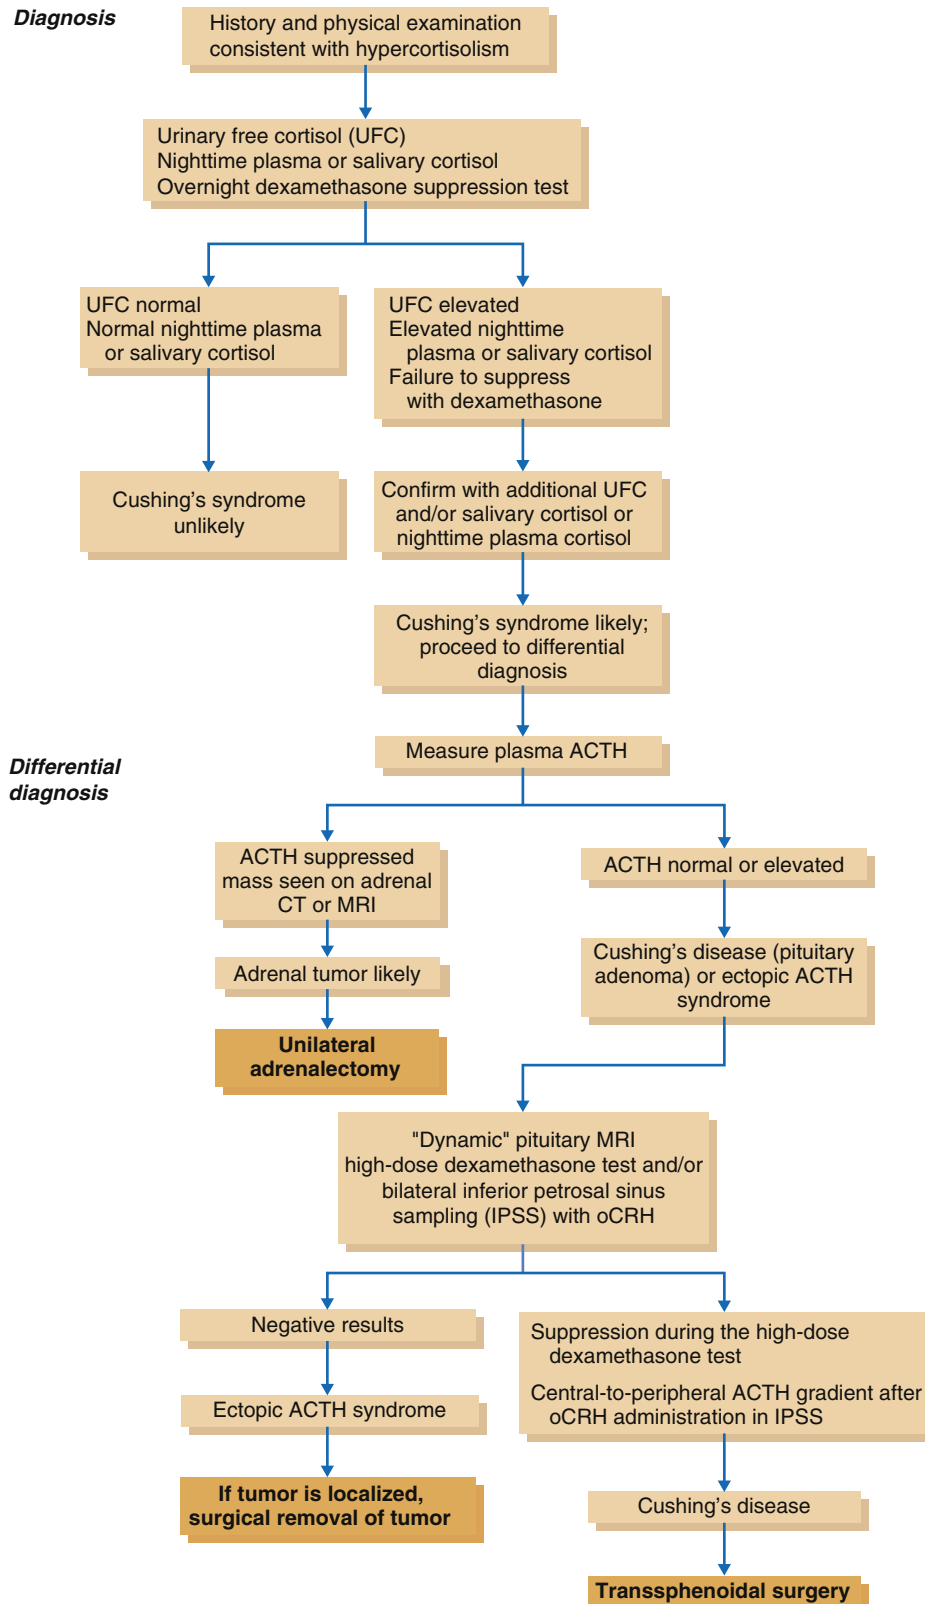

Fig. 66.5 Flowchart for evaluation of a patient with possible Cushing's syndrome. *ACTH*, Adrenocorticotropic hormone; *CT*, computed tomography; *MRI*, magnetic resonance imaging.

inotropic and chronotropic effects on the heart causing peripheral vasodilation and increasing plasma glucose concentrations in response to hypoglycemia. The action of circulating dopamine is unclear. Whereas norepinephrine is synthesized in the central nervous system and sympathetic postganglionic neurons, epinephrine is synthesized

almost entirely in the adrenal medulla. The adrenal medullary contribution to total body norepinephrine secretion is relatively small. Hypofunction of the adrenal medulla has little physiologic effect, whereas hypersecretion of catecholamines produces the clinical syndrome of pheochromocytoma.

Pheochromocytoma

Pathophysiology

Although pheochromocytomas can occur in any sympathetic ganglion in the body, more than 90% arise from the adrenal medulla. Most extra-adrenal tumors occur in the mediastinum or abdomen. Bilateral adrenal pheochromocytomas are present in about 5% of the cases and may occur as part of familial syndromes. Pheochromocytoma occurs as part of multiple endocrine neoplasia type IIA or IIB. The former, type IIA, is also called Sipple syndrome and is marked by medullary carcinoma of the thyroid, hyperparathyroidism, and pheochromocytoma; the latter, type IIB, is characterized by medullary carcinoma of the thyroid, mucosal neuromas, intestinal ganglioneuromas, marfanoid habitus, and pheochromocytoma. Pheochromocytomas are also associated with neurofibromatosis, cerebelloretinal hemangioblastoma (von Hippel–Lindau disease), and tuberous sclerosis.

Clinical Presentation

Because most pheochromocytomas secrete norepinephrine as the principal catecholamine, hypertension (often paroxysmal) is the most common finding. Other symptoms include the triad of headache, palpitations, and sweating as well as skin blanching, diarrhea, anxiety, nausea, fatigue, weight loss, and abdominal and chest pain. Emotional stress, exercise, anesthesia, abdominal pressure, or intake of tyramine-containing foods may precipitate these symptoms. Orthostatic hypotension can also occur. Wide fluctuations in blood pressure are characteristic, and the hypertension associated with pheochromocytoma usually does not respond to standard antihypertensive medicines. Cardiac abnormalities, as well as idiosyncratic reactions to medications, may also occur.

Diagnosis and Treatment

Although measurements of fractionated catecholamine and metanephrine levels in the urine are often used as screening tests, plasma free metanephrine and normetanephrine levels are the best tests for confirming or excluding pheochromocytoma. A plasma free metanephrine level greater than 0.61 nmol/L and a plasma free normetanephrine level greater than 0.31 nmol/L are consistent with the diagnosis of a pheochromocytoma. If these levels are only mildly elevated, a clonidine suppression test can be performed. In patients with pheochromocytoma, levels are unchanged or increased. Once the diagnosis of pheochromocytoma is made, a CT scan of the adrenal glands should be performed. Most intra-adrenal pheochromocytomas are readily visible on this scan and enhance with contrast. If the CT scan is negative, then extra-adrenal pheochromocytomas can often be localized by iodine 131-labeled metaiodobenzylguanidine (^{131}I -MIBG), positron emission tomography, octreotide scan, or abdominal MRI. Pheochromocytomas show high signal intensity on MRI T2-weighted images.

The treatment of pheochromocytoma is surgical if the lesion can be localized. Patients should undergo preoperative α -blockade with phenoxybenzamine 1 to 2 weeks before surgery. About 5% to 10% of pheochromocytomas are malignant. ^{131}I -MIBG or chemotherapy may be useful, but the prognosis is poor. α -Methyl-*p*-tyrosine, an inhibitor of tyrosine hydroxylase, the rate-limiting enzyme in catecholamine biosynthesis, may be used to decrease catecholamine secretion from the tumor.

Incidental Adrenal Mass

Clinically inapparent adrenal masses may be discovered inadvertently in the course of diagnostic testing or treatment for other clinical conditions not related to the signs and symptoms of adrenal disease; they are commonly known as *incidentalomas* (E-Fig. 66.2). Some of these

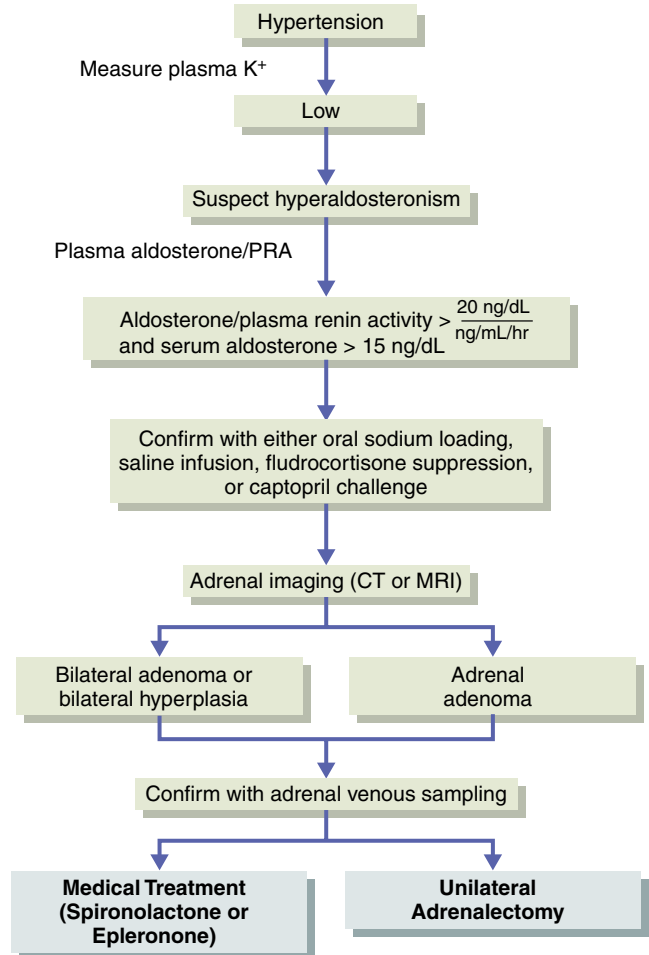

Fig. 66.6 Flowchart for evaluation of a patient with probable primary hyperaldosteronism. Plasma aldosterone is measured in ng/dL, and plasma renin activity (PRA) is measured in ng/mL/hour. *CT*, Computed tomography; *MRI*, magnetic resonance imaging.

tumors secrete a small amount of excess cortisol, leading to a condition that used to be called subclinical Cushing's syndrome and is now called *mild autonomous cortisol excess (MACE)* or *autonomous cortisol secretion*, a condition associated with comorbidities including hypertension, glucose intolerance/diabetes, obesity, dyslipidemia, osteoporosis, and increased cardiovascular events. This condition does not progress to overt Cushing's syndrome. An overnight 1-mg dexamethasone test is recommended for all patients with an adrenal mass seen on imaging. A morning cortisol post-dexamethasone of between 1.8 and 5 $\mu\text{g}/\text{dL}$ suggests possible autonomous cortisol secretion that usually does not need surgery, whereas values greater than 5 $\mu\text{g}/\text{dL}$ should be worked up for Cushing's syndrome as described previously. Under certain circumstances, surgical removal should be performed. Patients with hypertension should also undergo measurement of serum potassium, plasma aldosterone concentration, PRA, and plasma free metanephrines (only if the unenhanced CT attenuation value is greater than 10 Hounsfield units). Surgery should be considered for all patients with functional adrenal cortical tumors that are hormonally active or larger than 4 cm. Tumors not associated with hormonal secretion that are smaller than 4 cm and have benign imaging characteristics do not need follow-up.

Primary Adrenal Cancer

Primary adrenal carcinomas are rare, with an incidence of 1 to 5 per 1 million persons. The female-to-male ratio is 2.5:1, and the mean age at onset is 40 to 50 years. About 25% of patients have symptoms,

including abdominal pain, weight loss, anorexia, and fever. Eighty percent of primary adrenal carcinomas are functional, with secretion of glucocorticoid alone (45%) or glucocorticoid plus androgens (45%) being most common.

At presentation, metastatic spread is evident in 75% of cases. An incidentally discovered adrenal mass that is large is more likely to be malignant. Resection is recommended for tumors larger than 6 cm and often for those larger than 4 cm. In patients who do not have a known cancer, most adrenal masses that turn out to be malignant are primary adrenocortical carcinomas, whereas in patients with a known malignancy, an adrenal mass is likely to be a metastasis in about 75% of cases.

The treatment of adrenocortical carcinomas is surgery. These cancers are usually resistant to radiation and chemotherapy, but the adrenolytic compound mitotane has been shown to improve survival. Adrenocortical carcinomas carry a poor prognosis, with overall 5-year survival rates of less than 20%.

Male Reproductive Endocrinology

Glenn D. Braunstein

INTRODUCTION

The testes are composed of Leydig (interstitial) cells, which secrete testosterone and estradiol, and the seminiferous tubules, which produce sperm. They are regulated by the luteinizing hormone (LH) and follicle-stimulating hormone (FSH), which are secreted by the anterior pituitary under the influence of the hypothalamic decapeptide gonadotropin-releasing hormone (GnRH) (Fig. 67.1). LH stimulates the Leydig cells to secrete testosterone, which feeds back in a negative fashion at the level of the pituitary and hypothalamus to inhibit further LH production. FSH stimulates sperm production through interaction with the Sertoli cells in the seminiferous tubules. Feedback inhibition of FSH is through gonadal steroids, as well as through inhibin, a glycoprotein produced by Sertoli cells.

Biochemical evaluation of the hypothalamic-pituitary-Leydig axis is carried out by measurement of serum LH and testosterone concentrations, whereas a semen analysis and serum FSH determination provide an assessment of the hypothalamic-pituitary-seminiferous tubular axis. The ability of the pituitary to release gonadotropins can be tested dynamically through GnRH stimulation, and the ability of the testes to secrete testosterone can be evaluated through injections of human chorionic gonadotropin (HCG), a glycoprotein hormone that has biologic activity similar to that of LH.

HYPOGONADISM

Either testosterone deficiency or defective spermatogenesis constitutes *hypogonadism*. Often both disorders coexist. The clinical manifestations of androgen deficiency depend on the time of onset and the degree of deficiency. Testosterone is required for development of the Wolffian duct into the epididymis, vas deferens, seminal vesicles, and ejaculatory ducts, as well as for virilization of the external genitalia through the major intracellular testosterone metabolite, dihydrotestosterone (DHT). Consequently, early prenatal androgen deficiency leads to the formation of ambiguous genitalia and to male pseudohermaphroditism. Androgen deficiency occurring later during gestation may result in micropenis or *cryptorchidism*, the unilateral or bilateral absence of testes in the scrotum resulting from the failure of normal testicular descent.

During puberty, androgens are responsible for male sexual differentiation, which includes growth of the scrotum, epididymis, vas deferens, seminal vesicles, prostate, penis, skeletal muscle, and larynx. Additionally, androgens stimulate the growth of axillary, pubic, facial, and body hair and increase sebaceous gland activity. They are also responsible through conversion to estrogens for the growth and fusion of the epiphyseal cartilaginous plates, clinically seen as the *pubertal growth spurt*. Prepubertal androgen deficiency leads to poor muscle development, decreased strength and endurance, a

high-pitched voice, sparse axillary and pubic hair, and the absence of facial and body hair. The long bones of the lower extremities and arms may continue to grow under the influence of growth hormone; this condition leads to eunuchoid proportions (i.e., arm span exceeding total height by ≥ 5 cm) and greater growth of the lower extremities relative to total height. Postpubertal androgen deficiency may result in a decrease in libido, impotence, low energy, fine wrinkling around the corners of the eyes and mouth, and diminished facial and body hair.

Male hypogonadism may be classified into three categories according to the level of the defect (Table 67.1). Diseases directly affecting the testes result in *primary* or *hypergonadotropic hypogonadism*, which is characterized by oligospermia or azospermia and low testosterone levels but exhibits elevations of LH and FSH because of a decrease in the negative feedback regulation on the pituitary and hypothalamus by androgens, estrogens, and inhibin. In contrast, hypogonadism from lesions in the hypothalamus or pituitary gives rise to *secondary* or *hypogonadotropic hypogonadism*; the low testosterone level or ineffective spermatogenesis results from inadequate concentrations of the gonadotropins. The third category of hypogonadism is the result of defects in androgen action.

Hypothalamic-Pituitary Disorders

Panhypopituitarism occurs congenitally from structural defects or from inadequate production or release of the hypothalamic-releasing factors. The condition may also be acquired through replacement by tumors, infarction from vascular insufficiency, infiltrative disorders, autoimmune diseases, trauma, and infections.

Kallmann syndrome is a form of hypogonadotropic hypogonadism that is associated with problems in the ability to discriminate odors, either incompletely (*hyposmia*) or completely (*anosmia*). This syndrome results from a defect in the migration of the GnRH neurons from the olfactory placode into the hypothalamus. Therefore, it represents a GnRH deficiency. Patients remain prepubertal, with small, rubbery testes, and they develop eunuchoidism (E-Fig. 67.1).

Hyperprolactinemia may result in hypogonadotropic hypogonadism because prolactin elevation inhibits normal release of GnRH, decreases the effectiveness of LH at the Leydig cell level, and also inhibits some of the actions of testosterone at the level of the target organ. Normalization of prolactin levels through withdrawal of an offending drug, by surgical removal of the pituitary adenoma, or with the use of dopamine agonists reverses this form of hypogonadism.

Weight loss or systemic illness in male patients can cause another form of secondary hypogonadism, *hypothalamic dysfunction*. Weight loss or illness induces a defect in the hypothalamic release of GnRH and results in low levels of gonadotropin and testosterone. This condition is commonly observed in patients with cancer, AIDS, or chronic

Fig. 67.1 Regulation of the hypothalamic-pituitary-testicular axis. The plus (+) and minus (–) symbols indicate positive and negative feedback, respectively. FSH, Follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone.

inflammatory processes. Prolonged use of opioids and therapeutic doses of glucocorticoids may suppress gonadotropin production and cause secondary hypogonadism.

Primary Gonadal Abnormalities

The most common congenital cause of primary testicular failure is *Klinefelter's syndrome*, which occurs in about 1 of every 600 live male births and is usually caused by a maternal meiotic chromosomal nondisjunction that results in an XXY genotype. At puberty, clinical findings include the following: a variable degree of hypogonadism; gynecomastia; small, firm testes measuring less than 2 cm in the longest axis (normal testes, 3.5 cm or greater); azoospermia; eunuchoid skeletal proportions; and elevations of FSH and LH (E-Fig. 67.2). Primary gonadal failure is also found in patients with another congenital condition, *myotonic dystrophy*, which is characterized by progressive weakness; atrophy of the facial, neck, hand, and lower extremity muscles; frontal baldness; and myotonia.

About 3% of full-term male infants have *cryptorchidism*, which spontaneously corrects during the first year of life in most cases; consequently, by 1 year of age, the incidence of this condition is about 0.8%. When the testes are maintained in the intra-abdominal position, the increased temperature leads to defective spermatogenesis and oligospermia. Leydig cell function usually remains normal, resulting in normal levels of adult testosterone.

Bilateral anorchia, also known as the vanishing testicle syndrome, is a rare condition in which the external genitalia are fully formed, indicating that ample quantities of testosterone and DHT were produced during early embryogenesis. However, the testicular tissue disappears before or shortly after birth, and the result is an empty scrotum. This condition is differentiated from cryptorchidism by an

- Adult Leydig cell failure
- Androgen biosynthesis enzyme deficiency

Defects in Androgen Action

- Testicular feminization (complete androgen insensitivity)
- Incomplete androgen insensitivity
- 5 α -Reductase deficiency

HCG stimulation test. Patients with cryptorchidism have an increase in serum testosterone level after an injection of HCG, whereas patients with bilateral anorchia do not.

Acquired gonadal failure has numerous causes. The adult seminiferous tubules are susceptible to a variety of injuries, and seminiferous tubular failure is found after infections such as mumps, gonococcal or leptomatous orchitis, irradiation, vascular injury, trauma, alcohol ingestion, and use of chemotherapeutic drugs, especially alkylating agents. The serum FSH concentration may be normal or elevated, depending on the degree of damage to the seminiferous tubules. The Leydig cell compartment may also be damaged by these same conditions. In addition, some men experience a gradual decline in testicular function as they age, possibly because of microvascular insufficiency. Patients with decreased testosterone production may clinically exhibit lowered libido and potency, emotional lability, fatigue, and vasomotor symptoms such as hot flashes. The serum LH concentration is usually elevated in this situation.

Defects in Androgen Action

When either testosterone or its metabolite, DHT, binds to the androgen receptor in target cells, the receptor is activated and binds DNA; the resulting stimulation of transcription, protein synthesis, and cell growth collectively constitutes androgen action. An absence of androgen receptors causes the syndrome of *testicular feminization*, a form of male pseudohermaphroditism. These genetic males have cryptorchid testes but appear to be phenotypic females. Because androgens are inactive during embryogenesis, the labial-scrotal folds fail to fuse, and a short vagina results. The fallopian tubes, uterus, and upper portion of the vagina are absent because the fetal testicular Sertoli cells secrete Anti-Müllerian duct hormone (Müllerian duct inhibitory factor) during early fetal development. At puberty, these patients have breast enlargement because the testes secrete a small amount of estradiol and the peripheral tissues convert testosterone and adrenal androgens to estrogens. Axillary and pubic hair does not grow because androgen action is required for their development. The serum testosterone concentrations are elevated as a result of continuous stimulation by elevated concentrations of LH. LH is high because of the inability of the testosterone to act in a negative feedback fashion at

E-Fig. 67.1 A boy aged 15 years, 10 months, with isolated gonadotropin deficiency and anosmia (Kallmann syndrome). He had undescended testes, but after administration of 10,000 U of human chorionic gonadotropin (HCG), the testes descended and were palpable in the scrotum. Height was 163.9 cm (−1.5 standard deviation); the upper-to-lower body ratio was 0.86, which is eunuchoid. The phallus measured 6.3 × 1.8 cm, and the testes were 1.2 × 0.8 cm. The concentration of plasma luteinizing hormone (FSH) was 1.2 ng/mL, and that of testosterone was 16 ng/mL. After administration of 100 µg of LH-releasing hormone (LHRH), the plasma LH (LER-960) was 0.7 ng/mL, and the FSH (LER-869) was 2.4 ng/mL. (From Styne DM, Grumbach MM: Puberty in the male and female: its physiology and disorders. In Yen SCC, Jaffee RB, editors: Reproductive endocrinology, ed 2, Philadelphia, 1986, Saunders, p. 313-384.)

E-Fig. 67.2 (A) A 19-year-old phenotypic male with chromatin-positive seminiferous tubule dysgenesis (Klinefelter's syndrome). The karyotype was 47,XXY, gonadotropin levels were elevated, and testosterone levels were low-normal. Notice normal virilization with long legs and gynecomastia (B). (C) The testes were small and firm and measured 1.8×0.9 cm. Testicular biopsy revealed a severe degree of hyalinization of the seminiferous tubules and clumping of Leydig cells. (D) A 48-year-old male with 47, XXY Klinefelter's syndrome with severe leg varicosities. (From Larsen PR, Kronenberg HM, Melred S, et al, editors: *Williams textbook of endocrinology*, ed 10, Philadelphia, 2002, Saunders.)

the hypothalamus. Patients may have incomplete forms of androgen insensitivity caused by point mutations affecting the androgen receptor gene, and clinically these patients show varying degrees of male pseudohermaphroditism.

Patients who lack the 5α -reductase enzyme that is required to convert testosterone to DHT are born with a *bifid scrotum*, which reflects abnormal fusion of the labial-scrotal folds, and *hypospadias*, in which the urethral opening is in the perineal area or in the shaft of the penis. At puberty, androgen production is sufficient to partially overcome the defect; the scrotum, phallus, and muscle mass enlarge, and these patients appear to develop into physiologically normal men.

Diagnosis

Fig. 67.2 illustrates an algorithm for the laboratory evaluation of hypogonadism in a phenotypic man. Serum concentrations of LH, FSH, and testosterone should be obtained, and a semen analysis should be performed. A low testosterone level with low concentrations of gonadotropins indicates a hypothalamic-pituitary abnormality, which needs to be evaluated with serum prolactin determination and radiographic examination. Elevated concentrations of gonadotropins with a normal or low testosterone level reflect a primary testicular abnormality. If no testes are palpable in the scrotum and careful *milking* of the patient's

lower abdomen does not bring retractile testes into the scrotum, an HCG stimulation test should be performed. A rise in serum testosterone concentrations indicates the presence of functional testicular tissue, and a diagnosis of cryptorchidism can be made. Absence of a rise in testosterone suggests bilateral anorchia. Small, firm testes in the scrotum are highly suggestive of Klinefelter's syndrome; this diagnosis needs to be confirmed with a chromosomal karyotype. Testes that are more than 3.5 cm in longest diameter and that are either of normal consistency or are soft indicate postpubertal acquired primary hypogonadism.

If the major abnormality is a deficient sperm count with or without an elevation of FSH, differentiation between a ductal problem and acquired primary hypogonadism must be made. If spermatozoa are present, at least the ducts emanating from one testicle are patent; this condition indicates an acquired testicular defect. If the patient has no sperm in the ejaculate, a primary testicular or ductal problem may be responsible. The seminal vesicles secrete fructose into the seminal fluid. Therefore, the presence of fructose in the ejaculate should be followed by a testicular biopsy to determine whether the defect results from spermatogenic failure or from an obstruction of the ducts leading from the testes to the seminal vesicles. Absence of seminal fluid fructose indicates a congenital absence of the seminal vesicles and vas deferens.

Male Infertility

The inability to conceive after 1 year of unprotected sexual intercourse affects about 15% of couples, and male factors appear to be responsible in about 20% of cases. Female factors account for close to 40%, and a couple factor is present in about 25% of cases with about 15% being undefined. In addition to the defects in spermatogenesis that occur in patients with hypothalamic, pituitary, testicular, or androgen action disorders, hyperthyroidism, hypothyroidism, adrenal abnormalities, and systemic illnesses can result in defective spermatogenesis, as can microdeletions of genetic material on the Y chromosome. Disorders of the vas deferens, seminal vesicles, and prostate may also lead to infertility, as may diseases affecting the bladder sphincter that result in *retrograde ejaculation*, in which the sperm passes into the bladder rather than through the penis. Anatomic defects of the penis (as observed in patients with hypospadias), poor coital technique, and the presence of antisperm antibodies in the male or female genital tract also are associated with infertility.

Therapy for Hypogonadism and Infertility

Treatment of androgen deficiency in patients who have hypothalamic-pituitary or primary testicular abnormalities is best accomplished with exogenous testosterone administration—either intramuscular injection of intermediate (1-3 weeks)- or long (3 months)-acting testosterone esters or transdermal testosterone patches or gel. Buccal, nasal, and subcutaneous testosterone pellets are also available but are less often used. Testosterone therapy increases libido, potency, muscle mass, strength, athletic endurance, hair growth on the face and body, and bone density. The most common side effect is erythrocytosis. Other side effects include acne, fluid retention, benign prostate hyperplasia, and, rarely, sleep apnea. This therapy is contraindicated in patients with cancer of the prostate.

If fertility is desired, patients with hypothalamic abnormalities may develop virilization and spermatogenesis with the use of GnRH delivered in a pulsatile fashion subcutaneously by an external pump. Direct stimulation of the testes in patients with hypothalamic or pituitary abnormalities may be accomplished with the use of exogenous gonadotropins, which increase testosterone and sperm production. If primary testicular failure is present and the patient has oligospermia, an attempt can be made to concentrate the sperm for intrauterine insemination or in vitro fertilization. If the azoospermia is caused by ductal obstruction, repair of the obstruction may be undertaken or aspiration of sperm from the epididymis may be accomplished for in vitro fertilization.

GYNECOMASTIA

Gynecomastia refers to a benign enlargement of the male breast that results from proliferation of the glandular component. This common condition is found in close to 70% of pubertal boys and in about one third of adults 50 to 80 years old. Estrogens stimulate and androgens inhibit breast glandular development; gynecomastia results from an imbalance between estrogen and androgen actions at the breast tissue level. This condition may result from an absolute increase in free estrogens, a decrease in endogenous free androgens, androgen insensitivity of the tissues, or enhanced sensitivity of the breast tissue to estrogens. [Table 67.2](#) lists the common conditions associated with gynecomastia.

Gynecomastia must be differentiated from fatty enlargement of the breasts without glandular proliferation and from other disorders of the breasts, especially breast carcinoma. *Male breast cancer* usually manifests as a unilateral, eccentric, hard or firm mass that is fixed to the underlying tissues. It may be associated with skin dimpling or

Idiopathic

retraction or with crusting of the nipple or nipple discharge. In contrast, gynecomastia occurs concentrically around the nipple and is not fixed to the underlying structures. Although physical examination is usually sufficient to differentiate gynecomastia from breast carcinoma, mammography or ultrasonography may be required.

Painful and tender gynecomastia in a pubertal adolescent should be monitored with periodic examinations because, in most patients, pubertal gynecomastia disappears within 1 year. Incidentally discovered, asymptomatic gynecomastia in an adult requires a careful assessment for alcohol, drug, or medication use; liver, lung, or kidney dysfunction; and signs and symptoms of hypogonadism or hyperthyroidism. If these conditions are not present, only follow-up is required. In contrast, in an adult with recent onset of progressive painful gynecomastia, thyroid, liver, and renal function should be determined. If test results are normal, serum concentrations of HCG, LH, testosterone, and estradiol should be measured. Further evaluation should be carried out according to the schema outlined in [Fig. 67.3](#).

Removal of the offending drug or correction of the underlying condition causing the gynecomastia may result in regression of the breast glandular tissue. If the gynecomastia persists, an off-label trial of antiestrogens (e.g., tamoxifen) may be given for 3 months to see whether regression occurs. Gynecomastia that has been present for longer than 1 year usually contains a fibrotic component that does not respond to medications. In these cases, correction usually requires surgical removal of the tissue.

For a deeper discussion on this topic, please see Chapter 223, “Reproductive Endocrinology and Infertility,” in *Goldman-Cecil Medicine*, 26th Edition. ❖

Diabetes Mellitus, Hypoglycemia

Robert J. Smith

DIABETES MELLITUS

Definition and Diagnostic Criteria

Diabetes mellitus is not a single disease but a group of disorders that develop as a consequence of absolute or relative deficiency of the hormone insulin. Inadequate actions of insulin in stimulating the uptake of glucose by body tissues and regulating the metabolism of carbohydrate, fat, and protein result in *hyperglycemia*. Other metabolic disturbances in addition to hyperglycemia typically occur in uncontrolled diabetes, including altered lipoprotein dynamics and elevated free fatty acid levels. These abnormalities contribute to the acute and chronic clinical consequences of diabetes.

The criteria used to diagnose diabetes mellitus in nonpregnant individuals are summarized in [Table 68.1](#). The diagnosis can be made on the basis of a fasting blood glucose level of 126 mg/dL or higher, a random blood glucose concentration (i.e., determined at any time in association with meals or fasting) of 200 mg/dL or higher, or a 2-hour glucose level of 200 mg/dL or higher as part of a 75-g oral glucose tolerance test. Alternatively, diabetes can be diagnosed if the hemoglobin A_{1c} (HbA_{1c}) level is 6.5% or higher. HbA_{1c}, a measure of the percentage of hemoglobin in circulating erythrocytes that is glycosylated, correlates with mean circulating glucose levels. HbA_{1c} provides an index of the average blood glucose level over the preceding 2 to 3 months. Because HbA_{1c} accumulates progressively throughout the lifespan of an erythrocyte, spurious values may occur in states of altered erythrocyte turnover (e.g., with various anemias) or with certain hemoglobinopathies that increase or decrease the susceptibility of hemoglobin to glycosylation. In patients with marked elevations in blood glucose or HbA_{1c} and coincident symptoms typical for hyperglycemia (e.g., polyuria and polydipsia), the diagnosis can be made based on a single test result. With less marked glucose elevations in the absence of symptoms, the diagnosis should be confirmed by repeat testing on a separate day.

Patients who have mild elevations in plasma glucose levels that do not reach the threshold for diagnosis of diabetes (e.g., HbA_{1c} levels between 5.7% and 6.4%) are at increased risk for progression to diabetes and therefore are considered to have *prediabetes*. Prediabetes patients with fasting blood glucose levels between 100 and 125 mg/dL are more specifically labeled as having *impaired fasting glucose*, and those with 2-hour postprandial plasma glucose levels between 140 and 199 mg/dL (most reliably measured after a standardized 75-g oral glucose load) have *impaired glucose tolerance* (see [Table 68.1](#)). Although not all individuals with prediabetes will become diabetic, the mean progression rate to overt diabetes is approximately 6% per year. There also is evidence from observational studies that the prediabetic state is associated with an increased risk of cardiovascular disease.

Gestational diabetes mellitus (GDM) is a term applied to diabetes first recognized during pregnancy. The most widely accepted

thresholds for diagnosis of GDM are a fasting plasma glucose level of 92 mg/dL or higher at any gestational stage and values on a 75-g oral glucose tolerance test at 24 to 28 weeks' gestation of 92 mg/dL or higher fasting, 180 mg/dL or higher at 1 hour, or 153 mg/dL or higher at 2 hours after glucose loading ([Table 68.2](#)). Untreated diabetes in pregnancy is associated with increased fetal malformations, problems in delivery, and possibly more frequent diabetes complications in the mother.

Etiologic Classification

Once the diagnosis is made based on elevated blood glucose or HbA_{1c} values, it is important to establish the specific subtype of diabetes based on a combination of clinical and molecular pathophysiologic features [Table 68.3](#).

Type 1 diabetes (T1DM) is characterized by extensive destruction of the insulin-producing beta cells within the islets of Langerhans in the pancreas and dependence on insulin therapy for survival. In previous medical literature, the terms *juvenile-onset diabetes* or *insulin-dependent diabetes* were used for T1DM. This terminology is no longer used, because T1DM not uncommonly has its onset in adulthood, and multiple other forms of diabetes often require treatment with insulin. T1DM accounts for 5% to 10% of all diabetes in the United States. In most patients, it involves autoimmune mechanisms leading to beta cell destruction (the *type 1A* form). Rare individuals have no markers for autoimmunity and are classified as having *type 1B (idiopathic) diabetes*. Most patients with T1DM progress to marked insulin deficiency over a period of several weeks to months after initial presentation. A smaller number of individuals with evidence of beta-cell autoimmunity but much slower disease progression have a variant form of T1DM that has been designated *latent autoimmune diabetes of adulthood* (LADA).

In patients with marked elevations in glucose and accompanying ketoacidosis, particularly if they are young and nonobese, the diagnosis of T1DM is highly probable. This can be confirmed by measuring autoantibodies against glutamic acid decarboxylase (GAD65), insulin, tyrosine phosphatases (IA-2 and IA2-beta), and zinc transporter 8 (ZnT8), with several of these often obtained as a panel, and also by a clinical course demonstrating an ongoing need for insulin to control hyperglycemia. A fasting C-peptide level can be measured later in the disease to confirm marked deficiency in insulin secretion. C-peptide is a fragment of the insulin precursor proinsulin, which is cleaved during the synthesis of insulin. It is secreted and circulates in proportion to endogenous insulin production but is absent from injected exogenous insulin preparations.

Type 2 diabetes (T2DM) is a heterogeneous, clinically defined subtype that accounts for more than 90% of all diabetes in the United States. It typically has a gradual onset with progression over multiple years or even decades. There is often prolonged preservation of at least partial insulin secretory capacity together with evidence

TABLE 68.1 Criteria for the Diagnosis of Diabetes Mellitus

Measurement	Normal	Prediabetes	Diabetes Mellitus
Plasma glucose (mg/dL)			
Fasting ^a	<100	100-125 ^b	≥126
2-hr Postload ^c	<140	140-199 ^d	≥200
Random ^e			≥200
Hemoglobin A _{1c} (%)	≤5.6	5.7-6.4	≥6.5

^aFasting: no caloric intake for ≥8 hr.

^bImpaired fasting glucose.

^cPostload: Following a standardized 75-g oral glucose load or after a meal.

^dImpaired glucose tolerance.

^eRandom: any time of day, unrelated to meals.

Data from the American Diabetes Association Standards of Medical Care in Diabetes 2019, Diabetes Care 42(Suppl 1):S13-S28, 2019.

TABLE 68.2 Criteria for the Diagnosis of Gestational Diabetes Mellitus

Measurement	Diagnostic Threshold (mg/dL)
Plasma glucose	
Fasting ^a	≥92
After 75-g oral glucose load	
1 hr	≥180
2 hr	<153

^aFasting: no caloric intake for ≥8 hr.

of insulin resistance. Most patients have associated obesity (80% to 90%), although a subset of patients with a clinical picture otherwise typical for T2DM are nonobese. T2DM usually can be presumptively distinguished from T1DM by its indolent course in the presence of risk factors such as obesity and by the milder hyperglycemia and absence of ketoacidosis due to residual insulin secretion. If there is clinical suspicion of T1DM based on earlier age at onset, degree of hyperglycemia, absence of obesity, or presence of ketoacidosis, an autoantibody panel (which should be negative) and a C-peptide level (which should be positive) can be measured.

An expanding number of diabetes etiologies distinct from T1DM and T2DM are classified under a broad category designated *other specific types*. Although these forms of diabetes are uncommon (<5% of all diabetes), it is important to recognize them in clinical practice. They include a group of inherited, monogenic, autosomal dominant disorders that previously were designated *maturity-onset diabetes of the young (MODY)*; many of these patients have clinical features similar to those of T2DM but onset typically before 25 years of age. Patients with hepatocyte nuclear factor-1 α mutations (MODY3) are particularly sensitive to sulfonylureas, whereas those with glucokinase mutations (MODY2) have mild, nonprogressive blood glucose elevations and often require no treatment except during pregnancy. Because the genetic diagnosis can direct the treatment plan for these individuals, patients with early-onset diabetes, lack of autoimmune markers, and family histories suggestive of autosomal dominant inheritance should be considered for MODY gene sequencing.

TABLE 68.3 Etiologic Classification of Diabetes Mellitus

Type 1 Diabetes Mellitus

Immune-mediated (type 1A)

Idiopathic (type 1B)

Type 2 Diabetes Mellitus

Other Specific Types

Genetic defects of beta-cell function

Maturity-onset diabetes of the young (MODY) and other disorders

Genetic defects in insulin action

Insulin receptor mutations and other disorders

Diseases of the exocrine pancreas

Endocrinopathies

Cushing's syndrome, acromegaly, and other disorders

Drug- or chemical-induced

Glucocorticoids most common

Infections

Uncommon forms of immune-mediated diabetes

Insulin receptor–blocking antibodies and other disorders

Other genetic syndromes sometimes associated with diabetes

Gestational Diabetes Mellitus

Classification consistent with the American Diabetes Association Standards of Medical Care in Diabetes 2019, Diabetes Care 42 (Suppl 1):S13-S28, 2019.

Much less common monogenic causes include mutations in insulin receptors or various other genes involved in insulin action. Exocrine pancreatic disease from disorders such as chronic pancreatitis or surgery results in loss of the glucagon-producing islet alpha cells as well as the insulin-producing beta cells. These patients often exhibit greater sensitivity to insulin and more of a propensity for hypoglycemia than T1DM patients because of the absent insulin counter-regulatory effects of glucagon. Endocrine disorders with excess production of hormones that counteract insulin, such as growth hormone in acromegaly or cortisol in Cushing's syndrome, are important to recognize as causes of diabetes because removal of the source of excess hormone can lead to resolution of the diabetic state. Many drugs have been associated with diabetes, most notably glucocorticoids.

The category GDM includes any woman in whom diabetes is first recognized during pregnancy and usually represents T2DM.

Type 1 Diabetes

Epidemiology and Pathology

The principal features of T1DM, contrasted with T2DM, are summarized in Table 68.4. The peak incidence occurs between the ages of 6 and 14 years, but onset in approximately half of patients with T1DM occurs after the age of 20. The role of genetic factors in T1DM risk is supported by an observed increased incidence of T1DM among family members of affected patients: approximately 5% in siblings, 6% in offspring of a diabetic father, and 2% in offspring of a diabetic mother. It is hypothesized that the immune destruction of beta cells is predisposed by genetic risk factors and precipitated by environmental factors, the latter possibly including microbial, chemical, or dietary triggers (Fig. 68.1). The operation of a combination of genetic and environmental factors is thought to explain the high but not absolute concordance observed in monozygotic twins (30% to 50%).

The prevalence of T1DM varies substantially in different populations; for example, it is relatively high in northwestern Europe and much lower in parts of Asia. The overall prevalence in the United

TABLE 68.4 General Comparison of the Two Most Common Types of Diabetes Mellitus

	Type 1	Type 2
Previous terminology	Insulin-dependent diabetes mellitus, type I; juvenile-onset diabetes	Non-insulin-dependent diabetes mellitus, type II; adult-onset diabetes
Age at onset	Usually <30 yr, particularly childhood and adolescence, but any age	Usually >40 yr, but increasingly at younger ages
Genetic predisposition	Moderate; environmental factors required for expression; 35-50% concordance in monozygotic twins; multiple candidate genes proposed	Strong; 60-90% concordance in monozygotic twins; many candidate genes proposed
Human leukocyte antigen associations	Linkage to DQA and DQB, influenced by DRB3 and DRB4 (DR2 protective)	None known
Other associations	Autoimmune; Graves' disease, Hashimoto thyroiditis, vitiligo, Addison's disease, pernicious anemia	Heterogeneous, ongoing subclassification based on identification of specific pathogenic processes and genetic defects
Precipitating and risk factors	Largely unknown; microbial, chemical, dietary, other	Age, obesity (central), sedentary lifestyle, previous gestational diabetes
Findings at diagnosis	85-90% of patients have one and usually more autoantibodies to GAD ₆₅ , insulin, IA-2, IA-2 β , ZnT8	Possibly complications (microvascular and macrovascular) caused by significant hyperglycemia in the preceding asymptomatic period
Endogenous insulin levels	Low or absent	Usually present (relative deficiency), early hyperinsulinemia
Insulin resistance	Only with hyperglycemia or coincident obesity	Mostly present
Prolonged fast	Hyperglycemia, ketoacidosis	Euglycemia
Stress, withdrawal of insulin	Ketoacidosis	Nonketotic hyperglycemia, occasionally ketoacidosis

GAD, Glutamic acid decarboxylase; IA-2, IA-2 β , insuloma-associated protein 2 and 2 β (tyrosine phosphatases); ZnT8, zinc transporter 8.

Fig. 68.1 Natural history of type 1 diabetes mellitus. The honeymoon period with temporary improvement in beta-cell function occurs with the initiation of insulin therapy at the time of clinical diagnosis. GAD, Glutamic acid decarboxylase; HLA, human leukocyte antigen; IA-2, IA-2 β , tyrosine phosphatases; ICA, islet cell antibody; ICA512, islet cell autoantigen 512 (fragment of IA-2); IL-1, interleukin-1; NK, natural killer; Th1, subset of CD4+ helper T cells responsible for cell-mediated immunity; Th2, subset of CD4+ helper T cells responsible for humoral immunity; TNF- α , tumor necrosis factor- α .

States is approximately 2.4 cases per 1000 individuals. The frequent onset before age 20 makes T1DM one of the most common chronic, serious childhood diseases. It is the most common subtype of diabetes in childhood, accounting for approximately 70% of all cases, with T2DM accounting for most of the remainder. LADA, an uncommon variant form of autoimmune T1DM, is characterized by onset in adulthood and a more prolonged waxing and waning course than is typical for T1DM.

The onset of overt T1DM follows a preclinical phase of variable duration (typically extending from months to years) during which there is destruction of beta cells resulting predominantly from cell-mediated immune mechanisms (mononuclear cells; mainly CD8⁺ T lymphocytes). It is believed that the autoantibodies (against glutamic acid decarboxylase, insulin, tyrosine phosphatases, and zinc transporter 8) are generated for the most part in response to exposure of beta-cell and islet antigens and do not function as primary mediators of the destructive process. Nevertheless, demonstration of one or more autoantibodies represents the most sensitive and useful way to establish preclinical disease in patients at risk (e.g., first-degree relatives of patients with T1DM).

The complement of beta cells in a healthy individual normally provides enough excess insulin secretory capacity to maintain blood glucose levels until 80% to 90% of beta cells have been lost. In some patients, the subclinical loss of beta cells may be unmasked, resulting in hyperglycemia and possibly diabetic ketoacidosis (DKA) during the course of an intercurrent illness such as an incidental upper respiratory tract infection. This reflects a lack of adequate insulin reserve to compensate for stress-induced insulin resistance. After institution of insulin and other therapy, stress-induced insulin resistance resolves, and there may be an improvement in beta-cell function. Some patients then revert to a state in which no insulin is required. This phenomenon, designated the *honeymoon* period, can last for several weeks to as long as 1 year. Patients generally should continue insulin administration at doses low enough to be tolerated during this interval, because progressive beta-cell function can be expected eventually to result in recurrent hyperglycemia and, potentially, DKA.

Screening for T1DM is not a part of standard medical care. Autoantibody determinations in individuals with a family history of T1DM can help to define risk but do not reliably predict time of onset or otherwise guide clinical care. Screening for thyroid, adrenal, or other associated autoimmune disorders should be considered in patients with T1DM on an individual basis.

Clinical Presentation

T1DM most often manifests clinically with symptoms resulting from hyperglycemia and consequent osmotic diuresis. Patients typically have a history extending over days to weeks of worsening polyuria, plus polydipsia (as a compensatory response to hypovolemia and increased serum osmolality). The polyuria may be evident as bed wetting or daytime incontinence in children and as nocturia in adults. There typically also is weight loss, and patients often describe low energy and lethargy. Approximately 25% of patients with T1DM have progressed to DKA by the time of clinical presentation.

Treatment

The management of T1DM involves immediate treatment at the outset to correct hyperglycemia, fluid deficits, and DKA, if present, plus attention to possible precipitating or complicating factors such as infection. The initial treatment of T1DM should be coupled with education of patients and their family members (appropriate to the patient's age) concerning the needed skills to manage insulin administration, blood glucose testing, nutrition, and exercise. This often is best accomplished

by a team involving the physician, educators (typically specially trained nurses or pharmacists), and a dietician. Medical advice, patient education, and psychological support should be provided on an ongoing, long-term, individualized basis. The primary goal of glucose management is to minimize the degree of hyperglycemia and its attendant risks of long-term complications of diabetes, while avoiding the acute and chronic risks of hypoglycemia. Medical care should include attention to control of lipid levels, blood pressure, and other factors that affect the risks of long-term diabetes complications. Routine assessments of foot care, peripheral nerve function, retinal status, and renal function should be used to detect incipient diabetes complications and enable early treatment interventions. Other sources should be consulted for information on specific issues related to T1DM management in children and adolescents.

Blood glucose control. Patients with T1DM have an absolute requirement for exogenous insulin. The Diabetes Control and Complications Trial (DCCT) and other studies have established that improved glycemic control in patients with T1DM decreases long-term microvascular complications (retinopathy, nephropathy, and neuropathy). A follow-up study of the same patients (the Epidemiology of Diabetes Interventions and Complications [EDIC] study) further demonstrated lower cardiovascular morbidity and mortality with intensive insulin management. Based on these and other studies, the most generally accepted target goal for HbA_{1c} in T1DM is 7.0%, although selected individuals may safely target HbA_{1c} of 6.5%. For patients who have difficulty sensing hypoglycemia or who have other factors complicating blood glucose management (e.g., renal failure), it is appropriate to set an individualized HbA_{1c} goal of 8.0% or even higher.

Many preparations of insulin are available. They differ in rapidity of absorption, degree of peaking of blood levels, and duration of action after subcutaneous injection (Table 68.5). The different kinetics of recombinant human insulin preparations derive from their specific complexing with proteins and zinc. Additionally, multiple analogues of human insulin are available that have rapid or slow kinetics as a consequence of altered solubility at subcutaneous injection sites. Most insulin preparations are provided at a concentration of 100 U/mL (U-100), with some available at higher concentrations (200 or 500 U/mL). Self-monitoring of blood glucose (SMBG) by patients using glucose meters is critical to the implementation of an effective insulin regimen. Ideally, SMBG should be performed as frequently as practicable: fasting, preprandial, 2 hours postprandial, at bedtime, and occasionally at 2:00 to 3:00 AM. Values and times are saved in most meters for subsequent review. It is helpful for patients to manually record these data on a flowchart, and it is also possible to download meter data to a computer. SMBG records are most useful when annotated with relevant details on food intake, exercise, or the occurrence of symptoms. HbA_{1c} determinations generally should be obtained every 3 months.

Most cases of T1DM should be managed with an *intensive insulin therapy regimen* involving multiple (three or more) daily subcutaneous injections or continuous subcutaneous insulin infusion (CSII) using an insulin pump. Multiple-injection regimens, also termed *basal-bolus therapy*, typically involve injections of a long-acting insulin analogue (glargine, detemir, or degludec) once or twice daily to establish a stable basal insulin level. Regular insulin or a rapid-acting insulin analogue is additionally injected three or more times daily (before each meal and sometimes before snacks) to provide appropriate post-meal peaks in insulin levels. Usually, once glucose levels are stabilized on a regimen, the doses of long-acting insulin are kept constant from day to day. The rapid-acting insulin doses can be kept constant with efforts to ingest a fixed amount of carbohydrate and total calories at each meal. Alternatively, better control and greater flexibility can be achieved if

TABLE 68.5 Types of Insulin^a

Insulin Type	Generic Name	Preprandial Injection Timing (hr)	Onset (hr)	Peak (hr)	Duration (hr)	Bg Nadir (hr)
Rapid-acting	Lispro ^b	0-0.2	0.1-0.5	0.5-2	<5	2-4

BG, Blood glucose; NPA, neutral protamine aspart; NPH, neutral protamine Hagedorn; NPL, neutral protamine lispro.

^aTime profiles depend on several factors, including dose, anatomic site of injection, method (profiles in this table are for subcutaneous injections), duration of diabetes, type of diabetes, degree of insulin resistance, level of physical activity, presence of obesity, and body temperature. Preprandial injection timing depends on premeal BG values and insulin type.

^bInsulin analogue with reversal of lysine and proline at positions 28 and 29 on the B chain of the insulin molecule.

^cInsulin analogue with substitution of aspartic acid for proline at position 28 on the B chain of the insulin molecule.

^dInsulin analogue with substitution of lysine for asparagine at position 3 on the B chain and glutamic acid for lysine at position 29 on the B chain of the insulin molecule.

^eInsulin analogue with substitution of glycine for asparagine at position 21 on the A chain and addition of two arginines to the carboxyl terminus of the B chain of the insulin molecule.

^fDo not mix glargine or detemir in the same syringe with other insulins.

^gAdminister at same time each day, unrelated to meals. Morning administration may result in greater glucose lowering and less nocturnal hypoglycemia.

rapid-acting insulin doses are adjusted according to the blood glucose level (measured before each meal) and the carbohydrate calories ingested with the meal. The long-acting insulin glargine and detemir analogues cannot be mixed in a single syringe with other insulins; for this reason, basal-bolus regimens often require four or more daily injections.

For patients newly diagnosed with T1DM, a typical starting dose of insulin is a total of 0.2 to 0.4 U/kg/day, with the expectation that this will be increased to 0.6 to 0.7 U/kg/day over time. Approximately half of the total dose should be given as basal insulin. Basal glargine or detemir insulin may be administered as a single daily dose (in the morning or at bedtime), or two equally divided doses may be required, depending on individual patient blood glucose responses. Degludec normally requires only once daily injection. For a basal regimen using intermediate acting insulin (NPH), two thirds of the dose typically is given in the morning and one third at bedtime. This decreases the risk of nocturnal hypoglycemia and times the maximum NPH peak to approximately match the midday meal. The rapid-acting component of the daily insulin dose is distributed before meals according to meal size and content.

An insulin pump (continuous subcutaneous insulin infusion, CSII) represents the preferred method of insulin administration for many T1DM patients. These small, wearable devices contain a reservoir of

rapid-acting insulin that is infused via an easily placed subcutaneous catheter. A microprocessor-controlled pump provides the basal insulin infusion and can be programmed to adjust basal rates at multiple points during the day according to predetermined patient needs. The patient further instructs the pump to make bolus insulin injections to cover meals, snacks, or needed corrections in hyperglycemia. Controlled studies have shown that modestly better blood glucose control can be achieved with CSII, compared to basal-bolus regimens with multiple daily injections. When used appropriately, CSII represents the most flexible means of managing insulin doses, with options for dose adjustments and supplementation that do not require separate injections. Limitations include need for greater patient involvement, lack of a protective, long-acting subcutaneous insulin reservoir, and pump failure. Newly diagnosed T1DM should be managed for a period of time (at least 6 to 12 months) with intermittently injected insulin before transition to a pump is considered. During the transition from intermittent insulin injections to CSII in a patient with well-controlled blood glucose levels ($HbA_{1c} \leq 7.0\%$), the total daily insulin dose typically is decreased by 10% to 20% initially.

Many CSII patients require a slightly higher basal infusion rate in the early morning hours to accommodate the *dawn phenomenon*, a period of decreased insulin sensitivity secondary to circadian changes in secretion of insulin counter-regulatory hormones such as growth

hormone and cortisol. Adjustments in the basal rate may also be needed at other times of day because of changes in insulin sensitivity (e.g., in response to exercise). Premeal insulin boluses are calculated to include a correction dose if needed, based on the premeal blood glucose level, plus a meal coverage dose calculated from the patient's predetermined individual carbohydrate/insulin ratio. It often is most effective for a patient to be seen in a specialty setting during transition to CSII, so that an experienced educator (often a specially trained RN) can assist with needed patient education. Devices are available that provide continuous glucose monitoring (CGM), either as a separate device or integrated into a sensor-augmented insulin pump. Some of the latter devices have the capacity to automatically interrupt insulin delivery for a proscribed period in response to low blood glucose levels as a protection against hypoglycemia (especially useful for nocturnal hypoglycemia). One approved sensor-augmented insulin pump can adjust the basal insulin infusion rate based on the CGM data but still requires manual control of premeal insulin boluses and periodic confirmation of blood glucose levels by fingerstick testing.

Intensive insulin therapy is not appropriate for all T1DM patients. Some patients are unwilling or unable to manage the required frequent glucose monitoring, diet adherence, and multiple insulin boluses. In other patients, the tight blood glucose control and low HbA_{1c} targets that are the goals of intensive insulin therapy may not be feasible. For example, there may be an increased risk of hypoglycemia because of autonomic neuropathy and inability to sense hypoglycemia, or gastrointestinal neuropathy may cause gastroparesis resulting in unpredictable variations in nutrient digestion and absorption. Under such circumstances, simpler approaches to insulin therapy and blood glucose management, previously termed *conventional insulin therapy*, may be appropriate. Such a regimen may be based, for example, on two injections per day of intermediate-acting insulin with or without short- or rapid-acting insulin. As one example, a *split-mixed regimen* uses NPH/regular or NPH/lispro (or aspart or glulisine) formulations twice daily. Initially, two thirds of the estimated total daily dose is given before breakfast and one third before dinner; at each of these times, two thirds of the insulin is given as NPH and one third as regular or rapid-acting insulin. The amount of each insulin type at each of the injection times is then adjusted according to measured blood glucose levels, with the expectation that the peak of the morning NPH will cover lunch, the rapid-acting insulins will cover the other meals, and the NPH will otherwise ensure adequate basal blood glucose control. Two daily injections are made possible by mixing the intermediate- and rapid-acting insulins in a single syringe. Premixed insulin preparations, such as 70% NPH plus 30% rapid-acting insulin or 50% NPH plus 50% regular insulin, also are available for injection with syringes or with preloaded insulin pens. Premixed insulins provide greater ease of use but are less likely to achieve good glycemic control.

Hypoglycemia management. Irrespective of the specific treatment regimen, patients with T1DM need to learn how to manage hypoglycemia. Patients usually experience adrenergic symptoms (e.g., sweating, anxiety, tremulousness) as blood glucose levels decrease below the normal range (<50 to 70 mg/dL). If a patient is taking β -blockers, symptoms such as tachycardia and tremulousness might be blunted or absent. If glucose levels decrease markedly enough, patients may experience central nervous system (CNS) symptoms ranging from difficulty thinking clearly to confusion, obtundation, and loss of consciousness. If low blood glucose is confirmed (e.g., <70 mg/dL), 10 to 15 g of rapidly absorbed carbohydrate should be ingested. For a glucose level lower than 50 mg/dL, 20 to 30 g of carbohydrate is advisable. This can be provided as orange juice or crackers, or patients can carry glucose tablets or squeeze tubes of glucose solution (obtainable over the counter from pharmacies) for use in treating hypoglycemia.

The blood glucose level should be retested after 15 minutes, and the treatment should be repeated as needed until hypoglycemia is resolved. An alternative is to inject glucagon. For patients who have a history of hypoglycemia severe enough (including loss of consciousness) to require assistance from others, it often is helpful for a family member to be trained in glucagon injection. With severe hypoglycemia, there is a risk of injury, such as from a fall or automobile accident, as well as neurologic damage if hypoglycemia is sustained.

Nutritional management. Appropriate nutritional management is an essential component of an effective T1DM treatment program, both to facilitate blood glucose control and reduce risks of long-term diabetes complications. Patients should work with a medical professional who is trained in diabetes care to establish nutritional goals. Rather than target specific percentages or sources of dietary carbohydrate, protein, and fat, the diet should be individualized to the patient's lifestyle, exercise regimen, eating habits, culture, and financial resources.

Most diets focus on measuring and controlling the amounts rather than the sources of carbohydrates. Patients can learn how to estimate the grams of carbohydrate in a meal (*carbohydrate counting*) as a means of ensuring that a consistent amount of carbohydrate is ingested. Alternatively, they can use carbohydrate counting with each meal as part of a strategy that enables day-to-day variations in consumption with adjustments of mealtime insulin doses according to a predetermined, patient-specific *insulin/carbohydrate ratio*.

Because of the contribution of excess body weight to increased cardiovascular risk, a fundamental goal of nutritional management should be to maintain normal body weight or to achieve weight reduction in overweight or obese patients. Eating disorders including binge eating, anorexia nervosa, and bulimia are relatively common in T1DM, especially among younger female patients.

Exercise. Regular physical exercise should be encouraged for its beneficial effects on weight control, risks of long-term complications, and overall quality of life. The general recommendation of several expert panels is 30 minutes or more of moderate-intensity physical exercise on at least 5 days per week. Physical exercise burns calories in proportion to its duration and intensity and also may result in increased insulin sensitivity after exercise (sometimes lasting for many hours). It often is most effective for patients to schedule exercise periods with a consistent temporal relationship to meals and insulin injections. Blood glucose should be tested before and after exercise, and exercise should not be undertaken if the initial blood glucose level is low (because of increased risk of hypoglycemia) or if it is higher than 250 mg/dL (because of risk of inducing further blood glucose elevation and development of ketosis). Patients with T1DM should be encouraged to pursue age- and overall health-appropriate athletic interests, including competitive sports, but this should be done only with careful attention to blood glucose monitoring and appropriate adjustments in insulin regimen and diet.

Type 2 Diabetes

Epidemiology and Pathology

T2DM is an extraordinarily common disorder, affecting nearly 10% of the population in the United States and with a similar prevalence in most other developed or developing countries. Many additional individuals (approximately 8% of the US population) have a prediabetic state. T2DM is characterized by varying degrees of insulin resistance and insulin deficiency, which are believed to result from the impact of environmental factors on a background of genetic risk. The principal features of T2DM, contrasted with T1DM, are summarized in Table 68.4. The prevalence of T2DM has increased more than 10-fold over the past 50 years, driven primarily by population-wide increased

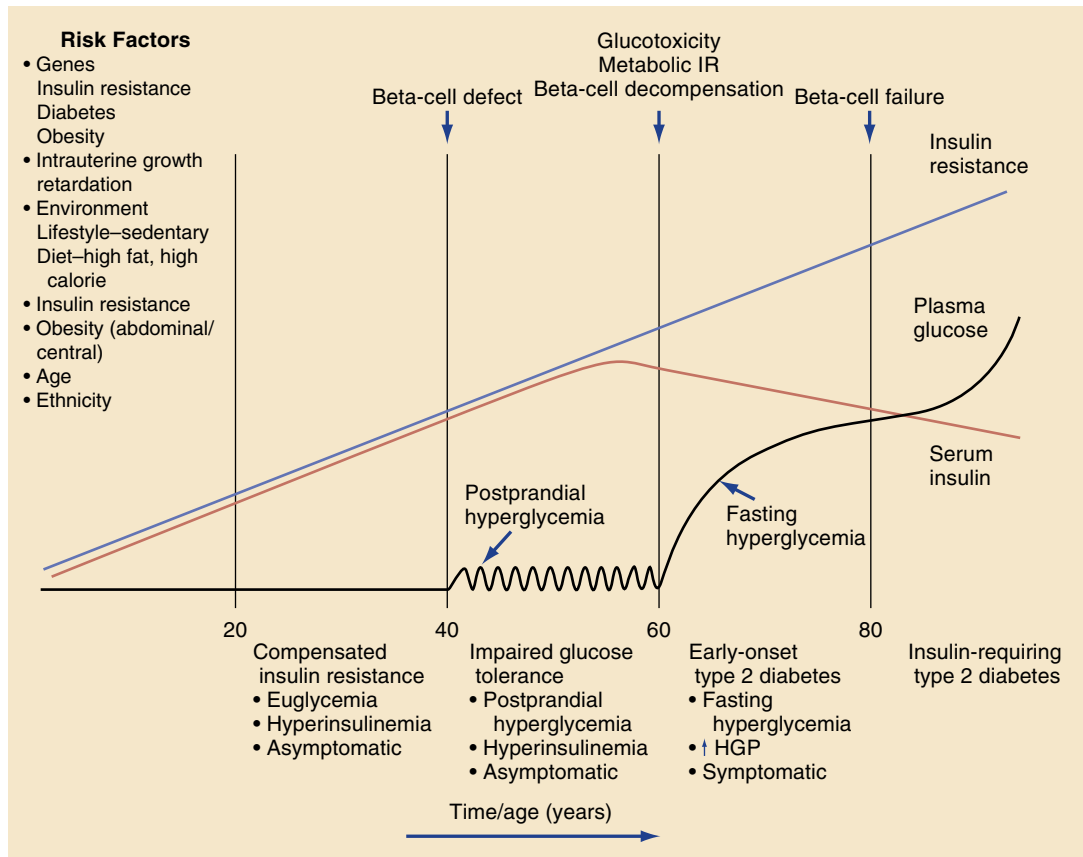

Fig. 68.2 Natural history of type 2 diabetes mellitus. The numbers for time/age markers in years for the different phases of beta-cell decompensation toward overt diabetes and an insulin-requiring state are approximate guides. Certain groups are more insulin sensitive and require a greater loss of beta-cell function to precipitate diabetes, compared with obese insulin-resistant people, who develop diabetes after small declines in beta-cell function. Use of insulin in patients with type 2 diabetes varies considerably and is not age dependent. *HGP*, Hepatic glucose production; *IR*, insulin resistance.

calorie intake, decreased exercise, and resulting obesity. More than 80% of patients with T2DM are obese. The peak incidence of T2DM occurs in the fifth and sixth decades; however, T2DM now accounts for up to 30% of childhood diabetes in some populations. The lifetime risk of developing T2DM is approximately 40% among the offspring of a single affected parent, and approximately 70% if both parents are affected. The incidence of T2DM in the United States is higher in Hispanic/Latino populations, among African Americans, and in some east Asian populations, compared to populations of northern and western European ancestry. This is thought to result in part from effects of socioeconomic and cultural factors (e.g., differences in consumption of low-cost, calorie-dense foods) and also from genetic differences among these populations. The genetic predisposition is thought to reflect the combined influence of more than 100 genes. No single gene or small group of genes with dominant influence on diabetes risk in any population has been identified.

T2DM is typically preceded by a prolonged preclinical or prediabetic phase during which there is a gradual deterioration in glucose tolerance (Fig. 68.2). This process occurs over a decade or more on average, with marked individual variation in the rate of progression. Most patients are insulin resistant during the preclinical phase but are able to compensate by producing enough insulin to maintain euglycemia. With time, there is progressive deterioration in the capacity to compensate for the insulin resistance. This is associated with a decrease in beta cell-mass during the preclinical phase of T2DM, but substantial

residual beta cells (typically 40% to 50% of the normal complement) are still present at the time that overt hyperglycemia develops. Therefore, there is compromised function as well as a reduced number of beta cells in T2DM. As blood glucose levels rise, the hyperglycemia itself may contribute to progression of the diabetic state by further decreasing insulin secretion and insulin resistance through mechanisms that are not well understood (referred to as *glucotoxicity*).

Screening of certain high-risk populations for T2DM and prediabetes by determination of a fasting or random plasma glucose measurement is considered cost-effective. Approximately 25% of people with T2DM and an even higher percentage of those with prediabetes are undiagnosed. Expert panel recommendations from the ADA for screening based on age, lifestyle factors, family history, and ethnicity are summarized in Table 68.6. Because of the insidious nature of T2DM, patients have a high risk for development of complications by the time of clinical diagnosis (see later discussion).

Clinical Presentation

Many patients are asymptomatic and are diagnosed on routine blood glucose testing. Blood glucose levels that rise high enough to exceed the renal threshold for glucose reabsorption (>170 mg/dL) induce an osmotic diuresis, resulting in the typical presenting symptoms of polyuria and polydipsia, as well as blurred vision secondary to osmotic shifts in the lens. Patients may also have weight loss or bacterial urinary tract or cutaneous fungal infections at presentation. Osmotic diuresis

TABLE 68.6 Screening Criteria for Diabetes in Asymptomatic Adults

1. Testing for diabetes should be considered in all persons ≥ 45 yr of age; if normal, the test should be repeated at 3-yr intervals.
2. Testing should be considered at a younger age (< 30 yr) or performed more frequently in individuals who
 - a. Have BMI ≥ 25 kg/m² (≥ 23 kg/m² in Asian Americans)
 - b. Have a sedentary lifestyle
 - c. Have a first-degree relative with diabetes (i.e., parent or sibling)
 - d. Are members of a high-risk ethnic population (e.g., African American, Latino/Hispanic American, Native American, Asian American, Pacific Islander)
 - e. Have been diagnosed with gestational diabetes
 - f. Are hypertensive ($\geq 140/90$ mm Hg)
 - g. Have an HDL cholesterol level < 35 mg/dL (0.9 mmol/L) and/or a triglyceride level > 250 mg/dL (2.82 mmol/L)
 - h. Have other clinical conditions associated with insulin resistance (e.g., PCOS, acanthosis nigricans)
 - i. Have a history of cardiovascular disease
 - j. Had prediabetes on previous testing (see criteria in Table 68.1); should be tested annually

BMI, Body mass index (weight [kg]/height [m²]); HbA_{1c}, glycosylated hemoglobin; HDL, high-density lipoprotein; PCOS, polycystic ovary syndrome; T1DM, type 1 diabetes mellitus; T2DM, type 2 diabetes mellitus. Modified from the American Diabetes Association Clinical Practice Recommendations 2013, Diabetes Care 36(Suppl 1):S11-S66, 2013.

secondary to hyperglycemia may lead to electrolyte abnormalities and even occasionally to a severe hyperosmolar state associated with clinical symptoms and signs including fatigue, weakness, and ultimately compromised mental status that can range from confusion to coma (see later discussion). This most frequently occurs in elderly patients who may have compromised baseline renal function. In contrast to patients with T1DM, those with T2DM usually have enough residual insulin activity to partially suppress lipolysis, and this protects them from developing DKA. In a subset of T2DM patients, DKA can develop, possibly reflecting individual variations in the degree of suppression of insulin secretion by glucotoxicity.

As a consequence of prolonged exposure to hyperglycemia and associated metabolic disturbances, patients with T2DM may already have developed long-term microvascular or macrovascular complications of diabetes by the time of diagnosis. Therefore, patients may experience a cardiovascular event, such as acute myocardial infarction, and then incidentally be found to have T2DM.

The metabolic syndrome. Susceptibility to cardiovascular disease is further increased by the frequent association of insulin resistance, prediabetes, and T2DM with other cardiovascular risk factors, including abdominal or visceral obesity, dyslipidemia, and hypertension. The term *metabolic syndrome* has been applied to patients who have a combination of these risk factors. Different but overlapping diagnostic criteria for the metabolic syndrome have been proposed by various expert panels. The National Cholesterol Education Program Adult Treatment Panel III (ATP III) defines this syndrome as the presence of any three of the following five characteristics:

1. Fasting blood glucose level ≥ 100 mg/dL or drug treatment for elevated blood glucose
2. High-density lipoprotein (HDL)-cholesterol < 40 mg/dL in men or < 50 mg/dL in women or drug treatment for low HDL-cholesterol
3. Plasma triglycerides ≥ 150 mg/dL or drug treatment for elevated triglycerides

4. Abdominal obesity (waist ≥ 102 cm in men or ≥ 88 cm in women)
5. Blood pressure $\geq 130/85$ mm Hg or drug treatment for hypertension.

There is debate about whether the metabolic syndrome represents a discrete pathologic entity, but its recognition does draw attention to the frequent clustering of cardiovascular risk factors.

Treatment

Patients with T2DM should receive nutrition counseling starting at the time of diagnosis. This should include efforts at weight loss in overweight or obese patients. Adjustments in diet, especially reductions in calorie intake, can rapidly improve blood glucose levels in many patients independent of other interventions. Weight reduction by as little as 10% to 20% of body weight can have marked beneficial effects on insulin resistance and glycemia in some patients.

Depending on initial blood glucose levels, the presence or absence of symptoms related to hyperglycemia, and the presence of other complicating medical conditions, a decision can be made on whether to treat the patient initially with diet alone or to also start medication. Patients with marked hyperglycemia, fluid deficits, altered mental status related to hyperosmolar state, and DKA should be hospitalized for acute treatment (see later discussion).

For most patients, treatment of T2DM can be conducted on an outpatient basis. Useful guidelines are available online from the American Diabetes Association (ADA) and the European Association for the Study of Diabetes. Most expert panels recommend starting with one or two oral glucose-lowering medications (depending on the degree of hyperglycemia) with progression to a third oral agent or insulin if this proves ineffective. In patients with marked hyperglycemia (≥ 300 mg/dL or HbA_{1c} $> 10\%$), consideration should be given to starting insulin from the outset. There typically is gradually progressive loss of beta-cell function in T2DM, extending sometimes over many years, and this results in a need over time for increased doses or additional glucose-lowering agents and often, ultimately, the use of insulin. As for T1DM, the overall management of T2DM should include not only the treatment of hyperglycemia but also interventions that assess, decrease the risks for, and treat long-term microvascular and macrovascular complications.

Blood glucose control. The United Kingdom Prevention of Diabetes Study (UKPDS) and other randomized, controlled trials have established that improved blood glucose control lowers the risk of microvascular long-term complications (retinopathy, nephropathy, and neuropathy) in T2DM. The risk appears to increase progressively, starting with any increment above normoglycemia. Randomized clinical trial data have not convincingly demonstrated improved macrovascular (i.e., cardiovascular disease) outcomes in response to improved blood glucose control in T2DM. T2DM patients, particularly those who are older or have complicating comorbid conditions, may have limited capacity to manage a tight blood glucose control regimen and also increased susceptibility to adverse effects of hypoglycemia. HbA_{1c} goals therefore should be developed on an individualized basis, such that the benefits of improving microvascular complications are balanced against the risks of hypoglycemia. Whereas HbA_{1c} of 7% or less is an appropriate target for younger T2DM patients, 8% or less may be an acceptable and safer target for older patients with complicating medical conditions and limited life expectancy. HbA_{1c} should be measured every 6 months, or at intervals of 3 months if glucose control is unstable or the treatment regimen is being adjusted. SMBG should be performed on a regular basis if patients are being treated with agents that can cause hypoglycemia (sulfonylureas, meglitinides, and insulin). Regular SMBG is not generally needed for patients on agents that do not cause hypoglycemia, although testing during intercurrent

TABLE 68.7 Non-Insulin Antidiabetic Agents by Drug Class^a

Drug Class	Available Agents (Generic Name)	Route of Administration	Mode of Action
Biguanide	Metformin	Oral	Insulin sensitizer
SGLT2 inhibitors	Canagliflozin, dapagliflozin, empagliflozin, ertugliflozin	Oral	Increase urinary glucose excretion
GLP-1 receptor agonists	Dulaglutide, exenatide, liraglutide, lixisenatide, semaglutide	Subcutaneous injection, semaglutide oral	Incretin mimetic
DPP-4 inhibitors	Alogliptin, linagliptin, saxagliptin, sitagliptin	Oral	Incretin amplifier
Thiazolidinediones	Pioglitazone, rosiglitazone	Oral	Insulin sensitizer
Sulfonylureas	Glipizide, glyburide, glimeperide, gliclazide, chlorpropamide, tolazamide	Oral	Insulin secretagogue
Meglitinides	Repaglinide, nateglinide	Oral	Insulin secretagogue
α -Glucosidase inhibitors	Acarbose, miglitol	Oral	Delay carbohydrate digestion/absorption
Amylin mimetics	Pramlintide	Subcutaneous injection	Delay gastric emptying, suppress glucagon

DPP-4, Dipeptidyl peptidase-4; GLP-1, glucagon-like peptide-1; SGLT2, sodium glucose co-transporter 2.

^aConsult current manufacturer information for details on available combinations, prescribing, and safety.

illnesses or with occurrence of symptoms suggestive of hyperglycemia is advisable.

Non-insulin pharmacologic (antidiabetic) agents in T2DM.

Non-insulin pharmacologic agents from many different drug classes are available for treatment of T2DM, some taken orally and others by injection (Table 68.7). When non-insulin pharmacologic agents are appropriate, metformin is generally preferred as first-line therapy because of its glucose-lowering efficacy, absence of weight gain and hypoglycemia, favorable safety and tolerability profile based on many years of clinical experience, and low cost. For patients who are unable to tolerate metformin, the choice of an alternative drug may be influenced by considerations such as glucose-lowering efficacy, patient preference for an oral versus an injectable agent, potential adverse effects (e.g., hypoglycemia, weight gain, or fluid retention), the presence of comorbidities (cardiovascular disease, heart failure, or chronic renal insufficiency), and cost. For patients with established atherosclerotic cardiovascular disease or chronic kidney disease (CKD), a sodium glucose cotransporter (SGLT2) inhibitor or glucagon-like peptide-1 (GLP-1) receptor agonist with established cardiovascular disease or CKD benefit should be considered. For patients with atherosclerotic heart disease and heart failure or high risk of heart failure, an SGLT2 inhibitor might be most appropriate. Dipeptidyl peptidase-4 (DPP-4) inhibitors represent another reasonable option as well-tolerated agents with established cardiovascular safety. When drug cost is a critical issue, a sulfonylurea is a reasonable choice, although these drugs have the disadvantages of inducing modest weight gain and causing hypoglycemia. Pioglitazone is another low-cost agent that is effective in lowering blood glucose, but it is associated with increased risk of fluid retention and heart failure.

If a single drug is tolerated but does not adequately control blood glucose levels, the usual practice is to continue that drug and add a second from a distinct drug class with choice of agent influenced by the factors stated previously. In patients with marked hyperglycemia (e.g., with HbA_{1c} \geq 1.5% above target) that is not judged severe enough to merit insulin treatment, two agents may be started from the outset. This has the potential advantage of more rapidly achieving blood glucose control but the disadvantage of exposing patients to the potential side effects of taking two drugs simultaneously. Many combination preparations are available for administration of more than one drug; these are more convenient for patients and sometimes less expensive than taking the multiple drugs separately.

Available non-insulin antidiabetic agents are summarized here and in Table 68.7. Current manufacturer information should be consulted before prescribing these drugs to ensure updated and adequately

detailed information on available single and combination agents and their effective and safe use.

Metformin. Metformin is an oral agent in the biguanide class that produces its most prominent effects by decreasing gluconeogenesis and thus reducing hepatic glucose production. This insulin-sensitizing effect is associated with a low risk of hypoglycemia. It has been in use for more than 30 years and is available in inexpensive generic form. The usual starting dose is 500 mg once or twice daily with incremental advancement at several-week intervals to a usual maximum of 2000 mg daily in two or three divided doses. Metformin typically decreases HbA_{1c} by up to 1.5%. Further benefits include modest weight loss (approximately 3 kg on average) and a small improvement in plasma lipid profile (decrease in low-density lipoprotein [LDL]-cholesterol and triglycerides and increase in HDL). Adverse reactions include gastrointestinal effects and, rarely, lactic acidosis. The drug should be avoided in patients with an estimated glomerular filtration rate (eGFR) of <30 mL/min/1.73m² and used at decreased dosage with an eGFR of 30 to 45 mL/min/1.73m².

SGLT2 inhibitors. Canagliflozin, dapagliflozin, empagliflozin, and ertugliflozin function by inhibiting SGLT2. SGLT2 mediates more than 90% of glucose reabsorption in the proximal renal tubule, and the drug lowers blood glucose levels by promoting excretion of glucose in the urine. This typically results in a decrease in HbA_{1c} in the range of 0.5% to 1.0%, plus modest weight loss (2-3 kg on average) and decrease in blood pressure. The mechanism of action is independent of insulin, and this class of drugs does not cause hypoglycemia. Large-scale, prospective, randomized clinical trials have shown decreased major cardiovascular events in T2DM patients with established cardiovascular disease with canagliflozin and empagliflozin. These studies, plus a similar trial with dapagliflozin in T2DM patients with milder cardiovascular disease history, have shown decreases in hospitalization for heart failure and progression of diabetic nephropathy. As a result, drugs in this class appear to be a favorable choice in patients with established cardiovascular disease or diabetic nephropathy. Concerns about potential side effects include urinary and genital infections, hypotension, acute renal injury, fractures in the context of low bone mineral density, increased lower extremity amputations, and DKA. Further studies will be needed to validate the benefits and potential adverse effects of these drugs and determine whether some of these responses are specific to individual members of the drug class. They are taken orally once daily, with dosage specific to each drug.

Glucagon-like peptide-1 receptor agonists. GLP-1 is one of several hormones produced in the small intestine (designated *incretins*) that modify gastrointestinal motility and insulin secretion. The GLP-1 receptor agonists, dulaglutide, exenatide, liraglutide, lixisenatide, and

semaglutide, bind to GLP-1 receptors and improve blood glucose control by enhancing glucose-dependent insulin secretion, slowing gastric emptying, suppressing postprandial glucagon production, and decreasing food intake through enhanced satiety. This results in decreases in HbA_{1c} by 0.5% to 1.5% and modest weight loss (in the range of 3 kg). There is evidence for improved cardiovascular outcomes for several of these agents in patients with established cardiovascular disease and possibly an improvement in CKD outcomes. They may be a favorable choice as a second-line drug for glycemia management if weight loss is a goal and in patients with established cardiovascular disease, with attention to the data available for specific agents. Because of their relatively high efficacy, GLP-1 receptor agonists are a reasonable option to consider before starting insulin in patients not adequately controlled on other agents. Most members of this drug class are administered via injection with prefilled pens, twice daily, once daily, or once weekly depending on the specific drug, and semaglutide also is available in an orally administered form. The most common side effects are nausea and sometimes diarrhea, likely related to effects on gastrointestinal motility, and these agents should not be used in patients with a history of pancreatitis or in combination with DPP-4 inhibitors.

Dipeptidyl peptidase-4 inhibitors. DPP-4 inhibitors (alogliptin, linagliptin, saxagliptin, and sitagliptin) block the deactivation of GLP-1 (described in the previous section) and glucose-dependent insulinotropic peptide (GIP), peptide hormones that are important in the regulation of glucose homeostasis. DPP-4 inhibitors are taken orally and result in decreased HbA_{1c} in the range of 0.5% to 1.0%. They have a low risk of causing hypoglycemia, have neutral effects on cardiovascular disease outcomes and body weight, and can be used in the context of CKD with agent-specific dose reductions. They have generally favorable side effect profiles, although there is concern that some members of the class may increase heart failure risk. They should not be used in combination with GLP-1 receptor agonists.

Pioglitazone. The thiazolidinedione, pioglitazone, activates the nuclear peroxisome proliferator-activated receptor- γ , which leads to changes in transcription rates of multiple genes. The net effect is reduced insulin resistance, resulting in increased glucose uptake in peripheral tissues and reduced hepatic glucose production. Pioglitazone typically lowers HbA_{1c} by 0.5% to 1.4% and is available as a low-cost drug. It carries a low risk of hypoglycemia, but potential side effects include weight gain, fluid retention and heart failure, hepatotoxicity, concerns about increased fracture risk in the setting of low bone density, and a potential link to bladder cancer. Another member of this drug class, rosiglitazone, is little used because of its potential link to increased cardiovascular events.

Sulfonylureas. Sulfonylureas stimulate endogenous insulin secretion by binding and activating potassium channels in beta cells. In patients with adequate residual beta-cell function, they can lower HbA_{1c} levels by 1% to 2%. Drugs in this class have been in clinical use for more than 40 years, and many inexpensive, generic sulfonylureas are available that differ in duration of action, metabolism, and mode of clearance. Because they can increase insulin secretion even in the absence of hyperglycemia, they have significant potential to cause hypoglycemia. Patients need to be instructed how to recognize and treat hypoglycemia before starting a sulfonylurea. Factors that increase the risk for hypoglycemia with sulfonylureas include advanced age, poor nutrition, alcohol ingestion, and hepatic and renal insufficiency. Other disadvantages of this drug class are a tendency to cause weight gain and a yet unresolved concern about increased risk for cardiovascular events.

Meglitinides. Repaglinide and nateglinide activate beta cell potassium channels and thus stimulate endogenous insulin secretion

through a mechanism similar to that of sulfonylureas, although they generally result in less reduction in blood glucose than sulfonylureas. They have rapid action and have less tendency to cause hypoglycemia than sulfonylureas. Their use has been limited by high cost and lack of advantage over the sulfonylureas.

α -Glucosidase inhibitors. The α -glucosidase inhibitors, acarbose and miglitol, are oral agents that improve glycemia by inhibiting the enzymatic breakdown of complex carbohydrates within the lumen of the small intestine. They have modest glucose-lowering effects, decreasing HbA_{1c} in the range of 0.5% to 0.8%. Their use is limited by the frequent occurrence of flatulence and diarrhea as a consequence of undigested carbohydrates reaching lower intestinal regions.

Pramlintide. Pramlintide is a stable analogue of the beta-cell peptide, amylin, which has actions that include slowing of gastric emptying, satiety effects that decrease food intake, and decrease in postmeal glucagon. It is not widely used because of required multiple injections and limited efficacy in lowering HbA_{1c}.

Insulin treatment in T2DM. For patients who have inadequate glycemic control with oral agents, insulin may be started as a basal supplement to the oral regimen. Frequently used choices include glargine or detemir (once or twice daily), degludec (once daily), or NPH (once daily at bedtime) (see later discussion and [Table 68.5](#) for more details on different types of insulin). Starting doses are typically in the range of 10 U (or can be more specifically calculated as 0.2 U/kg), with increases of 2 to 4 U at intervals of 3 days or longer based on blood glucose response. Oral agent regimens commonly are simplified at the time of starting insulin (e.g., shifting from multiple agents to a single oral agent). For patients who do not achieve adequate control with basal insulin, mealtime coverage is provided by a rapid-acting insulin. Often, under this circumstance, all oral agents are discontinued, and blood glucose control is achieved with the use of exogenous insulin alone. Compared to patients with T1DM, those with T2DM may not require as tight a match of carbohydrate to insulin doses at meals, perhaps because of some residual insulin secretion. For this reason, insulin pumps are less frequently used in T2DM.

Nutritional and weight management. Patients should receive counseling from a dietician and be assisted in developing a nutritional plan that is individualized to their lifestyle, exercise, culture, and financial resources. Guidelines from many current expert panels allow flexibility in the relative amounts of carbohydrate, fat, and protein. Nutritional management in T2DM often has a major focus on achieving reductions in calorie intake and weight loss. Achieving weight loss may be made more difficult by a tendency of some oral antidiabetic agents and also insulin to induce a degree of weight gain.

An important goal of nutritional management should be to balance the timing and quantities of ingested macronutrients with medications and exercise to help achieve targets for blood glucose control without periods of hypoglycemia.

For overweight or obese patients, it often is practical to set an initial goal of losing 5% to 10% of body weight. This may significantly improve diabetes control and increase the patient's motivation to then set goals for further weight loss (see [Chapter 69](#)).

Bariatric surgical procedures represent a method for achieving weight loss and potentially dramatic improvements in glycemia and risk factors for long-term complications in T2DM. Patients typically have improvements in glycemic control and lower requirements for antidiabetic medications within days after undergoing the Roux-en-Y gastric bypass procedure. This is thought to reflect changes in gut hormones and metabolic factors independent of weight loss. Beneficial effects on glucose control develop more gradually after the placement of an adjustable gastric band, sleeve gastrectomy, or other device.

Randomized trials comparing bariatric surgery with medical nutrition therapy alone for weight loss have shown greater efficacy in achieving HbA_{1c} goals with surgery, and some studies have shown dramatic rates of remission, with 75% of patients or more becoming normoglycemic off all antidiabetic agents (see [Chapter 69](#)).

Exercise. Physical exercise should be encouraged in T2DM as an important component of weight loss regimens and also for its beneficial effects in decreasing the risks of long-term complications. The general recommendation of several expert panels is 30 minutes or more of moderate-intensity physical exercise on at least 5 days per week, but the regimen needs to be highly individualized according to a patient's capabilities and limitations imposed by other medical conditions such as cardiovascular disease. Patients who are unwilling or unable to undertake significant aerobic exercise should be encouraged to do daily walking or other physical activities within their limitations.

Standards of Care in T1DM and T2DM in Addition to Blood Glucose Control

A number of assessments and interventions should be performed at intervals in patients with T1DM or T2DM. These include blood pressure measurement and examination of the feet at each physician visit. Patients who smoke should receive counseling at each visit about the importance of and strategies for discontinuing. A dilated eye examination should be performed annually, or more often in patients with diabetic eye disease. A dental examination also should be performed at least annually. Starting 5 years after disease onset in T1DM and at the time of diagnosis in T2DM, patients should have annual measurement of their urinary albumin/creatinine ratio with confirmation if elevated (>30 mg albumin per gram of creatinine). A fasting lipid profile should be obtained annually. Aspirin (75 to 162 mg daily) is usually recommended for secondary prevention of cardiovascular disease (supported by clinical trial evidence) or for primary prevention in patients with a 10-year cardiovascular risk greater than 10% (based on expert opinion). Influenza vaccination should be provided yearly; pneumococcal immunization should be given once and then repeated after age 65 (see latest CDC recommendations).

Management of Diabetes During Intercurrent Illness

Diabetes often requires changes in the blood glucose management regimen during an intercurrent illness to accommodate potential decreases in nutrient intake and increases in insulin resistance secondary to disease-related release of stress hormones. Patients with T1DM require exogenous insulin administration at all times to prevent marked hyperglycemia and DKA, even if they are unable to consume nutrients during an illness (e.g., with gastroenteritis). Depending on the degree and duration of interruption of food intake, they may require a transient, partial reduction in insulin dosage as well as more frequent glucose monitoring. Alternatively, if they are consuming a normal diet, they may require a modest increase in insulin dose because of insulin resistance related to the stress of illness. T2DM patients taking oral agents who are undergoing surgical procedures or are hospitalized for serious illness often require discontinuation of the oral agents and use of insulin to control blood glucose until normal eating patterns are resumed.

For hospitalized patients, blood glucose target goals are adjusted to prevent marked hyperglycemia and at the same time protect against hypoglycemia. For noncritical illness, typical blood glucose targets include lowest levels of 90 to 100 mg/dL, premeal levels lower than 140 mg/dL, and random levels lower than 180 mg/dL. For critically ill patients, intravenous insulin infusion may be needed to allow for rapid

adjustments in dosage, and the blood glucose range recommended by most expert panels is 140 to 180 mg/dL.

Gestational Diabetes Mellitus

The hormonal environment of pregnancy results in insulin resistance and therefore predisposes to the development or unmasking of diabetes during pregnancy. GDM occurs in 2% to 5% of all pregnancies and is associated with consequences for both mother and fetus if untreated. For this reason, screening for GDM is routinely performed between 24 and 28 weeks of gestation in women older than 25 years of age and in younger women who fulfill one or more of the risk criteria in [Table 68.6](#) (2a through 2d and 2g). Women who are at high risk (i.e., those who are obese, have a personal history of GDM, glycosuria, or have a first-degree relative with diabetes) should be screened at their initial obstetric or prenatal visit. A broadly accepted approach to screening is a 2-hour 75-g oral glucose tolerance test with cutoff values as specified in [Table 68.2](#).

A detailed discussion of the approach to managing GDM and also preexisting diabetes during pregnancy is beyond the scope of this chapter. The fundamental principles include diet, exercise, and glucose-lowering oral agents or insulin as needed. Blood glucose goals are set lower than in nonpregnant individuals because of the importance of minimizing exposure of the fetus to hyperglycemia: fasting, 95 mg/dL (5.3 mmol/L) or lower; 1-hour postprandial, 140 mg/dL (7.8 mmol/L) or lower; and 2-hours postprandial, 120 mg/dL (6.7 mmol/L) or lower. HbA_{1c} levels may be useful in establishing the presence of hyperglycemia before its discovery during pregnancy, but they have limited value in managing GDM. Women with GDM should be reevaluated with a 75-g glucose tolerance test 6 to 12 weeks after delivery, at which point approximately 10% will still have overt diabetes. Up to 40% of women with GDM go on to develop diabetes in the subsequent 20 years, with this risk varying substantially depending on ethnic background and obesity. Pregnancy serves as a provocative test and not as a risk factor for the future development of diabetes.

Management of Severe Metabolic Decompensation in Diabetes

Diabetic Ketoacidosis

DKA develops most commonly in patients with T1DM (approximately 2.5 cases per 100 T1DM patients per year). It also can occur in those with T2DM, especially during acute illness (severe infection, medical illness, or trauma), and in a subset of *ketosis-prone* T2DM patients. DKA is present in approximately 25% of T1DM patients at diagnosis and otherwise most often develops when patients with known T1DM stop taking prescribed insulin. It is a potentially life-threatening condition that has an overall mortality rate of approximately 1% to 2%, with most deaths resulting from complicating or precipitating medical conditions rather than the metabolic disturbances of DKA itself.

The pathophysiology of DKA results from the combined effects of insulin deficiency and increased levels of *insulin counter-regulatory (stress) hormones*. With insulin deficiency, glucose levels rise as a consequence of decreased uptake and metabolism by body tissues, the breakdown of hepatic glycogen stores (*glycogenolysis*), and net glucose production by the liver and kidney (*gluconeogenesis*). Catabolism of muscle proteins as a result of low insulin levels leads to the release of amino acids, which provide substrate that further drives gluconeogenesis. Because glucose is being synthesized endogenously, blood glucose levels rise markedly, even in the fasted state. Blood glucose levels greater than 170 mg/dL result in glycosuria. Excretion of glucose in the urine necessitates the co-excretion of large amounts of water and electrolytes (Na⁺ and K⁺). Patients experience polyuria but cannot

compensate adequately and become progressively more fluid and electrolyte depleted. The osmotic diuresis is characterized by greater losses of water than electrolytes, and this leads to progressively increasing hyperosmolality. Because of insulin deficiency, there is decreased *lipogenesis* and accelerated *lipolysis* leading to increased levels of circulating free fatty acids, which serve as a substrate for the hepatic synthesis of ketone bodies (β -hydroxybutyrate, acetoacetate, and acetone). β -Hydroxybutyrate and acetoacetate are acids, and their rising plasma levels contribute to the development of a metabolic acidosis.

These processes can result from simple insulin deficiency, but often they are exacerbated by an underlying or precipitating illness, such as an infection. Infection results in insulin resistance secondary to increased levels of *stress hormones* (cortisol, catecholamines, glucagon, and growth hormone). A series of positive feedback loops are thus generated and lead to ever-accelerating hyperglycemia, fluid and electrolyte depletion, ketosis, and metabolic acidosis. More than simple restoration of insulin dosing is required, and patients usually need hospital admission and multicomponent interventions.

Common presenting symptoms in DKA include polyuria, thirst and polydipsia, recent weight loss (especially in new-onset diabetes), blurred vision, weakness, anorexia, nausea and vomiting, abdominal pain (which can mimic acute abdomen), and mental status changes varying from somnolence to coma. DKA and these associated symptoms usually evolve over 2 to 4 days but can have an onset of less than 12 hours in patients using insulin pumps. On physical examination, patients typically have evidence of dehydration, especially intravascular volume depletion, including decreased skin turgor, hypotension, and tachycardia (best assessed in skin overlying the sternum and forehead). The skin may be warm and dry from the vasodilating effects of acidosis, and marked hypotension should generate concern for impending vascular collapse. Patients often have deep, rapid respirations (Kussmaul breathing) as respiratory compensation for the metabolic acidosis, together with a characteristic fruity odor on their breath from exhaled acetone. The diagnosis is made in patients who have (1) a high blood glucose concentration (>250 mg/dL), (2) moderate to severe ketonemia (β -hydroxybutyrate >5 mmol/L or positive ketone levels by Ketostix at a serum dilution of 1:2 or higher), and (3) acidosis (pH <7.3 or plasma bicarbonate ≤ 15 mEq/L). Measurements of urine ketones may be misleading, because urinary ketones can be positive during fasting in the absence of DKA.

Additional evaluation besides the diagnostic tests already mentioned should include electrolytes, blood urea nitrogen, creatinine, phosphate, liver function tests, and amylase; arterial or mixed venous blood gases (including pH); complete blood count; urinalysis; electrocardiogram; and chest radiographs. The serum anion gap, which is usually greater than 12 mEq/L in DKA, should be calculated (anion gap = $[\text{Na}^+] - [\text{Cl}^- + \text{HCO}_3^-]$). Serum osmolality should be measured directly or calculated: estimated osmolality = $(2 \times [\text{Na}^+]) + ([\text{glucose in mg/dL}]/18)$.

Precipitating causes of DKA include infection (most common), myocardial infarction (including silent infarction), inflammatory processes (appendicitis, pancreatitis), and medications (especially glucocorticoids).

Treatment of DKA should start promptly with institution of measures to correct life-threatening abnormalities, including insulin deficiency, fluid and electrolyte depletion, potassium (K^+) depletion, and metabolic acidosis. In a typical regimen, regular insulin or a rapid-acting insulin analog is administered as a bolus (0.1 U/kg) followed by a continuous intravenous infusion at 0.1 U/kg/hour. Plasma glucose is monitored hourly until it is less than 250 mg/dL, and the rate of insulin infusion is adjusted as needed to target a rate of blood glucose

decline of 75 to 100 mg/dL/hour to avoid potential complications of rapid shifts in osmolality.

At the time of starting insulin, it is essential to begin fluid and electrolyte replacement. The initial fluid deficit should be estimated based on the magnitude of weight loss (if known), mucous membrane dryness, skin turgor, and whether or not there is postural hypotension, with the knowledge that losses in DKA usually range from 3 to 8 L. A typical program for intravenous fluid replacement starts with 1 L of normal saline in the first hour. Normal saline may then be continued at 15 mL/minute for a second hour depending on the estimated severity of initial fluid depletion. This then may be changed to 0.45% (half-normal) saline at 7.5 mL/minute for the next 2 hours and gradually tapered thereafter to achieve full replacement of the estimated fluid deficit in approximately 8 hours. During that time, there should be frequent monitoring for jugular venous distention and chest auscultation to ensure early detection of fluid overload. Central venous pressure should be monitored in patients who are at risk for congestive heart failure.

Potassium repletion is needed in all patients, and there should be careful monitoring and replacement to ensure that patients do not develop potentially harmful hypokalemia or hyperkalemia. Urine output should be verified with the use of a Foley catheter if necessary before K^+ replacement is started. Unless patients are anuric, K^+ replacement should be initiated within 1 to 2 hours after starting insulin. A key goal is to maintain serum K^+ at all times higher than 3.5 mEq/L, and it is especially important to administer K^+ early in the course of treatment if there is initial hypokalemia or if bicarbonate is administered to correct acidosis, because the latter action promotes a shift of extracellular K^+ into cells. Potassium typically is withheld if the serum K^+ is 5 mEq/L or higher; otherwise, it is administered as part of the intravenous fluid regimen at 10 to 40 mEq/hour depending on the measured serum level. Serum K^+ should be monitored every 2 hours if it is less than 4 or greater than 5 mEq/L.

Bicarbonate infusion in general should be avoided but needs to be considered for patients who have a pH lower than 7, a serum bicarbonate level lower than 5.0 mEq/L, a K^+ concentration greater than 6.5 mEq/L, hypotension unresponsive to fluid replacement, severe left ventricular failure, or respiratory depression. Under these circumstances, 50 to 100 mEq (1 to 2 ampules) of bicarbonate may be infused intravenously over 2 hours. Serum phosphate should be measured, and phosphate repletion should be considered if the level falls below 1 mg/dL, especially if there is coincident heart failure, respiratory depression, or hemolytic anemia. Under these circumstances, 20 to 30/L potassium or sodium phosphate can be added to IV fluids. Phosphate repletion is not recommended with less marked decreases in serum levels, because this has not been shown to improve outcomes in DKA and may lead to hypocalcemia or hypomagnesemia.

As DKA resolves, it is important to continue providing adequate insulin to effectively resolve the ketosis, which may correct more slowly than the other abnormalities. This can be accomplished by adding glucose to the intravenous regimen (e.g., 5% glucose in half-normal saline) when blood glucose levels decrease to less than 200 to 250 mg/dL and continuing insulin infusion at 1 to 2 U/hour.

In patients with resolved DKA, transition to subcutaneous insulin can be made when the patient is clinically stable with normal vital signs, the acidosis is fully corrected, the patient is able to take fluids orally without nausea or vomiting, and any precipitating conditions (e.g., infection) are controlled.

Hyperglycemic Hyperosmolar State

A hyperglycemic hyperosmolar state (HHS) occurs almost exclusively in patients with T2DM, one third of whom have not been previously

diagnosed. Patients often are elderly and frequently have compromised renal function. Insulin deficiency, often exacerbated by insulin resistance resulting from the stress of an intercurrent illness, leads to hyperglycemia, glucosuria, and an osmotic diuresis. However, the presence of some endogenous insulin secretion suppresses lipolysis and ketogenesis enough to prevent ketoacidosis. Patients with HHS typically develop more marked hyperglycemia, fluid and electrolyte deficits, and hyperosmolality compared to those with DKA. HHS usually develops insidiously over days to weeks, and patients may be vulnerable to development of more severe hyperglycemia and volume deficits over this extended period.

HHS is associated with infections (40%), diuretic use (35% to 40%), and residency in nursing homes (25% to 30%). Other precipitating and complicating factors may include intestinal obstruction, mesenteric thrombosis, pulmonary embolism, peritoneal dialysis, subdural hematoma, and an extensive list of medications. The overall mortality rate exceeds that of DKA (10% to 40%), with higher mortality rates associated with age older than 70 years, nursing home residency, and higher osmolality or serum Na^+ concentration. Clinically, patients have evidence of the marked fluid and electrolyte deficits and tend to have more prominent neurologic abnormalities than those with DKA, including confusion, obtundation, and coma.

Therapy for HHS follows the same general principles as that for DKA, with a greater volume replacement required (typically 8 to 12 L in fully developed HHS). Restoration of the fluid and electrolyte deficits should proceed more slowly than in DKA (e.g., over 36 to 72 hours). Insulin therapy should be started only after rehydration is in progress. There is a need for K^+ replacement, but less than in DKA. Patients with HHS may be more sensitive to insulin than those with DKA and may require lower insulin doses. In view of the severe dehydration and predisposition to vascular thrombosis, heparin prophylaxis usually should be provided. Despite the very marked hyperglycemia of HHS, patients may be able to ultimately return to oral medications.

Chronic Complications of Diabetes

Chronic complications of T1DM and T2DM are similar and include microvascular complications (nephropathy, retinopathy, and neuropathy) and macrovascular or cardiovascular complications (coronary artery disease, peripheral vascular disease, and cerebrovascular disease). The long-term complications of diabetes result in substantial morbidity and shorten average lifespan by approximately 10 years. Candidate mechanisms for microvascular and macrovascular complications include activation of the polyol pathway (with accumulation of sorbitol), formation of glycated proteins and advanced glycation end products (cross-linked glycated proteins), abnormalities in lipid metabolism, increased oxidative damage, hyperinsulinemia, hyperperfusion of certain tissues, hyperviscosity, platelet dysfunction (increased aggregation), endothelial dysfunction, and activation of various growth factors.

Microvascular Complications

Retinopathy. Diabetic retinopathy affects almost all patients with T1DM and 60% to 80% of those with T2DM by 20 years after the diagnosis of diabetes. It is the most common cause of blindness in persons between the ages of 20 and 74 years in the developed world. The incidence and progression of diabetic retinopathy increase with duration of diabetes, poor glycemic control, the type of diabetes (T1DM more than T2DM), and the presence of hypertension, smoking, dyslipidemia, nephropathy, and pregnancy.

Early interventions often are beneficial in slowing or sometimes reversing diabetic retinopathy, but most patients have no symptoms until the lesions are advanced. Therefore, annual ophthalmologic

screening is recommended starting at 5 years after diagnosis in T1DM and at the time of diagnosis in T2DM.

In nonproliferative retinopathy, the progression to visual loss in patients with clinically significant macular edema is improved by focal laser photocoagulation. Panretinal photocoagulation improves outcomes in patients with proliferative retinopathy and also in the subset of T2DM patients with severe nonproliferative diabetic retinopathy. Patients who have had vitreous hemorrhage and resulting visual loss may have significant restoration of vision with vitrectomy. Patients with macular edema also may benefit from intravitreal anti-vascular endothelial factor (VEGF) pharmacotherapy. In addition to diabetic retinopathy, patients with diabetes are at increased risk for development of cataracts.

Nephropathy. Diabetic nephropathy is the most common cause of end-stage renal disease (ESRD) in developed countries (about 30% of cases). However, the risk of progression to ESRD has been markedly decreasing over the last several decades. ESRD now appears to affect fewer than 10% of patients. The risk of developing advanced renal disease in diabetes is increased by poor glycemic control, hypertension, smoking, and possibly use of oral contraceptives, obesity, dyslipidemia, and more advanced age.

Diabetic nephropathy is primarily a glomerulopathy, with pathologic features that include mesangial expansion, glomerular basement membrane thickening, and glomerular sclerosis. Many but not all patients develop albuminuria early in the course, and the level of albumin correlates with the rate of progression and the degree of renal injury. For this reason, patients should be monitored annually for albuminuria starting 5 years after diagnosis in T1DM and at the time of diagnosis in T2DM. Measurement of the ratio of microalbumin to creatinine in a random urine sample is adequate, because this ratio correlates well with results from 24-hour collections. Albumin excretion of 30 to 300 mg per gram of creatinine (designated *moderately increased albuminuria*) indicates probable diabetic nephropathy. Albumin excretion of greater than 300 mg per gram of creatinine (designated *severely increased albuminuria*) indicates high risk for progression to nephrotic-range proteinuria and ESRD.

Efforts to achieve blood glucose targets and rigorously control blood pressure (appropriate to age and overall risk profile) should be part of the strategy for primary prevention of nephropathy in all patients with diabetes. For patients with greater than 300 mg protein per gram creatinine and an eGFR greater than 30 mL/min/1.73m², canagliflozin should be considered for blood glucose management, since it has been shown to delay progression to ESRD. Blood pressure should be maintained lower than 140/90 mm Hg unless otherwise contraindicated. In patients with high risk for adverse cardiovascular events, a target of 130/80 mm Hg should be considered. Angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs) are preferable first-line agents. The calcium-channel blockers diltiazem and verapamil can be used as alternatives in patients who are unable to tolerate ACE inhibitors or ARBs, or as additive therapy in patients who need multiple drugs to control blood pressure. Diuretics and moderate Na^+ restriction also frequently are needed to reach blood pressure goals.

Neuropathy. The likelihood of development of diabetic neuropathy increases with duration of disease and is influenced by the degree of glycemic control (occurring overall in up to 70% of people with diabetes). Any part of the peripheral or autonomic nervous system may be affected. *Peripheral polyneuropathy* occurs most commonly, usually manifesting as a bilaterally symmetrical, distal, primarily sensory polyneuropathy (with or without motor involvement) in a *glove-and-stocking* distribution. Pain, numbness, hyperesthesias, and paresthesias progress to sensory loss. This condition, together with loss of proprioception, can lead to

an abnormal gait with repeated trauma and potential for fractures of the tarsal bones, sometimes resulting in the development of Charcot joints. These changes lead to abnormal pressures in the feet that, together with the soft tissue atrophy related to peripheral arterial insufficiency, result in foot ulcers that may progress to osteomyelitis and gangrene. Detailed, regular neurologic examination of all patients is essential to elicit the early loss of light touch (using a size 5.07/10-g monofilament), reflexes, and vibratory sensation.

A second common form of diabetic neuropathy is autonomic neuropathy, which may develop in concert with or separate from distal polyneuropathy. Resulting symptoms can be debilitating, including postural hypotension leading to falls or syncope, gastroparesis, enteropathy with constipation or diarrhea, and bladder outflow obstruction with urinary retention. Diabetic autonomic neuropathy together with vascular disease is a contributor to erectile dysfunction in males. Gastrointestinal dysfunction with autonomic neuropathy can complicate efforts to achieve blood glucose control by causing variable absorption of food. A suspected diagnosis of autonomic neuropathy can be strengthened by demonstrating loss of normal variability in heart rate with deep respirations or the Valsalva maneuver.

Other, less common manifestations of diabetic neuropathy include thoracic and lumbar nerve root *polyradiculopathies*, individual peripheral and cranial nerve *mononeuropathies*, and asymmetrical neuropathies of multiple peripheral nerves (mononeuropathy multiplex). Diabetic amyotrophy causing muscle atrophy and weakness most often involving the anterior thigh muscles and pelvic girdle is an uncommon form of diabetic neuropathy that often resolves after several months.

The primary approach to all diabetic neuropathies consists of efforts to improve blood glucose control. Clinical trials have shown decreased development of distal polyneuropathy with improved glycemia in T1DM. It also is particularly important for patients with neuropathies to receive regular foot care, including daily self-inspection of the feet, regular physician examinations, and early interventions for developing callouses, infections, or other foot lesions. Painful polyneuropathies cause substantial morbidity and are difficult to treat. First-line drugs include amitriptyline, venlafaxine, duloxetine, and pregabalin. For patients who do not respond adequately to one drug, combination therapy with two drugs of different classes can be tested. Alternative treatments that may be effective in some patients include topical capsaicin cream, lidocaine patch, α -lipoic acid, isosorbide dinitrate topical spray, and transcutaneous electrical nerve stimulation (TENS). *Gastroparesis* secondary to autonomic neuropathy may improve symptomatically with metoclopramide or domperidone (dopamine D2 antagonists), erythromycin (motilin agonist) for bacterial overgrowth, cisapride (cholinergic agonist), or mosapride (selective serotonin 5-HT₄ receptor agonist). Diarrhea may respond to loperamide or diphenoxylate and atropine. Orthostatic hypotension can be treated by attention to mechanical factors such as elevation of the head of the bed, gradual rising from a lying to standing position, use of support stockings, and sometimes use of the mineralocorticoid fludrocortisone.

Macrovascular Complications

The risk of macrovascular disease including cardiovascular disease, transient ischemic attacks and strokes, and peripheral vascular disease is increased 2-fold to 4-fold and accounts for 70% to 80% of deaths in patients with diabetes. This increased risk is believed to result from the altered metabolism in diabetes and also from the frequent occurrence of associated risk factors in diabetic patients, including hypertension and dyslipidemia. Screening for macrovascular disease and predisposing factors were discussed earlier. Approaches to decreasing the risk of macrovascular disease should include optimization of blood glucose

control (including consideration of specific drugs for T2DM that may decrease cardiovascular event risk as discussed previously), weight loss for overweight and obese patients, smoking cessation, control of blood pressure, and treatment of dyslipidemia. (See [Chapter 71](#) for details on the management of dyslipidemia.)

HYPOGLYCEMIA

Definition

Hypoglycemia most often occurs in patients with T1DM or T2DM under circumstances in which insulin or other antidiabetic therapies result in blood glucose levels decreasing below the lower limit of normal (<50 to 60 mg/dL for most laboratories). This may be caused by overtreatment with glucose-lowering agents, failure to take in anticipated calories, or the combination of increased glucose utilization and increased insulin sensitivity induced by exercise.

Hypoglycemia much less commonly occurs as a primary disorder in patients who do not have drug-treated diabetes. Under these circumstances, clinically significant hypoglycemia can be difficult to identify based on blood glucose measurements alone, because the normal lower limit of blood glucose varies in individuals and is influenced by duration of fasting and gender. Plasma glucose levels during a fast in men decrease to approximately 55 mg/dL at 24 hours and 50 mg/dL at 48 and 72 hours, whereas in premenopausal women they may be as low as 35 mg/dL at 24 hours without symptoms of hypoglycemia. In evaluating glucose determinations, it is important to recognize that plasma levels are approximately 15% higher than glucose levels in whole blood. Clinically significant hypoglycemia can be most readily established if patients manifest *Whipple triad*, which refers to the combination of: (1) symptoms suggestive of hypoglycemia, (2) documented low plasma glucose levels (<50 to 60 mg/dL), and (3) prompt resolution of symptoms when the low blood glucose is corrected.

Signs and Symptoms

Typical signs and symptoms of hypoglycemia are listed in [Table 68.8](#). *Autonomic* symptoms result from sympathetic neural outflow that occurs as part of the counter-regulatory response to hypoglycemia. Although most patients appear to fully recover CNS function after a neuroglycopenic episode, there is a risk of irreversible brain damage or death with sustained or repeated episodes of severe neuroglycopenia.

Pathology

Hypoglycemic disorders can result when there is overproduction of hormones that lower glucose concentrations, underproduction of hormones that serve to elevate glucose levels, deficiency of substrates for endogenous glucose synthesis, or changes in cells and tissues that result in their increased consumption of glucose.

Etiologic Classification

Causes of hypoglycemia by etiologic categories are listed in [Table 68.9](#).

Drug-Induced

The most common causes of hypoglycemia are excess insulin or insulin secretagogues (especially sulfonylureas) administered in the treatment of diabetes. Ethanol can cause hypoglycemia, most often in the context of chronic alcoholism in an individual who is nutritionally depleted after binge drinking for several days or longer. Under these circumstances, hepatic glycogen stores become depleted, and the process of alcohol metabolism blocks gluconeogenesis by depriving the liver of nicotinamide adenine dinucleotide (NAD⁺). Commonly used pharmacologic agents that have been associated with hypoglycemia include β -blockers (especially nonselective β_2 -adrenergic antagonists), ACE

TABLE 68.8 Signs and Symptoms of Hypoglycemia

Autonomic		
Sweating	Palpitations	Hunger
Pallor	Tachycardia	Nausea
Anxiety	Hypertension	Vomiting
Tremor	Irritability	Paresthesias
Neuroglycopenic		
Difficulty thinking	Dizziness	Seizures
Fatigue, weakness	Visual blurring	Loss of consciousness
Somnolence	Confusion	Coma
Headache	Abnormal behavior	Death

inhibitors, pentamidine (through toxic effects on beta cells), quinine, and quinolones.

Excess Endogenous Insulin or Insulin-like Hormones

Alimentary hypoglycemia is a disorder in which low blood glucose levels occur typically 90 to 180 minutes after meals in patients who have undergone gastric outlet surgery with resulting accelerated gastric emptying. This is distinct from the more common *dumping syndrome*, which results from rapid entry of an osmotic load into the small intestine and associated fluid shifts and autonomic responses and is not associated with hypoglycemia. “Reactive hypoglycemia” is a now outmoded term that previously was applied to adrenergic symptoms occurring 2 to 4 hours after a meal in patients who are not hypoglycemic; these individuals may experience decreased symptoms with frequent feedings and avoidance of high-carbohydrate meals.

Tumors of islet beta cells (*insulinomas*) can cause hypoglycemia by producing excess insulin in an unregulated manner. They are uncommon (1 in 250,000 patient-years) but important to recognize when they do occur. Insulinomas usually are small (1 to 2 cm), benign (>90%), solitary (>90%), and confined to the endocrine pancreas (99%). Some patients have an indolent course extending over many years before diagnosis, but insulinomas can produce profound hypoglycemia. There is a tendency for adrenergic symptoms to become suppressed as a consequence of repeated exposures to hypoglycemia, and neuroglycopenic symptoms may predominate, including sometimes bizarre behavioral abnormalities. Patients may eat frequently in response to the hypoglycemia and exhibit moderate weight gain.

Non-insulinoma pancreatogenous hypoglycemia is a disorder that may manifest with symptoms similar to those of insulinomas, but the pathology involves beta-cell hypertrophy and hyperplasia rather than the presence of a discrete tumor. More recently, the development of hypoglycemia with similar beta-cell hyperplasia has been described in some patients months to years after Roux-en-Y gastric bypass surgery.

Non-islet cell neoplasms are a rare cause of hypoglycemia; they produce an insulin-like growth factor (IGF), usually a partially processed form of IGF-II designated *big IGF-II*, that can have insulin-like effects. The tumors typically are large and malignant and are most often located in the retroperitoneal space, abdomen, or thoracic cavity. Tumor types include hemangiopericytomas, hepatocellular carcinomas, lymphomas, adrenocortical carcinomas, gastrointestinal carcinoids, and mesenchymal tumors. Some large tumors cause hypoglycemia in the absence of detectable insulin-like factors.

Hormone Deficiencies

Deficiencies of insulin counter-regulatory hormones, which normally function to raise glucose levels, can result in or contribute to

TABLE 68.9 Etiologic Classification of Hypoglycemic Disorders Manifesting in Adults

Drug-Induced
Antidiabetic agents (insulin, sulfonylureas, meglitinides)
Alcohol
Other pharmacologic agents (β -blockers, ACE inhibitors, pentamidine, quinine, quinolones and many others)
Altered Gastrointestinal Function
Alimentary hypoglycemia
Beta-Cell Insulin Oversecretion
Insulinoma
Non-insulinoma pancreatogenous hypoglycemia (without or with bariatric surgery)
Non-Islet Cell Neoplasms
Tumor insulin-like growth factor-II secretion
Tumor glucose consumption
Autoimmune
Circulating insulin antibodies
Insulin receptor activating antibodies
Endocrine Deficiencies
Glucocorticoids (adrenal insufficiency), growth hormone, catecholamines, glucagon
Severe Illness
Sepsis
Hepatic failure
Renal failure
Malnutrition
Anorexia nervosa

ACE, Angiotensin-converting enzyme.

hypoglycemia. An example is low levels of corticosteroids caused by primary or secondary adrenocorticoid insufficiency. Deficiencies of other hormones, including catecholamines, glucagon, and growth hormone, also can cause hypoglycemia.

Severe Illness

Hypoglycemia can occur during severe illness through a number of different mechanisms in association with sepsis, hepatic insufficiency, and renal failure. Patients with severe illness appear to be particularly vulnerable to hypoglycemia when they are poorly nourished, although malnutrition alone is rarely associated with hypoglycemia.

Approach to the Diagnosis

For patients who have well-documented hypoglycemia, the diagnosis often is evident or strongly suggested by the clinical setting, history, and physical examination findings. Hypoglycemia induced by insulin or other glucose-lowering agents in diabetic patients often is immediately apparent from the medical history. Alcohol-induced hypoglycemia may be suspected in a patient with a known or suspected history of alcohol use and binge drinking. Identification of other candidate drugs as a cause of hypoglycemia requires a thorough medical history, and the condition can be expected to resolve if the suspect medication is stopped. The patient may have a known diagnosis of adrenal

insufficiency, or this may be suggested by other clinical findings (e.g., orthostatic hypotension, increased skin pigmentation) or the development of markedly increased insulin sensitivity in a patient with T1DM. The patient may have a known tumor, suggesting the possibility of a non- β -cell neoplasm as a cause of hypoglycemia. There may be a history of Roux-en-Y bypass surgery, raising the possibility of beta-cell hyperplasia. The co-occurrence of sepsis, hepatic failure, renal failure, profound malnutrition, or a diagnosis of anorexia nervosa may suggest one of these potential underlying causes.

A number of algorithms have been developed to guide the evaluation of documented or potential hypoglycemia, including a recommended approach from an expert panel published by the Endocrine Society. If there is an opportunity to observe the patient during a symptomatic episode of presumed hypoglycemia, plasma should be obtained, if possible before treatment, for measurement of glucose, insulin, proinsulin, C-peptide, β -hydroxybutyrate, and screening for sulfonylureas and meglitinides. Hypoglycemia can be rapidly, provisionally confirmed with a test meter and later confirmed by laboratory analysis. After blood samples have been obtained for the tests described, glucose should be administered orally (15 to 30 g) or intravenously (25 g, or 1 ampule of 50% dextrose), and recovery of glucose levels and symptoms should be observed.

For patients with suspected or confirmed hypoglycemia developing specifically in the fasted state, it may be possible to replicate the condition by observing during several hours of daytime fasting, with or without a preceding overnight fast. The same laboratory testing panel as described earlier then can be obtained if symptoms suggestive of hypoglycemia occur. For patients who describe postprandial hypoglycemic symptoms (within 5 hours after a meal), a mixed meal (not a pure glucose load) should be provided, with blood sampling at baseline and every 30 minutes thereafter for 5 hours.

For patients who do not manifest hypoglycemia with the testing procedures described despite a strong suspicion of hypoglycemia, the most frequently utilized approach is a 72-hour fast according to a protocol developed at the Mayo Clinic. Blood is obtained every 6 hours and at test termination. The test is ended at 72 hours or at an earlier time point if the plasma glucose level decreases (by glucose meter testing) with associated symptoms to 45 mg/dL (2.5 mmol/L) or lower or to less than 55 mg/dL (3 mmol/L) in a patient with prior documentation of Whipple triad. At the end of the 72-hour test period, the patient is given 1 mg of glucagon intravenously, and blood is obtained at 10, 20, and 30 minutes, after which the patient is given a meal. The final blood sample obtained at the end of the fast (before glucagon administration) is analyzed additionally for β -hydroxybutyrate and a sulfonylurea/meglitinide panel.

For any of these test protocols, elevations of insulin, proinsulin, and C-peptide associated with hypoglycemia at the same time point are consistent with an insulinoma, beta-cell hyperplasia, or the effects of an insulin secretagogue (sulfonylurea or meglitinide), or the presence of insulin antibodies. An elevation in these three hormones during a meal test in a patient who has had gastric surgery is suggestive of alimentary hypoglycemia. Plasma insulin, proinsulin, and C-peptide are not elevated in patients with hypoglycemia secondary to extrapancreatic neoplasms. This diagnosis usually can be further confirmed by evidence of a large tumor with various imaging techniques. High insulin levels, together with low proinsulin and C-peptide concentrations in the presence of hypoglycemia, are indicative of exogenous insulin administration. Factitious hypoglycemia secondary to insulin or insulin secretagogue administration is uncommon and has been observed in individuals with or without diabetes.

Treatment

The most important therapeutic step in hypoglycemia is to identify and treat the underlying causes, including drugs, alcohol, serious infection, tumors, and hypoadrenalism. The occurrence of hypoglycemia usually can be substantially improved in patients with alimentary hypoglycemia by a modified feeding regimen with frequent, small meals and avoidance of concentrated sources of rapidly digested and absorbed carbohydrate.

Non- β -cell tumor hypoglycemia is treated by tumor resection if possible. For nonresectable tumors, a debulking procedure may be effective in reducing hypoglycemia. Hypoglycemia in patients with insulinomas can be cured by resection. Persistent hypoglycemia secondary to nonresectable insulinoma can sometimes be treated effectively with diazoxide, long-acting somatostatin analogues (octreotide or lanreotide), verapamil, or phenytoin. For patients with beta-cell hyperplasia after bariatric surgery, first-line treatment includes diet modifications with more frequent, small meals and avoidance of concentrated sources of carbohydrate to decrease meal-induced insulin secretion.

For a deeper discussion of this topic, please see Chapter 216, “Diabetes Mellitus,” and Chapter 217, “Hypoglycemia and Pancreatic Islet Cell Disorders,” in *Goldman-Cecil Medicine*, 26th Edition.

Obesity

Osama Hamdy, Marwa Al-Badri

DEFINITION AND EPIDEMIOLOGY

Obesity is a disease that is usually defined as a body mass index (BMI) greater than or equal to 30 kg/m^2 ($\text{weight [kg]} / (\text{height [m]})^2$). A BMI of 30 to 34.9 is considered class 1 obesity, 35 to 39.9 is class 2 obesity, and 40 or higher is class 3 or severe obesity. The term “morbid obesity” previously was applied to individuals weighing at least 45 kg (100 lb) more than, or typically about 60% more than, desirable body weight; the term also has been applied to any individual with BMI greater than or equal to 40 kg/m^2 .

There is increasing recognition of limitations to defining obesity based on BMI resulting from the variable correlation between BMI and amount of body fat in different ethnic (genetic) populations or in individuals with different degrees of muscularity. Many investigators and clinicians are moving toward a definition that defines obesity as an excess of body fat sufficient to confer risk. According to the percentage of body fat, obesity is defined in men as percentage of body fat greater than 25%, with 21% to 25% being borderline, and in women as percentage of body fat greater than 33%, with 31% to 33% being borderline.

Linking obesity to cardiometabolic risk, body fat distribution, and waist circumference is more important than measuring percentage body fat or BMI alone. People who accumulate abdominal visceral fat and clinically have higher waist circumference (metabolic obesity) are at much higher risk for cardiovascular disease and diabetes than those with the same BMI or the same percentage of body fat but with lower waist circumference. The National Cholesterol Education Program Adult Treatment Panel III (ATP III) considered a waist circumference greater than 40 inches (102 cm) in American men or 35 inches (88 cm) in American women to be among the five criteria that define the cardiometabolic syndrome. In spite of its limitations, BMI remains a simple measurement with utility in estimating a person’s health risks and comparing outcomes between trials.

During the last 30 years, there has been a dramatic increase in the percentage of both adults and children in the United States who are overweight (defined as BMI of 25 to 30) or obese. According to the 2015-2016 National Health and Nutrition Examination Survey (NHANES) conducted by the Centers for Disease Control and Prevention (CDC), 39.8% of US adults were obese, including 7.6% with severe obesity, and an additional 31.8% are overweight. This was more than double the prevalence in the 1976-1980 NHANES data (15.0%). Mexican Americans had the highest age-adjusted percentage of obesity (49.25%), followed by all Hispanic individuals (46.85%), non-Hispanic black (45.8%), and non-Hispanic white individuals (37.95%). More recently, there appears to have been a slowing in the rate of obesity increase or even a leveling off. In 2017, obesity prevalence seemed to vary significantly across states, from 20% or less in Colorado, Hawaii, and District of Columbia to 35% or more in seven

states (Alabama, Arkansas, Iowa, Louisiana, Mississippi, Oklahoma, and West Virginia). In general, higher prevalence of adult obesity was found in the south (32.4%) and the midwest (32.3%) and lower prevalence in the northeast (27.7%) and the west (26.1%). The percentage of children and adolescents who are overweight or obese has almost tripled since 1980. Currently, 18.5% of children and adolescents aged 2 to 19 years are obese, including 5.6% with severe obesity, and another 16.6% are overweight. NHANES data from 1976-1980 and from 2015-2016 show that the prevalence of obesity increased from 5.0% to 13.9% for children aged 2 to 5 years and from 5.0% to 20.6% for those aged 12 to 19 years. Among low-income preschool children, the prevalence of obesity increased between 1998 and 2016 from 13.0% to 13.9% and severe obesity from 1.8% to 2.1%.

Overweight and obesity and their associated health problems have a significant economic impact on the US health care system through direct medical expenses and indirect costs (e.g., loss of work time and productivity). Medical costs of obesity and their associated health problems account for an estimated 10% of total US medical expenditures.

PATHOLOGY OF OBESITY

Obesity develops as a consequence of genetic-environmental interactions, such that genetically prone individuals who lead a sedentary lifestyle and consume larger amounts of dietary calories are at higher risk. For example, children of obese parents are 80% more likely to become obese, and it is believed that this results from a combination of genetic and environmental influences.

The genetic contributions to obesity are most commonly considered to reflect the combined effects of variations in multiple genes and only rarely appear to result from a defect in a single powerful gene. Single-gene defects identified in experimental animals have been useful to demonstrate appetite and satiety mechanisms. Mutations in some of these same genes have subsequently been identified in rare human forms of genetic obesity. For example, loss-of-function mutations in the leptin gene and in the cellular receptor for leptin were first identified as a cause of obesity in laboratory mice (*ob/ob* and *db/db* mice, respectively). Leptin is a hormone that is produced in fat cells, mostly in subcutaneous fat. It is a potent satiety factor that acts in the arcuate nucleus of the hypothalamus to reduce the production of neuropeptide Y, a stimulator of food intake. After its discovery in mice, leptin gene mutations were identified as a cause of a rare form of heritable human obesity. Affected individuals develop marked obesity in childhood as a consequence of increased food intake. Leptin secretion normally follows a circadian pattern, with higher levels during evening and night hours. Loss of leptin secretion has particularly marked effects during these hours, resulting in a phenomenon known as the night-eating syndrome, in which patients tend to consume large amounts of food during the night.

Other single-gene defects identified as rare causes of human obesity include loss-of-function mutations in genes encoding carboxypeptidase E, melanocortin-4 or melanocortin-3 receptors, and serotonin-2C or serotonin-1B receptors. Obesity is also a feature of many other genetic disorders in which the specific mechanisms of the obesity are less well understood. These different syndromes may have autosomal dominant, autosomal recessive or X-linked inheritance patterns, consistent with multiple different genetic causes. Among the best known of these disorders is the Bardet-Biedl syndrome, which is an autosomal recessive disorder characterized by obesity and other abnormalities, including hypogonadism in men, mental retardation, retinal dystrophy, polydactyly, and renal malformations. In Prader-Willi syndrome, loss of portions of the long arm of chromosome 15 (q11-13) is associated with obesity, poor muscle tone in infancy, defects in cognition, behavioral abnormalities (irritability), short stature, and hypogonadotropic hypogonadism.

Although known single-gene mutations account for only a small percentage of human obesity, there is evidence for widespread heritable influences in more common forms of human obesity. For example, in twin and adoptee studies, both members of identical twin pairs tend to become obese in concordance with the same weight pattern as their biologic parents, even when raised apart. Metabolic rate, spontaneous physical activity, and thermic response to food seem to be heritable to a variable extent, but the specific genes that contribute to prevalent forms of human obesity have not yet been identified. Genomic analyses in large populations have identified multiple genes or genetic regions in which polymorphisms are associated with obesity risk. These include polymorphisms in or near genes for the melanocortin-4 receptor (a protein involved in appetite suppression pathways in the hypothalamus), brain-derived neurotrophic factor (role in energy balance), the β_3 -adrenergic receptor (role in visceral fat accumulation), and peroxisome proliferator-activated receptor- γ 2 (PPAR- γ 2), a transcription factor involved in adipocyte differentiation. Multiple other sites of genetic variation associated with increased obesity risk have been identified for which potential mechanistic links to obesity are not yet apparent. It is hypothesized that the heritable component of common forms of human obesity derives from the effects of variations in these and many yet unidentified genes acting both additively and synergistically.

Important environmental factors driving the recent increased prevalence of obesity include increased caloric intake (reflecting greater availability of high-calorie, low-cost foods) and decreased energy expenditure (as a consequence of decreased physical activity). Lower socioeconomic status, lower education level, cessation of smoking, and high consumption of carbohydrates with a high glycemic index have been identified as specific confounders of obesity. Additional factors that may influence obesity risk include intrauterine growth, weight gain during pregnancy, hormonal changes during menopause, history of depression, use of major antipsychotic medications, and factors that may alter the feedback between energy intake and expenditure.

Many hormones affect appetite and food intake. Ghrelin, which is secreted from the stomach fundus, is a major hunger hormone. Endocannabinoids, through their effects on endocannabinoid receptors in the brain, increase appetite, promote nutrient absorption, and promote lipogenesis. Melanocortin hormone, through its effects on various melanocortin receptors in the brain, modifies appetite. Meanwhile, several gut hormones play significant roles in influencing satiety, including glucagon-like peptide-1 (GLP-1), neuropeptide YY (PYY), and cholecystokinin. Leptin and pancreatic amylin are other potent satiety hormones. Ultimately, an increase in total body fat results from an increase in energy intake that exceeds energy expenditure.

This occurs through the operation of genetic and environmental influences, together with individual behavioral characteristics.

PATHOLOGY OF OBESITY-ASSOCIATED HEALTH RISKS

Adipose tissue is not just a passive depot for lipids. Adipocytes also function as a complex and active endocrine organ with metabolic and secretory products (hormones, prohormones, cytokines, and enzymes) that play a major role in whole-body metabolism. Relationships between obesity and both insulin resistance and endothelial dysfunction (the early stage of atherosclerosis) are mediated through the release of several hormones from adipose tissue. These hormones, designated adipocytokines or adipokines, comprise a group of pharmacologically active low- and medium-molecular-weight proteins that possess autocrine and paracrine effects and are known products of the inflammatory and immune systems. They play an important role in adipose tissue physiology and in initiating metabolic and cardiovascular abnormalities, not only in overweight and obese individuals, but also in lean persons with higher visceral fat mass. These adipokines include adiponectin, leptin, tumor necrosis factor- α (TNF- α), interleukin-6 (IL-6), resistin, plasminogen activator inhibitor-1 (PAI-1), angiotensinogen, and monocyte chemoattractant protein-1 (MCP-1). An increased amount of adipose tissue or its disproportionate distribution between central and peripheral body regions is related to altered serum levels of these factors. With the exceptions of leptin and adiponectin, the adipokines are produced both from fat cells and from adipose tissue-resident macrophages in the stromal tissues surrounding fat cells. For unknown reasons, an increase in the amount of body fat is associated with increases in the number of adipose tissue macrophages and their production of cytokines.

Human adiponectin is a relatively abundant, 244-amino-acid polypeptide in plasma, accounting for 0.01% of total plasma proteins. Adiponectin gene expression in adipose tissue is associated with obesity, insulin resistance, and type 2 diabetes (T2DM). Hypoadiponectinemia is more strongly related to the degree of insulin resistance than to the degree of adiposity or glucose intolerance. Genetic polymorphisms may influence the regulation of adiponectin and lead to variations in its levels among different individuals. Several human studies have shown that high adiponectin levels protect against development of T2DM and point to the possible future use of adiponectin as an indicator of diabetes risk. Low plasma concentrations of adiponectin are observed in patients with coronary artery disease (CAD), and lower adiponectin levels have been found in patients with diabetes and CAD than in those without CAD. In obesity, a 10% reduction in body weight leads to a significant increase in adiponectin (40% to 60%) in both patients with and without diabetes. Adiponectin is also involved in the modulation of inflammatory responses through attenuation of TNF- α -mediated inflammatory effects, regulation of endothelial function, and inhibition of growth factor-induced proliferation of vascular smooth muscle cells.

Leptin is a 167-amino-acid adipocyte-derived hormone that circulates in the plasma in free and bound forms. It affects energy balance by activating specific centers in the hypothalamus to decrease food intake, increase energy expenditure, modulate glucose and fat metabolism, and alter neuroendocrine function. Leptin plasma levels increase exponentially with increased fat mass (4-fold higher in obese compared with lean individuals in one study), and this is thought to reflect resistance to leptin in obesity. Leptin therapy in lipodystrophic patients has been shown to lower blood glucose, improve insulin-stimulated hepatic and peripheral glucose metabolism, and reduce hepatic and muscle triglyceride content, suggesting that leptin acts as a signal that

contributes to regulation of total body sensitivity to insulin. It has also been found that leptin is independently associated with cardiovascular mortality. Although both adiponectin and leptin are integrally related to insulin resistance, adiponectin is more strongly related to visceral abdominal fat stores, whereas leptin is more closely related to subcutaneous fat.

Adipose tissue, especially visceral fat and intermuscular fat, serves as a major source of TNF- α and substantial amounts of IL-6. Levels of these two proinflammatory cytokines correlate with obesity and are strongly related to insulin resistance. Several studies have demonstrated a strong link between TNF- α and cardiovascular disease. Plasma levels of TNF- α are increased in individuals with premature cardiovascular disease independent of insulin sensitivity. Conversely, circulating levels of TNF- α decrease after weight reduction in parallel with the improvement in endothelial function.

Resistin is an adipocyte-derived, cysteine-rich signaling protein that is expressed predominantly in white adipose tissue and is also detectable in serum. Resistin is thought to act at sites remote from adipose tissue, similar to other adipokines, and to contribute to insulin resistance in obesity. *PAI-1* is another bioactive peptide produced by subcutaneous and visceral fat. Its circulating levels correlate better with visceral than with subcutaneous adiposity and are strong predictors of CAD. High PAI-1 levels are associated with increased blood coagulability. Improvement in insulin sensitivity by either weight reduction or medication lowers circulating levels of PAI-1. This decrease in PAI-1 correlates with the amount of weight loss and the decline in serum triglycerides.

Visceral, subcutaneous, and intermuscular fat differ in their production of specific adipokines, pointing to differences in endocrine function between these three adipose depots. Removal of a significant amount of only subcutaneous fat by liposuction in obese individuals with and without diabetes resulted in reduction in serum leptin but did not change the serum levels of other cytokines or any other metabolic parameters. It also did not improve insulin sensitivity or decrease the high serum insulin level observed initially in those individuals. In animal models, removal of subcutaneous fat resulted in an increase in mesenteric fat volume and increased production of TNF- α by visceral fat. Although surgical removal of visceral fat has not been attempted in humans, two studies of aging in rodent models showed that removal of visceral fat reduces the production of inflammatory adipokines and improves glucose tolerance and insulin sensitivity. More recently, it was shown that inflammatory adipokines are also secreted from intermuscular and subfascial fat and in excess of those secreted from abdominal visceral fat. Excess accumulation of intermuscular and subfascial fat (myosteatosis) is seen with ageing in both men and women and is strongly associated with insulin resistance.

Risks Associated With Obesity

Individuals who are overweight or obese are at increased risk for the following health conditions:

- Cardiometabolic syndrome
- T2DM
- Hypertension
- Dyslipidemia
- Coronary heart disease
- Congestive heart failure
- Atrial fibrillation
- Osteoarthritis
- Stroke
- Gallbladder disease
- Hepatic steatosis and nonalcoholic steatohepatitis (NASH)
- Obstructive sleep apnea

- Asthma
- Gastroesophageal reflux (GERD)
- Some cancers (endometrial, breast, and colon)
- Gynecologic disorders (abnormal menses, infertility, polycystic ovarian syndrome)
- Erectile dysfunction
- Depression

Weight loss of 7% to 10% is associated with reduced risk for many if not all of these disorders. Recent studies have shown that significant weight reduction (15% to 25% of initial body weight) after bariatric surgery in class 2 and class 3 obese patients with T2DM may result in partial or complete remission of diabetes, especially in patients with recent history of diabetes.

DIAGNOSIS AND ASSESSMENT OF OBESITY

The form of obesity that characteristically occurs in men—android or abdominal obesity (apple-shaped body configuration)—is closely associated with metabolic complications such as insulin resistance, hypertension, dyslipidemia, and hyperuricemia. By contrast, the typical female or gynecoid obesity (pear-shaped body configuration), in which fat accumulates in the hips and gluteal and femoral regions, has milder metabolic complications. The waist-to-hip circumference ratio (WHR) has been used to distinguish these forms of obesity. A ratio greater than 1.0 in men or greater than 0.8 in women, indicative of visceral fat deposition and abdominal obesity, correlates with increased health risks.

Standard laboratory studies in the evaluation of obesity should include the following:

- Fasting lipid panel
- Liver function tests
- Thyroid function tests
- Fasting plasma glucose
- Hemoglobin A1c (A1C)

Previously, the “gold standard” technique for measuring total body fat was *hydrodensitometry* (underwater weighing). This is based on the principle that fatty tissue is less dense than muscle. Currently, *dual-energy x-ray absorptiometry* (DXA) scanning is used to accurately measure body composition, particularly fat mass and fat-free mass. It has an additional advantage of measuring regional fat distribution. DXA is more accurate than anthropometric measures and is more cost-effective than computerized tomography (CT) or magnetic resonance imaging (MRI) scans. However, DXA cannot distinguish between subcutaneous and visceral abdominal fat depots, or between subcutaneous and intramuscular peripheral fat depots. Bioelectric impedance is a simpler and less expensive method for measuring total body fat, but it is greatly affected by the hydration state of the body and is less accurate than DXA.

BMI is widely used as a measure of obesity. It is calculated by dividing a person’s body weight in kilograms by the square of the person’s height in meters; alternatively, weight in pounds multiplied by 703 is divided by the square of the height in inches). A BMI between 19 and 27 has little association with cardiometabolic risk in white individuals. Adverse health consequences occur with a BMI of 27 or more and increase with increasing levels of BMI. Risks associated with increased BMI are more pronounced in older patients.

Waist circumference or *WHR* or both are often used to indirectly estimate intra-abdominal fat volume in epidemiologic studies. Although these measures show good correlation with intra-abdominal fat volume as measured by CT, they are less accurate than CT. At present, waist circumference is the easiest anthropometric measurement for routine use by health care professionals to estimate visceral adiposity and monitor changes in visceral fat volume.

The current gold standard techniques for measuring visceral fat volume are abdominal CT (at the L4-L5 vertebral level) and MRI. These methods are not widely used because of high cost. In contrast to CT, MRI requires additional definition of adipose tissue by adjusting settings on the MRI scanner. Several commercial software packages are available for calculation of visceral fat volume, and it is possible to further subdivide body fat into at least three separate and measurable compartments; subcutaneous, intramuscular, and visceral fat.

Visceral fat volume determination by abdominal ultrasonography has been investigated for use in research and clinical settings. Several studies found good correlation between intra-abdominal fat volume measured by abdominal ultrasound and that measured by abdominal CT scanning. Measurements should be performed with the patient in the supine position at the end of a quiet inspiration with compression of the transducer against the abdomen. Intra-abdominal fat is quantified based on the distance between the peritoneum and the lumbar spine. Studies have shown that intra-abdominal fat measured by ultrasound has a stronger association with metabolic risk factors for CAD than does waist circumference or WHR. Recently, visceral fat has been measured using *bioelectric impedance*, but this technique is less accurate than CT. Determinations of intrahepatic fat by ultrasonography, CT and *vibration controlled transient elastography* (VCTE) are of significant clinical value. Determination of intermuscular and subfascial fat volume by CT has been investigated for use in research but not used yet in routine clinical setting.

TREATMENT OF OBESITY

Current guidelines for treatment of obesity are summarized in Table 69.1. The preferred intervention varies with the obesity level based on five BMI categories. The major four therapeutic options are lifestyle modification (diet and exercise), behavior modification, pharmacologic intervention, and bariatric surgery. In general, better results are obtained with a combination of different interventions rather than a single modality.

Lifestyle Modification

Key components of effective lifestyle modification most often include structured dietary interventions and individualized physical activity programs. Behavior modification strategies and patient education are also critical for achievement and maintenance of target weight loss. Evidence-based dietary guidelines should be used to design individualized patient plans in consultation with a registered dietitian or qualified health care provider. First, daily caloric intake should be reduced by a modest 250 to 500 calories. Reasonable and paced reductions can help patients continue on the recommended dietary plan for a longer time. Daily calories from carbohydrate should be reduced to

approximately 40% to 45% of intake, with a total daily carbohydrate intake of no less than 130 g/day. Except in patients with renal impairment (creatinine clearance <60 mL/min) or significant microalbuminuria, protein intake should not be less than 1.2 g/kg of adjusted body weight (adjusted body weight = ideal body weight + 0.25 [current weight – ideal body weight]). This typically accounts for 20% to 30% of total calorie intake and is intended to minimize loss of lean body mass during weight reduction. The remaining 30% to 35% of calorie intake should come from fat. *Trans*-fats should be eliminated, and saturated fat, especially from meat and meat-products, should be reduced. Meal plans should also include substantial soluble fiber (e.g., from fresh fruits) and insoluble fiber (e.g., from vegetables) and consumption of healthy carbohydrates, especially foods that have a low glycemic index and high fiber content. Approximately 14 g of fiber per 1000 calories (20 to 35 g of fiber) per day is recommended.

Caloric intake should be adjusted downward over time until weight loss is achieved. Underlying all of these steps should be the goal of designing an individualized plan that can be maintained over the long term. Many patients find it helpful to receive a structured dietary intervention that includes specific suggestions for daily meals and snacks. Such structured diets may increase adherence and can be easier to follow than a list of general guidelines. Nutritionally complete meal replacement (e.g., in the form of shakes or bars) can be useful for some patients, especially at the start of a weight reduction program. If meal replacement is used, 100- to 200-calorie snacks (e.g., fruits and nuts) may be added at breakfast, lunch, or between meals. A recent study showed that a structured meal plan that includes menus, snack lists, and meal replacements in obese patients with T2DM resulted in 2.7 to 3.5 kg weight loss over 16 weeks in comparison to individualized meal plans.

Each patient should meet with an exercise physiologist to construct an individualized plan that is responsive to his or her lifestyle, capabilities, and potential cardiovascular risks. Because obese individuals frequently have difficulty exercising, this process requires careful attention. A balanced exercise plan incorporates a mix of cardiovascular, stretching, and strength exercises and should be graded to increase gradually in both duration and intensity. Patients can start with 10 to 20 minutes of daily stretching and aerobic exercise (e.g., moderate-intensity walking) with subsequent progressive increases. Any exercise should be preceded by a warm-up period to minimize injuries.

Long-term lifestyle modification trials, such as the Diabetes Prevention Program, have targeted 150 minutes of exercise per week. Newer guidelines recommend 60 to 90 minutes of daily exercise, with a minimum of 150 to 175 minutes per week needed to obtain weight loss benefit. Emphasis should be placed on moderate-intensity exercise, such as walking 20-minute miles, rather than strenuous exercise. Because patients who are not used to exercising may find it difficult

TABLE 69.1 Guide to Selecting Treatment Based on BMI Category^a

Treatment	BMI CATEGORY				
	25-26.9	27-29.9	30-34.9	35-39.9	≥40
Diet, physical activity, behavior therapy	Yes with comorbidities	Yes with comorbidities	Yes	Yes	Yes
Pharmacotherapy	No	Yes with comorbidities	Yes	Yes	Yes
Weight-loss surgery	No	No	Yes with comorbidities	Yes with comorbidities	Yes with comorbidities

^a“Yes” indicates that the treatment is indicated regardless of comorbidities.

From National Institutes of Health (NIH), National Heart, Lung, and Blood Institute (NHLBI), North American Association for the Study of Obesity (NAASO): The practical guide to the identification, evaluation, and treatment of overweight and obesity in adults. NIH Publication No. 00-4084, Bethesda, Md., October 2000, NIH. http://www.nhlbi.nih.gov/files/docs/guidelines/prctgd_c.pdf. Accessed November 2014.

to incorporate physical activity into daily practice, it is also important to use a variety of exercises to maintain interest. Increasing exercise duration to 300 minutes/week was found to help in long-term maintenance of weight reduction. Frequent short bouts of exercise as brief as 10 minutes each can increase adherence to an exercise regimen and increase overall duration of exercise.

Behavior Modification and Patient Education

Cognitive-behavioral intervention and patient education are important components of successful weight loss programs. Whenever possible, cognitive-behavioral intervention should be conducted by an experienced psychologist. The fundamental principles of intervention typically include behavioral goal setting, stimulus control techniques, cognitive restructuring, assertive communication skills, stress management, and relapse prevention. Cognitive-behavioral support conducted in a group setting with weekly meetings is frequently successful. Patients should learn how to set *SMART* goals (specific, measurable, action-oriented, realistic, time-limited). It can be helpful to emphasize real-life examples (e.g., success stories, logbook learning, recommitting to progress). The behavioral modification strategy should assist patients in identifying precipitants for deviations from a diet (e.g., timing, types of food or exercise, situations, feelings), overcoming challenges (planning ahead, delay and distraction, problem solving), managing automatic negative thinking (“detour thoughts”), coping with cravings through mindful strategic eating, preventing relapses using logbook learning, navigating social eating, and setting personal weight maintenance plans.

Pharmacologic Treatment of Obesity

Several anti-obesity drugs are currently approved by the US Food and Drug Administration (FDA) for use in the United States. These drugs include orlistat, phentermine, lorcaserin, a combination of phentermine and long-acting topiramate, liraglutide, and a combination of bupropion and naltrexone. Generally, all these medications are indicated for patients with a BMI of 30 kg/m² or more or with BMI of 27 kg/m² or more with other weight-related comorbidities (e.g., diabetes, hypertension, dyslipidemia, obstructive sleep apnea) in combination with caloric restriction, increased physical activity, and behavioral modifications.

Orlistat

Orlistat limits caloric intake through inhibition of the lipase-mediated breakdown of fat in the gastrointestinal tract. This mechanism results in an approximately 30% reduction of fat absorption and an increase in fecal fat content. In addition to weight loss, orlistat use has been associated with decreased incidence of diabetes, improved concentrations of total cholesterol and low-density lipoprotein (LDL)-cholesterol, and improved blood pressure and glycemic control in patients with diabetes. However, high-density lipoprotein (HDL)-cholesterol has been found to be slightly lowered. Most people develop side effects with variable degrees of diarrhea, flatulence, oily stools, fecal urgency, and, rarely, fecal incontinence. There also is an increased risk of cholelithiasis. Gastrointestinal side events are usually proportional to the amount of fat intake. Supplemental fat-soluble vitamins A, D, E, and K must be taken to prevent possible deficiencies. The usual dose of orlistat is 120 mg before each meal. A 60 mg dose formulation is currently available over the counter. The lower dose is less effective but is associated with fewer side effects.

Phentermine

Phentermine is approved for short-term treatment of obesity (up to 6 months). Because phentermine has actions similar to amphetamines, it can elevate blood pressure, increase heart rate, and stimulate the central nervous system (frequently causing insomnia), in addition to

suppressing the appetite. The recommended phentermine dose is 30 mg once daily. Combining phentermine with tricyclic antidepressants or monoamine oxidase inhibitors may result in substantial increases in blood pressure and other serious reactions because of elevated serotonin levels in the blood.

Lorcaserin

Lorcaserin is a selective serotonin (5-hydroxytryptamine) receptor agonist with specificity for the 5-HT_{2C} receptor subtype. The activation of these receptors in the hypothalamus is thought to activate production of pro-opiomelanocortin (POMC) and, consequently, to promote weight loss through satiety signals. Lorcaserin has 100-fold higher selectivity for 5-HT_{2C} versus the closely related 5-HT_{2B} receptor. Activation of the 5-HT_{2B} receptor by the less selective agents like fenfluramine and dexfenfluramine was linked to serious cardiac valvulopathy, but there is no evidence for this adverse effect with lorcaserin. Clinical trials showed that 47.5% of patients treated with lorcaserin lost at least 5% of their initial body weight, and 22.6% lost at least 10%, in 1 year. Lorcaserin treatment also resulted in significantly lower A_{1C} values in patients with T2DM and improved lipid profile and decreased blood pressure in clinical studies.

Lorcaserin is approved for use as an adjunct to a reduced-calorie diet and exercise for chronic weight management in patients with initial BMI values of 30 kg/m² or higher and in those with BMI values of 27 kg/m² or higher with at least one weight-related comorbid condition. It is given in a dose of 10 mg twice daily or 20 mg of extended release (XR) form once daily. Side effects usually are mild to moderate, with the most common being headache, upper respiratory tract infection, nasopharyngitis, sinusitis, dizziness, nausea, and fatigue. The US Drug Enforcement Administration has classified lorcaserin as a schedule IV drug because it has hallucinogenic properties that could lead to psychiatric complications.

Phentermine and Long-Acting Topiramate

Phentermine is an appetite suppressant and stimulant of the amphetamine and phenethylamine class (see earlier discussion for details on the use of phentermine alone for weight reduction). Topiramate is an anticonvulsant that was found to have weight loss side effects. The combination of phentermine plus low doses of topiramate has been shown to have synergistic effects on weight loss. As with lorcaserin, this combination tablet is indicated as an adjunct to a reduced-calorie diet and exercise for chronic weight management. Clinical trials showed that average weight loss after 1 year of 10.9% for patients receiving the maximum dose (phentermine/topiramate, 15 mg/92 mg) and 5.1% for those taking the recommended starting dose (3.75 mg/23 mg). The drug is taken once daily in the morning to avoid insomnia caused by the phentermine component. The initial dose of 3.75 mg/23 mg is given for 2 weeks before titration to 7.5 mg/46 mg for another 12 weeks. If a patient has not lost at least 3% of baseline body weight on the higher dosage, the drug may be discontinued or the dose may be escalated to 11.25 mg/69 mg for an additional 2 weeks before a further increase to the maximum dose of 15 mg/92 mg. If a patient has not lost at least 5% of baseline body weight after 12 weeks, the drug is discontinued gradually. Side effects include paresthesias, dry mouth, constipation, metabolic acidosis, nasopharyngitis, upper respiratory infection, and headache.

Data indicate that fetuses exposed during the first trimester to topiramate (when used alone as an anticonvulsant) have an increased risk (9.6%) of cleft lip with or without cleft palate. Therefore, the drug should not be given to women of childbearing age unless an effective method of contraception is used and a pregnancy test is conducted monthly during use. Phentermine/topiramate may increase resting heart rate up to 20 beats/minute, so the drug should be used cautiously in patients with a

history of cardiac or cerebrovascular disease. Topiramate also increases the risk of suicidal thoughts or behaviors and mood disorders including depression, anxiety, and insomnia. It can also cause cognitive dysfunction, including impairment of concentration or attention, difficulty with memory, and speech or language problems, particularly word-finding difficulties. It is contraindicated in patients with closed-angle glaucoma because it increases intraocular pressure and the risk of permanent loss of vision.

Bupropion and Naltrexone

This combination is thought to cause a reduction in appetite and an increase in energy expenditure by increasing activity of POMC neurons. Bupropion is a dopamine and norepinephrine reuptake antagonist, which increases dopamine activity in the brain and in turns leads to reduction in appetite and increase in energy expenditure by increasing activity of POMC neurons. Naltrexone blocks opioid receptors on the POMC neurons, preventing feedback inhibition of these neurons and further increasing POMC activity.

The combination tablet of 8 mg of naltrexone and 90 mg of bupropion is initially taken once daily in the morning for 1 week then increased each week by one tablet until reaching the effective dose of two tablets taken twice daily. Average weight loss after 56 weeks of full dose of 32 naltrexone/360 bupropion was 8.4% of the initial body weight (6.4% in intention to treat analysis). The major side events include nausea, constipation, headache, vomiting, dizziness, and insomnia. Bupropion also increases the risk of suicidal thoughts similar to all other antidepressant medications.

Liraglutide

Liraglutide is a GLP-1 analog. GLP-1 is a physiologic regulator of appetite and calorie intake, and the GLP-1 receptor is present in several areas of the brain involved in appetite regulation. GLP-1 analogs, including liraglutide, are used for management of T2DM, but liraglutide dose for obesity indication is much higher, up to 3 mg/day by subcutaneous injection in comparison to a maximum dose of 1.8 mg/day for treatment of T2DM. The dose is escalated gradually every week from 0.6 mg/day to 1.2, 1.8, 2.4, and finally 3 mg/day to reduce nausea. Average weight loss with liraglutide 3 mg daily for 56 weeks is around 5.9%. Side effects include nausea, vomiting, constipation, diarrhea or, rarely, acute pancreatitis. There is an FDA warning about the possibility of developing medullary-cell carcinoma of the thyroid gland, which was seen in experimental animals during preclinical studies, but this is very rare in humans.

Other Drugs for Short-term Treatment of Obesity

Besides phentermine, three other FDA-approved drugs are available in the United States for the short-term (8-12 weeks) treatment of obesity:

diethylpropion, phendimetrazine, benzphetamine. Any of these drugs can be used as an adjunct in a regimen of weight reduction based on caloric restriction in patients with an initial BMI of 30 kg/m² or higher who have not responded to an appropriate weight-reduction regimen alone.

Bariatric Surgery

At present, there are three broad categories of bariatric surgical procedures: (1) pure gastric restriction; (2) gastric restriction with some malabsorption, as represented by the Roux-en-Y gastric bypass (RYGB) procedure; and (3) gastric restriction with significant intestinal malabsorption. The number of bariatric procedures performed in the United States increased from an estimated 13,365 in 1998 to almost 228,000 in 2017. Bariatric surgery is considered to be indicated for adults with class 3 obesity (BMI \leq 40 kg/m²). In patients with less severe obesity (BMI 35 to 40 kg/m²), bariatric surgery can be considered if there are one or more high-risk comorbid conditions present, such as life-threatening cardiopulmonary disease (e.g., severe obstructive sleep apnea, obesity-related cardiomyopathy) or uncontrolled T2DM. Bariatric surgery is sometimes performed for patients with diabetes or metabolic syndrome and a BMI of 30 to 35 kg/m², although current evidence on benefit in this weight bracket is limited. For teenagers younger than 17 years old who have attained skeletal maturity (usually by 13 years for girls and 15 years for boys), bariatric surgery has been recommended with different guidelines: BMI 35 to 40 kg/m² with at least one serious comorbid condition (e.g., T2DM, obstructive sleep apnea, pseudotumor cerebri) or BMI 50 kg/m² or higher with less serious comorbidities. Contraindications for bariatric surgery include high operative risk (e.g., congestive heart failure, unstable angina), active substance abuse, and significant psychopathology.

The three most common bariatric procedures are RYGB, sleeve gastrectomy (SLG), and laparoscopic adjustable gastric banding (LAGB). Currently, the most common bariatric procedure in the United States is sleeve gastrectomy. Other procedures such as biliopancreatic diversion (BPD), biliopancreatic diversion with duodenal switch (BPD/DS), and staged bariatric surgical procedures are less commonly performed. Different types of commonly used bariatric procedures are shown in Fig. 69.1. Gastric restriction procedures induce weight loss by producing early satiety and limiting food intake.

LAGB carries a very low operative mortality rate (0.1%). However, it is associated with significantly lower loss of excess weight at 5 years and 10 years and with higher risk of weight regain compared with RYGB and sleeve gastrectomy. LAGB has been demonstrated to be safe in patients older than 55 years of age. Complications associated with the LAGB procedure include band slippage, band erosion, balloon failure, injection port malposition, band and port infections, and esophageal dilatation. Some of these problems have been decreased by

Fig. 69.1 Common bariatric procedures. *BPD*, Biliopancreatic diversion; *BPD/DS*, BPD with duodenal switch; *LAGB*, laparoscopic adjustable gastric band; *RYGB*, Roux-en-Y gastric bypass; *SLG*, sleeve gastrectomy; *VBG*, vertical banded gastroplasty.

use of a different method of band insertion and revision of the port connection. Because the absorptive surface of the entire small intestine remains intact, nutritional deficiencies are rare.

In RYGB, the upper stomach is transected, thereby creating a very small proximal gastric pouch measuring 10 to 30 mL. The gastric pouch is anastomosed to a Roux-en-Y proximal jejunal segment, bypassing the remaining stomach, duodenum, and a small portion of jejunum. The standard Roux (alimentary) limb length is about 50 to 100 cm, and the biliopancreatic limb is 15 to 50 cm. As a result, the RYGB serves to limit food intake and induces some nutritional deficiencies such as vitamin B₁₂, vitamin B₁ (thiamine), iron, calcium, copper and vitamin D, which can be corrected by supplementation. It may also lead to protein malnutrition. Dumping syndrome is another complication that occurs as a result of mechanical and hormonal changes that are commonly seen after any gastric restrictive procedure such as RYGB. The primary management of dumping syndrome is dietary modification for prevention of symptoms.

SLG is another popular restrictive surgery in which the stomach is reduced to about 25% of its original size by surgical removal of a large portion of the stomach fundus, resulting in a tube-like structure. Although the procedure permanently reduces stomach size, some dilatation of the stomach may occur later. The procedure is frequently performed by a laparoscopic technique. Sleeve gastrectomy is a similar procedure done by gastroenterologists through gastrectomy without surgical removal of the stomach fundus. Nutritional deficiencies are less common in SLG when compared to RYGB and include vitamin D, vitamin B₁₂, vitamin B₁, folic acid, and iron. Dumping syndrome may also occur but to a lesser extent than with RYGB. This could be caused by an increase in gastric motility consequent to the increase in intraluminal pressure within the remaining stomach.

Currently, most bariatric procedures are performed laparoscopically. This approach has the advantages of fewer wound complications, less postoperative pain, a shorter hospital stay, and more rapid postoperative recovery with comparable efficacy.

The Agency for Healthcare Research and Quality (AHRQ) identified a 0.19% in-hospital mortality rate for all bariatric discharges in the United States. One meta-analysis showed that the mortality rate from bariatric surgery within 30 days was 0.08% and the mortality rate after 30 days was 0.31%. Bariatric surgery is not uniformly a “low-risk” procedure, and judicious patient selection and diligent perioperative care are mandatory. Preoperative patient selection and education as well as careful postsurgical follow-up are important for successful outcomes.

The mortality rate associated with standard bariatric surgical procedures in an experienced center should not exceed 1.5% to 2%. The surgical mortality rate is less than 0.5% at centers specializing in bariatric surgery. Mortality rates exceeding 2% suggest a risk-to-benefit ratio that probably is unacceptable.

The benefits of bariatric surgery extend beyond calorie restriction and weight loss. Foregut bypass leads to improvement in the physiologic responses of gut hormones involved in glucose regulation and appetite control, including ghrelin, GLP-1, and peptide YY³⁻³⁶ (PYY). Mechanical improvements include less weight-bearing burden on joints, improved lung compliance, and reduced fatty tissue around the neck, which can relieve obstruction to breathing and sleep apnea.

In an extensive meta-analysis of 22,000 bariatric surgeries, patients lost on average 61% of excess body weight and exhibited improvements in T2DM, hypertension, sleep apnea, and dyslipidemia. The beneficial effect of bariatric surgery on T2DM is one of the most important outcomes observed, with RYGB, SLG, and malabsorptive

procedures having the greatest impact. A shorter duration of diabetes and greater weight loss are independent predictors of diabetes partial or complete remission after bariatric surgery. Improvements in fasting blood glucose levels occur before significant weight loss is achieved. Insulin-treated patients experience significant decreases in insulin requirements, and most T2DM patients are able to discontinue insulin therapy by 6 weeks after surgery. Euglycemia is maintained in some patients for up to 5 years after RYGB and SLG. Two recent randomized controlled studies compared RYGB to intensive lifestyle intervention in moderately obese patients with T2DM and found RYGB to be superior in inducing diabetes remission and reducing use of antihyperglycemic medications.

Weight loss after malabsorptive bariatric surgery usually reaches a nadir after 12 to 18 months. Over the following decade, there is weight regain of approximately 10% of body weight. In purely restrictive procedures, failure to experience optimal weight loss has been associated with increased consumption of calorically dense liquids that can pass through the stoma without producing satiety.

Other FDA-approved procedures include *gastric pacing*. Gastric pacing achieved by using implantable electrodes induces weight loss. This outcome was initially discovered with the use of gastric pacemaker devices for gastroparesis in patients with diabetes. Currently, it is an FDA-approved procedure for obesity management.

Gastric aspiration system is an obesity management technique which consists of an endoscopically placed gastrostomy tube and siphon assembly that allows patients to aspirate gastric contents 20 min after meal consumption three times daily. Aspiration takes about 10 min to perform and removes approximately 30% of ingested calories. The side effects include pain, leakage or tube displacement, and stoma site-related problems.

Intra-gastric balloons are used to occupy space in the stomach. Each inflated balloon with air occupies approximately 250 mL volume. Up to three balloons can be placed over a 6-month treatment period, then deflated and removed with an endoscopic procedure.

PROGNOSIS

Although recent clinical data show that patients on average can maintain a 4% to 6.9% weight loss for 10 years with ongoing medically supervised intensive lifestyle intervention, many patients are subjected to less intensive intervention and regain their initial weight loss over months or years. Weight regain even after bariatric surgery is not uncommon and most often occurs after 2 years of peak weight loss. Loss of 10% to 20% of the initial body weight is associated with a decrease in total and resting energy expenditure, a change that retards further weight loss. Similarly, weight gain is associated with an increase in energy expenditure, which retards further weight gain. These observations suggest that the human body adopts a biologic set point or mechanism that tends to maintain body weight, and they lend support to the theory that behavior is not the sole determinant of obesity. Although long-term intensive lifestyle intervention in obese patients with T2DM resulting in approximately 5% body weight loss can significantly decrease the risks of chronic kidney disease and depression and further improve glucose control, blood pressure, physical fitness, and some lipid parameters in patients with T2DM and obesity, it has not been shown to reduce cardiovascular events or mortality. Further understanding of genetic and hormonal regulation of obesity may help researchers create more effective and long-lasting interventional tools.

For further discussion on this topic, please see Chapter 207, “Obesity,” in *Goldman-Cecil Medicine*, 26th Edition. ❖

Malnutrition, Nutritional Assessment, and Nutritional Support in Adult Patients

Thomas R. Ziegler

MALNUTRITION IN HOSPITALIZED PATIENTS

Numerous surveys conducted in developed countries in the 21st century continue to demonstrate the frequent rate of protein-energy malnutrition as well as depletion of specific micronutrients in hospitalized patients with chronic illnesses and those requiring elective or emergent hospital admission. Hospitalized patients commonly receive inadequate amounts of calories, protein, vitamins, and minerals during their stay, and ad libitum intake of prescribed diets is typically inadequate. Studies have shown that worsening of malnutrition during hospitalization is common. This is problematic because adequate intake of essential macronutrients (energy, carbohydrate, protein/amino acids, and fats) and micronutrients (vitamins, minerals, and electrolytes) is critical for optimal cellular and organ structure and function, muscle mass, tissue repair, immune function, ambulatory capacity, and patient recovery. Significant erosion of lean body mass (predominately derived from skeletal muscle) and deficiencies of specific vitamins and minerals are variously associated with weakness and fatigue, increased rates of infection, impaired wound healing, and delayed convalescence. This relationship is especially apparent in patients with chronic protein-energy malnutrition and body weight loss associated with illness.

Patients with acute or chronic illnesses typically have experienced several days to several months of continuous or intermittent decreased food intake due to anorexia, gastrointestinal symptoms, depression and anxiety, and other medical factors. They may also have had food intake restricted by surgical operations or diagnostic or therapeutic procedures and recovery from these. Some patients have abnormal nutrient losses due to diarrhea (e.g., with chronic malabsorptive and maldigestive disorders or infectious diarrhea), vomiting, polyuria (as in uncontrolled diabetes mellitus), wound drainage, dialysis, or other causes. Certain drugs, including corticosteroids, chemotherapeutic agents, antirejection drugs, and diuretics, are associated with skeletal muscle breakdown, gastrointestinal injury, or loss of electrolytes or water-soluble vitamins. Bedrest or markedly decreased ambulation are common in outpatient and inpatient settings and are associated with skeletal muscle wasting and impaired protein synthesis.

Catabolic and critical illnesses are associated with concomitantly increased blood concentrations of “counterregulatory” hormones derived from the adrenal glands and pancreas (e.g., cortisol, catecholamines, glucagon); release of pro-inflammatory cytokines from stimulated immune, endothelial, and epithelial cells, such as interleukins (e.g., IL-1, IL-6, IL-8) and tumor necrosis factor- α (TNF- α); and peripheral tissue resistance to anabolic hormones such as insulin and insulin-like growth factor-I (IGF-I). These hormonal and cytokine alterations increase the availability of endogenous metabolic substrates

that are critical for cellular and organ function, wound healing, and host survival (e.g., glucose via glycogenolysis and gluconeogenesis, amino acids via skeletal muscle breakdown, and free fatty acids via lipolysis). This combination of decreased nutrient intake and increased tissue nutrient losses (from the actions of these hormones and cytokines), coupled with increased energy (calorie), protein, and micronutrient needs due to inflammation, infection, and cytokinemia, is responsible for the wasting and micronutrient depletion commonly observed in medical patients with acute and chronic illnesses. Common causes of protein-energy malnutrition and micronutrient depletion in medical patients are shown in [Table 70.1](#). Obesity has become a widespread medical problem and is also a form of malnutrition; it is considered in detail in [Chapter 69](#).

NUTRITIONAL ASSESSMENT

Serial assessment of nutritional status is a critically important component of routine medical care. The major objectives are to detect preexisting depletion of body protein, energy reserves, and micronutrients; to identify risk factors for malnutrition (see [Table 70.1](#)); and to take steps to prevent nutrient deficiencies, depletion of lean body mass, and loss of skeletal muscle. There are still no practical “gold standard” tests that can provide an index of general nutritional status. Blood concentrations of specific micronutrients (e.g., copper, zinc, thiamine, 25-hydroxyvitamin D, vitamin B₆, folate, vitamin B₁₂) and electrolytes (e.g., magnesium, potassium, phosphorus) are important to guide needs and repletion responses. Nutritional assessment involves an integration of multiple factors, including the patient’s medical and surgical history, type and severity of the acute or chronic underlying illness and its anticipated medical and surgical course, fluid drainage sites and amounts, physical examination findings, history of body weight change (degree and temporal aspects), dietary intake pattern, use of nutritional supplements including prior administration of specialized enteral nutrition (EN) or parenteral nutrition (PN), evaluation of current organ function and fluid status, and determination of selected vitamin, mineral, and electrolyte concentrations in blood ([E-Table 70.1](#)). In the intensive care unit (ICU) setting, measured body weight typically reflects recent intravenous fluid administration and is typically much higher than recent “dry” or preoperative body weight, which is the best parameter to use.

Integration of the factors outlined in [E-Table 70.1](#) provides important information on whether patients are likely to be adequately nourished; to have mild, moderate, or severe protein-energy malnutrition; or to have depletion or deficiency of specific vitamins, minerals, or electrolytes. Patients who have experienced an involuntary

TABLE 70.1 Common Causes of Protein-Energy Malnutrition and Micronutrient Depletion in Medical Patients With Acute or Chronic Illnesses

Decreased spontaneous food intake due to anorexia from chronic or acute illness, gastrointestinal symptoms (e.g., nausea, vomiting, abdominal pain), or depression and anxiety
Restricted food intake required for surgical operations or diagnostic or therapeutic procedures and gastrointestinal dysfunction after these procedures
Abnormal macronutrient and micronutrient losses from the body due to malabsorption (e.g., celiac sprue, short gut syndrome, inflammatory bowel disease, cystic fibrosis, diarrhea), maldigestion (e.g., pancreatitis), emesis, polyuria (e.g., in diabetes), wound drainage, or renal replacement therapy
Periods of increased energy expenditure (caloric needs), protein requirements, and micronutrient needs (e.g., critical illness, increased inflammation)
Catabolic effects of counterregulatory hormones (e.g., cortisol, catecholamines, glucagon), release of pro-inflammatory cytokines from stimulated immune cells and endothelial and epithelial cells such as interleukins (e.g., IL-1, IL-6, IL-8) and tumor necrosis factor- α (TNF- α), and peripheral tissue resistance to the anabolic hormones insulin and insulin-like growth factor-I (IGF-I)
Bedrest, decreased ambulation, and chemical paralysis during mechanical ventilation (skeletal muscle wasting due to impaired protein synthesis)
Administration of drugs that induce skeletal muscle breakdown, gastrointestinal injury, or loss of electrolytes and water-soluble vitamins (e.g., corticosteroids, chemotherapeutic agents, diuretics, antirejection regimens)
Socioeconomic deprivation, inadequate caregivers, ambulation difficulties in the home setting
Inadequate provision of calories, protein, and essential micronutrients (vitamins, minerals, trace elements) during hospitalization

body weight loss of 5% to 10% or more of their usual body weight in the previous few weeks or months, those who weigh less than 90% of their ideal body weight (IBW), and those who have a body mass index (BMI) lower than 18.5 kg/m² should be carefully evaluated, because these individuals are likely to be malnourished.

Among hospitalized patients, especially those in the ICU, circulating concentrations of proteins (e.g., albumin, prealbumin) are often quite low and not useful as protein nutritional status biomarkers given their lack of specificity. Plasma concentrations of albumin and prealbumin typically fall during active inflammation or infection, in critical illness, and after traumatic injury (due to decreased synthesis by the liver and catabolism of blood proteins). They are markedly affected by non-nutritional factors, including fluid status, capillary leak, decreased hepatic synthesis, and increased clearance from blood. Because of the long circulating half-life of albumin (18 to 21 days), concentrations in blood remain low despite adequate feeding and are slow to respond to nutritional repletion, irrespective of other confounding factors. Prealbumin has a much shorter circulating half-life (several days), and serial blood levels can be used as a general indicator of protein status in clinically stable outpatients. [E-Table 70.2](#) illustrates physical examination findings that may be observed in associated with depletion of specific nutrients.

Energy requirements can be estimated with the use of standard equations, such as the Harris-Benedict equation, which incorporate the patient's age, gender, weight, and height to determine basal energy expenditure (BEE) (see [E-Table 70.1](#)). Recently published European and American Clinical Practice Guidelines suggest that an adequate

energy goal for most patients can be estimated at 20 to 25 kcal/kg/day (using the most recent prehospital clinic dry body weight), which is approximately equivalent to measured or estimated BEE multiplied by 1.0 to 1.3. Ongoing RCTs are designed to better define caloric dosing guidelines in hospitalized general and ICU patients.

Typically, lower amounts of calories are now given to ICU patients (as discussed later). Use of data obtained from a bedside metabolic cart machine (indirect calorimeter), which measures expired breath to determine oxygen consumption and carbon dioxide production, provides accurate actual energy expenditure in most settings and can be very useful (see [E-Table 70.1](#)).

In ICU patients, even lower caloric doses (equivalent to 15-20 kcal/kg dry weight/day) have been advocated by some, based on known complications of overfeeding (see later discussion) and limited data on clinical outcome as a function of energy dose. In clinically stable, malnourished, non-ICU patients who require nutritional repletion, higher doses of calories (up to 35 kcal/kg/day) appear to be generally well tolerated if refeeding syndrome is avoided (see later discussion). In obese subjects (defined for these calculations as patients with body weight 20% to 25% greater than ideal), an adjusted body weight value should be used for calculation of energy and protein needs, as determined by the following equation:

$$\text{Adjusted body weight} = (\text{current weight} - \text{IBW}) \times 0.25 + \text{IBW}$$

Guidelines for protein or amino acid administration are given in [E-Table 70.3](#). Studies in nonburned ICU patients indicate that protein loads of more than 2.0 g/kg/day may not be efficiently utilized for protein synthesis, and the excess may be oxidized, contributing to azotemia. In most catabolic patients requiring specialized feeding, a recommended protein dose is 1.5 g/kg/day for individuals with normal renal function. This is about twice the recommended dietary allowance (RDA) for healthy adults of 0.8 g/kg/day. The administered protein dose should be adjusted downward as a function of the degree and tempo of azotemia (in the absence of dialysis therapy) and of hyperbilirubinemia (see [E-Table 70.3](#)). These strategies take into account the relative inability of catabolic patients to efficiently use exogenous nutrients and knowledge that most protein and lean tissue repletion occurs over a period of several weeks to months during posthospital convalescence. Adequate nonprotein energy is essential to allow amino acids to be effectively used for protein synthesis and not oxidized for production of energy (adenosine triphosphate, or ATP). The commonly recommended protein/amino acid dose range is 1.2 to 1.5 g/kg/day for most adults with normal renal and hepatic function (50% to 100% above the RDA of 0.8 g/kg/day); although some guidelines recommend higher doses (up to 2.0 to 2.5 g/kg/day) in specific conditions such as in patients requiring renal replacement therapy or burns.

NUTRITIONAL SUPPORT

[Table 70.2](#) lists common clinical scenarios in which specialized oral/EN or PN support may be indicated. In these settings, consultation with a multidisciplinary nutrition support team, if available, has been shown to reduce complications and costs and to increase the appropriate use of EN and PN in both academic and community medical centers.

Oral Nutrition Support

Oral nutrition supplementation includes provision of balanced oral diets of usual foods supplemented with complete liquid (or solid) nutrient products, protein supplements (e.g., hydrolyzed whey or casein powder that can be mixed with dietary beverages), high-potency multivitamin-multimineral supplements, and/or specific micronutrients required to treat a diagnosed deficiency (e.g., zinc, copper, vitamin B₆, vitamin

E-TABLE 70.1 Comprehensive Nutritional Assessment of Medical and Surgical Patients

1. Review past medical and surgical history and current illness
 - a. Degree of catabolic stress (e.g., fever, infections, sepsis, surgeries, lung failure)
 - b. Organ function (e.g., liver, kidneys, lung, heart/vascular, GI)
 - c. Use of medications that may decrease nutrient absorption (e.g., phenytoin, sulfasalazine, elixir-based medications), alter metabolism or utilization (e.g., warfarin, isoniazid, methotrexate), or increase excretion (e.g., gentamicin, loop diuretics)
 - d. Recent intravenous fluid and electrolyte therapy
 - e. Medical and surgical procedures that are likely in the near term
 - f. Hemodynamic status and requirements for pressor agents to maintain blood pressure
2. Obtain body weight history
 - a. Current body weight (dry weight if available preoperatively or from a recent clinic visit) + usual body weight when healthy or clinically stable; calculate % body weight loss from usual body weight over the last several weeks or months
 - b. Calculate current weight as % of ideal body weight^a
 - c. Determine BMI (weight in kg divided by square of height in m); BMI <18.5 is considered underweight
3. Determine dietary intake pattern in relation to nutrient needs
 - a. General food and beverage intake pattern, % of usual dietary intake consumed in recent weeks and months, unusual or excessive consumption of specific foods or beverages (including alcoholic beverages)
 - b. Previous use and type of enteral tube feedings or parenteral nutritional support
 - c. Previous use of liquid or solid nutritional supplements, multivitamin-multimineral preparations, specific vitamins or minerals
 - d. Consult registered dietitian for more detailed nutrient intake assessment
4. Perform detailed physical examination
 - a. Skeletal muscle wasting (cannot be assessed accurately in overweight or obese patients)
 - b. Loss of body fat stores
 - c. Presence and qualities of wounds
 - d. Skin, hair, tongue, and conjunctival lesions suggestive of micronutrient deficiency (see E-Table 70.2)
 - e. Evidence of organ dysfunction (GI, liver, renal, cardiopulmonary)
 - f. Fluid status (e.g., normal, dehydrated, fluid overload, capillary leak); daily fluid requirements are typically 30-40 mL/kg body weight
5. Evaluate GI tract function
 - a. Swallowing or chewing difficulties, nausea, emesis, abdominal pain
 - b. Intestinal ileus, motility disorders, partial or complete obstruction
 - c. Diarrhea history (frequency, amount, other characteristics)
 - d. Acute or chronic GI bleeding
 - e. Presence of fistulas; history of recent abdominal surgery
 - f. Drainage tube losses (e.g., gastric, biliary, intestinal, peritoneal)
6. Determine functional status
 - a. Ability to perform daily activities, ambulatory capacity, bedrest, chemical paralysis
 - b. History or physical examination evidence of muscle weakness and fatigue
 - c. Mental capacity, history of psychiatric disorders that may preclude oral food intake
7. Serial evaluation of selected biochemical tests
 - a. Standard blood measures of organ function
 - b. Electrolyte concentrations (e.g., calcium, magnesium, phosphorus, potassium)
 - c. Blood pH (in ICU patients on mechanical ventilation)
 - d. Blood triglyceride concentrations (in patients receiving intravenous lipid emulsion)
 - e. Blood concentrations of selected vitamins and minerals if suggested by medical or dietary history, physical examination, or underlying illness (e.g., zinc, selenium, copper, thiamine, vitamin B₆, vitamin B₁₂, folate, 25-hydroxyvitamin D, iron, ferritin)
 - f. Serum prealbumin (in stable outpatients)^b
8. Estimate caloric (kcal), protein, and micronutrient needs
 - a. Caloric needs are based on the Harris-Benedict equation^c, guidelines on kcal/kg body weight^d, or indirect calorimetry results (use serially in ICU patients and in the initial assessment of very underweight or obese hospital patients requiring prolonged nutritional support)
 - b. Protein needs vary as a function of recognized clinical situations (see E-Table 70.3)
 - c. Vitamin and mineral needs are based on conventional requirements, serial blood levels, and clinical judgment regarding intake and estimated losses from comprehensive nutritional assessment
 - d. Nitrogen balance studies are not useful in nonresearch settings because of their variability and inaccuracy
 - e. Serial body composition measurements for lean body mass and body fat estimates may be useful in the outpatient setting (by BIA or DXA) but are not practical or reliable in inpatient nonresearch settings because of fluid shifts and other factors
9. Evaluate enteral and parenteral access for nutrient delivery
 - a. Ability to take oral diet and/or liquid supplements
 - b. Central venous or PICC line access; peripheral line access
 - c. Nasogastric, nasoenteric, or percutaneous feeding tube availability or feasibility
10. Consultation with multidisciplinary nutrition support team

BIA, Bioelectrical impedance analysis; BMI, body mass index; DXA, dual energy x-ray absorptiometry; GI, gastrointestinal; ICU, intensive care unit; PICC, peripherally inserted central venous catheter.

^aIdeal body weight can be estimated in men as 48 kg (106 lb) per 5 ft of height + 2.7 kg (6 lb) for each inch of height above 5 ft and in women as 45 kg (100 lb) per 5 ft of height + 2.3 kg (5 lb) for each inch of height above 5 ft.

^bBlood concentrations of albumin and prealbumin in hospitalized patients, especially in the ICU setting, are markedly affected by non-nutritional factors (e.g., inflammation, infection, fluid status, capillary leak, decreased hepatic synthesis, increased clearance from blood).

^cHarris-Benedict equation to estimate basal energy expenditure (BEE) in kcal/24 hr: for males, BEE = 66.5 + (13.8 × kg body weight) + (5.0 × height in cm) – (6.8 × age in years); for females, BEE = 655 + (9.6 × kg body weight) + (1.8 × height in cm) – (4.7 × age in years).

^dCaloric needs can also be estimated as follows (using dry weight or ideal body weight in ICU patients with fluid overload): in ICU settings, 20-25 kcal/kg/day (some studies suggest that 15-20 kcal/kg/day or lower may be appropriate); in non-ICU settings, 25-35 kcal/kg/day.

E-TABLE 70.2 Clinical Manifestations of Specific Nutrient Deficiencies

Sign or Symptom of Nutrient Depletion ^a	Specific Nutrients Depleted
Muscle and fat wasting, weakness	Calories, protein, combined calories + protein
Anorexia	Calories, protein
Glossitis (discolored, smooth, painful tongue)	Folate, vitamin B ₁₂ , niacin, riboflavin, thiamine, iron
Cheliosis, angular stomatitis	Riboflavin, niacin, folate, vitamin B ₁₂
Symmetrical motor/sensory dysfunction, ataxia, nystagmus, heart failure, mental status changes or confusion	Thiamine (beriberi)
Peripheral edema	Thiamine (heart failure), protein (low oncotic pressure)
Loss of vibratory or position sense, fatigue	Vitamin B ₁₂
Dermatitis (sun-exposed skin), diarrhea, dementia	Niacin (pellagra)
Bleeding gums, petechiae, ecchymosis	Vitamins C and K
Poor wound healing	Calories, protein, calories + protein, vitamin C, vitamin A, zinc, others
Bone pain	Vitamin D (osteomalacia)
Follicular hyperkeratosis, night blindness, Bitot's spots	Vitamin A
Flaky, whitish dermatitis	Essential fatty acid (linoleic, α -linolenic)
Hair sparse or easily pluckable	Zinc, protein
Pale skin, nail spooning (koilonychia)	Iron
Loss of taste; reddish dermatitis around nose, mouth, groin; hair loss	Zinc
Peripheral neuropathies, gait abnormalities, weakness, fatigue	Copper
Muscle pain, heart failure,	Selenium
Paresthesias, carpal pedal spasm	Calcium, magnesium, phosphorus, or potassium

^aTypically, severe deficiency of specific nutrients (with depletion initially in tissue and later in blood) has occurred before physical manifestations of deficiency are evident.

E-TABLE 70.3 Estimation of Protein or Amino Acid Requirements in Adult Patients

Clinical Condition	Protein or Amino Acid Dose (b/kg/day) ^a
Well-nourished with acute illness	1.2-1.5
Malnourished and/or severe catabolic stress	1.2-2.0
Postoperative	1.2-1.5
Hepatic failure	0.6-1.2
Encephalopathy	0-0.6
Acute renal failure, not on renal replacement therapy	0.6-0.8
Renal failure, on renal replacement therapy	1.2-2.5

^aOral/enteral nutrient supplements and tube feedings contain either intact or partially hydrolyzed high-quality protein (typically casein, soy, and/or whey). Parenteral nutrition solutions for peripheral or central vein administration provide known essential L-amino acids combined with several nonessential amino acids. These may be limiting in certain conditionally essential amino acids (e.g., cysteine, taurine) in some clinical conditions.

TABLE 70.2 Some Clinical Indications for Specialized Oral/Enteral or Parenteral Nutrition Support

Patient currently exhibits moderate to severe protein or protein-energy malnutrition or has evidence of specific deficiency of one or more essential micronutrients
Patient with involuntary body weight loss of 5-10% or more of their usual body weight in the previous few weeks or months, weighs less than 90% of ideal body weight, or has a BMI lower than 18.5 kg/m ²
Dietary food intake in a hospital or outpatient setting likely to be <50% of needs for more than 5-10 days due to underlying illness
Patient with severe catabolic stress (e.g., ICU care, serious infection) and adequate nutrient intake unlikely for >3-5 days
After major gastrointestinal surgery or other major operation (e.g., hip replacement, partial organ resection)
Medical illness associated with prolonged (>5-10 days) GI dysfunction (diarrhea, nausea and vomiting, GI bleeding, severe ileus, partial obstruction) and/or short bowel syndrome, chronic or severe diarrhea, or other malabsorptive disorders
Clinical settings in which adequate oral food intake may be contraindicated or otherwise significantly decreased, such as respiratory or other acute or severe organ failure, dementia, dysphagia, chemotherapy or irradiation, inflammatory bowel disease, pancreatitis, high-output enterocutaneous fistula, alcoholism, drug addiction
Chronic obstructive lung disease, chronic infection, or other chronic inflammatory or catabolic disorders with documented poor nutrient intake and/or recent weight loss

BMI, Body mass index; GI, gastrointestinal; ICU, intensive care unit; PN, parenteral nutrition.

B₁₂, vitamin D). Special supplements designed for patients with chronic renal failure (featuring concentrated calories and low amounts of protein and electrolytes) are available, as are a variety of formulations designed for other specific disease categories (see later discussion). Several studies have shown that convalescence after stresses such as total hip replacement or gastrointestinal surgery is enhanced with the addition of one or two containers per day of complete liquid nutrient supplements. These provide calories, carbohydrate, high-quality protein, fat, and micronutrients; are lactose and gluten free; and may contain small peptides and medium-chain triglycerides to facilitate absorption of amino acid and fat, respectively. Some formulations also contain soluble fiber or prebiotics (e.g., fructo-oligosaccharides) designed to decrease diarrhea. It is probably prudent to place outpatients who exhibit or are at risk for undernutrition (see E-Tables 70.1 and 70.2) and can tolerate oral medications on a potent oral multivitamin-multimineral preparation, at least for several months.

Administration of Enteral Tube Feeding

Patients with conditions outlined in Table 70.2 may have a functional gastrointestinal tract and yet be unable to consume adequate diet orally due to medical or surgical conditions (e.g., mechanical ventilation, pancreatitis, dementia, dysphagia, trauma, or burns). Although PN is commonly administered in these settings, this practice is not evidence based; academic guidelines strongly suggest that oral nutritional supplements or enteral tube feedings should be used if specialized nutrition support is indicated in patients with a functional gastrointestinal tract (“if the gut works, use it”). EN is more physiologic, associated with less severe infectious, mechanical, and metabolic complications, and is less costly than PN. Although not evidence based, common contraindications to EN include paralytic ileus, bowel ischemia, and hemodynamic

instability requiring mid- to high-dose vasopressors, inability to gain access to the gastrointestinal (GI) tract, intestinal obstruction, intractable vomiting, severe diarrhea, and peritonitis.

E-Table 70.4 shows major characteristics of common complete liquid tube feeding formulations and the types of patients for which these are typically prescribed. These products can be used for oral nutrient supplementation as tolerated. When delivered in appropriate amounts, the liquid diets provide complete nutrition for most patients, although some ICU patients and patients with malabsorption or other conditions may have special needs (see later discussion).

The feedings can be delivered by conventional nasogastric tubes into the stomach or by small-bore nasogastric or nasojejunal tubes, percutaneous gastrostomy or jejunostomy tubes, or percutaneous gastrojejunostomy tubes (in which the gastric port may be used for suction and the jejunal port for feeding). Gastric feedings can be administered by either continuous or bolus feeds, whereas small bowel feeds must employ a continuous slow infusion using an infusion pump to avoid diarrhea. Tube feedings should be initiated at a slow rate (e.g., 10 to 20 mL/hr) for 8 to 24 hours and slowly advanced to the goal rate in 8- to 24-hour increments to deliver the calculated caloric and protein needs over the next 24 to 48 hours, depending on clinical tolerance and clinical conditions. Recent guidelines emphasize placing tube-fed patients in the semirecumbent position (e.g., increase head of bed), advancing feedings cautiously (with serial evaluations for diarrhea, nausea, emesis, abdominal distention, and significant gastric residuals), and using prokinetic agents and/or postpyloric feedings if gastric feedings are not well tolerated. Recent data suggest that higher volumes of gastric residuals (e.g., >250 mL) are usually well tolerated in patients being tube fed.

Primarily based on results of animal studies, EN is associated with improved gut barrier function, decreased infectious complications, less hypermetabolism, and decreased morbidity and mortality in catabolic models, compared with PN. Salutory clinical outcomes have been shown in randomized clinical trials in patients with pancreatitis receiving EN into the jejunum, compared with PN. The current Society for Critical Care Medicine (SCCM) and American Society for Parenteral and Enteral Nutrition (ASPEN) guidelines recommend starting early EN (within 24-48 hours) in ICU patients who cannot achieve adequate caloric needs (e.g., >60%) with oral diet and supplements alone, especially for patients with existing malnutrition. Many studies have shown that ICU patients actually receive only 60% to 75% of the amount of tube feeding ordered by physicians. This can occur because of tube feeding intolerance (e.g., high gastric residuals, emesis, diarrhea, tube dislodgement) or discontinuation of feeding for diagnostic tests or therapeutic interventions. Although supplemental PN (see later discussion) is commonly ordered in patients who are not able to achieve tube-feeding rates adequate for their needs, this practice remains controversial because of the limited number of good clinical trials. Rigorous studies are now in progress to address the efficacy of this approach, motivated by data suggesting that an increase in net caloric deficit (i.e., the difference between daily calorie requirements and daily actual calories delivered, summed over time) is associated with worse clinical outcomes in medical and surgical ICU patients.

Most outpatients and hospitalized ICU and non-ICU patients tolerate standard, inexpensive enteral formulas delivered via gastric or intestinal routes that provide between 1.0 and 1.5 kcal/mL. A large variety of enteral tube-feeding products are available for clinical use. The specific product chosen should be based both on clinical conditions and underlying organ function, as outlined in E-Table 70.4. Because EN products can be marketed without efficacy data from randomized, controlled clinical trials, there remains a clear need for such trials to determine optimal EN formulations for different clinical conditions.

E-TABLE 70.4 Complete Enteral Nutrient Formulas and Clinical Indications

Formula Type and Characteristics ^a	Clinical Indication
Intact protein, complex ^b	Normal intestinal function
Hydrolyzed protein/peptides, semi-elemental ^c	Gut mucosal disease, injury
High calories, lower protein, lower electrolytes ^d	Renal failure
High calories, complex ^d	Fluid restriction (e.g., cardiac failure)
"Immune-modulating" enriched in arginine, glutamine, nucleotides, omega-3 fatty acids, and/or antioxidants ^{e,f}	Postoperative, immunosuppressed, severe stress, injury, gut mucosal disease
EPA, γ -linolenic acid, and antioxidants ^g	ARDS

ARDS, Acute respiratory distress syndrome; EPA, eicosapentanoic acid; MCT, medium-chain triglycerides.

^aAll formulations are lactose and gluten free, are relatively low in sodium, and provide adequate vitamins and minerals with daily volumes of 1-1.5 L.

^bLeast expensive; protein sources are intact casein, whey, and/or soy; fat sources are corn, safflower, or soy oils and MCT; carbohydrate sources are maltodextrin, corn syrup, hydrolyzed corn starch, sucrose; caloric density varies from 1 to 2.0 kcal/mL (primarily by increasing fat content); may feature high-protein composition and soluble fiber or prebiotics; osmolality 350-550 mOsm/kg.

^cProtein sources are hydrolyzed casein, soy, and/or whey; may feature more MCT, hydrolyzed corn starch, and sucrose for enhanced digestion and absorption; caloric density is 1 to 1.5 kcal/mL.

^dCalorically dense (2.0 kcal/mL); low to moderate protein; low potassium, magnesium, phosphorus, and vitamin A content; higher calcium content.

^eUse in septic or hemodynamically compromised patients is currently controversial.

^fGlutamine is supplied as L-glutamine or glutamine peptides; several randomized, controlled clinical trials show conflicting results regarding decrease in infections with enteral glutamine supplementation; some formulas combine glutamine and other supplements (e.g., enriched in antioxidants, omega-3 fatty acids).

^gSeveral, but not all, randomized, controlled clinical trials show clinical efficacy with this formulation in patients who require mechanical ventilation due to ARDS; formula is not enriched in arginine, glutamine, or nucleotides.

Complications of enteral feeding include diarrhea. Diarrhea is common in hospital patients receiving tube feedings but is typically caused by factors independent of the feeding, including administration of antibiotics, sorbitol-containing or hypertonic medications (e.g., acetaminophen elixir), and infections. Diarrhea caused by tube feeding itself does occur with rapid formula administration, in patients with underlying gut mucosal disease, and in those with severe hypoalbuminemia, which causes bowel wall edema. A fiber-containing enteral formula is sometimes useful to decrease diarrhea. Other complications of tube feeding include aspiration of tube feedings into the lung; mechanical problems with nasally placed feeding tubes, including discomfort, sinusitis, pharyngeal or esophageal mucosal erosion due to local tube trauma; and, with percutaneous feeding tubes, entrance site leakage, skin breakdown, cellulitis, and pain. Metabolic complications of tube feeding include fluid imbalances, hyperglycemia, electrolyte abnormalities, azotemia, and, occasionally, refeeding syndrome (discussed later). In general, if tube feedings are deemed to be required for more than 4 to 6 weeks, a percutaneous feeding tube should be placed.

In tube-fed patients who are receiving either subcutaneous or intravenous insulin to control hyperglycemia, significant hypoglycemia due to the continued actions of insulin may occur if tube feedings are discontinued inadvertently or for diagnostic or therapeutic tests. Hospitalized patients receiving tube feedings should have their blood glucose concentration monitored on a daily basis (or several times per day as indicated) and their blood electrolytes (including magnesium, potassium, and phosphorus) and renal function monitored several times each week (or daily in the ICU setting). Other blood chemistries should be determined at least weekly. This should be accompanied by close monitoring of intake and output records (including urine, stool, and drainage outputs) and gastrointestinal tolerance. When patients are able to consume oral food, tube feeding should be decreased and then discontinued (e.g., with daily calorie counts by a registered dietitian). For patients requiring home tube feeding, it is important to consult social service professionals to ensure appropriate care and follow-up.

EN administration must be individualized to each patient's specific needs. In order to determine the appropriate EN delivery method, GI tract integrity and functional capacity, presence and degree of malnutrition, underlying disease states, and patient tolerance must be assessed prior to and following the initiation of tube feeding. Gastrointestinal, mechanical, and metabolic complications, as well as pulmonary aspiration of feeds, can occur with enteral tube feeding. It is therefore essential to monitor enterally fed patients closely in order to identify complications.

A recent randomized study of 894 clinically similar, critically ill adults with medical or surgical issues at seven academic centers assigned patients to permissive enteral underfeeding (40-60% of calculated energy needs) versus standard EN (70-100% of calculated energy needs), with similar daily protein intake (approximately 60 g/day). During intervention, the permissive underfed group received 835 plus or minus 297 kcal/day versus 1299 plus or minus 467 kcal/day in the standard group; no difference in mortality or other clinical outcomes occurred.

Administration of Parenteral Nutrition

The basic principle in considering PN therapy is that the patient must be unable to achieve adequate nutrient intake via the enteral route. PN support includes administration of standard complete nutrient mixtures that contain dextrose, L-amino acids, lipid emulsion, electrolytes, vitamins, and minerals (in addition to certain medications as indicated, such as insulin or octreotide), given via a peripheral or central vein. Administration of complete PN therapy to patients with gastrointestinal tract dysfunction has become a standard of care in most hospitals and ICUs throughout the world, although use in individual institutions varies widely. PN is life-saving in patients with intestinal

failure (e.g., short bowel syndrome). Existing data indicate that PN benefits patients with preexisting moderate to severe malnutrition or critical illness by decreasing overall morbidity, and possibly mortality, compared with patients receiving inadequate EN or hydration (intravenous dextrose) therapy alone. A consensus is emerging, based on recent rigorous studies in critical illness, that PN should probably not be initiated until days 3 to 4 after ICU admission in patients who are unable to tolerate adequate EN.

Compared with PN, EN is less expensive, probably maintains intestinal mucosal structure and function to a greater extent, is safer in terms of mechanical and metabolic complications (see later discussion), and is associated with reduced rates of nosocomial infection. Therefore, the enteral route of feeding should be used and advanced whenever possible, and the amount of administered PN should be correspondingly reduced.

Generally recognized indications for PN include the following situations:

1. Patients with short bowel syndrome or other conditions causing intestinal failure (e.g., motility disorders, obstruction, severe ileus, severe inflammatory bowel disease), especially those with preexisting malnutrition.
2. Clinically stable patients in whom adequate enteral feeding (e.g., >50% of needs) is unlikely for 7 to 10 days because of an underlying illness.
3. Patients with severe catabolic stress requiring ICU care in whom adequate enteral nutrient intake is unlikely for more than 3 to 5 days.

There is no reason to withhold PN in hospitalized patients for any period of time if they exhibit preexisting moderate to severe malnutrition and are deemed to be unlikely to meet their needs by the oral or enteral route.

Generally accepted contraindications for PN include the following conditions:

1. If the GI tract is functional and access for enteral feeding is available.
2. If PN is thought to be required for 5 days or less.
3. If the patient cannot tolerate the extra intravenous fluid required for PN or has severe hyperglycemia or electrolyte abnormalities on the planned day of PN initiation.
4. If the patient has an uncontrolled bloodstream infection or severe hemodynamic instability.
5. If new placement of an intravenous line solely for PN poses undue risks based on clinical judgment.
6. On an individualized basis, if aggressive nutritional support is not desired by the competent patient or legally authorized representative, such as in preterminal patients or those with terminal illness.

PN can be delivered either as peripheral vein solutions or as central vein solutions through a percutaneous subclavian vein or internal jugular vein catheter for infusion into the superior vena cava (nontunneled in the hospital setting), through a subcutaneously tunneled central venous catheter (e.g., Hickman catheter) or central venous port (for chronic home PN therapy), or through a peripherally inserted central venous catheter (PICC). Although data are limited, it is clearly preferable to manage long-term central venous PN to be managed at home with the use of a tunneled central venous catheter rather than a PICC line because of the higher rate of local complications (e.g., phlebitis, catheter breakage) and possibly catheter-associated infections with PICC lines.

A comparison of typical fluid, macronutrient, and micronutrient content of peripheral and central vein PN solutions is shown in [Table 70.3](#). Complete PN provides intravenous lipid emulsions (IVF) as a source of both energy and essential linoleic and linolenic fatty acids.

In the United States, historically the only commercially available lipid emulsion was soybean oil (SO)-based; now, an intravenous soybean oil/olive oil emulsion, an intravenous soybean oil/medium-chain triglyceride mixture, a fish oil/medium-chain triglyceride/olive oil/soybean oil emulsion, and a fish oil–based emulsion have been approved for use in PN. The different formulations vary in the fatty acid content and dosing. The use of SO-based emulsions has been associated with elevated serum bilirubin levels, intestinal failure–associated liver disease, and cholestasis in some patients, particularly at chronic doses exceeding 1.0 g/kg/day. Recent reviews of fish oil–containing IVF lowered inflammatory markers, improved triglyceride levels and liver enzymes, and reduced infectious complications in ICU patients. When compared with SO-based IVF, olive oil–based IVF are a safe alternative but clinical and metabolic differences between these two IVF were not statistically significant.

The maximal recommended rate of fat emulsion infusion is approximately 1.0 g/kg/day but larger doses may be given for shorter term use in hospital settings and are well tolerated. Most patients are well able to clear triglyceride from plasma after intravenous administration of fat emulsion. It is important to monitor blood triglyceride levels at baseline and then approximately weekly and as indicated to assess clearance of intravenous fat; triglyceride levels should be maintained lower than 400 mg/dL to decrease the risk of pancreatitis or diminished pulmonary diffusion capacity in patients with severe chronic obstructive lung disease.

Central venous administration of PN allows higher concentrations of dextrose (3.4 kcal/g) and amino acids (4 kcal/g) to be delivered as hypertonic solutions; thus, lower amounts of fat emulsion are needed to reach caloric goals (see Table 70.3). Requirements for potassium, magnesium, and phosphorus are typically higher with central vein PN compared to peripheral vein PN. The higher concentrations of dextrose and amino acids allow most patients to achieve caloric and amino acid goals with only 1 to 1.5 L of PN per day. In central vein PN, initial orders typically provide 60% to 70% of non–amino acid calories as dextrose and 30% to 40% of non–amino acid calories as fat emulsion. These percentages are adjusted as indicated based on levels of blood glucose and triglyceride, respectively. Based on comprehensive data associating hyperglycemia with hospital morbidity and mortality, expert panels now recommend tight blood glucose control in ICU settings (between 80 and 130 to 150 mg/dL) and close blood glucose monitoring. Separate intravenous insulin infusions should usually be administered in the ICU when patients receiving central vein PN develop hyperglycemia.

Specific requirements for intravenous trace elements and vitamins have not been rigorously defined for patient subgroups, and in most stable patients, therapy is directed at meeting published recommended doses using standardized intravenous preparations to maintain blood levels in the normal range (see Table 70.3). Several studies have shown that a significant proportion of ICU patients have low levels of zinc, selenium, vitamin C, vitamin E, and vitamin D despite receiving specialized PN (or EN). Depletion of these essential nutrients may impair antioxidant capacity, immunity, wound healing, and other important body functions, and supplementation is recommended if serum concentrations are low. For example, zinc (and other micronutrients such as copper) should probably be increased in the PN of patients with burns, large wounds, significant gastrointestinal fluid losses, and other conditions if serum concentrations indicate low levels. Recent data suggest that thiamine depletion is not uncommon in patients receiving chronic diuretic therapy, renal replacement therapy, or in those with severe malabsorption.

The most common complication of peripheral vein PN is local phlebitis resulting from use of the catheter. In such cases, a small dose of hydrocortisone and heparin is typically added to the solution.

TABLE 70.3 Composition of Typical Parenteral Nutrition Solutions

Component ^a	Peripheral PN	Central PN
Volume (L/day)	2-3	1-1.5
Dextrose (%)	5	10-25
Amino acids (%) ^b	2.5-3.5	3-8
Lipid (%) ^c	3.5-5.0	2.5-5.0
Sodium (mEq/L)	50-150	50-150
Potassium (mEq/L)	20-35	30-50
Phosphorus (mmol/L)	5-10	10-30
Magnesium (mEq/L)	8-10	10-20
Calcium (mEq/L)	2.5-5	2.5-5
Trace elements ^d		
Vitamins ^e		

^aElectrolytes in parenteral nutrition (PN) are adjusted as indicated to maintain serially measured serum levels within the normal range. The percentage of sodium and potassium salts as chloride is increased to correct metabolic alkalosis, and the percentage of salts as acetate is increased to correct metabolic acidosis. Regular insulin is added to PN as needed to achieve blood glucose goals (separate intravenous insulin infusions are commonly required with hyperglycemia in intensive care unit settings).

^bProvides all essential amino acids and several nonessential amino acids. The dose of amino acids is adjusted downward or upward to goal as a function of the degree of azotemia or hyperbilirubinemia in patients with renal or hepatic failure, respectively.

^cLipid is given as soybean oil– or olive oil/soybean oil–based fat emulsion in the United States. Intravenous fish oil, olive oil, medium-chain triglycerides, and combinations of these are also now available for use in PN. Lipid is typically mixed with dextrose and amino acids in the same PN infusion bag (“all-in-one” solution).

^dTrace elements added on a daily basis to peripheral vein and central vein PN are mixtures of chromium, copper, manganese, selenium, and zinc. (These elements can also be supplemented individually.)

^eVitamins added on a daily basis to peripheral vein and central vein PN are mixtures of vitamins A, B₁ (thiamine), B₂ (riboflavin), B₃ (niacinamide), B₆ (pyridoxine), B₁₂, C, D, and E, biotin, folate, and pantothenic acid. Vitamin K is added on an individual basis (e.g., for patients with cirrhosis). Specific vitamins can also be supplemented individually.

Alterations in blood electrolytes can be treated with adjustment of concentrations in the peripheral PN prescription. Hypertriglyceridemia typically responds well to lowering of the total PN lipid dose. Central vein PN is associated with a much higher rate of mechanical, metabolic, and infectious complications than peripheral vein PN. Mechanical complications include those related to insertion of the central venous catheter (e.g., pneumothorax, hemothorax, malposition of the catheter, thrombosis). Infectious complications include catheter-related bloodstream infections and non–catheter-related infections. The risk for these infections appears to be increased with use of non–subclavian vein central venous access (e.g., jugular vein, femoral vein) and multiple-use catheters with non-dedicated PN infusion ports used for additional purposes such as blood drawing or medication administration. Poorly controlled blood glucose levels (>140 to 180 mg/dL) are not uncommon in patients requiring central vein PN and are associated with an increased risk of nosocomial infection. Risk factors for hyperglycemia include poorly controlled blood glucose at PN initiation; use of high dextrose concentrations (>10%) in the initial few days of PN administration or too rapid an increase in total dextrose load; insufficient exogenous insulin administration; inadequate monitoring of blood glucose responses to central vein PN administration; and administration of corticosteroids and vasopressor agents such as

norepinephrine (which stimulate gluconeogenesis and cause insulin resistance).

Studies on nutrient utilization efficiency and metabolic complications in severely catabolic patients suggest that lower amounts of total energy and protein/amino acids should be administered than were routinely given in the past, particularly in unstable and ICU patients. High calorie, carbohydrate, amino acid, and fat loads (“hyperalimentation”) are easily administered via central vein PN but can induce severe metabolic complications, including carbon dioxide overproduction, azotemia, hyperglycemia, electrolyte alterations, and hepatic steatosis and injury (E-Table 70.5). Dextrose and lipid doses in PN should be advanced over several days after initiation, with close monitoring of the blood glucose concentration, electrolytes, triglycerides, organ function tests, intake and output measurements, and the clinical course.

Refeeding syndrome with central vein PN administration is relatively common in patients at risk, including those with preexisting malnutrition, electrolyte depletion, alcoholism, or prolonged periods of intravenous hydration therapy (e.g., 5% dextrose) without nutritional support, all of which are common in hospital patients. Refeeding syndrome is mediated by administration of excessive intravenous dextrose (>150 to 250 g, for example in 1 L of PN containing 15% to 25% dextrose). This, in turn, markedly stimulates insulin release, which rapidly lowers blood concentrations of potassium, magnesium, and especially phosphorus as a result of intracellular shifts and utilization in carbohydrate metabolic pathways. Administration of high doses of carbohydrate also consumes thiamine, which is required as a cofactor for carbohydrate metabolism and can precipitate symptoms of thiamine deficiency (see E-Table 70.2), especially in patients with poor thiamine nutriture at baseline. Hyperinsulinemia also tends to cause sodium and fluid retention at the level of the kidney. Together, fluid and sodium retention, the drop in electrolytes (which can cause arrhythmias), and hypermetabolism due to excessive calorie provision can result in heart failure, especially in patients with preexisting heart disease and cardiac muscle atrophy due to prolonged protein-energy malnutrition. Prevention of refeeding syndrome requires vigilance to identify patients at risk; use of initially low PN dextrose concentrations; empiric provision of higher doses of potassium, magnesium, and phosphorus based on current blood levels and renal function; and supplemental thiamine (100 mg/day for 3 to 5 days).

If home PN is indicated, the primary physician should consult with social service professionals to identify appropriate home care companies and nutrition support professionals to assess intravenous line

access, metabolic status, and the home PN order and to arrange for follow-up care and monitoring of PN. It is important not to arrange for rapid discharge of hospitalized patients newly started on PN. Obtaining appropriate venous access and monitoring of fluid and electrolyte status over a 2- to 3-day period is an important aspect of care for most patients started on PN, and it is imperative for those with severe malnutrition and those at risk for refeeding syndrome.

For a deeper discussion on this topic, please see Chapters 203, “Protein-Energy Malnutrition,” and 204, “Malnutrition: Assessment and Support,” in *Goldman-Cecil Medicine*, 26th Edition.

E-TABLE 70.5 Some Common Metabolic Complications of Parenteral Nutrition

PN Order Problem	Metabolic or Clinical Consequence
Excess kcal, CHO, fat	Abnormal liver function tests
Excess kcal, CHO, fat	Hepatic steatosis
Excess CHO	Hypercapnia
Excess fluid, kcal, CHO, fat	Respiratory insufficiency
Excess amino acids	Azotemia
Excess sodium and fluid	Sodium and fluid retention
Excess CHO, inadequate insulin	Hyperglycemia-mediated immune cell dysfunction, infection
Inadequate or excessive electrolytes	Abnormal blood electrolyte levels
Excess fluid, kcal, sodium, CHO, inadequate electrolytes	Cardiac failure, arrhythmias
Excess CHO, inadequate electrolytes, thiamine	Refeeding syndrome

CHO, Carbohydrate; *kcal*, calories; *PN*, parenteral nutrition.

Disorders of Lipid Metabolism

Russell Bratman, Geetha Gopalakrishnan

DEFINITION AND EPIDEMIOLOGY

Lipids such as free fatty acids (FFA), cholesterol, and triglycerides are hydrophobic molecules that bind proteins for transport. Nonesterified FFA travel as anions complexed to albumin. Esterified complex lipids are transported in lipoprotein particles. Lipoproteins have a hydrophobic core (cholesteryl esters and triglycerides) and an amphiphilic surface monolayer (phospholipids, unesterified cholesterol, and apolipoproteins). Ultracentrifugation separates lipoproteins into five classes based on their density (Table 71.1).

Proteins on the surface of lipoproteins (i.e., apolipoproteins) activate enzymes and receptors that guide lipid metabolism. Defects in the synthesis and catabolism of lipoproteins result in dyslipidemia. Prevalence of dyslipidemia in the United States is approximately 20% and varies with the population studied. An estimated 70% of individuals with premature coronary heart disease (CHD) have dyslipidemia. In clinical trials, treatment of dyslipidemia improved both CHD and all-cause mortality rates. Two classes of lipids, triglyceride and cholesterol, play a significant, yet modifiable, role in the pathogenesis of atherosclerosis and therefore are the focus of this chapter.

PATHOLOGY

In the intestinal lumen, dietary triglycerides and cholesterol esters are hydrolyzed by pancreatic lipase to produce glycerol, FFA, and free cholesterol. Bile acids aid in the formation of amphiphilic droplets known as micelles. Micelles enable the absorption of glycerol and FFA into the intestinal cell. The transport of free cholesterol is mediated by a cholesterol gradient that exists between the lumen and the intestinal cell. Within the cell, glycerol combines with three fatty acid chains to form triglycerides, and cholesterol is esterified to form cholesterol esters. Chylomicrons are formed from triglycerides (85% of chylomicron mass) and cholesterol esters assembled with surface lipoproteins. Chylomicrons enter the circulation and acquire more surface apolipoproteins such as apo C-II and apo E from high-density lipoprotein (HDL) particles (Fig. 71.1). Apo C-II activates lipoprotein lipase (LPL), which is located on the capillary endothelium. LPL hydrolyzes the core chylomicron triglycerides to release FFA. FFA functions as an energy source. Excess FFA are stored in adipose tissue or utilized in hepatic lipoprotein synthesis. The triglyceride-poor chylomicron remnant is then cleared from the circulation by hepatic LDL receptors. These receptors are activated by apo E located on the surface of chylomicrons.

Very-low-density lipoproteins (VLDL) are synthesized by the liver (see Fig. 71.1) using FFA and cholesterol obtained from the circulation or synthesized by the liver. Any condition that increases the flux of FFA to the liver, such as poorly controlled diabetes, will

increase VLDL production. The liver assembles triglycerides (55% of VLDL mass), cholesterol (20%), and surface apolipoproteins to form VLDL particles. Apo C-II, the cofactor for LPL, hydrolyzes the triglyceride core of VLDL particles to generate VLDL remnant or intermediate-density lipoprotein (IDL). The IDL, depleted of triglycerides (25%), can be cleared from the circulation by apo E-mediated LDL receptors, or it can be hydrolyzed further to form low-density lipoproteins (LDL). LDL particles are triglyceride poor (5% of LDL mass) and consist mostly of cholesterol esters (60%) and apolipoproteins. Apo B100 on the surface of LDL binds LDL receptors and facilitates LDL clearance from the circulation. Internalized LDL-cholesterol is used to synthesize hormones, produce cell membranes, and store energy.

In the liver, LDL-cholesterol is used to synthesize bile acids (see Fig. 71.1), which are secreted into the intestinal lumen along with free cholesterol. Bile acids help transport fat. Approximately 50% of the cholesterol and 97% of the bile acid entering the lumen are reabsorbed back into the circulation. The reabsorbed cholesterol regulates cholesterol and LDL receptor synthesis.

Many cells in the body, including liver parenchymal cells, synthesize cholesterol (Fig. 71.2). Acetate is converted to 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA). HMG-CoA reductase converts HMG-CoA to mevalonic acid, which is then converted to cholesterol through a series of steps. HMG-CoA reductase catalyzes the rate-limiting step in the cholesterol synthesis pathway. Drugs that inhibit this enzyme decrease cholesterol biosynthesis and cellular cholesterol pools. The class of drugs that inhibit HMG-CoA inhibitors are often called “statins.” Internalization of LDL particles into cells is regulated by negative feedback (see Fig. 71.2). A negative cholesterol balance increases the expression of LDL receptors and subsequent uptake of cholesterol from the circulation. A positive cell cholesterol balance suppresses LDL receptor expression and decreases uptake of LDL-cholesterol into cells. Circulating LDL then enters macrophages and other tissues via scavenger receptors. Because the scavenger receptors are not regulated, these cells accumulate excess intracellular cholesterol, resulting in the formation of foam cells and atheromatous plaques.

The anti-atherogenic effect of HDL is attributed to the removal of excess cholesterol from tissue sites and other lipoproteins. HDL is synthesized in the liver and intestine (see Fig. 71.1). Excess phospholipids, cholesterol, and apolipoproteins on remnant chylomicrons, VLDL, IDL, and LDL are transferred to HDL particles and thus increase HDL mass. Apo A-I, a surface lipoprotein on HDL particles, mobilizes cholesterol from intracellular pools and accepts cholesterol released during lipolysis of triglyceride-rich lipoproteins. It also activates lecithin-cholesterol acyltransferase (LCAT), an enzyme that esterifies cholesterol. These cholesterol esters move the hydrophilic HDL

TABLE 71.1 Properties of Lipoproteins

Lipoprotein Class	Density (g/mL)	Origin	Apolipoproteins	Lipid
Chylomicrons	<0.95	Intestine	B48, C-II, E	TG (85%), cholesterol (10%)
VLDL	<1.006	Liver	B100, C-II, E	TG (55%), cholesterol (20%)
IDL	1.006–1.019	VLDL catabolism	B100, E	TG (25%), cholesterol (35%)
LDL	1.019–1.063	IDL catabolism	B100	TG (5%), cholesterol (60%)
HDL	1.063–1.25	Liver, intestine	A-I, E	TG (5%), cholesterol (20%)

HDL, High-density lipoprotein; IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; TG, triglyceride; VLDL, very-low-density lipoprotein.

Fig. 71.1 Normal metabolism of plasma lipoproteins (see text for details). *apo*, Apolipoprotein; *B, E*, membrane receptor for lipoproteins containing apo B and apo E (synonymous with the LDL receptor); *FC*, free (unesterified) cholesterol; *FFA*, free (unesterified) fatty acids; *HDL*, high-density lipoprotein; *IDL*, intermediate-density lipoprotein; *LDL*, low-density lipoprotein; *LPL*, lipoprotein lipase; *VLDL*, very-low-density lipoprotein.

surface to the hydrophobic HDL core. Cholesterol ester transfer protein (CETP) transfers core HDL cholesterol esters to other lipoproteins such as VLDL. These lipoproteins deliver cholesterol to peripheral sites for hormone and cell membrane synthesis.

Defects in the production or removal of lipoproteins results in dyslipidemia. Both genetic and acquired conditions have been implicated in the pathogenesis of lipid disorders (Tables 71.2 and 71.3). These are discussed later in the chapter.

CLINICAL PRESENTATION

Dyslipidemia plays a significant role in the development of atherosclerosis. Increased incidence of CHD with high LDL- and low HDL-cholesterol is well documented. Excess LDL can result in the formation of cholesterol plaques that deposit in arteries (atheroma), skin and tendon (xanthomas), eyelids (xanthelasma), and iris (corneal arcus). The impact of triglycerides on vascular disease is less clear. Metabolic disorders such as diabetes and obesity are often associated with vascular disease and hypertriglyceridemia. The atherogenic impact of other elements associated with metabolic disorders is difficult to separate from the effect of hypertriglyceridemia. However, in several population-based studies, abnormal triglyceride levels correlated with

increased risk for CHD. Marked hypertriglyceridemia (>1000 mg/dL) is associated with the chylomicronemia syndrome, characterized by pancreatitis and xanthomas.

DIAGNOSIS

Dyslipidemia is defined by a total cholesterol, triglyceride, or LDL level greater than the 90th percentile or an HDL level lower than the 10th percentile for the general population. Because chylomicrons are present in plasma for up to 10 hours after a meal, fasting total cholesterol, triglyceride, and lipoprotein assessments are required for diagnosis. It is advisable to confirm dyslipidemia with two separate determinations.

Total cholesterol, triglyceride, and HDL levels can be measured directly. VLDL and LDL levels usually are calculated. If the triglyceride concentration is lower than 400 mg/dL, then VLDL is calculated by dividing the triglyceride level by 5. LDL-cholesterol is estimated by subtracting VLDL and HDL from the total cholesterol. This is known as the Friedewald equation. LDL cholesterol calculated utilizing this equation is used to set therapeutic targets in most clinical trials and treatment guidelines. However, calculated LDL cholesterol becomes progressively inaccurate with increasing triglyceride levels and should not be estimated if triglyceride levels are greater the 400 mg/dL. In

TABLE 71.2 Genetic Disorders of Lipid Metabolism

Disorder	Genetic Defect	Dyslipidemia
Familial hypercholesterolemia	Mutation in the gene that encodes LDL receptor Gain of function mutation in <i>PCSK9</i> gene Mutation in the apolipoprotein B100 gene	Elevated TC and LDL
Elevated plasma Lp(a)	Increased binding of LDL to apolipoprotein(a)	Elevated Lp(a)
Polygenic hypercholesterolemia	Increased binding of apo E4-containing lipoprotein to LDL receptor resulting in downregulation of the LDL receptor	Elevated TC and LDL
Familial combined hyperlipoproteinemia	Polygenic disorder associated with increased hepatic VLDL production, resulting in increased LDL and decreased HDL production; some individuals have a mutation in the <i>LPL</i> gene that affects expression and function of LPL	Elevated TC, LDL, and TG Low HDL
Familial dysbetalipoproteinemia	Lower affinity of apo E2 for LDL receptor	Elevated TG, TC, and LDL
Lipoprotein lipase deficiency	Mutation in the <i>LPL</i> gene	Elevated TG
Apolipoprotein C-II deficiency	Decrease in activation of LPL due to a deficiency of apo CII	Elevated TG
Familial hypertriglyceridemia	Overproduction of hepatic VLDL and increased catabolism of HDL	Elevated TG Low HDL

HDL, High-density lipoprotein; *LDL*, low-density lipoprotein; *TC*, total cholesterol; *TG*, triglyceride; *VLDL*, very-low-density lipoprotein.

that case, assays are available to directly measure the concentration of LDL cholesterol. Furthermore, the lipoprotein abnormality associated with triglyceride levels greater than 400 mg/dL can be identified by inspecting the serum. When the triglyceride level exceeds 350 mg/dL, the serum is cloudy. After refrigeration, a white surface layer depicts excess chylomicrons, whereas a dispersed, opaque infranatant reflects a VLDL dysfunction.

In general, universal screening is recommended starting at 35 years of age for men and at 45 years of age for women. There is a paucity of data supporting long-term benefits from universal screening of younger individuals. Most guidelines suggest selective screening

of children who have a family history of lipoprotein abnormality or premature vascular disease. Baseline lipid levels are also recommended in adults with CHD, risk factors for CHD, or CHD equivalent (i.e., symptomatic carotid artery disease, peripheral arterial disease, abdominal aortic aneurysm, or diabetes). CHD risk factors include hypertension, diabetes mellitus, cigarette smoking, and family history of premature CHD (i.e., affected male first-degree relative <55 years or female first-degree relative <65 years of age). Either a fasting or a nonfasting total cholesterol and HDL measurement can be the initial screen. Treatment initiation is based on 10-year and lifetime risk of atherosclerotic cardiovascular disease (ASCVD) (Table 71.4).

TABLE 71.3 Mechanisms of Secondary Hyperlipidemia

Clinical	Elevated Lipoprotein	Mechanism
Diabetes	Chylomicron, VLDL, LDL	Increase in VLDL production and decrease in VLDL/LDL clearance
Obesity	Chylomicron, VLDL, LDL	Increase in VLDL production and decrease in VLDL/LDL clearance
Lipodystrophy	VLDL	Increase in VLDL production
Hypothyroidism	LDL, VLDL	Decrease in LDL/LDL clearance
Estrogen	VLDL	Increase in VLDL production
Glucocorticoids	VLDL, LDL	Increase in VLDL production and conversion to LDL
Alcohol	VLDL	Increase in VLDL production
Nephrotic syndrome	VLDL, LDL	Increase in VLDL production and conversion to LDL

LDL, Low-density lipoprotein; VLDL, very-low-density lipoprotein.

TABLE 71.4 Cardiovascular Risk Prevention

	Primary Prevention (Age 40–75 Years)	Secondary Prevention
Risk assessment	LDL 70–190 or 10-year risk of ASCVD 7.5–20% or diabetes	LDL >190 or 10-year risk of ASCVD >20% or diabetes with risk factors
Statin dosing	Moderate intensity statin	High intensity statin
LDL target	<100	<100
		Known ASCVD
		High intensity statin to lower LDL-C >50% <50–70

TABLE 71.5 Recommendations for Nutritional Intake

Nutrient	Recommended Intake
Total fat	25–35% of total calories
Saturated	<7%
Polyunsaturated	<10%
Monounsaturated	<20%
Carbohydrates	50–60% of total calories
Protein	15% of total calories
Cholesterol	<200 mg/day
Fiber	20–30 g/day

Individuals who do not meet the threshold for treatment should be screened every 3 to 5 years.

TREATMENT

Treatment of elevated total and LDL-cholesterol can slow the development and progression of CHD. Meta-analysis of primary and secondary prevention trials indicates that CHD mortality decreases by approximately 15% for every 10% reduction in serum cholesterol. LDL-cholesterol treatment strategies are based on risk indicators. There is strong evidence that dietary modifications can reduce LDL-cholesterol and triglyceride levels (Table 71.5). However, evidence that lifestyle-induced lipid modifications improve cardiovascular outcomes is limited. Ample evidence supports statin use in primary and secondary prevention of CHD (see Table 71.4 and Table 71.6). Treatment effects of statins can be assessed after 1 to 2 months. Additional agents can be considered if target goals are not achieved with maximal drug dosing (Table 71.7).

A fasting lipid panel is required to diagnose hypertriglyceridemia. Triglyceride levels higher than 200 mg/dL are classified as abnormal. Borderline triglyceride levels range from 150 to 200 mg/dL, and normal values are lower than 150 mg/dL. A diet and exercise program is

recommended for all individuals with abnormal triglyceride levels. However, pharmacologic treatments to reduce triglyceride levels may be considered if fasting levels are higher than 200 mg/dL, especially if the individual is at risk for CHD or pancreatitis (see Table 71.7). Fibrates, fish oil, and nicotinic acid should be considered if the triglyceride level is higher than 500 mg/dL. However, for levels lower than 500 mg/dL, statins are first-line therapy.

Low HDL concentrations (<40 mg/dL) can also increase the risk for CHD. In the Framingham Heart Study, every decrease in HDL of 5 mg/dL increased the risk for myocardial infarction. Both lifestyle modifications (e.g., diet low in saturated fat, exercise) and pharmacologic therapy (e.g., nicotinic acid, fibrate) can improve HDL levels. However, target goals and treatment recommendations have not been established due to a lack of evidence.

Lifestyle Modification

Lifestyle modification should be the initial step in the management of hyperlipidemia (see Table 71.5). Restricting the dietary intake of fat lowers total cholesterol by approximately 15% and LDL cholesterol by 25%. Low-fat diets that limit saturated fat content promote LDL receptor expression and increase the uptake of LDL-cholesterol from the circulation. By contrast, saturated fat downregulates hepatic LDL receptors and increases circulating LDL. Because unsaturated fats (polyunsaturated and monounsaturated) generally do not have this effect, they are the preferred form of fat intake. However, polyunsaturated fats containing fatty acids with a *trans* rather than *cis* double bond configuration (*trans*-fatty acids) increase plasma cholesterol levels similarly to saturated fat.

Limiting the intake of saturated and *trans*-unsaturated fatty acids requires appropriate calorie substitutions. Increasing carbohydrate content to achieve this goal can increase the hepatic synthesis of triglyceride. Dietary substitution with soluble fibers (e.g., oat bran) has been recommended, because these fibers have a limited effect on triglyceride levels. They also bind bile acids in the gut and thereby decrease cholesterol levels. Other polyunsaturated fats, such as omega-3 fatty acids, are cardioprotective. They are abundant in fatty fish, flaxseed oil, canola oil, and nuts. They reduce VLDL production, inhibit platelet

TABLE 71.6 Statins

High-Intensity Statins: Lowers LDL-C by >50%	Moderate-Intensity Statins: Lowers LDL-C 30–50%	Low-Intensity Statins: Lowers LDL-C by 30%
Atorvastatin 40–80 mg Rosuvastatin 20–40 mg	Atorvastatin 10–20 mg Rosuvastatin 5–10 mg Simvastatin 20–40 mg Pravastatin 40–80 mg Lovastatin 40 mg Fluvastatin 80 mg Pitavastatin 2–4 mg	Simvastatin 10 mg Pravastatin 10–20 mg Lovastatin 20 mg Fluvastatin 20–40 mg Pitavastatin 1 mg

TABLE 71.7 Drugs Commonly Used for the Treatment of Hyperlipidemia

Drug Class	LDL (% Change)	HDL (% Change)	Triglycerides (% Change)	Side Effects
HMG-CoA inhibitors	↓ 20–60	↑ 5–10	↓ 10–30	Liver toxicity, myositis, rhabdomyolysis; enhanced warfarin effect
Cholesterol absorption inhibitors	↓ 17	No effect	↓ 7–8	Abnormal liver enzymes in combination with an HMG-CoA inhibitor, myalgia, hepatitis, rhabdomyolysis, pancreatitis, potential increase in cancer risk and cancer death
PCSK-9 inhibitor	↓ 38–72	↑ 4–9	↓ 2–23	Injection site reaction, hypersensitivity, drug neutralizing antibody
Bempedoic acid	↓ 15–19	No change	No change	Hyperuricemia, tendon rupture, and may potentiate statin-related myopathy
Bile acid sequestrants	↓ 15–30	Slight increase	No effect	Nausea, bloating, cramping, abnormal liver function; interferes with absorption of other drugs such as warfarin and thyroxine
Fibric acid	↓ 6–20	↑ 5–20	↓ 41–53	Nausea, cramping, myalgias, liver toxicity, enhanced warfarin effect
Nicotinic acid	↓ 10–25	↑ 15–35	↓ 25–30	Hepatotoxicity, hyperuricemia, hyperglycemia, flushing, pruritus, nausea, vomiting, diarrhea
Omega-3 fatty acids	Variable	↑ 5–9	↓ 23–45	Eructation, taste perversion, dyspepsia

HMG-CoA, Hydroxymethylglutaryl-coenzyme A reductase.

aggregation, and decrease CHD. Even two servings per week of fatty fish such as salmon can be beneficial.

Dietary restriction of fat (<10%) is essential for the treatment of marked hypertriglyceridemia. Other factors such as carbohydrate and alcohol intake can also increase the synthesis of triglyceride. Restriction of alcohol intake to one or two servings per week and adherence to a low-fat, high-fiber diet will improve hypertriglyceridemia.

Exercise has been shown to increase LPL activity. Even a single exercise session can reduce triglycerides and increase HDL. The impact of exercise on LDL is less clear. With low- to moderate-intensity exercise regimens, clearance of VLDL particles increases LDL production. However, this effect is not seen with high-intensity exercise programs. A decrease in LDL-cholesterol occurs with high-intensity exercise, and this effect is independent of weight loss.

Pharmacotherapy

In addition to diet and exercise modifications, pharmacologic agents are prescribed to reduce cardiovascular risk and to achieve therapeutic goals. The ASCVD Risk algorithm is used to calculate a 10-year risk of heart disease or stroke. This algorithm calculates risk by evaluating the following factors: history of ASCVD, LDL-cholesterol levels, age, current diagnosis of diabetes, gender, race, total cholesterol, HDL-cholesterol levels, medication controlled hypertension, and smoking history. History of the following conditions is considered as known

ASCVD: acute coronary syndrome, myocardial infarction, stable angina, coronary revascularization, stroke, transient ischemic attack, or peripheral arterial disease. Cardiovascular risk profile determines therapeutic plan including drug dosing and LDL targets in individuals 40 to 75 years of age (see Tables 71.4 and 71.6). High-risk patients may require additional agents to achieve target goals. Likely benefit of each agent needs to be balanced against potential adverse effects when determining drug therapy (see Table 71.7). In individuals younger than 40 years or with 10-year risk below 7.5%, lifestyle modification is recommended unless risk enhancers such as family history of premature ASCVD, LDL-cholesterol greater than 160 mg/dL, chronic kidney disease, and metabolic syndrome, are noted.

HMG-CoA reductase is the rate-limiting enzyme involved in cholesterol biosynthesis. Inhibition of this enzyme decreases intracellular cholesterol pools and subsequently increases uptake of LDL cholesterol from the circulation. HMG-CoA reductase inhibitors (e.g., atorvastatin and rosuvastatin) increase cholesterol utilization, decrease VLDL synthesis, and increase HDL synthesis. As a result, lower LDL and triglyceride levels and higher HDL levels are observed with treatment. Meta-analysis of primary and secondary CHD prevention trials found reductions in all-cause and cardiovascular mortality rates with statin therapy. These agents limit progression and may even cause regression of coronary atherosclerosis. Therefore, they represent first-line therapy in the management of abnormal LDL-cholesterol levels and

for prevention of cardiovascular outcomes. Elevated liver enzymes and muscle toxicity are potential dose-related complications. Myositis can occur with statins alone, but the risk is higher when statins are used in combination with nicotinic acid or fibric acid derivatives.

Ezetimibe is a Niemann-Pick C1 Like 1 (NPC1L1) inhibitor. NPC1L1 is a protein that aids in the transport of cholesterol across the intestinal brush border. Ezetimibe inhibits this enzyme, decreasing cholesterol absorption and thus increasing cholesterol utilization and decreasing LDL-cholesterol levels. Ezetimibe may be used as a single agent or in combination with an HMG-CoA reductase inhibitor to lower LDL-cholesterol levels. In combination with a statin, this agent may reduce cardiovascular events in high-risk individuals.

Proprotein convertase subtilisin kexin type 9 (PCSK9) inhibitors represent an exciting new frontier in LDL-cholesterol reduction. PCSK9 is a protease whose function is the degradation of LDL receptors. Inhibition of this protease leads to increased LDL receptor survival, which in turn leads to the reduction of circulating LDL-cholesterol. The two approved agents, evolocumab and alirocumab, are both monoclonal antibodies against PCSK9 that are administered by subcutaneous injection every 2 to 4 weeks. They are indicated in patients with LDL greater than 190 mg/dL or ASCVD judged to be high risk who have not achieved desired LDL reduction on statin and ezetimibe. Cost of these therapies is significant and may be a limiting factor. Antisense therapy (injectable oligonucleotides to prevent mRNA translation) against PCSK9 mRNA is an area of active investigation.

Bempedoic acid inhibits adenosine triphosphate citrate lyase, an enzyme in the cholesterol biosynthesis pathway. This enzyme is upstream of 3-hydroxy-3-methylglutaryl-CoA reductase, the target of statin drugs. Bempedoic acid alone or in combination with other agents lowers LDL-cholesterol and is recommended for individuals intolerant to statins, unable to achieve target goals, and in circumstances where PCSK-9 inhibitors are not an option.

Drugs that interfere with the absorption of cholesterol from the intestinal lumen increase cholesterol utilization and decrease circulating levels of cholesterol. Bile acid sequestrants (e.g., cholestyramine, colestipol, and colesevelam) bind bile acids in the intestinal lumen and increase fecal excretion. Subsequently, more LDL-cholesterol is used by the liver to synthesis bile acids. The decrease in cellular cholesterol pools upregulates LDL receptors and decreases the amount of LDL-cholesterol in the circulation. Mild increases in HDL-cholesterol are also seen with this agent as a result of increased intestinal HDL formation. Treatment is associated with a reduction in the incidence of CHD. Bile acid sequestrants may be used alone for mild lipid dysfunction or in combination with another lipid-lowering agent such as an HMG-CoA reductase inhibitor. Abnormal liver function and gastrointestinal symptoms (e.g., nausea, bloating, cramping) are common side effects that limit the use of bile acid sequestrants. They can also interfere with the absorption of other drugs such as warfarin and thyroxine.

Fibric acid derivatives such as gemfibrozil and fenofibrate increase FFA oxidation in muscle and liver. The reduced lipogenesis in the liver decreases VLDL and subsequent LDL production. Fibric acid derivatives also enhance LPL activity and HDL synthesis. As a result, treatment is usually associated with not only lower triglyceride and LDL levels, but also higher HDL levels. Reduced cardiovascular events have been demonstrated in a subset of individuals with high triglyceride (>200 mg/dL) and low HDL (<40 mg/dL) levels, but improvements in cardiovascular or all-cause mortality otherwise have not been confirmed with these agents. Liver toxicity and myositis are potential side effects of fibric acid derivatives, and they also interfere with the metabolism of warfarin, leading to a need for its dose adjustment.

Nicotinic acid has an antilipolytic effect and therefore decreases the influx of FFA to the liver. As a result, hepatic VLDL synthesis and LDL production are reduced. Nicotinic acid also decreases HDL catabolism. Lower triglyceride and LDL levels and higher HDL levels are observed with treatment. In addition, nicotinic acid stimulates tissue plasminogen activator and prevents thrombosis. It also reduces lipoprotein(a), or Lp(a), which is an independent risk factor for developing vascular disease (discussed later). The cardioprotective effect of nicotinic acid may be linked to its effect on Lp(a) and HDL. Side effects include hepatotoxicity, hyperuricemia, hyperglycemia, and flushing.

Omega-3 fatty acids reduce VLDL production and subsequently lower triglyceride levels (by 35%). They also modestly increase HDL (3%) and LDL (5%). The impact on lipids can occur over months to years and requires treatment doses as high as 3 to 4 g of fish oil per day. Omega-3 fatty acids constitute 30% of fish oil supplements and 85% of prescribed pharmacologic preparations (i.e., Lovaza and Vascepa). In clinical trials, both Lovaza and Vascepa 4 g/day lowered triglyceride levels by 45%. Fish oil supplements seem to be a reasonable, cost-effective means to reduce triglyceride levels; side effects include eructation, taste perversion, and dyspepsia. A large clinical trial recently demonstrated that Vascepa may reduce the incidence of cardiovascular events in patients with cardiovascular disease, well-controlled LDL, and modest triglyceride elevations.

Other agents to consider are neomycin, lomitapide, and mipomersen. These agents can be considered in the management of patients with refractory LDL elevations. Neomycin complexes with bile acid and lowers LDL levels. It also inhibits production of apolipoprotein(a) in the liver and lowers Lp(a). It is recommended as adjuvant therapy for patients with familial hypercholesterolemia and Lp(a) excess. Important side effects include nephrotoxicity and ototoxicity. Lomitapide inhibits microsomal triglyceride transfer protein in the liver and decreases apo B. Significant reductions in LDL (up to 50%) are seen with treatment. Liver toxicity is a serious adverse event associated with this agent. Mipomersen is another agent approved for use in homozygous familial hypercholesterolemia. It binds apo B messenger RNA and inhibits apo B production. Apo B is a structural component of VLDL, IDL, and LDL. Treatment reduces LDL by up to 50%. Side effects include flu-like symptoms, injection site reactions, elevations in liver enzymes, and liver toxicity. The side effect profile and expense associated with both lomitapide and mipomersen limit the use of these agents to individuals with homozygous familial hypercholesterolemia.

LIPID DISORDERS

A number of specific disorders of overproduction or impaired removal of lipoproteins result in dyslipidemia (see [Tables 71.2](#) and [71.3](#)). These disorders are often familial, but secondary causes also need to be considered. Comorbid conditions (diabetes, hypothyroidism), medications (estrogen, glucocorticoids, β -adrenergic receptor blockers), and lifestyle factors (diet, alcohol) can increase the production and clearance of lipoproteins. Addressing these factors can often normalize lipid levels. If abnormalities persist, evaluation of genetic factors and treatment with pharmacologic therapy may need to be considered.

Familial Hypercholesterolemia

Familial hypercholesterolemia (FH) is an autosomal dominant disorder that alters LDL receptor synthesis and function. It is caused by mutations in one of three genes that decrease the clearance of LDL particles and increase circulating LDL levels. Gene mutations that result in FH exhibit an additive effect with more severe clinical presentations noted in individuals with homozygous or compound heterozygous mutations. A defect in the LDL (apo B/E) receptor gene is the most

common cause of FH. Receptor defects are classified based on receptor activity: receptor-negative (<2% activity) and receptor-defective (2% to 25% activity). Defects in the PCSK9 and apolipoprotein B gene are less common. PCSK9 is a serine protease produced by the liver. It binds the LDL receptor leading to internalization and eventual destruction of the LDL receptor. Gain of function mutation in the PCSK9 gene results in decreased LDL receptor expression, decreased LDL catabolism, and increased LDL-cholesterol. Mutation in the apolipoprotein B gene results in impaired binding of LDL particles to the LDL receptors. Apo B100 protein defect has a milder presentation than LDL (apo B/E) receptor defect. This is because apo E-mediated clearance of remnant particles is still functional.

The homozygous form of the LDL receptor mutation is rare. Affected individuals present early in life with elevated levels of total cholesterol (600 to 1000 mg/dL) and LDL-cholesterol (550 to 950 mg/dL). Triglyceride and HDL-cholesterol levels are normal. These patients develop CHD, aortic stenosis due to atherosclerosis of the aortic root, and tendon xanthomas (often in the Achilles tendon). If the condition remains untreated, patients with homozygous familial hypercholesterolemia typically die of myocardial infarction before 20 years of age. The heterozygous form of FH affects 1 in every 500 individuals. Partial receptor defect results in cells that display half the normal number of fully functional LDL receptors. These individuals have lower concentrations of total cholesterol (>300 to 600 mg/dL) and LDL-cholesterol (250 to 500 mg/dL) than do those with the homozygous form. Premature CHD and tendon xanthomas are characteristic clinical findings.

Although the diagnosis of familial hypercholesterolemia can be established by genetic testing, the diagnosis is usually made based on clinical features. Elevated total cholesterol (>300 mg/dL) and LDL-cholesterol (>250 mg/dL) in an individual with a personal or family history of premature CHD and tendon xanthomas identifies patients at risk for familial hypercholesterolemia. Treatment requires a low-fat (<20% of total calories), low-cholesterol (<100 mg/day) diet in combination with drug therapy. Usually, patients with familial hypercholesterolemia require multiple agents including high-intensity statin, ezetimibe, and/or PCSK9 inhibitors to lower cholesterol levels to the target range. For patients who are unable to achieve target goals, additional intervention with liver transplantation to provide functional receptors, ileal bypass surgery to decrease gastrointestinal absorption of bile acids, LDL apheresis to remove excess LDL, and novel therapies with lomitapide and mipomersen may be considered.

Elevated Plasma Lipoprotein(a)

Lp(a) is a specialized form of LDL that is assembled extracellularly from apolipoprotein(a) and LDL. Lp(a), when present at elevated levels, interferes with fibrinolysis by competing with plasminogen. This leads to decreased thrombolysis and increased clot formation. Lp(a) also binds macrophages, promoting foam cell formation and atherosclerotic plaques. Screening should be considered in individuals who have a family or personal history of premature CHD without dyslipidemia and in those for whom cholesterol-lowering therapy has failed. The diagnosis can be made by documenting Lp(a) levels higher than 30 mg/dL in a patient with premature CHD. The primary goal of therapy is to lower LDL levels with agents such as statins, ezetimibe, and PCSK-9 inhibitors. Niacin can also reduce Lp(a); however, the effectiveness of this strategy in ASCVD prevention remains unproven.

Polygenic Hypercholesterolemia

Hypercholesterolemia in a population is mostly due to small influences of many different genes. The exact nature of these genetic defects is poorly defined, but apo E may play a role in the pathogenesis. Apo

E4 on chylomicrons and VLDL remnants has a high affinity for the LDL receptor. Elevated binding of apo E4-containing lipoproteins to LDL receptors may downregulate LDL receptor synthesis and increase circulating LDL levels. Environmental factors such as diet can influence production of chylomicrons and VLDL, resulting in downregulation of the LDL receptor in conditions with high apo E4. This leads to an increased propensity for CHD, and treatment with LDL-lowering agents is recommended based on risk factors (see Table 71.7).

Familial Combined Hyperlipoproteinemia

Familial combined hyperlipoproteinemia (FCHL) is a polygenic disorder that affects 1% to 2% of the population. Factors such as diet, glucose intolerance, and medications can influence the phenotypic presentation. In FCHL, the liver synthesizes excess VLDL. VLDL is hydrolyzed by LPL to produce LDL. Mutations in the *LPL* gene affecting its expression or function can decrease the efficiency of VLDL catabolism. Dysfunction of LPL is observed in one third of patients with FCHL. Diminished LPL activity increases circulating VLDL-triglyceride; furthermore, fewer VLDL remnant particles are available for HDL synthesis. Therefore, FCHL needs to be considered in all patients whose total cholesterol level is greater than 250 mg/dL, triglycerides greater than 175 mg/dL, or HDL-cholesterol less than 35 mg/dL.

There are no definitive diagnostic tests, but family screening can help confirm the diagnosis. The phenotype of FCHL is variable, with individuals displaying high LDL-cholesterol, high VLDL-triglyceride, or both based on the genetic defect and environmental factors. Patients also typically have high apo B (>120 mg/dL) and a low ratio of LDL-cholesterol to apo B100 (<1.2). They accumulate small dense LDL particles, which are thought to be atherogenic and contribute to premature CHD. Xanthomas or xanthelasmas are not a feature of this disorder. Affected individuals require a low-fat, low-cholesterol diet plus multiple lipid-lowering drugs to achieve target goals. Statins are recommended to lower LDL-cholesterol and to reduce the risk of cardiovascular disease and mortality. Addition of ezetimibe, fibric acid derivatives, niacin, and omega-3 fatty acid are often considered to achieve LDL-cholesterol and triglyceride target goals. However, these agents have not been shown to decrease cardiovascular events or improve overall survival.

Familial Dysbetalipoproteinemia

Apo E on the surface of lipoprotein particles binds LDL receptors and facilitates clearance of remnant particles from the circulation. The apo E2 allele has a lower affinity for LDL receptors than apo E3 or apo E4. In individuals who are homozygous for apo E2, LPL hydrolyzes the triglyceride core and the resulting cholesterol-rich chylomicrons. VLDL and IDL remnant particles accumulate in the circulation. Expression of this phenotype usually requires a precipitating condition that increases lipoprotein production (e.g., diabetes, alcohol consumption) or decreases clearance (e.g., hypothyroidism). In addition to the more common autosomal recessive mutation of apo E described previously, several apo E mutations have been described that result in an autosomal dominant phenotype manifesting in childhood. Premature CHD, peripheral vascular disease, and xanthomas involving the palmar crease are characteristic clinical features. Individuals with familial dysbetalipoproteinemia have elevated levels of total cholesterol (300 to 400 mg/dL) and triglycerides (300 to 400 mg/dL). Definitive diagnosis requires genetic testing to identify apo E2 homozygosity or mutation. Treatment of coexisting conditions such as diabetes and hypothyroidism can normalize lipid levels in apo E2 homozygotes. If target levels are not achieved, dietary therapy and lipid-lowering drugs such as fibric acid derivatives and HMG-CoA reductase inhibitors should also be considered.

Familial Chylomicronemia

Mutations in the *LPL* gene resulting in deficiency of LPL synthesis or function lead to increased circulating chylomicron and VLDL particles and severe hypertriglyceridemia. Homozygous LPL deficiency is rare. It manifests in childhood with triglyceride levels higher than 1000 mg/dL. Heterozygous LPL deficiency occurs in 2% to 4% of the population and usually requires a precipitating factor, such as uncontrolled diabetes or estrogen therapy, to manifest the phenotype. These individuals have moderate hypertriglyceridemia (250 to 750 mg/dL) that can increase to levels greater than 1000 mg/dL with secondary factors. This can result in the chylomicronemia syndrome, which is characterized by marked hypertriglyceridemia (>1000 to 2000 mg/dL), pancreatitis, eruptive xanthomas, lipemia retinalis, and hepatosplenomegaly. Visual inspection demonstrates lipemic plasma. After refrigeration for 12 hours, a creamy top layer (increased chylomicrons) or turbid plasma infranatant (increased VLDL), or both, can be demonstrated. Documentation of diminished LPL activity confirms the diagnosis. A diet low in fat (<10% of total calories or 20 to 25 g/day) is the primary treatment. Secondary factors such as uncontrolled diabetes and alcohol use should be addressed, and VLDL-lowering agents (e.g., fibric acid derivatives, niacin) may be needed to prevent severe hypertriglyceridemia.

Apolipoprotein C-II Deficiency

Apo C-II is an activating cofactor for LPL. Deficiency of apo C-II is a rare autosomal recessive disorder that leads to increased chylomicrons and VLDL particles in the circulation, resulting in severe hypertriglyceridemia. Clinical manifestations are similar to those of LPL deficiency, including hypertriglyceridemia (>1000 mg/dL) and symptoms of pancreatitis, eruptive xanthomas, lipemia retinalis, and hepatosplenomegaly. Treatment recommendations include appropriate management of secondary factors such as diabetes and hypothyroidism, dietary fat restriction (<10% of calories), and drug therapy (e.g., fibric acid derivatives). For severe hypertriglyceridemia, plasma transfusion (with apo C-II) can be considered.

Familial Hypertriglyceridemia
