In Memoriam

Thomas E. Andreoli, MD

Dr. Thomas Andreoli, along with Drs. Lloyd Hollingsworth (Holly) Smith, Jr., Fred Plum, and Charles C.J. Carpenter, was one of the four founding editors of *Cecil Essentials of Medicine*. He served as editor for editions one through eight before he passed away on April 14, 2009. Dr. Andreoli was born in the Bronx, New York, in 1935, attended Catholic primary and high schools, and graduated from St. Vincent College and the Georgetown School of Medicine. He trained as a resident at Duke University under legendary Chair of Medicine Dr. Eugene Stead, who recognized him as a brilliant physician and scientist and encouraged his research career. Dr. Andreoli received his research training at the NIH and then in the laboratory of Dr. Tosteson at Duke. His research focused on the biochemical and biophysical properties of renal tubular cell membranes and their role in water and electrolyte transport. He made fundamental discoveries on the normal renal physiology, illuminating the way to subsequent work by many others on renal health and disease. His research was recognized with numerous awards and election to honorific societies both in the United States and in Europe. Dr. Andreoli also served as editor of *The American Journal of Physiology: Renal Physiology* and Editor in Chief of *Kidney International*.

Tom's national prominence and leadership qualities were recognized early in his career when he became head of Nephrology at the University of Alabama in Birmingham. There he helped faculty and trainees develop outstanding research, organized clinical services, and created a hemodialysis program to build one of the outstanding Divisions of Nephrology in the country. In 1979, Dr. Andreoli was appointed Chair of the Department of Internal Medicine at the University of Texas, Houston, where he assembled an outstanding faculty focused on research, clinical care, and teaching. In 1988, he accepted the position as Chairman of Internal Medicine at the University of Arkansas School of Medicine, a position he held until his death. There he again assembled a distinguished faculty who were outstanding researchers but also dedicated to outstanding clinical care and teaching. Morning report and clinical rounds with Dr. Andreoli were rigorous and riveting, focusing on the individual patient, not only their diagnoses and treatment but also on each patient's personal concerns and well-being. Dr. Andreoli was revered by medical students, his house staff, faculty, and colleagues, and I (EJW) personally can attest to what he regarded as his most cherished role—the mentorship and education of the next generation of physicians.

One of Dr. Andreoli's great interests was *Cecil Essentials of Medicine*, for which he was the editor/chief editor for eight of its ten editions, an interest that reflected his commitment to the education of students, house staff, and other physicians in the "essentials" of Internal Medicine.

Dr. Andreoli was devoted to his family. He was married to Elizabeth Berglund Andreoli from 1987 until his death. He was previously married to Dr. Kathleen Gainor Andreoli, mother of his three children and their ten grandchildren. Being of Italian ancestry and from Bronx, New York, it is not surprising that Dr. Andreoli was a passionate fan of the New York Yankees, Italian opera, which he could sing in Italian, and Frank Sinatra.

Dr. Andreoli's legacy lives on in his numerous previous students, house staff, colleagues, and in this book.

Charles C.J. Carpenter, MD

Dr. Charles C.J. Carpenter joined Drs. Thomas Andreoli, Lloyd Hollingsworth Smith, Jr., and Fred Plum as a founder of *Cecil Essentials of Medicine*. He served as editor for seven editions and was followed in that role by Dr. Ivor Benjamin and then Dr. Edward Wing. Sadly, Chuck passed away on March 19, 2020, surrounded by his wife and children. He was Professor Emeritus of Medicine at The Warren Alpert Medical School of Brown University and Physician-in-Chief Emeritus at The Miriam Hospital.

Chuck was born in Savannah, Georgia, on January 5, 1931. He attended college at Princeton and medical school at Johns Hopkins where he also did his house staff training, including chief residency, and then joined the Johns Hopkins faculty. With his young family, he travelled to Calcutta, India, where he carried out landmark studies for the treatment of cholera.

Before coming to Brown in 1986, he was Chair of Medicine at Baltimore City Hospital and Case Western Reserve University.

His contributions to medical science and clinical care were many. While in Calcutta, using basic scientific evidence coupled with practical approaches, Dr. Carpenter developed “oral rehydration therapy” to address the cholera epidemic there. This treatment has saved millions of lives. While at Case, one of his innovations was to develop the nation’s first Division of Geographic Medicine because of his strong belief that all physicians should be medical citizens of the world. In 1987, as he became deeply involved in the clinical management of persons living with HIV, he initiated a unique program in which Brown University faculty and trainees assumed responsibility for all HIV care in the Rhode Island State prison system.

Dr. Carpenter served as Chairman of the American Board of Internal Medicine and President of the Association of American Physicians. He has been a member of the NIH AIDS Executive Committee, the National Advisory Allergy and Infectious Diseases Council, and the USPHS AIDS Task Force. He was Chair of the Antiretroviral Treatment Panel of the International AIDS Society-USA and authored their recommendations on antiretroviral treatment. He also served as Chair of the Treatment Committee to evaluate the President’s Emergency Plan for HIV/AIDS Relief. He became the director of the Brown University International Health Institute and the director of the Lifespan/Brown Center for AIDS Research with several Boston hospitals.

Throughout his career, Dr. Carpenter was the recipient of many international, national, and regional awards, accepting each with characteristic humility. With both small and large groups of learners, Chuck made certain that every member of his team was well educated, and each felt that they contributed to the well-being of their patients. His ability to sit calmly at the bedside, hold the patient’s hand, comfort them, and listen in a genuinely focused way, influenced so many physicians. He was truly grateful for the opportunity to care for those less fortunate than he, and the feeling of being privileged to do so was clearly transmitted to all. Dr. Carpenter was a wonderful blend of profound compassion combined with the adherence to scholarship and teaching. Sir William Osler wrote that physicians should “Do the kind thing and do it first.” Chuck lived by this precept. Vigor and insight characterized his approach to clinical and ethical challenges, always with younger colleagues at his side. In a recent tribute to him, many emphasized that Dr. Carpenter dedicated his life to his patients, many of whom were the most vulnerable members of society. We hope that we will have some of his strength and use his example as our compass as we are challenged to reduce suffering and improve the health of all for whom we are responsible.

He is survived by his wife of 61 years, Sally; three sons, Charles, Murray, and Andrew; and seven grandchildren.

ABOUT THE EDITORS

Dr. Edward J. Wing was an editor of *Cecil Essentials of Medicine*, editions 8 and 9, and is the lead editor of edition 10. He graduated from Williams College in 1967 and from the Harvard Medical School in 1971. He was a resident in Internal Medicine at the Peter Bent Brigham and completed an Infectious Diseases Fellowship at Stanford University. Joining the faculty at the University of Pittsburgh in 1975, he focused his NIH-funded research on mechanisms of cell-mediated immunity as well as various clinical aspects of Infectious Diseases. From 1990 to 1998, the University and UPMC appointed him as Physician-in-Chief at Montefiore Hospital, then Chief of Infectious Diseases, and finally Interim Chair of Medicine.

In 1998, Dr. Wing became Chair of Medicine at Brown University (1998–2008) where he consolidated the department across hospitals, practice plans, and training programs. As Dean of Medicine and Biological Sciences at Brown University (2008–2013) he strengthened ties with affiliated hospitals (Lifespan and Care New England), increased research, and oversaw the construction of a new medical school building. International exchange programs with medical schools in Kenya, the Dominican Republic, and Haiti were established during his years as chairman and dean. Dr. Wing has cared for patients with HIV since the beginning of the epidemic in outpatient clinics. He continues to be active in research, clinical care, and teaching.

Dr. Fred J. Schiffman, who along with Dr. Edward Wing is editor of *Cecil Essentials of Medicine*, 10th edition, attended Wagner College and then the New York University School of Medicine, from which he graduated in 1973. He performed his early house staff training at Yale-New Haven Hospital and then spent two years at the National Cancer Institute. He returned to Yale as Chief Medical Resident followed by a hematology fellowship. He became Medical Director of Yale's Primary Care Center before coming to Brown University in 1983, where he has been a leader in the medical residency program as well as Associate Physician-in-Chief at The Miriam Hospital.

Dr. Schiffman holds The Sigal Family Professorship in Humanistic Medicine at The Warren Alpert Medical School of Brown University. His scholarly interests include the structure and function of the human spleen and the intersection of the arts and medical care. He has directed or championed many projects and programs, including those that encourage and reinforce wellness and resilience in patients, families, and caregivers. He began a novel program that places medical students and physicians with other nonmedical professionals as they share in the viewing of works of art in the Museum of the Rhode Island School of Design. Dr. Schiffman recently led a Brown University edX course entitled, "Artful Medicine: Art's Power to Enrich Patient Care," with worldwide participation. Dr. Schiffman has also edited texts on hematologic pathophysiology, consultative hematology, and the anemias.

Beth Israel Lahey Health
Burlington, Massachusetts

Nicole L. Lohr, MD, PhD

Associate Professor
Medicine
Medical College of Wisconsin
Milwaukee, Wisconsin

John R. Lonks, MD, FACP, FIDSA, FSHEA

Associate Professor of Medicine
Department of Medicine
Warren Alpert Medical School
Brown University
Providence, Rhode Island

Gary H. Lyman, MD, MPH

Professor
Public Health Sciences
Fred Hutchinson Cancer Research Center
Professor
Medicine
University of Washington
Seattle, Washington

Jeffrey M. Lyness, MD

Senior Associate Dean for Academic Affairs
and Professor of Psychiatry & Neurology
Office of Academic Affairs
University of Rochester School of Medicine
& Dentistry
Rochester, New York

Shane Lyons, MD, MRCPI, MRCP(UK)

Specialist Registrar in Neurology
Department of Neurology
St James's Hospital
Dublin, Ireland

Diana Maas, MD

Associate Professor of Medicine
Division of Endocrinology
Medical College of Wisconsin
Milwaukee, Wisconsin

Talha A. Malik, MD, MSPH

Assistant Professor of Medicine
Gastroenterology and Hepatology
Mayo Clinic Arizona
Scottsdale, Arizona

Sonia Manocha, MD

Rheumatologist
Lupus Center of Excellence
Allegheny Health Network
Pittsburgh, Pennsylvania
Assistant Professor
Drexel University College of Medicine
Philadelphia, Pennsylvania

Susan Manzi, MD, MPH

Chair
Medicine Institute
Director
Lupus Center of Excellence
Allegheny Health Network
Professor of Medicine
Temple University School of Medicine
Philadelphia, Pennsylvania

Frederick J. Marshall, MD

Professor
Neurology
University of Rochester
Rochester, New York

F. Dennis McCool, MD

Professor of Medicine
Division of Pulmonary and Critical Care
Medicine
Warren Alpert Medical School
Brown University
Providence, Rhode Island

Russell J. McCulloh, MD

Associate Professor
Pediatrics
University of Nebraska College of Medicine
Division Chief
Pediatric Hospital Medicine
University of Nebraska Medical Center
Omaha, Nebraska

Kelly McGarry, MD, FACP

Professor of Medicine
Warren Alpert Medical School
Brown University
Providence, Rhode Island

Eavan Mc Govern, MD, PhD

Consultant Neurologist
Senior Clinical Lecturer
Beaumont Hospital
Royal College of Surgeons in Ireland
Ireland

Robin L. McKinney, MD

Assistant Professor of Pediatrics
Pediatric Critical Care Medicine
Warren Alpert Medical School
Brown University
Providence, Rhode Island

Anthony Mega, MD

Associate Professor of Medicine
Program Director Hematology/Oncology
Fellowship
Division Hematology/Oncology
Warren Alpert Medical School
Brown University
Lifespan Cancer Institute
Providence, Rhode Island

Shivang Mehta, MD

Assistant Professor of Medicine
Gastroenterology, Hepatology, and
Nutrition
Department of Internal Medicine
University of Arizona–Phoenix
Phoenix, Arizona

Douglas F. Milam, MD

Associate Professor
Department of Urology
Vanderbilt University Medical Center
Nashville, Tennessee

Maria D. Mileno, MD

Associate Professor of Medicine
Division of Infectious Diseases
Warren Alpert Medical School
Brown University
Attending Physician, Infectious Disease
Consultant
Brown Medicine
The Miriam Hospital
Former Director of Travel Medicine Services
Providence, Rhode Island

Abhinav Kumar Misra, MBBS, MD

Assistant Professor of Medicine
Pulmonary, Critical Care and Sleep
Medicine
Warren Alpert Medical School
Brown University
Providence, Rhode Island

Orson W. Moe, MD

Professor
Internal Medicine and Physiology
Division of Nephrology
Director
Charles and Jane Pak Center for Mineral
Metabolism and Clinical Research
Chief
Division of Nephrology
UT Southwestern Medical Center
Dallas, Texas

Niveditha Mohan, MBBS

Associate Professor
Department of Medicine
Division of Rheumatology and Clinical
Immunology
University of Pittsburgh
Pittsburgh, Pennsylvania

Larry W. Moreland, MD

Margaret J. Miller Endowed Professor of
Arthritis Research
Division of Rheumatology and Clinical
Immunology
Professor of Medicine, Immunology,
Clinical and Translational Science
Chief
Division of Rheumatology and Clinical
Immunology
University of Pittsburgh
Pittsburgh, Pennsylvania

Alan R. Morrison, MD, PhD

Assistant Professor of Medicine
Medicine (Cardiology)
Warren Alpert Medical School
Brown University
Providence, Rhode Island

Steven F. Moss, MD

Professor of Medicine
Division of Gastroenterology and
Hepatology
Warren Alpert Medical School
Brown University
Providence, Rhode Island

Christopher J. Mullin, MD, MHS

Assistant Professor of Medicine, Clinician
Educator
Pulmonary, Critical Care, and Sleep
Medicine
Warren Alpert Medical School
Brown University
Providence, Rhode Island

Sin ad M. Murphy, MB, BCh, MD, FRCPI

Consultant Neurologist
Neurology
Tallaght University Hospital
Clinical Associate Professor
Medicine
University of Dublin, Trinity College
Dublin, Ireland

Sagarika Nallu, MD, FAAP, FAAN, FAASM

Director of Pediatric Sleep Medicine
Department of Pediatrics
University of South Florida
Tampa, Florida

Javier A. Neyra, MD, MSCS

Assistant Professor of Medicine
Director
Critical Care Nephrology
Division of Nephrology, Bone and Mineral
Metabolism
University of Kentucky Medical Center
Lexington, Kentucky

Ghaith Noaiseh, MD

Associate Professor
Department of Internal Medicine
Division of Allergy, Clinical Immunology
and Rheumatology
University of Kansas
Kansas City, Kansas

Thomas A. Ollila, MD

Assistant Professor of Medicine
Warren Alpert Medical School
Brown University
Providence, Rhode Island

Steven M. Opal, MD

Clinical Professor of Medicine
Infectious Diseases Division
Department of Medicine
Warren Alpert Medical School
Brown University
Rhode Island Hospital
Providence, Rhode Island

Biff F. Palmer, MD

Professor of Internal Medicine
Internal Medicine
University of Texas Southwestern Medical
Center
Dallas, Texas

Jen Jung Pan, MD, PhD

Associate Professor of Medicine
Gastroenterology and Hepatology
Department of Internal Medicine
University of Arizona–Phoenix
Phoenix, Arizona

Anna Papazoglou, MD

Clinical Instructor
Postdoctoral Research Scholar
Division of Rheumatology and Clinical
Immunology
University of Pittsburgh
Pittsburgh, Pennsylvania

Aric Parnes, MD

Attending Hematologist
Medicine
Brigham and Women’s Hospital
Assistant Professor
Harvard Medical School
Boston, Massachusetts

Nayan M. Patel, DO, MPH

Assistant Professor of Medicine
Gastroenterology and Hepatology
Department of Internal Medicine
University of Arizona–Phoenix
Phoenix, Arizona

Ari Pelcovits, MD

Department of Medicine
Division of Hematology and Oncology
Warren Alpert Medical School
Brown University
Providence, Rhode Island

Mark A. Perazella, MD

Medical Director
Yale Physician Associate Program
Department of Medicine
Professor of Medicine
Section of Nephrology
Yale University School of Medicine
Director
Acute Dialysis Services
Yale-New Haven Hospital
New Haven, Connecticut

Michael F. Picco, MD, PhD

Director
Division of Gastroenterology and
Hepatology
Mayo Clinic
Jacksonville, Florida

Heart Failure Cardiologist
Cardiology
Houston Methodist Hospital
Houston, Texas

Thomas R. Ziegler, MD

Professor of Medicine and Co-Director
Emory University Hospital Nutrition and
Metabolic Support Service
Emory University School of Medicine
Atlanta, Georgia

Rebecca Zon, MD

Resident
Internal Medicine
Brigham and Women's Hospital
Boston, Massachusetts

ACKNOWLEDGMENTS

Dr. Schiffman and I wish to thank first of all, the authors of the 128 chapters that make up the tenth edition of *Cecil Essentials of Medicine*. They have worked diligently to compose the material for each chapter and apply their mastery as they added the newest information, in clear language, to the text. Their efforts are apparent in the excellence of the book, and we are immensely grateful for their work. We wish to also thank Marybeth Thiel, Jennifer Ehlers, and Dan Fitzgerald from Elsevier who guided and supported our work as editors and whose expertise has made this volume possible. Finally, we are always thankful to our wives, Dr. Rena Wing and Ms. Gerri Schiffman, without whose love, support, and especially humor, this book would not have happened.

This page intentionally left blank

SECTION I Introduction to Medicine

- 1 Introduction to Medicine, 2**
Edward J. Wing, Fred J. Schiffman

SECTION II Cardiovascular Disease

- 2 Structure and Function of the Normal Heart and Blood Vessels, 4**
Nicole L. Lohr, Ivor J. Benjamin
- 3 Evaluation of the Patient With Cardiovascular Disease, 10**
James Kleczka, Noura M. Dabbouseh
- 4 Diagnostic Tests and Procedures in the Patient With Cardiovascular Disease, 24**
Esseim Sharma, Alan R. Morrison
- 5 Heart Failure and Cardiomyopathy, 43**
Daniel J. Levine, Hyeon-Ju Ryou Ali, Rayan Yousefzai
- 6 Congenital Heart Disease, 55**
Scott Cohen, Michael G. Earing
- 7 Valvular Heart Disease, 64**
Christopher Song
- 8 Coronary Heart Disease, 77**
David E. Lewandowski, Michael P. Cinquegrani
- 9 Cardiac Arrhythmias, 99**
Marcie G. Berger, Jason C. Rubenstein, James A. Roth
- 10 Pericardial and Myocardial Disease, 123**
Jennifer L. Strande
- 11 Other Cardiac Topics, 131**
Jinnette Dawn Abbott, Sena Kilic
- 12 Vascular Diseases and Hypertension, 139**
Thomas Sperry, Wanpen Vongpatanasin

SECTION III Pulmonary and Critical Care Medicine

- 13 Lung in Health and Disease, 162**
Sharon Rounds, Debasree Banerjee, Eric J. Gartman
- 14 General Approach to Patients With Respiratory Disorders, 165**
Michael Raymond Goggins, Brian Casserly, Eric J. Gartman
- 15 Evaluating Lung Structure and Function, 169**
Patrick Koo, F. Dennis McCool, Jigme Michael Sethi
- 16 Obstructive Lung Diseases, 185**
Zoe G.S. Vazquez, Matthew D. Jankowich, Debasree Banerjee
- 17 Interstitial Lung Diseases, 199**
Abhinav Kumar Misra, Matthew D. Jankowich, Barry S. Shea
- 18 Pulmonary Vascular Diseases, 216**
Christopher J. Mullin, James R. Klinger
- 19 Disorders of the Pleura, Mediastinum, and Chest Wall, 221**
Eric J. Gartman, F. Dennis McCool
- 20 Respiratory Failure, 227**
Andrew E. Foderaro, Abhinav Kumar Misra
- 21 Transitions in Care From Pediatric to Adult Providers for Individuals With Pulmonary Disease, 234**
Kate E. Powers, Debasree Banerjee, Robin L. McKinney

SECTION IV Preoperative and Postoperative Care

- 22 Preoperative and Postoperative Care, 240**
Kim A. Eagle, Kwame Dapaah-Afriyie, Arkadiy Finn

SECTION V Renal Disease

- 23 Renal Structure and Function, 251**
Orson W. Moe, Javier A. Neyra
- 24 Approach to the Patient With Renal Disease, 258**
Rajiv Agarwal
- 25 Fluid and Electrolyte Disorders, 268**
Biff F. Palmer
- 26 Glomerular Diseases, 282**
Sanjeev Sethi, An S. De Vriese, Fernando C. Fervenza
- 27 Major Nonglomerular Disorders of the Kidney, 298**
Nilum Rajora, Shani Shastri, Pooja Koolwal, Ramesh Saxena
- 28 Vascular Disorders of the Kidney, 312**
Abdallah Geara, Jeffrey S. Berns
- 29 Acute Kidney Injury, 324**
Mark A. Perazella, Jeffrey M. Turner
- 30 Chronic Kidney Disease, 334**
T. Alp Ikizler, Anna Marie Burgner, Beatrice P. Concepcion

SECTION VI Gastrointestinal Disease

- 31 Common Clinical Manifestations of Gastrointestinal Disease: Abdominal Pain, 343**
Charles M. Bliss, Jr.
- 32 Common Clinical Manifestations of Gastrointestinal Disease: Gastrointestinal Hemorrhage, 347**
Waihong Chung, Abbas Rupawala
- 33 Common Clinical Manifestations of Gastrointestinal Disease: Malabsorption, 351**
Brisas M. Flores, Sharheel K. Wasan
- 34 Common Clinical Manifestations of Gastrointestinal Disease: Diarrhea, 358**
Ronan Farrell, Sean Fine
- 35 Endoscopic and Imaging Procedures, 363**
Andrew Canakis, Christopher S. Huang
- 36 Esophageal Disorders, 370**
Harlan Rich, Zilla Hussain, Neal D. Dharmadhikari
- 37 Diseases of the Stomach and Duodenum, 379**
Alma M. Guerrero Bready, Akwi W. Asombang, Steven F. Moss
- 38 Inflammatory Bowel Disease, 392**
Talha A. Malik, Michael F. Picco, Francis A. Farraye
- 39 Diseases of the Pancreas, 402**
David R. Lichtenstein, Pushpak Taunk

SECTION VII Diseases of the Liver and Biliary System

- 40 Laboratory Tests in Liver Diseases, 417**
Michael B. Fallon, Ester Little
- 41 Jaundice, 420**
Mohanad T. Al-Qaisi, Mashal Batheja, Michael B. Fallon

- 42 Acute and Chronic Hepatitis, 426**
Nayan M. Patel, Jen Jung Pan, Michael B. Fallon
- 43 Acute Liver Failure, 434**
Anil Seetharam, Michael B. Fallon
- 44 Cirrhosis of the Liver and Its Complications, 437**
Shivang Mehta, Michael B. Fallon
- 45 Disorders of the Gallbladder and Biliary Tract, 448**
Stacie A. F. Vela, Michael B. Fallon

SECTION VIII Hematologic Disease

- 46 Hematopoiesis and Hematopoietic Failure, 457**
Eunice S. Wang, Nancy Berliner
- 47 Clonal Disorders of the Hematopoietic Stem Cell, 470**
Eunice S. Wang, Nancy Berliner
- 48 Disorders of Red Blood Cells, 489**
Ellice Wong, Michal G. Rose, Nancy Berliner
- 49 Clinical Disorders of Granulocytes and Monocytes, 501**
Ellice Wong, Michal G. Rose, Nancy Berliner
- 50 Disorders of Lymphocytes, 506**
Iris Isufi, Stuart Seropian
- 51 Normal Hemostasis, 522**
Lauren Shevell, Alfred I. Lee
- 52 Disorders of Hemostasis: Bleeding, 530**
Aric Parnes
- 53 Disorders of Hemostasis: Thrombosis, 550**
Rebecca Zon, Nathan T. Connell

SECTION IX Oncologic Disease

- 54 Cancer Biology, 563**
Andre De Souza, Wafik S. El-Deiry
- 55 Cancer Epidemiology, 571**
Gary H. Lyman, Nicole M. Kuderer
- 56 Principles of Cancer Therapy, 577**
Davendra P.S. Sohal, Alok A. Khorana
- 57 Lung Cancer, 583**
Zoe G.S. Vazquez, Jason M. Aliotta, Christopher G. Azzoli
- 58 Gastrointestinal Cancers, 589**
Khalidoun Almhanna
- 59 Genitourinary Cancers, 595**
Andre De Souza, Benedito A. Carneiro, Anthony Mega, Timothy Gilligan
- 60 Breast Cancer, 601**
Mary Anne Fenton, Rochelle Strenger
- 61 Gynecological Cancer, 607**
Christina Bandera, Tarra B. Evans, Don Dizon
- 62 Other Solid Tumors (Head and Neck, Sarcomas, Melanoma, Unknown Primary), 615**
Christopher G. Azzoli, Ariel E. Birnbaum, Maria Constantinou, Thomas A. Ollila
- 63 Complications of Cancer and Cancer Treatment, 620**
Pamela Egan, Ari Pelcovits, John Reagan

SECTION X Endocrine Disease and Metabolic Disease

- 64 Hypothalamic-Pituitary Axis, 626**
Diana Maas, Jenna Sarvaideo
- 65 Thyroid Gland, 635**
Theodore C. Friedman

- 66 Adrenal Gland, 645**
Theodore C. Friedman
- 67 Male Reproductive Endocrinology, 657**
Glenn D. Braunstein
- 68 Diabetes Mellitus, Hypoglycemia, 662**
Robert J. Smith
- 69 Obesity, 678**
Osama Hamdy, Marwa Al-Badri
- 70 Malnutrition, Nutritional Assessment, and Nutritional Support in Adult Patients, 686**
Thomas R. Ziegler
- 71 Disorders of Lipid Metabolism, 692**
Russell Bratman, Geetha Gopalakrishnan

SECTION XI Women's Health

- 72 Women's Health Topics, 701**
Vidya Gopinath, Yael Tarshish, Kelly McGarry

SECTION XII Men's Health

- 73 Men's Health Topics, 714**
Niels V. Johnsen, Douglas F. Milam, Joseph A. Smith, Jr.

SECTION XIII Diseases of Bone and Bone Mineral Metabolism

- 74 Normal Physiology of Bone and Mineral Homeostasis, 729**
Clemens Bergwitz, John J. Wysolmerski
- 75 Disorders of Serum Minerals, 739**
Emily M. Stein, Yi Liu, Elizabeth Shane
- 76 Metabolic Bone Diseases, 748**
Marcella D. Walker, Thomas J. Weber
- 77 Osteoporosis, 757**
Susan L. Greenspan, Mary P. Kotlarczyk

SECTION XIV Musculoskeletal and Connective Tissue Disease

- 78 Approach to the Patient With Rheumatic Disease, 767**
Niveditha Mohan
- 79 Rheumatoid Arthritis, 771**
Larry W. Moreland, Rayford R. June
- 80 Spondyloarthritis, 778**
Douglas W. Lienesch
- 81 Systemic Lupus Erythematosus, 783**
Sonia Manocha, Tanmayee Bichile, Susan Manzi
- 82 Systemic Sclerosis, 794**
Anna Papazoglou, Robyn T. Domsic
- 83 Systemic Vasculitis, 801**
Kimberly P. Liang, Kelly V. Liang
- 84 Crystal Arthropathies, 807**
Pooja Bhadbhade, Ghaith Noaiseh
- 85 Osteoarthritis, 813**
Joanne S. Cunha, Zuhai Arzomand, Philip Tsoukas
- 86 Nonarticular Soft Tissue Disorders, 818**
Niveditha Mohan
- 87 Rheumatic Manifestations of Systemic Disorders and Sjögren's Syndrome, 822**
Andreea Coca, Ghaith Noaiseh

SECTION XV Infectious Disease

- 88 Host Defenses Against Infection, 830**
Richard Bungiro, Edward J. Wing
- 89 Laboratory Diagnosis of Infectious Diseases, 842**
Kimberle Chapin
- 90 Fever and Febrile Syndromes, 848**
Maria D. Mileno
- 91 Bacteremia and Sepsis, 858**
Russell J. McCulloh, Steven M. Opal
- 92 Infections of the Central Nervous System, 865**
Su N. Aung, Allan R. Tunkel
- 93 Infections of the Head and Neck, 882**
David Kim, Roberto Cortez, Tareq Kheirbek
- 94 Infections of the Lower Respiratory Tract, 887**
John R. Lonks, Edward J. Wing
- 95 Infections of the Heart and Blood Vessels, 895**
Raul Macias Gil, Cheston B. Cunha
- 96 Acute Bacterial Skin and Skin Structure Infections, 903**
Sajeev Handa
- 97 Intraabdominal Infections, 910**
Eric Benoit
- 98 Infectious Diarrhea, 916**
Awewura Kwara
- 99 Infections Involving Bone and Joints, 922**
Jerome Larkin
- 100 Urinary Tract Infections, 925**
Abdullah Chahin, Steven M. Opal
- 101 Health Care–Associated Infections, 929**
Paul G. Jacob, Thomas R. Talbot
- 102 Sexually Transmitted Infections, 935**
Philip A. Chan, Susan Cu-Uvin
- 103 Human Immunodeficiency Virus Infection, 944**
Joseph Metmowlee Garland, Timothy Flanigan, Edward J. Wing
- 104 Infections in the Immunocompromised Host, 963**
Dimitrios Farmakiotis, Ralph Rogers
- 105 Infectious Diseases of Travelers: Protozoal and Helminthic Infections, 973**
Jessica E. Johnson, Rebecca Reece

SECTION XVI Neurologic Disease

- 106 Neurologic Evaluation of the Patient, 981**
Frederick J. Marshall
- 107 Disorders of Consciousness, 986**
Leah Dickstein, Paul M. Vespa
- 108 Disorders of Sleep, 992**
Sagarika Nallu, Selim R. Benbadis
- 109 Cortical Syndromes, 997**
Sinéad M. Murphy, Timothy J. Counihan
- 110 Dementia and Memory Disturbances, 1001**
Frederick J. Marshall
- 111 Major Disorders of Mood, Thoughts, and Behavior, 1007**
Jeffrey M. Lyness, Jennifer H. Richman

- 112 Autonomic Nervous System Disorders, 1013**
William P. Cheshire, Jr.
- 113 Headache, Neck and Back Pain, and Cranial Neuralgias, 1017**
Shane Lyons, Timothy J. Counihan
- 114 Disorders of Vision and Hearing, 1025**
Eavan Mc Govern, Timothy J. Counihan
- 115 Dizziness and Vertigo, 1033**
Jonathan Cahill
- 116 Disorders of the Motor System, 1037**
Ruth B. Schneider, Adolfo Ramirez-Zamora, Christopher G. Tarolli
- 117 Congenital, Developmental, and Neurocutaneous Disorders, 1048**
Kristin A. Seaborg, Jennifer M. Kwon
- 118 Cerebrovascular Disease, 1056**
Mitchell S. V. Elkind
- 119 Traumatic Brain Injury and Spinal Cord Injury, 1069**
Geoffrey S.F. Ling, Jeffrey J. Bazarian
- 120 Epilepsy, 1073**
Andrew S. Blum
- 121 Central Nervous System Tumors, 1087**
Bryan J. Bonder, Lisa R. Rogers
- 122 Demyelinating and Inflammatory Disorders, 1092**
Anne Haney Cross
- 123 Neuromuscular Diseases: Disorders of the Motor Neuron and Plexus and Peripheral Nerve Disease, 1101**
Carlayne E. Jackson, Ratna Bhavaraju-Sanka
- 124 Muscle Diseases, 1111**
Johanna Hamel, Jeffrey M. Statland
- 125 Neuromuscular Junction Disease, 1122**
Emma Ciafaloni

SECTION XVII Geriatrics

- 126 The Aging Patient, 1126**
Laura A. Previll, Mitchell T. Heflin, Harvey Jay Cohen

SECTION XVIII Palliative Care

- 127 Palliative Care, 1141**

Introduction to Medicine

1 Introduction to Medicine, 2

Introduction to Medicine

Edward J. Wing, Fred J. Schiffman

Cecil Essentials of Medicine presents a core of internal medicine and neurology information that every physician should know. This book provides an essential framework so physicians can appropriately assemble the key elements of history, physical examination, and laboratory data to understand their patient's illness and develop an appropriate diagnostic and therapeutic strategy. Furthermore, in order to understand advances in medicine, physicians must have a strong background for the acquisition and categorization of new medical knowledge.

Cecil Essentials of Medicine is designed for medical students as well as physicians in training, and we hope it will be an appropriate vehicle for course and examination review. We also believe, however, that physicians at all stages in their careers will find it to be a valuable resource for review and reference. This book also serves as a companion to the 26th edition of *Goldman-Cecil Medicine*, which is more comprehensive in scope and detailed in its content.

Cecil Essentials of Medicine is organized into sections, most often representing organ systems, with introductory and then organ-specific, disease-based chapters. The chapters themselves are subdivided. For example, the cardiovascular disease chapter is divided into Epidemiology, Anatomy, Pathophysiology, Clinical Diagnosis, and Treatment. The Suggested Readings sections at the end of each chapter include selected critical reviews, guidelines, and important randomized controlled trials. They are not meant to be an exhaustive reference list, but rather to highlight the essential information that physicians should know.

We believe that the information in *Cecil Essentials of Medicine* will encourage evidence-based diagnostic and therapeutic decision making. Importantly, the rational approach to medical problem-solving must be interwoven with the attentive presence of the physician at

the bedside, clinic or office, undistracted by electronic devices (particularly the computer), displaying mindful humanistic patient care. Humanistic practice includes integrity, compassion, altruism, respect, service, and empathy, but also excellence. Both the art and the science of medicine must be part of the approach to any patient encounter. The editors believe that these concepts have been best expressed by Frances Peabody, who famously stated that "the significance of the intimate personal relationship between physician and patient cannot be too strongly emphasized, for in an extraordinary large number of cases both the diagnosis and treatment directly depend upon it. One of the essential qualities of the clinician is interest in humanity for the secret of the care of the patient is in caring for the patient," and by Sir William Osler, who said, "The practice of medicine is an art not a trade; a calling not a business; a calling in which your heart will be exercised equally with your head."

We believe that the fundamentally important bond between caregiver and patient is the starting point to the care of the patient. This is followed by a thorough history and a directed physical examination, which allow a diagnosis in the great majority of encounters. Laboratory data and imaging are supplementary. The focus of the diagnostic process should be on diseases that are common and treatable. Common presentations of common diseases account for the vast majority of cases; next in frequency are unusual presentations of common diseases; less common are typical presentations of rare diseases. Concentrate on common diseases, but know the rare ones as well.

We sincerely hope that *Cecil Essentials of Medicine* will be used to provide the basic and clinical data that are essential for us to practice medicine in a manner informed by both compassion and evidence, so that we may truly heal those with whose care we are entrusted.

Structure and Function of the Normal Heart and Blood Vessels

Nicole L. Lohr, Ivor J. Benjamin

DEFINITION

The circulatory system comprises the heart, which is connected in series to the arterial and venous vascular networks. These vascular networks are arranged in parallel and connect at the level of the capillaries (Fig. 2.1). The heart is composed of two atria, which are low-pressure capacitance chambers that function to store blood during ventricular contraction (systole) and then fill the ventricles with blood during ventricular relaxation (diastole). The two ventricles are high-pressure chambers responsible for pumping blood through the lungs (right ventricle) and to the peripheral tissues (left ventricle). The left ventricle is thicker than the right, in order to generate the higher systemic pressures required for perfusion.

There are four cardiac valves that facilitate unidirectional blood flow through the heart. Each of the four valves is surrounded by a fibrous ring, or annulus, that forms part of the structural support of the heart. Atrioventricular (AV) valves separate the atria and ventricles. The mitral valve is a bileaflet valve that separates the left atrium and left ventricle. The tricuspid valve is a trileaflet valve that separates the right atrium and right ventricle. Thin, fibrous connective tissue (chordae tendineae) attaches the ventricular aspects of these valves to the papillary muscles of their respective ventricles for proper opening of the valves. Additional valves include the aortic valve that separates the left ventricle from the aorta, and the pulmonic valve that separates the right ventricle from the pulmonary artery.

A thin, double-layered membrane called the pericardium surrounds the heart. The inner, or visceral, layer adheres to the outer surface of the heart, also known as the epicardium. The outer layer is the parietal pericardium, which attaches to the sternum, vertebral column, and diaphragm to stabilize the heart in the chest. Between these two membranes is a pericardial space filled with a small amount of fluid (<50 mL). This fluid serves to lubricate contact surfaces and limit direct tissue-surface contact during myocardial contraction. A normal pericardium exerts minimal external pressure on the heart, thereby facilitating normal movement of the interventricular septum during the cardiac cycle. Too much fluid in this space (i.e., pericardial effusion) can cause impaired ventricular filling and abnormal septal movement. (Please refer to Chapter 68, "Pericardial Diseases," in

❖ *Goldman-Cecil Medicine, 26th Edition*).

CIRCULATORY PATHWAY

The purpose of the circulatory system is to bring deoxygenated blood, carbon dioxide, and other waste products from the tissues to the lungs for disposal and reoxygenation (see Fig. 2.1A). Deoxygenated blood drains from peripheral tissues through venules and veins, eventually entering the right atrium through the superior and inferior venae cavae during ventricular systole. Venous drainage from the heart enters the

right atrium through the coronary sinus. During ventricular diastole, the blood in the right atrium flows across the tricuspid valve and into the right ventricle. Blood in the right ventricle is ejected across the pulmonic valve and into the main pulmonary artery, which bifurcates into the left and right pulmonary arteries and perfuses the lungs. After multiple bifurcations, blood reaches the pulmonary capillaries, where carbon dioxide is exchanged for oxygen across the alveolar-capillary membrane. Oxygenated blood then enters the left atrium from the lungs via the four pulmonary veins. Blood flows across the open mitral valve and into the left ventricle during diastole and is ejected across the aortic valve and into the aorta during systole. The blood reaches various organs, where oxygen and nutrients are exchanged for carbon dioxide and metabolic wastes, and the cycle begins again.

The heart receives its blood supply through the left and right coronary arteries, which originate in outpouchings of the aortic root called the *sinuses of Valsalva*. The left main coronary artery is a short vessel that bifurcates into the left anterior descending (LAD) and the left circumflex (LCx) coronary arteries. The LAD supplies blood to the anterior and anterolateral left ventricle through diagonal branches and to the anterior interventricular septum through septal perforator branches. The LAD travels anteriorly in the anterior interventricular groove and terminates at the cardiac apex. The LCx traverses posteriorly in the left AV groove (between left atrium and left ventricle) to perfuse the lateral aspect of the left ventricle (through obtuse marginal branches) and the left atrium. The right coronary artery (RCA) courses down the right AV groove to the *crux* of the heart, the point at which the left and right AV grooves and the inferior interventricular groove meet. The RCA gives off branches to the right atrium and acute marginal branches to the right ventricle.

The blood supply to the diaphragmatic and posterior aspects of the left ventricle varies. In 85% of individuals, the RCA bifurcates at the *crux* to form the posterior descending coronary artery (PDA), which travels in the inferior interventricular groove to supply the inferior left ventricle and the inferior third of the interventricular septum, and the posterior left ventricular (PLV) branches. This course is termed a *right-dominant circulation*. In 10% of individuals, the RCA terminates before reaching the *crux*, and the LCx supplies the PLV and PDA. This course is termed a *left-dominant circulation*. In the remaining individuals, the RCA gives rise to the PDA and the LCx gives rise to the PLV in a *co-dominant circulation*.

CONDUCTION SYSTEM

The sinoatrial (SA) node is a collection of specialized pacemaker cells, 1 to 2 cm long, located in the right atrium between the superior vena cava and the right atrial appendage (see Fig. 2.1B). The SA node is supplied by the SA nodal artery, which is a branch of the RCA in about 60% of the population and a branch of the LCx in about 40%. An

A

B

Fig. 2.1 (A) Schematic representation of the systemic and pulmonary circulatory systems. The venous system contains the greatest amount of blood at any one time and is highly distensible, accommodating a wide range of blood volumes (high capacitance). The arterial system is composed of the aorta, arteries, and arterioles. Arterioles are small muscular arteries that regulate blood pressure by changing tone (resistance). (B) A schematic representation of the cardiac conduction system.

electrical impulse originates in the SA and is conducted to the AV node by internodal tracts within the atria.

The AV node is a critical electrical interface between the atria and ventricles, because it facilitates electromechanical coupling. The AV node is located at the inferior aspect of the right atrium, between the coronary sinus and the septal leaflet of the tricuspid valve. The

AV node is supplied by the AV nodal artery, which is a branch of the RCA in about 90% of the population and a branch of the LCx in 10%. Electrical impulse conduction slows through the AV node and continues to the ventricles by means of the His-Purkinje system. The increased impulse time through the AV node allows for adequate ventricular filling.

The bundle of His extends from the AV node down the membranous interventricular septum to the muscular septum, where it divides into the left and right bundle branches, finally terminating in Purkinje cells, which are specialized cells that facilitate the rapid propagation of electrical impulses. The Purkinje cells directly stimulate myocytes to contract. The right bundle and the left bundle are supplied by septal perforator branches from the LAD. The distal and posterior portion of the left bundle has an additional blood supply from the AV nodal artery (PDA origin); for that reason, it is more resistant to ischemia. Conduction can be impaired at any point, from ischemia, medications (e.g., β -blockers, calcium channel blockers), infection, or congenital abnormalities. (Please refer to Chapter 55, "Principles of Electrophysiology," in *Goldman-Cecil Medicine*, 26th Edition.)

NEURAL INNERVATION

The autonomic nervous system is an integral component in the regulation of cardiac function. In general, sympathetic stimulation increases the heart rate (HR) (chronotropy) and the force of myocardial contraction (inotropy). Sympathetic stimulation commences in preganglionic neurons located within the superior five or six thoracic segments of the spinal cord. They synapse with second-order neurons in the cervical sympathetic ganglia and then propagate the signal through cardiac nerves that innervate the SA node, AV node, epicardial vessels, and myocardium. The parasympathetic system produces an opposite physiologic effect by decreasing HR and contractility. Its neural supply originates in preganglionic neurons within the dorsal motor nucleus of the medulla oblongata, which reach the heart through the vagus nerve. These efferent neural fibers synapse with second-order neurons located in ganglia within the heart that terminate in the SA node, AV node, epicardial vessels, and myocardium to decrease HR and contractility. Conversely, afferent vagal fibers from the inferior and posterior aspects of the ventricles, the aortic arch, and the carotid sinus conduct sensory information back to the medulla, which mediates important cardiac reflexes.

MYOCARDIAL STRUCTURE

The proper cellular organization of cardiac tissue (myocardium) is critical for the generation of efficient myocardial contraction. Disruptions in this structure and organization lead to cardiac dys-synchrony and arrhythmias, which cause significant morbidity and mortality. Atrial and ventricular myocytes are specialized, branching muscle cells that are connected end to end by intercalated disks. These disks aid in the transmission of mechanical tension between cells. The myocyte plasma membrane, or sarcolemma, facilitates excitation and contraction through small transverse tubules (T tubules). Subcellular features specific for myocytes include increased mitochondria number for production of adenosine triphosphate (ATP); an extensive network of intracellular tubules, called the *sarcoplasmic reticulum*, for calcium storage; and *sarcomeres*, which are myofibrils comprised of repeating units of overlapping thin actin filaments and thick myosin filaments and their regulatory proteins troponin and tropomyosin. Specialized myocardial cells form the cardiac conduction system (described earlier) and are responsible for the generation of an electrical impulse and

Fig. 2.2 Calcium dependence of myocardial contraction. (1) Electrical depolarization of the myocyte results in an influx of Ca^{2+} ions into the cell through channels in the T tubules. (2) This initial phase of calcium entry stimulates the release of large amounts of Ca^{2+} from the sarcoplasmic reticulum (SR). (3) The Ca^{2+} then binds to the troponin-tropomyosin complex on the actin filaments, resulting in a conformational change that facilitates the binding interaction between actin and myosin. In the presence of adenosine triphosphate (ATP), the actin-myosin association is cyclically dissociated as the thick and thin filaments slide past each other, resulting in contraction. (4) During repolarization, the Ca^{2+} is actively pumped out of the cytosol and sequestered in the SR. *ATPase*, Adenosine triphosphatase; *M*, mitochondrion.

organized propagation of that impulse to cardiac myocytes, which, in turn, respond by mechanical contraction.

MUSCLE PHYSIOLOGY AND CONTRACTION

Calcium-induced calcium release is the primary mechanism for myocyte contraction. When a depolarizing stimulus reaches the myocyte, it enters special invaginations within the sarcolemma called T tubules. These specialized channels open in response to depolarization, permitting calcium flux into the cell (Fig. 2.2). The sarcoplasmic reticulum closely proximates the T tubules, and the initial calcium current triggers the release of large amounts of calcium from the sarcoplasmic reticulum into the cell cytosol. Calcium then binds to the calcium-binding regulatory subunit, troponin C, on the actin filaments of the sarcomere, resulting in a conformational change in the troponin-tropomyosin complex. The myosin binding site on actin is now exposed, to facilitate binding of actin-myosin cross-bridges, which are necessary for cellular contraction. The energy for myocyte contraction

is derived from ATP. During contraction, ATP promotes dissociation of myosin from actin, thereby permitting the sliding of thick filaments past thin filaments as the sarcomere shortens.

The force of myocyte contraction is regulated by the amount of free calcium released into the cell by the sarcoplasmic reticulum. More calcium allows for more frequent actin-myosin interactions, producing a stronger contraction. On repolarization of the sarcolemmal membrane, intracellular calcium is rapidly and actively resealed into the sarcoplasmic reticulum, where it is stored by various proteins, including calsequestrin, until the next wave of depolarization occurs. Calcium is also extruded from the cytosol by various calcium pumps in the sarcolemma. The active removal of intracellular calcium by ATP ion pumps facilitates ventricular relaxation, which is necessary for proper ventricular filling during diastole.

Circulatory Physiology and the Cardiac Cycle

The term *cardiac cycle* describes the pressure changes within each cardiac chamber over time (Fig. 2.3). This cycle is divided into *systole*,

Fig. 2.3 Simultaneous electrocardiogram (ECG) and pressure tracings obtained from the left atrium (LA), left ventricle (LV), and aorta and the jugular venous pressure during the cardiac cycle. (For simplification, pressures on the right side of the heart have been omitted. Normal right atrial (RA) pressure closely parallels that of the LA, and right ventricular and pulmonary artery pressures are timed closely with their corresponding left-sided counterparts; they are reduced only in magnitude. Normally, closure of the mitral and aortic valves precedes closure of the tricuspid and pulmonic valves, whereas valve opening reverses this order. The jugular venous pulse lags behind the RA pulse.) During the course of one cardiac cycle, the electrical (ECG) events initiate and therefore precede the mechanical (pressure) events, and the latter precede the auscultatory events (heart sounds) that they themselves produce (red boxes). Shortly after the P wave, the atria contract to produce the *a* wave. The QRS complex initiates ventricular systole, followed shortly by LV contraction and the rapid buildup of LV pressure. Almost immediately, LV pressure exceeds LA pressure, closing the mitral valve and producing the first heart sound. After a brief period of isovolumic contraction, LV pressure exceeds aortic pressure and the aortic valve opens (AVO). When the ventricular pressure once again falls to less than the aortic pressure, the aortic valve closes to produce the second heart sound and terminate ventricular ejection. The LV pressure decreases during the period of isovolumic relaxation until it drops below LA pressure and the mitral valve opens (MVO). See text for further details.

the period of ventricular contraction, and *diastole*, the period of ventricular relaxation. Each cardiac valve opens and closes in response to pressure gradients generated during these periods. At the onset of systole, ventricular pressures exceed atrial pressures, so the AV valves passively close. As myocytes contract, the intraventricular pressures rise initially, without a change in ventricular volume (isovolumic

contraction), until they exceed the pressures in the aorta and pulmonary artery. At this point, the semilunar valves open, and ventricular ejection of blood occurs. When intracellular calcium levels fall, ventricular relaxation begins; arterial pressures exceed intraventricular pressures, so the semilunar valves close. Ventricular relaxation initially does not change ventricular volume (isovolumic relaxation). At the point at which intraventricular pressures fall below atrial pressures, the AV valves open. This begins the rapid and passive ventricular filling phase of diastole, during which blood in the atria empties into the ventricles. At the end of diastole, active atrial contraction augments ventricular filling. When the myocardium exhibits increased stiffness due to age, hypertension, diabetes, or heart failure, the early passive phase of ventricular filling is decreased. To compensate for the reduction in passive ventricular filling, there is reliance on atrial contraction to sufficiently fill the ventricle during diastole. A pathologic consequence of atrial fibrillation, a disease in which the atrium does not contract, is that patients often have worse symptoms because this additional ventricular filling is lost.

Pressure tracings obtained from the periphery complement the hemodynamic changes exhibited in the heart. In the absence of valvular disease, there is no impediment to blood flow moving from the ventricles to the arterial beds, so the systolic arterial pressure rises sharply to a peak. During diastole, no further blood volume is ejected into the aorta, so the arterial pressure gradually falls as blood flows to the distal tissue beds and elastic recoil of the arteries occurs.

Atrial pressure can be directly measured in the right atrium, but the left atrial pressure is indirectly measured by occluding a small pulmonary artery branch and measuring the pressure distally (the pulmonary capillary wedge pressure). An atrial pressure tracing is shown in Fig. 2.3. It is composed of several waves. The *a* wave represents atrial contraction. As the atria subsequently relax, the atrial pressure falls, and the *x* descent is seen on the pressure tracing. The *x* descent is interrupted by a small *c* wave, generated as the AV valve bulges toward the atrium during ventricular systole. As the atria fill from venous return, the *v* wave is seen, after which the *y* descent appears as the AV valves open and blood from the atria empties into the ventricles. The normal ranges of pressures in the various cardiac chambers are shown in Table 2.1.

Cardiac Performance

The amount of blood ejected by the heart each minute is referred to as the cardiac output (CO). It is the product of the stroke volume (SV), which is the amount of blood ejected with each ventricular contraction, and the HR:

$$CO = SV \times HR$$

The cardiac index is a way of normalizing the CO to body size. It is the CO divided by the body surface area and is measured in L/min/m². The normal CO is 4 to 6 L/min at rest and can increase fourfold to sixfold during strenuous exercise.

The main determinants of SV are preload, afterload, and contractility (Table 2.2). *Preload* is the volume of blood in the ventricle at the end of diastole; it is primarily a reflection of venous return. Venous return is determined by the plasma volume and the venous compliance. Clinically, intravenous fluids increase preload, whereas diuretics or venodilators such as nitroglycerin decrease preload. When the preload is increased, the ventricle stretches, and the ensuing ventricular contraction becomes more rapid and forceful, because the increased sarcomere length facilitates actin and myosin cross-bridge kinetics by means of an increased sensitivity of troponin C to calcium. This phenomenon is known as the Frank-Starling relationship. Ventricular filling pressure (ventricular end-diastolic pressure, atrial pressure, or

TABLE 2.1 Normal Values for Common Hemodynamic Parameters

Heart rate	60-100 beats/min
Pressures (mm Hg)

Pulmonary vascular resistance	30-120 dynes-sec/cm ⁻⁵
Cardiac output	4-6 L/min
Cardiac index	2.5-4 L/min

pulmonary capillary wedge pressure) is frequently used as a surrogate measure of preload.

Afterload is the force against which the ventricles must contract to eject blood. The main determinants of afterload are the arterial pressure and the dimensions of the left ventricle. As the arterial blood pressure increases, the amount of blood that can be ejected into the aorta decreases. Wall stress, a significant and often overlooked determinant of afterload, is directly proportional to the size of the ventricular cavity and inversely proportional to the ventricular wall thickness (Laplace's law). Diuretics reduce the increased wall stress associated with pathologic dilatation in cardiomyopathy by decreasing left ventricular volume and size. In addition, ventricular wall hypertrophy is a compensatory mechanism to reduce afterload caused by systemic hypertension. Drugs that treat hypertension, such as angiotensin-converting enzyme (ACE) inhibitors and hydralazine, reduce blood pressure (BP) and thereby reduce afterload.

Contractility, or inotropy, represents the force of ventricular contraction in the presence of constant preload and afterload. Inotropy is regulated at a cellular level through stimulation of catecholaminergic (epinephrine, norepinephrine, and dopamine) receptors, intracellular signaling cascades (phosphodiesterase inhibitors), and intracellular calcium levels (affected by levosimendan and, indirectly, by digoxin). Many antihypertensive medications (e.g., β -blockers, calcium channel antagonists) interfere with adrenergic receptor activation or intracellular calcium levels, which can decrease the strength of ventricular contractions. (Please refer to Chapter 47, "Cardiac and Circulatory Function," in *Goldman-Cecil Medicine*, 26th Edition.)

Physiology of the Coronary Circulation

The normally functioning heart maintains equilibrium between the amount of oxygen delivered to myocytes and the amount of oxygen consumed by them (myocardial oxygen consumption, or MvO_2). If a myocyte works harder because it is contracting with increased

TABLE 2.2 Factors Affecting Cardiac Performance

frequency (HR), with increased intensity (contractility), or against an increased load (wall stress), then it will use more oxygen and its MvO_2 will increase. In order to meet this increase in demand for more oxygen, the heart will have to either increase blood flow or increase its efficiency in extracting oxygen. The heart is unique in that its oxygen extraction is almost maximal at resting conditions. Therefore, increasing blood flow is the only reasonable means of increasing oxygen supply.

Microvascular blood flow in the coronary circulation is impaired during systole because the intramyocardial blood vessels are compressed by contracting myocardium. Therefore, most coronary flow occurs during diastole. Accordingly, the diastolic pressure is the major pressure driving flow within the coronary circulation. Systolic pressure impedes intramyocardial arterial blood flow but augments venous flow. On a clinical note, tachycardia is particularly detrimental because coronary flow is reduced when the diastolic filling time is abbreviated, and the MvO_2 increases with increasing HR. In order to sustain constant perfusion to the myocardium, coronary blood flow is maintained constant over a wide range of pressures in a process called autoregulation.

In response to a change in MvO_2 , the coronary arteries dilate or constrict, which changes the vascular resistance and thereby appropriately changes flow. This regulation of arterial resistance occurs at the arterioles and is mediated by several factors. Adenosine, a metabolite of ATP, is released during contraction and acts as a potent vasodilator.

Other consequences of myocardial metabolism, such as decreased oxygen tension, increased carbon dioxide, hydrogen peroxide, acidosis, and hyperkalemia, also mediate coronary vasodilation. The endothelium produces several potent vasodilators, including nitric oxide and prostacyclin. Nitric oxide is released by the endothelium in response to acetylcholine, thrombin, adenosine diphosphate (ADP), serotonin, bradykinin, platelet aggregation, and an increase in shear stress (called *flow-dependent vasodilation*). Finally, the coronary arteries are innervated by the autonomic nervous system, and activation of sympathetic neurons mediates vasoconstriction or vasodilation through α - or β -receptors, respectively. Parasympathetic neurons from the vagus nerve secrete acetylcholine, which mediates vasodilation. Vasoconstricting factors, notably endothelin, are produced by the endothelium and may be important in conditions such as coronary vasospasm. (Please refer to Chapter 47, “Cardiac and Circulatory Function,” in *Goldman-Cecil*

❖ *Medicine*, 26th Edition.)

Physiology of the Systemic Circulation

The normal cardiovascular system delivers appropriate blood flow to each organ of the body under a wide range of conditions. This regulation is achieved by maintaining BP through adjustments in cardiac output and tissue blood flow resistance by neural and humoral factors.

Poiseuille’s law generally describes the relationship between pressure and flow in a vessel. Fluid flow (F) through a tube is proportional (proportionality constant = K) to the pressure (P) difference between the ends of the tube:

$$F = K \times \Delta P$$

K is equivalent to the inverse of resistance to flow (R); that is, $K = 1/R$. Resistance to flow is determined by the properties of both the fluid and the tube. In the case of a steady, streamlined flow of fluid through a rigid tube, Poiseuille found that these factors determine resistance:

$$R = 8\eta L / \pi r^4$$

Where r is the radius of the tube, L is its length, and η is the viscosity of the fluid. Notice that changes in radius have greater influence than changes in length, because resistance is inversely proportional to the fourth power of the radius. Poiseuille’s law incorporates the factors influencing flow, so that:

$$F = \Delta P/R = \Delta P \pi r^4 / 8 \eta L$$

Therefore, the most important determinants of blood flow in the cardiovascular system are ΔP and r^4 . Small changes in arterial radius can cause large changes in flow to a tissue or organ. Practically, systemic

vascular resistance (SVR) is the total resistance to flow caused by changes in the radius of resistance vessels (small arteries and arterioles) of the systemic circulation. The SVR can be calculated as the pressure drop across the peripheral capillary beds (mean arterial pressure – right atrial pressure) divided by the blood flow across the beds (i.e., $SVR = BP/CO$). It is normally in the range of 800 to 1500 dynes-sec/cm⁻⁵.

The autonomic nervous system alters systemic vascular tone through sympathetic and parasympathetic innervation as well as metabolic factors (local oxygen tension, carbon dioxide levels, reactive oxygen species, pH) and endothelium-derived signaling molecules (NO, endothelin). Neural regulation of BP occurs by means of constitutive and reflex changes in autonomic efferent outflow to modulate cardiac chronotropy, inotropy, and vascular resistance.

The baroreflex loop is the primary mechanism by which BP is neurally modulated. Baroreceptors are stretch-sensitive nerve endings that are distributed throughout various regions of the cardiovascular system. Those located in the carotid artery (e.g., carotid sinus) and aorta are sometimes referred to as *high-pressure baroreceptors* and those in the cardiopulmonary areas as *low-pressure baroreceptors*. After afferent impulses are transmitted to the central nervous system, the signals are integrated, and the efferent arm of the reflex projects neural signals systemically through the sympathetic and parasympathetic branches of the autonomic nervous system. In general, an increase in systemic BP increases the firing rate of the baroreceptors. Efferent sympathetic outflow is inhibited (reducing vascular tone, chronotropy, and inotropy), and parasympathetic outflow is increased (reducing cardiac chronotropy). The opposite occurs when BP decreases. (Please refer to Chapter 47, “Cardiac and Circulatory Function,” in *Goldman-Cecil*

❖

Physiology of the Pulmonary Circulation

Like the systemic circulation, the pulmonary circulation consists of a branching network of progressively smaller arteries, arterioles, capillaries, and veins. The pulmonary capillaries are separated from the alveoli by a thin alveolar-capillary membrane through which gas exchange occurs. The partial pressure of oxygen (PO₂) is the main regulator of pulmonary blood to optimize blood flow toward well-ventilated lung segments and away from poorly ventilated segments.

Evaluation of the Patient With Cardiovascular Disease

James Kleczka, Noura M. Dabbouseh

DEFINITION AND EPIDEMIOLOGY

Cardiovascular disease is a major cause of morbidity and mortality around the world, and its spectrum is wide-reaching. Included in this population of patients are people with coronary artery disease (CAD), congestive heart failure, stroke, hypertension, peripheral arterial disease, atrial fibrillation and other arrhythmias, valvular disease, and congenital heart disease. The impact of cardiovascular disease is unmistakable: It is the leading cause of death in both males and females in the United States, with reports estimating that heart disease accounts for between one in three and one in four deaths. It accounted for more inpatient hospital days in the years of 1990–2009 than other disorders such as chronic lung disease and cancer. The high number of inpatient days associated with cardiovascular disease led to a total economic cost of more than \$297 billion in the year 2008 alone. In 2011, an estimated \$316.6 billion in health care costs and lost productivity was attributable to heart disease and stroke.

Given these facts, the proper evaluation of a patient with cardiovascular disease is imperative in order to potentially decrease an individual's morbidity and mortality and potentially impact health care expenditures. An understanding of the basics of the pathophysiology of heart disease as well as a thorough history and detailed physical examination are required to accurately assess and manage patients with cardiovascular disease.

PATHOLOGY

The term *cardiovascular disease* encompasses a wide array of patient problems. The heart's circulation, myocardium, rhythm, valves, and pericardial structures may be affected, as can the arterial or venous vascular systems. *Coronary artery disease (CAD)*, discussed in depth in [Chapter 8](#), is a leading cause of morbidity and mortality. While many patients do have silent CAD or asymptomatic coronary atherosclerosis, this still impacts patient morbidity. At presentation, patients with symptomatic CAD may have stable angina or an acute coronary syndrome, further stratified into unstable angina (UA), non–ST segment elevation myocardial infarction (NSTEMI), or ST segment elevation myocardial infarction (STEMI). The initial presentation for some patients with CAD is sudden cardiac death, the result of arrhythmia often caused by atherosclerosis of the coronary vasculature.

Congestive heart failure is the end result of many cardiac disorders and has been historically classified as systolic or diastolic in etiology. More recently, the terms heart failure with reduced ejection fraction (HFrEF) and heart failure with preserved ejection fraction (HFpEF), which is often due to diastolic dysfunction, have gained widespread acceptance. In patients with ventricular enlargement or systolic dysfunction, the term cardiomyopathy is appropriate whether or not a patient has clinically demonstrated signs of heart failure. Various forms of

cardiomyopathy may lead to systolic dysfunction and a decline in ejection fraction. Without proper management, this will inevitably lead to alterations in hemodynamics that result in development of pulmonary vascular congestion, edema, and a decline in functional capacity, all symptoms of clinical heart failure. Diastolic dysfunction can be present with systolic dysfunction and is often the result of uncontrolled hypertension or infiltrative disorders such as hemochromatosis or amyloidosis. Various forms of heart failure are further discussed in [Chapter 5](#).

Stroke is caused by cerebral hypoperfusion, which can result from such problems as carotid disease, thromboembolism, or emboli of infectious origin. A more detailed discussion can be found in [Chapter 118](#).

Peripheral arterial disease (PAD), addressed in [Chapter 12](#), includes such entities as aneurysms of the ascending, descending, and abdominal aorta and its branches; aortic or peripheral arterial dissection; carotid disease; and atherosclerosis of branch vessels of the aorta and vessels in the limbs. PAD is often present in patients with CAD.

Atrial fibrillation and *hypertension* (see [Chapter 9](#)) are not uncommon and increase in prevalence with age. Although they are not typically the primary cause of mortality, these problems often predispose to other causes of cardiovascular disease mortality, such as stroke and heart failure. Arrhythmias other than atrial fibrillation are also common and can lead to significant morbidity and mortality.

Valvular heart disease may lead to cardiomyopathy and is found in all age groups.

Congenital heart disease includes a wide variety of disorders, ranging from valve abnormalities and coronary anomalies to cardiomyopathy and other structural abnormalities including shunts and malformations of the cardiac chambers. With advances in surgical techniques and medical therapy, life expectancy has improved significantly for patients with congenital heart disease. Congenital heart disease is discussed further in [Chapter 6](#).

CLINICAL PRESENTATION

Technologic advancements have allowed for specialized testing to assist in the diagnosis of cardiovascular diseases. We now rely on such tests as angiography, ultrasound scanning, and advanced imaging modalities such as high-resolution computed tomography and magnetic resonance imaging to determine how to manage an individual case. However, these techniques should be used not as a primary method of assessment but rather to supplement the findings from a thorough history and physical examination. Despite the availability of rather costly imaging techniques and laboratory tests, a relatively inexpensive but detailed history and physical examination is a clinician's strongest tool in helping to establish a diagnosis.

TABLE 3.1 Cardiovascular Causes of Chest Pain

Condition	Location	Quality	Duration	Aggravating or Alleviating Factors	Associated Symptoms or Signs
Angina	Retrosternal region; radiates to or occasionally isolated to neck, jaw, shoulders, arms (usually left), or epigastrium	Pressure, squeezing, tightness, heaviness, burning, indigestion	<2-10 min	Precipitated by exertion, cold weather, or emotional stress; relieved by rest or nitroglycerin; variant (Prinzmetal) angina may be unrelated to exertion, often early in the morning	Dyspnea; S ₃ , S ₄ , or murmur of papillary dysfunction during pain
Myocardial infarction	Same as angina	Same as angina, although more severe	Variable; usually >30 min	Unrelieved by rest or nitroglycerin	Dyspnea, nausea, vomiting, weakness, diaphoresis
Pericarditis	Left of the sternum; may radiate to neck or left shoulder, often more localized than pain of myocardial ischemia	Sharp, stabbing, knifelike	Lasts many hours to days; may wax and wane	Aggravated by deep breathing, rotating chest, or supine position; relieved by sitting up and leaning forward	Pericardial friction rub
Aortic dissection	Anterior chest; may radiate to back, interscapular region	Excruciating, tearing, knifelike	Sudden onset, unrelenting	Usually occurs in setting of hypertension or predisposition, such as Marfan syndrome	Murmur of aortic insufficiency; pulse or blood pressure asymmetry; neurologic deficit

A patient who is given the opportunity to outline his or her symptoms in his or her own words can help lead a clinician toward the right diagnosis. For example, many patients who deny chest pain when asked specifically about this symptom will go on to describe the symptom of chest pressure, which patients often feel is distinct from “pain.” Gathering further historical details such as provoking factors (e.g., activity, extreme emotional stress, or rest or unprovoked symptoms), location, quality, intensity, and radiation of the symptom is imperative when taking a thorough history. One should delve into aggravating or alleviating factors and whether there are other symptoms that accompany the primary symptom. It is also important to note the pattern of the symptom in terms of stability or progression in intensity or frequency over time. An assessment of functional status should always be a part of the history in a patient with cardiovascular disease; a recent decline in exercise tolerance can help determine severity of disease.

A detailed past medical history and review of systems are necessary in order to understand if the cardiovascular condition is isolated or part of a syndrome. For example, a patient may have arrhythmias in the setting of hyperthyroidism. Rheumatologic disorders often affect the heart. And cancer can increase the risk of thromboembolism, of pericardial effusion and, with some therapies, cardiomyopathy. A comprehensive list of medications must be reviewed, and a social history must be taken detailing alcohol use, smoking, and occupational history. Patients should also be questioned regarding major risk factors such as hypertension, hyperlipidemia, and diabetes mellitus. A thorough family history is needed, not only to identify such entities as early-onset CAD but also to assess for other potentially inherited disorders, such as familial cardiomyopathy or arrhythmic disorders (e.g., long-QT syndrome).

Chest Pain

Chest pain is one of the cardinal symptoms of cardiovascular disease, but it may also be present in many noncardiovascular diseases (Tables 3.1 and 3.2). Chest pain may be caused by cardiac ischemia but also may be related to aortic pathology such as dissection, pulmonary

disease such as pneumonia, gastrointestinal pathology such as gastroesophageal reflux, or musculoskeletal pain related to chest wall trauma. Issues with organs in the abdominal cavity such as the gallbladder or pancreas can also cause chest pain. It is therefore very important to characterize the pain in terms of location, quality, quantity, duration, radiation, aggravating and alleviating factors, and associated symptoms. These details will help determine the origin of the pain.

Myocardial ischemia due to obstructive CAD often leads to typical angina pectoris. Angina is often described as tightness, pressure, burning, or squeezing discomfort that patients may not identify as true pain. Patients frequently describe angina as a sensation of “bricks on the center of the chest” or an “elephant standing on the chest.” Angina is more common in the morning, and the intensity may be affected by heat or cold, emotional stress, or eating. This discomfort is typically located in the substernal region or left side of the chest. Anginal pain may radiate to other parts of the body, such as the left shoulder and arm (particularly the ulnar aspect), the neck, the jaw, or the epigastrium. Pain that radiates to the back may raise suspicion for aortic dissection. Anginal chest pain is usually brought on with exertion, in particular with more intense activity or walking up inclines, in extremes of weather, or after large meals. It is typically brief in duration, lasting 2 to 10 minutes, and frequently resolves with rest or administration of nitroglycerine within 1 to 5 minutes. Associated symptoms often include nausea, diaphoresis, dyspnea, palpitations, and dizziness. Patients typically report a stable pattern of angina that is relatively predictable and reproducible with a given amount of exertion. When this pain begins to increase in frequency and severity or occurs with lesser amounts of exertion or at rest, one must then consider unstable angina. Anginal pain that occurs at rest with increased intensity and lasts longer than 30 minutes may represent acute myocardial infarction (MI). Some patients endorse a feeling of doom when suffering an MI. Angina-like pain at rest may also occur with coronary vasospasm and noncardiac chest pain.

There are several other potential causes of chest pain that may be confused with angina pectoris (see Table 3.2). Pain associated

TABLE 3.2 Noncardiac Causes of Chest Pain

Condition	Location	Quality	Duration	Aggravating or Alleviating Factors	Associated Symptoms or Signs
Pulmonary embolism (chest pain often not present)	Substernal or over region of pulmonary infarction	Pleuritic (with pulmonary infarction) or angina-like	Sudden onset (minutes to hours)	Aggravated by deep breathing	Dyspnea, tachypnea, tachycardia; hypotension, signs of acute right ventricular heart failure, and pulmonary hypertension with large emboli; pleural rub; hemoptysis with pulmonary infarction
Pulmonary hypertension	Substernal	Pressure; oppressive	—	Aggravated by effort	Pain usually associated with dyspnea; signs of pulmonary hypertension
Pneumonia with pleurisy	Located over involved area	Pleuritic	—	Aggravated by breathing	Dyspnea, cough, fever, bronchial breath sounds, rhonchi, egophony, dullness to percussion, occasional pleural rub
Spontaneous pneumothorax	Unilateral	Sharp, well localized	Sudden onset; lasts many hours	Aggravated by breathing	Dyspnea; hyperresonance and decreased breath and voice sounds over involved lung
Musculoskeletal disorders	Variable	Aching, well localized	Variable	Aggravated by movement; history of exertion or injury	Tender to palpation or with light pressure
Herpes zoster	Dermatomal distribution	Sharp, burning	Prolonged	None	Vesicular rash appears in area of discomfort
Esophageal reflux	Substernal or epigastric; may radiate to neck	Burning, visceral discomfort	10-60 min	Aggravated by large meal, postprandial recumbency; relief with antacid	Water brash
Peptic ulcer	Epigastric, substernal	Visceral burning, aching	Prolonged	Relief with food, antacid	—
Gallbladder disease	Right upper quadrant; epigastric	Visceral	Prolonged	Spontaneous or after meals	Right upper quadrant tenderness may be present
Anxiety states	Often localized over pre-cordium	Variable; location often moves from place to place	Varies; often fleeting	Situational	Sighing respirations; often chest wall tenderness

with acute pericarditis is typically sharp, is located to the left of the sternum, and radiates to the neck, shoulders, and back. This may be rather severe pain that is present at rest and can last for hours. It typically improves with sitting up and forward and worsens with inspiration. Oftentimes history of causative viral prodrome can be elicited.

Acute aortic dissection usually causes sudden onset of severe tearing chest pain that radiates to the back between the scapulae or to the lumbar region. Typically, there is a history of hypertension, and pulses may be asymmetric between the extremities. A murmur of aortic regurgitation may also be heard. Pain associated with pulmonary embolism is also acute in onset and is usually accompanied by shortness of breath. This pain is typically pleuritic, worsening with inspiration.

Dyspnea

Dyspnea is another hallmark symptom of cardiovascular disease, but it is also a primary symptom of pulmonary disease. It is defined as an uncomfortable heightened awareness of breathing. This can be an entirely normal sensation in individuals performing moderate to extreme exertion, depending on their level of conditioning. When it occurs at rest or with minimal exertion, dyspnea is considered abnormal. Dyspnea may accompany a large number of noncardiac conditions such as anemia due to a lack of oxygen-carrying capacity,

pulmonary disorders such as obstructive or restrictive lung disease and asthma, obesity due to an increased work of breathing and restricted filling of the lungs, and deconditioning. In the cardiovascular patient, dyspnea may be caused by ventricular dysfunction, either systolic or diastolic; CAD and resultant ischemia; a large pericardial effusion causing impaired filling and resulting depressed cardiac output (cardiac tamponade); or valvular heart disease that, when severe, can lead to a drop in cardiac output. In cases of left ventricular dysfunction and valvular disease, the mechanism of dyspnea often involves increased intracardiac pressures that lead to pulmonary vascular congestion. Fluid then leaks into the alveolar space, impairing gas exchange and causing dyspnea.

Breathing difficulties can also be secondary to a low-output state without pulmonary vascular congestion. Patients often notice dyspnea with exertion, but it can also occur at rest in patients with severe cardiac disease. Shortness of breath at rest is also a symptom in patients with pulmonary edema, large pleural effusions, anxiety, or pulmonary embolism. A patient with left ventricular systolic or diastolic failure may describe the acute onset of breathing difficulty when sleeping. This problem, called paroxysmal nocturnal dyspnea (PND), is caused by pulmonary edema that is redistributed in a prone position; it is usually secondary to left ventricular failure. These patients often notice the acute onset of dyspnea followed by coughing roughly 2 to 4 hours after going to sleep. This can be a very uncomfortable feeling, and it leads

the patient to sit up immediately or get out of bed. Symptoms typically resolve over 15 to 30 minutes. Patients with left ventricular failure also often complain of orthopnea, which is dyspnea that occurs when one assumes a prone position. This is relieved by sleeping on multiple pillows or remaining seated to sleep. In severe cases of dyspnea due to heart failure, patients may have an immediate feeling of shortness of breath when attempting a supine position.

Patients with sudden onset of dyspnea may be experiencing flash pulmonary edema, which is very rapid and acute accumulation of fluid in the lungs. This can be associated with severe CAD and may also be a cause of dyspnea in patients with coarctation of the aorta and renal artery stenosis. Sudden dyspnea is associated with pulmonary embolism, and this symptom is typically accompanied by pleuritic chest pain and possibly hemoptysis in such patients. Pneumothorax can cause dyspnea accompanied by acute chest pain. Dyspnea due to lung disease is present with exertion, although in severe cases it may be present at rest. This is often accompanied by hypoxia and is relieved by pulmonary bronchodilators or steroids or both. Dyspnea may also be an “angina equivalent.” Not all patients with CAD develop typical anginal chest pain. Dyspnea that comes on with exertion or emotional stress, is relieved with rest, and is relatively brief in duration might be a manifestation of significant CAD. This type of dyspnea is also usually improved with the administration of nitroglycerine.

Palpitation

Palpitation is another symptom commonly seen in the cardiovascular patient. This is the subjective sensation of rapid or forceful beating of the heart. Patients are often able to describe in detail the sensation they feel, such as jumping, skipping, racing, fluttering, or an irregularity in the heartbeat. It is important to ask the patient about the onset of the palpitations because they may begin abruptly at rest, only with exertion, with emotional stress, or with ingestion of certain foods such as chocolate. One should also inquire about associated symptoms such as chest pain, dyspnea, dizziness, and syncope. It is important to note other medical issues, such as thyroid disease, and bleeding, which can lead to anemia, because these conditions may be associated with arrhythmias. A social history focusing on drug use and intake of alcohol, caffeine, or medications is important because use of many substances can lead to certain rhythm disturbances. Certain over-the-counter medicines contain pseudoephedrine, which can cause increased heart rate and palpitations. The family history is also important, because there are many inherited disorders (e.g., long-QT syndromes) that might lead to significant arrhythmias.

Potential etiologies of palpitations include premature atrial or ventricular beats, which are typically described as isolated skips and can be uncomfortable. Supraventricular tachycardias such as atrial flutter, AV nodal reentrant tachycardia, and paroxysmal atrial tachycardia often start and stop abruptly and can be rapid. Atrial fibrillation is an irregular heart rhythm originating from the atria. It can lead to rapid heart rates, which can be symptomatic. Even slowly conducted atrial fibrillation can be symptomatic for some patients. Ventricular arrhythmias are more often associated with severe dizziness or syncope. Gradual onset of tachycardia with a gradual decline in HR is more indicative of sinus tachycardia or anxiety.

Syncope

Syncope may be caused by a variety of cardiovascular diseases. It is the transient loss of consciousness due to inadequate cerebral blood flow. In the patient presenting with syncope as a primary complaint, one must try to differentiate true cardiac causes from neurologic issues such as seizure and metabolic causes such as hypoglycemia. Determination of the timing of the syncopal event and associated symptoms is very

helpful in determining the etiology. True cardiac syncope is typically very sudden, with no prodromal symptoms. It is typically caused by an abrupt drop in cardiac output that may be due to tachyarrhythmias such as ventricular tachycardia or fibrillation, bradyarrhythmias, such as complete heart block, severe valvular heart disease such as aortic or mitral stenosis, or obstruction of flow due to left ventricular outflow tract (LVOT) obstruction. It can also be caused by cardiac tamponade as well as by hemodynamically significant pulmonary embolism. True cardiac syncope often has no accompanying aura, though palpitations can be experienced in patients with tachyarrhythmia, or with pulmonary embolism or tamponade (due to frequently higher heart rates in these scenarios). In situations such as aortic stenosis or LVOT obstruction, syncope typically occurs with exertion. Patients may regain consciousness rather quickly with true cardiac syncope. It should be noted that some syncope is associated with a generalized shaking (i.e., convulsive syncope), which can mimic epileptic activity. Convulsive activity should not cause the clinician to rule out a cardiac etiology for syncope.

Neurocardiogenic syncope involves an abnormal reflexive response to a change in position. When one rises from a prone or seated position to a standing position, the peripheral vasculature usually constricts, and the HR increases, to maintain cerebral perfusion. With neurocardiogenic syncope, the peripheral vasculature abnormally dilates, the HR slows or doesn't increase normally, or both. This leads to a reduction in cerebral perfusion and syncope. A similar mechanism is responsible for carotid sinus syncope and syncope associated with micturition and cough. The patient usually describes a gradual onset of symptoms such as flushing, dizziness, diaphoresis, and nausea before losing consciousness, which lasts seconds. When these patients wake, they are often pale and have a lower HR.

In the patient with syncope due to seizures, a prodromal aura is typically present before loss of consciousness occurs. Patients regain consciousness much more slowly and at times are incontinent, complain of headache and fatigue, and have a “postictal” confusional state. Syncope due to stroke is rare, because there must be significant bilateral carotid disease or disease of the vertebrobasilar system causing brainstem ischemia. Neurologic deficits accompany the physical examination findings in these patients.

The history is very important in determining the cause of a syncopal episode. This was previously studied by Calkins and colleagues, who found that men older than 54 years of age who had no prodromal symptoms were more likely to have an arrhythmic cause of their episodes. However, those with prodromal symptoms such as nausea, diaphoresis, dizziness, and visual disturbances before passing out were more likely to have neurocardiogenic syncope. Many inherited disorders such as long-QT syndrome and other arrhythmias, hypertrophic cardiomyopathy with LVOT obstruction, and familial dilated cardiomyopathy lead to states conducive to syncope. For this reason, detailed family history is necessary.

Edema

Edema often accompanies cardiovascular disease but may be a manifestation of liver disease (cirrhosis), renal disease (nephrotic syndrome), thyroid disease (myxedema) or local issues such as chronic venous insufficiency or thrombophlebitis. Edema related to cardiac disease is caused by increased venous pressures that alter the balance between hydrostatic and oncotic forces. This leads to extravasation of fluid into the extravascular space. These patients, therefore, are intravascularly “volume up,” which has implications for therapeutic approaches. Peripheral edema is common with right-sided heart failure, whereas the same process in left-sided heart failure leads to pulmonary edema. Left- and right-sided heart failure often coexist.

Edema due to a cardiac etiology is typically bilateral and begins distally with progression in a proximal fashion. The feet and ankles are affected first, followed by the lower legs, thighs, and, ultimately, the abdomen, sometimes accompanied by ascites. If edema is visible, it is usually preceded by a weight gain of at least 5 to 10 pounds. Edema with heart disease is typically pitting, leaving an indentation in the skin after pressure is applied to the area. The edema is usually worse in the evening, and patients often describe an inability to fit into their shoes. There may also be a feeling of abdominal fullness, depressed appetite, and difficulty fitting into other clothing, such as pants, normally. While these patients are lying prone, the edema can shift to the sacral region after several hours, only to accumulate again the next day when they are on their feet again (dependent edema).

Total body edema, or anasarca, may be caused by heart failure but is also seen in nephrotic syndrome, cirrhosis, and severe hypothyroidism. Unilateral edema is more likely associated with a localized issue such as deep venous thrombosis or thrombophlebitis. Other parts of the history may shed light on the etiology of edema. Patients who report PND and orthopnea are likely to have a cardiac etiology, and in fact, PND is the most specific historical finding in heart failure. If there is a history of alcohol abuse and jaundice is present, liver disease should be a considered cause. Edema of the eyes and face in addition to lower-extremity edema is more likely related to nephrotic syndrome, though this may also occur in heart failure. Edema associated with discoloration or ulcers of the lower extremities is often seen with chronic venous insufficiency. In a patient with insidious onset of edema progressing to anasarca and ascites, one must consider a diagnosis of chronic constrictive pericarditis.

Cyanosis

Cyanosis is defined as an abnormal bluish discoloration of the skin resulting from an increase in the level of reduced hemoglobin or abnormal hemoglobin in the blood. When present, it typically represents an oxygen saturation of less than 85% (normal, >90%). There are several types of cyanosis. Central cyanosis often manifests in discoloration of the lips or trunk and usually represents low oxygen saturations due to right-to-left shunting of blood. This can occur with structural cardiac abnormalities such as large atrial or ventricular septal defects, but it also happens with impaired pulmonary function, as in severe chronic obstructive lung disease. Peripheral cyanosis is typically secondary to vasoconstriction in the setting of low cardiac output. This can also occur with exposure to cold and can represent local arterial or venous thrombosis. When localized to the hands, peripheral cyanosis suggests Raynaud's phenomenon. Cyanosis in childhood often indicates congenital heart disease with right-to-left shunting of blood, causing lower oxygen content in systemically circulated blood.

Other

There are other, nonspecific symptoms that may indicate cardiovascular disease. Although fatigue is present with myriad medical conditions, it is common in patients with cardiac disease and can be a manifestation of coronary disease, volume overload, low cardiac output, hypotension, or hypertension. Iatrogenic causes of fatigue in cardiac patients include aggressive medical treatment of hypertension and overdiuresis in patients with heart failure. Fatigue may also be a direct result of medical therapy for cardiac disease itself, such as with β -blocking agents.

Although cough is commonly associated with pulmonary disease, it may also indicate high intracardiac pressures which can lead to pulmonary edema. Cough may be present in patients with heart failure or significant left-sided valve disease. A patient with congestive heart failure may describe a cough productive of frothy pink sputum, as opposed

to frank bloody or blood-tinged sputum, which is more typically seen with primary lung pathology. Nausea and emesis can accompany acute myocardial infarction and are often the only symptoms of MI. These "abdominal" symptoms may also be a reflection of heart failure leading to hepatic or intestinal congestion due to high right heart pressures. Anorexia, abdominal fullness, and cachexia may occur with end-stage heart failure, and the term "cardiac cachexia" has been coined to describe this syndrome. Nocturia is also a symptom described with heart failure; renal perfusion improves when the patient lies in a prone position, leading to an increase in urine output. Hoarseness of voice can occur due to compression of the recurrent laryngeal nerve. This may happen with enlarged pulmonary arteries, enlarged left atrium, or aortic aneurysm (Ortner's syndrome).

Despite the myriad symptoms of cardiovascular disease described here, many patients with significant cardiac disease are asymptomatic. Patients with CAD may have periods of asymptomatic ischemia that can be documented on ambulatory electrocardiographic monitoring. Up to one third of patients who have suffered a myocardial infarction are unaware that they had an event. This is more common in diabetics and in older patients. A patient may have severely depressed ventricular function for some time before presenting with symptoms. In addition, patients with atrial fibrillation can be entirely asymptomatic, with this rhythm discovered only after a physical examination or electrocardiogram is performed.

It is also important to note that cardiovascular disease is a leading cause of morbidity and mortality in women, but women have not classically been included in large longitudinal or epidemiologic studies of cardiac disease. Thus, much of our knowledge has been gathered from the study of men, and women may have atypical symptoms and presentations for cardiovascular disease. A high clinical suspicion for cardiovascular disease, the leading cause of death in both men and women, is imperative during evaluation, especially of the patient with cardiovascular disease risk factors.

At times, patients do not report having symptoms related to usual activities of daily living, yet symptoms are present when functional testing is performed. Therefore, assessing functional capacity is a very important part of the history in a patient with known or suspected cardiovascular disease. The ability or inability to perform various activities plays a substantial role in determining the extent of disability and in assessing response to therapy and overall prognosis, and it can influence decisions regarding the timing and type of therapy or intervention. The New York Heart Association Functional Classification is a commonly used method to assess functional status based on "ordinary activity" (Table 3.3). Patients are classified in one of four functional classes. Functional class I includes patients with known cardiac disease who have no limitations with ordinary activity. Functional classes II and III describe patients who have symptoms with less and less activity, whereas patients in functional class IV have symptoms at rest. The Canadian Cardiovascular Society has provided a similar classification of functional status specifically for patients with angina pectoris. These tools are very useful in classifying a patient's symptoms at a given time, allowing comparison at a future point and determination as to whether the symptoms are stable or progressive.

DIAGNOSIS AND PHYSICAL EXAMINATION

General

Like the detailed history, the physical examination is also vital when assessing a patient with cardiovascular disease. This consists of more than simple cardiac auscultation. Many diseases of the cardiovascular system can affect and be affected by other organ systems. Therefore, a detailed general physical examination is essential. The general

TABLE 3.3 Classification of Functional Status^a

Class I	Uncompromised	Ordinary activity does not cause symptoms; symptoms occur only with strenuous or prolonged activity.
Class II	Slightly compromised	Ordinary physical activity results in symptoms; no symptoms at rest.
Class III	Moderately compromised	Less than ordinary activity results in symptoms; no symptoms at rest.
Class IV	Severely compromised	Any activity results in symptoms; symptoms may be present at rest.

^a*Symptoms* refers to undue fatigue, dyspnea, palpitations, or angina in the New York Heart Association classification and refers specifically to angina in the Canadian Cardiovascular Society classification.

appearance of a patient is helpful: Examination of skin color, breathing pattern, presence of pain, and overall nutritional status can provide clues regarding the diagnosis. Examination of the head may reveal evidence of hypothyroidism, such as hair loss and periorbital edema, and examination of the eyes may reveal exophthalmos associated with hyperthyroidism. Both conditions can affect the heart. Retinal examination may reveal macular edema or flame hemorrhages that can be associated with uncontrolled hypertension. Findings such as clubbing or edema when examining the extremities, and jaundice or cyanosis when evaluating the skin, may provide clues to undiagnosed cardiovascular disease.

Examination of the Jugular Venous Pulsations

Examination of the neck veins can provide a great deal of insight into right heart hemodynamics. The right internal jugular vein should be used, because the relatively straight course of the right innominate and jugular veins allows for a more accurate reflection of the true right atrial pressure. The longer and more winding course of the left-sided veins does not allow for as accurate a transmission of hemodynamics. For examination of the right internal jugular vein, the patient should be placed at a 45-degree angle—higher in patients with suspected elevated venous pressures and lower in those with lower venous pressures. The head should be turned slightly leftward, and a light shined at an angle over the neck can help the exam. Although the internal jugular vein itself is not visible, the pulsations from that vessel are transmitted to the skin and can be seen in most cases. The carotid artery lies in close proximity to the jugular vein, and its pulsations can sometimes be seen as well. Therefore, one must be certain one is observing the correct vessel.

Several techniques can help the clinician differentiate carotid and venous pulsations. A normal carotid pulsation pattern usually appears as a smooth and rapid upstroke, whereas a venous pulsation tends to have three “waves,” the *a* wave of atrial contract, the *c* wave of the tricuspid valve closure, and the *v* wave of ventricular contraction. Variations in the appearance of these waves can help the clinician diagnose arrhythmia, constriction and tamponade, valvular heart disease, and heart failure. These are further discussed in the following text. The carotid and venous pulsations can further be distinguished by response to attempted compression of the pulsations or vessel. An arterial pulse will not be obliterated by this maneuver, whereas a venous pulse likely will become diminished or absent with compression. The arterial pulsations will not change with changes

in positioning, whereas venous pulsations, as they are essentially reflections of a column of fluid draining into the right heart, will appear higher in the neck/head when a patient is more supine and lower when a patient is more upright. Finally, compression of the abdomen will cause an elevation or increase in prominence of the appearance of a venous wave and will not affect an arterial waveform in the neck.

Both the level of venous pressure and the morphology of the venous waveforms should be noted. Once the pulsations have been located, the vertical distance from the sternal angle (angle of Louis) to the top of the pulsations is determined. Because the right atrium lies about 5 cm vertically below the sternal angle, this number is added to the previous measurement to arrive at an estimated right atrial pressure in centimeters of water. The right atrial pressure is normally 5 to 9 cm H₂O. It can be higher in patients with decompensated heart failure, disorders of the tricuspid valve (regurgitation or stenosis), restrictive cardiomyopathy, or constrictive pericarditis.

With inspiration, negative intrathoracic pressure develops, venous blood drains into the thorax, and venous pressure in the normal patient falls; the opposite occurs during expiration. In a patient with conditions such as decompensated heart failure, constrictive pericarditis, or restrictive cardiomyopathy, this pattern is reversed (Kussmaul sign), and the venous pressure increases with inspiration. When the neck veins are examined, firm pressure should be applied for 10 to 30 seconds to the right upper quadrant over the liver. In a normal patient, this will cause the venous pressure to increase briefly and then return to normal. In the patient with conditions such as heart failure, constrictive pericarditis, or substantial tricuspid regurgitation, the neck veins will reveal a sustained increase in pressure due to passive congestion of the liver. This finding is called hepatogaugular reflux.

The normal waveforms of the jugular venous pulse are depicted in Fig 3.1A. The *a* wave results from atrial contraction. The *x* descent results from atrial relaxation after contraction and the pulling of the floor of the right atrium downward with right ventricular contraction. The *c* wave interrupts the *x* descent and is generated by bulging of the cusps of the tricuspid valve into the right atrium during ventricular systole. This occurs at the same time as the carotid pulse. Atrial pressure then increases as a result of venous return with the tricuspid valve closed during ventricular systole; this generates the *v* wave, which is typically smaller than the *a* wave. The *y* descent follows as the tricuspid valve opens and blood flows from the right atrium to the right ventricle during diastole.

Understanding of the normal jugular venous waveforms is paramount, as these waveforms can be altered in different disease states. Abnormalities of these waveforms reflect underlying structural, functional, and electrical abnormalities of the heart (see Fig. 3.1B to G). Elevation of the right atrial pressure leading to jugular venous distention can be found in heart failure (both systolic and diastolic), hypervolemia, superior vena cava syndrome, and valvular disease. The *a* wave is exaggerated in any condition in which a greater resistance to right atrial emptying occurs. Such conditions include pulmonary hypertension, tricuspid stenosis, and right ventricular hypertrophy or failure. *Cannon a waves* occur when the atrium contracts against a closed tricuspid valve, which can occur with complete heart block or any other situation involving AV dissociation. The *a* wave is absent during atrial fibrillation. With significant tricuspid regurgitation, the *v* wave becomes very prominent and may merge with the *c* wave, diminishing or eliminating the *x* descent. With tricuspid stenosis, there is impaired emptying of the right atrium, which leads to an attenuated *y* descent. In pericardial constriction and restrictive

Fig. 3.1 Normal and abnormal jugular venous pulse (JVP) tracings. (A) Normal jugular pulse tracing with simultaneous electrocardiogram (ECG) and phonocardiogram. (B) Loss of the *a* wave in atrial fibrillation. (C) Large *a* wave in tricuspid stenosis. (D) Large *c-v* wave in tricuspid regurgitation. (E) Prominent *x* and *y* descents in constrictive pericarditis. (F) Prominent *x* descent and diminutive *y* descent in pericardial tamponade. (G) JVP tracing and simultaneous ECG during complete heart block demonstrates cannon *a* waves occurring when the atrium contracts against a closed tricuspid valve during ventricular systole. *P*, *P* waves correlating with atrial contraction; *S*₁ to *S*₄, heart sounds.

cardiomyopathy, the *y* descent occurs rapidly and deeply, and the *x* descent may also become more prominent, leading to a waveform with a w-shaped appearance. With pericardial tamponade, the *x* descent becomes very prominent while the *y* descent is diminished or absent.

Examination of Arterial Pressure and Pulse

Arterial blood pressure is measured noninvasively with the use of a sphygmomanometer. Before the blood pressure is taken, the patient ideally should be relaxed, allowed to rest for 5 to 10 minutes in a quiet room, and seated or lying comfortably. The cuff is typically applied

Fig. 3.2 Normal and abnormal carotid arterial pulse contours. (A) Normal arterial pulse with simultaneous electrocardiogram (ECG). The dicrotic wave (*D*) occurs just after aortic valve closure. (B) Wide pulse pressure in aortic insufficiency. (C) Pulsus parvus et tardus (small amplitude with a slow upstroke) associated with aortic stenosis. (D) Bisferiens pulse with two systolic peaks, typical of hypertrophic obstructive cardiomyopathy or aortic insufficiency, especially if concomitant aortic stenosis is present. (E) Pulsus alternans, characteristic of severe left ventricular failure. (F) Paradoxical pulse (systolic pressure decrease >10 mm Hg with inspiration), most characteristic of cardiac tamponade.

to the upper arm, approximately 1 inch above the antecubital fossa. A stethoscope is then used to auscultate under the lower edge of the cuff. The cuff is rapidly inflated to approximately 30 mm Hg above the anticipated systolic pressure and then slowly deflated (at approximately 3 mm Hg/sec) while the examiner listens for the sounds produced by blood entering the previously occluded artery. These sounds are the Korotkoff sounds. The first sound is typically a very clear tapping sound that, when heard, represents the systolic pressure. As the cuff continues to deflate, the sounds will disappear; this point represents the diastolic pressure.

In normal situations, the pressure in both arms is relatively equal. If the pressure is measured in the lower extremities rather than the arms, the systolic pressure is typically 10 to 20 mm Hg higher. If the pressures in the arms are asymmetric, this may suggest atherosclerotic disease involving the aorta, aortic dissection, or obstruction of flow in the subclavian or innominate arteries. The pressure in the lower extremities can be lower than arm pressures in the setting of abdominal aortic, iliac, or femoral disease. Coarctation of the aorta

can also lead to discrepant pressures between the upper and lower extremities. Leg pressure that is more than 20 mm Hg higher than the arm pressure can be found in the patient with significant aortic regurgitation, a finding called Hill's sign. A common mistake in taking the arterial blood pressure involves using a cuff of incorrect size. Use of a small cuff on a large extremity leads to overestimation of pressure. Similarly, use of a large cuff on a smaller extremity underestimates the pressure.

Examination of the arterial pulse in a cardiovascular patient should include palpation of the carotid, radial, brachial, femoral, popliteal, posterior tibial, and dorsalis pedis pulses bilaterally. The carotid pulse most accurately reflects the central aortic pulse. One should note the rhythm, strength, contour, and symmetry of the pulses. A normal arterial pulse (Fig. 3.2A) rises rapidly to a peak in early systole, plateaus, and then falls. The descending limb of the pulse is interrupted by the incisura or dicrotic notch, which is a sharp deflection downward due to closure of the aortic valve. As the pulse moves toward the periphery, the systolic peak is higher and the dicrotic notch is later and less noticeable.

The normal pattern of the arterial pulse can be altered by a variety of cardiovascular diseases (see Fig. 3.2B to F). The amplitude of the pulse increases in conditions such as anemia, pregnancy, thyrotoxicosis, and other states with high cardiac output. Aortic insufficiency, with its resultant increase in pulse pressure (difference between systolic and diastolic pressure), leads to a bounding carotid pulse often referred to as a Corrigan pulse or a water-hammer pulse. The amplitude of the pulse is diminished in low-output states such as heart failure, hypovolemia, and mitral stenosis. Tachycardia, with shorter diastolic filling times, also lowers the pulse amplitude. Aortic stenosis, when significant, leads to a delayed systolic peak and diminished carotid pulse, referred to as *pulsus parvus et tardus*. A bisferiens pulse is most perceptible on palpation of the carotid artery. It is characterized by two systolic peaks and can be found in patients with pure aortic regurgitation. The first peak is the percussion wave, which results from the rapid ejection of a large volume of blood early in systole. The second peak is the tidal wave, which is a reflected wave from the periphery. A bisferiens pulse may also be found in those with hypertrophic cardiomyopathy, in which the initial rapid upstroke of the pulse is interrupted by LVOT obstruction. The reflected wave produces the second impulse. Pulsus alternans is beat-to-beat variation in the pulse and can be found in patients with severe left ventricular systolic dysfunction.

Pulsus paradoxus is an exaggeration of the normal inspiratory fall in systolic pressure. With inspiration, negative intrathoracic pressure is transmitted to the aorta, and systolic pressure typically drops by as much as 10 mm Hg. In pulsus paradoxus, this drop is greater than 10 mm Hg and can be palpable when marked (>20 mm Hg). It is characteristic in cardiac tamponade but can also be seen in constrictive pericarditis, pulmonary embolism, hypovolemic shock, pregnancy, and severe chronic obstructive lung disease.

Because peripheral vascular disease often accompanies CAD, a detailed examination of the peripheral pulses is a crucial part of the physical exam of a patient with known or suspected ischemic heart disease. In addition to the carotid, brachial, radial, femoral, popliteal, dorsalis pedis, and posterior tibial pulses, the abdominal aorta should be palpated. When the abdominal aorta is palpable below the umbilicus, the presence of an abdominal aortic aneurysm is suggested. Impaired blood flow to the lower extremities can cause claudication, a cramping pain located in the buttocks, thigh, calf, or foot, depending on the location of disease. With significant stenosis in the peripheral vasculature, the distal pulses may be significantly reduced or absent. Blood flow in a stenotic artery may be turbulent, creating an audible bruit. With normal aging, the peripheral arteries become less compliant and this change may obscure abnormal findings.

Examination of the Precordium

A complete cardiovascular examination should always include careful inspection and palpation of the chest. Abnormalities of the chest wall including skin findings should be observed. The presence of pectus excavatum is associated with Marfan syndrome and mitral valve prolapse. Pectus carinatum can also be found in patients with Marfan syndrome. Kyphoscoliosis can lead to right-sided heart failure and secondary pulmonary hypertension. One should also assess for visible pulsations, in particular in the regions of the aorta (second right intercostal space and suprasternal notch), pulmonary artery (third left intercostal space), right ventricle (left parasternal region), and left ventricle (fourth to fifth intercostal space at the left midclavicular line). Prominent pulsations in these areas suggest enlargement of these vessels or chambers. Retraction of the left parasternal area can be observed in patients with severe left ventricular hypertrophy, whereas systolic retraction at the apex or in the left axilla (Broadbent sign) is more characteristic of constrictive pericarditis.

Palpation of the precordium is best performed when the patient, with chest exposed, is positioned supine or in a left lateral position with the examiner located on the right side of the patient. The examiner should then place the right hand over the lower left chest wall with fingertips over the region of the cardiac apex and the palm over the region of the right ventricle. The right ventricle itself is typically best palpated in the subxiphoid region with the tip of the index finger. In those patients who have chronic obstructive lung disease, are obese, or are very muscular, the normal cardiac pulsations may not be palpable. In addition, chest wall deformities may make pulsations difficult or impossible to palpate. The normal apical cardiac impulse is a brief and discrete (1 cm in diameter) pulsation located in the fourth to fifth intercostal space along the left midclavicular line. In a patient with a normal heart, this represents the point of maximal impulse (PMI). If the heart cannot be palpated with the patient supine, a left lateral position should be tried. If the left ventricle is enlarged for any reason, the PMI will typically be displaced laterally. With volume overload states such as aortic insufficiency, the left ventricle dilates, resulting in a brisk apical impulse that is increased in amplitude. With pressure overload, as in long-standing hypertension and aortic stenosis, ventricular enlargement is a result of hypertrophy, and the apical impulse is sustained. Often, it is accompanied by a palpable S_4 gallop. Patients with hypertrophic cardiomyopathy can have double or triple apical impulses. Those with apical aneurysm may have an apical impulse that is larger and dyskinetic.

The right ventricle is usually not palpable. However, in those with right ventricular dilation or hypertrophy, which can be related to severe lung disease, pulmonary hypertension, or congenital heart disease, an impulse may be palpated in the left parasternal region. In some cases of severe emphysema, when the distance between the chest wall and right ventricle is increased, the right ventricle is better palpated in the subxiphoid region. With severe pulmonary hypertension, the pulmonary artery may produce a palpable impulse in the second to third intercostal space to the left of the sternum. This may be accompanied by a palpable right ventricle or a palpable pulmonic component of the second heart sound (S_2). An aneurysm of the ascending aorta or arch may result in a palpable pulsation in the suprasternal notch. Thrills are vibratory sensations best palpated with the fingertips; they are manifestations of harsh murmurs caused by such problems as aortic stenosis, hypertrophic cardiomyopathy, and septal defects.

Auscultation Techniques

Auscultation of the heart is accomplished by use of a stethoscope with dual chest pieces. The diaphragm is ideal for high-frequency sounds, whereas the bell aids in auscultation of low-frequency sounds. When one is listening for low-frequency tones, the bell should be placed gently on the skin with minimal pressure applied. If the bell is applied more firmly, the skin will stretch and higher-frequency sounds will be heard (as when using the diaphragm). Auscultation should ideally be performed in a quiet setting with the patient's chest exposed and the examiner best positioned to the right of the patient. Four major areas of auscultation are evaluated, starting at the apex and moving toward the base of the heart. The mitral valve is best heard at the apex or location of the PMI. Tricuspid valve events are appreciated in or around the left fourth intercostal space adjacent to the sternum. The pulmonary valve is best evaluated in the second left intercostal space. The aortic valve is assessed in the second right intercostal space. These areas should be evaluated from apex to base using the diaphragm and then evaluated again with the bell. Auscultation of the back, the axillae, the right side of the chest, and the supraclavicular areas should also be done. Having the patient perform maneuvers such as leaning forward,

exhaling, standing, squatting, and performing a Valsalva maneuver may help to accentuate certain heart sounds (Table 3.4).

Normal Heart Sounds

All heart sounds should be described according to their quality, intensity, and frequency. There are two primary heart sounds heard during auscultation: S_1 and S_2 . These are high-frequency sounds caused by closure of the valves. S_1 occurs with the onset of ventricular systole and is caused by closure of the mitral and tricuspid valves. S_2 is caused by closure of the aortic and pulmonic valves and marks the beginning of ventricular diastole. All other heart sounds are timed based on these two sounds.

S_1 has two components, the first of which (M_1) is usually louder, heard best at the apex, and caused by closure of the mitral valve. The second component (T_1), which is softer and thought to be related to closure of the tricuspid valve, is heard best at the lower left sternal border. Although there can be two components, S_1 is typically heard as a single sound. S_2 also has two components, which typically can be easily distinguished. A_2 , the component caused by closure of the aortic valve, is usually louder and heard earlier and is best heard at the right upper

sternal border. P_2 , caused by closure of the pulmonic valve, is recognized best over the left second intercostal space. With expiration, a normal S_2 is perceived as a single sound. With inspiration, however, venous return to the right heart is augmented, and the increased capacitance of the pulmonary vascular bed results in a delay in pulmonic valve closure. A slight decline in pulmonary venous return to the left ventricle leads to earlier aortic valve closure. Therefore, physiologic splitting of S_2 , with A_2 preceding P_2 during inspiration, is a normal finding.

Additional heart sounds can at times be heard in normal individuals. A third heart sound can sometimes be heard in healthy children and young adults. This is referred to as a physiologic S_3 , which is rarely heard after the age of 40 years in a normal individual. A fourth heart sound is caused by forceful atrial contraction into a noncompliant ventricle; it is rarely audible in normal young patients but is relatively common in older individuals.

Murmurs are auditory vibrations generated by high flow across a normal valve or normal flow across an abnormal valve or structure. Murmurs that occur early in systole and are soft and brief in duration are not typically pathologic and are termed *innocent murmurs*. These usually are caused by flow across normal left ventricular or right ventricular outflow tracts and are found in children and young adults. Some systolic murmurs may be associated with high-flow states such as fever, anemia, thyroid disease, and pregnancy and are not innocent, although they are not typically associated with structural heart disease. They are called *physiologic murmurs* because of their association with altered physiologic states. All diastolic murmurs are pathologic.

Abnormal Heart Sounds

Abnormalities in S_1 and S_2 are related to either intensity (Table 3.5) or respiratory splitting (Table 3.6). S_1 is accentuated with tachycardia and with short PR intervals, whereas it is softer in the setting of a long PR interval. S_1 varies in intensity if the relationship between atrial and ventricular systole varies. In those patients with atrial fibrillation, atrial filling and emptying is not consistent because of the variable HR leading to beat-to-beat changes in the intensity of S_1 . This also can occur with heart block or AV dissociation. In early mitral stenosis, S_1 is often accentuated, but with severe stenosis, there is decreased leaflet excursion and S_1 is diminished in intensity or altogether absent (Figs. 3.3 and 3.4). As previously mentioned, splitting of S_1 is not frequently heard. However, it is more apparent in conditions that delay closure of the tricuspid valve, including right bundle branch block and Ebstein's anomaly (Audio Clip 3.1, Ebstein Abnormalities).

TABLE 3.4 Effects of Physiologic Maneuvers on Auscultatory Events

Maneuver	Major Physiologic Effects	Useful Auscultatory Changes
Respiration	↑ Venous return with inspiration	↑ Right heart murmurs and gallops with inspiration; splitting of S_2 (see Fig. 3.3)
Valsalva (initial ↑ BP, phase I; followed by ↓ BP, phase II)	↓ BP, ↓ venous return, ↓ LV size (phase II)	↑ HCM ↓ AS, MR MVP click earlier in systole; murmur prolongs
Standing	↓ Venous return ↓ LV size	↑ HCM ↓ AS, MR MVP click earlier in systole; murmur prolongs
Squatting	↑ Venous return ↑ Systemic vascular resistance ↑ LV size	↑ AS, MR, AI ↓ HCM MVP click delayed; murmur shortens
Isometric exercise (e.g., handgrip)	↑ Arterial pressure ↑ Cardiac output	↑ Gallops ↑ MR, AI, MS ↓ AS, HCM
Post PVC or prolonged R-R interval	↑ Ventricular filling	↑ AS
Amyl nitrate	↑ Contractility ↓ Arterial pressure ↑ Cardiac output ↓ LV size	Little change in MR ↑ HCM, AS, MS ↓ AI, MR, Austin Flint murmur MVP click earlier in systole; murmur prolongs
Phenylephrine	↑ Arterial pressure ↑ Cardiac output ↓ LV size	↑ MR, AI ↓ AS, HCM MVP click delayed; murmur shortens

↑, Increased intensity; ↓, decreased intensity;

AI, aortic insufficiency; AS, aortic stenosis; BP, blood pressure; HCM, hypertrophic cardiomyopathy; LV, left ventricle; MR, mitral regurgitation; MS, mitral stenosis; MVP, mitral valve prolapse; PVC, premature ventricular contraction; R-R, interval between the R waves on an electrocardiogram.

TABLE 3.5 Abnormal Intensity of Heart Sounds

	S_1	A_2	P_2
Loud	Short PR interval Mitral stenosis with pliable valve	Systemic hypertension Aortic dilation Coarctation of the aorta	Pulmonary hypertension Thin chest wall
Soft	Long PR interval Mitral regurgitation Poor left ventricular function Mitral stenosis with rigid valve Thick chest wall	Calcific aortic stenosis Aortic regurgitation	Valvular or subvalvular pulmonic stenosis
Varying	Atrial fibrillation Heart block	—	—

A_2 , Component of second heart sound caused by closure of aortic valve; P_2 , component of second heart sound caused by closure of pulmonic valve; S_1 , first heart sound.

S₂ can be accentuated in the presence of hypertension, when the aortic component will be louder, or in pulmonary hypertension, when the pulmonic component will be enhanced. In the setting of severe aortic or pulmonic stenosis, leaflet excursion of the respective valves is reduced and the intensity of S₂ is significantly diminished. It may become absent altogether if the accompanying murmur obscures what remains of S₂.

There are several patterns of abnormal splitting of S₂. S₂ can remain single throughout respiration if either A₂ or P₂ is not present or if they occur simultaneously. A₂ can be absent, as previously mentioned, with severe aortic stenosis. P₂ can be absent with a number of congenital abnormalities of the pulmonic valve. Splitting may be persistent throughout the respiratory cycle if A₂ occurs early or if P₂ is delayed, as in the presence of right bundle branch block. In that case, splitting is always present but the interval between A₂ and P₂ varies somewhat. In fixed splitting, the interval between A₂ and P₂ is consistently wide and unaffected by respiration. This finding is observed in the presence of an ostium secundum atrial septal defect or right ventricular failure. Paradoxical splitting of S₂ occurs when P₂ precedes A₂. This leads to splitting with expiration and a single S₂ with inspiration. It is commonly found in situations of delayed electrical activation of the left ventricle, as in patients with left bundle branch block or right ventricular pacing. It can also be seen with prolonged mechanical contraction of the left ventricle, as in patients with aortic stenosis or hypertrophic cardiomyopathy.

The third heart sound, S₃, is a low-pitched sound heard best at the apex in mid diastole. Because it is low pitched, it is best recognized with use of the bell on the stethoscope. As stated previously, S₃ can be physiologic in children but is pathologic in older individuals and often associated with underlying cardiac disease. An S₃ occurs during the rapid filling phase of diastole and is thought to indicate a sudden limitation of the expansion of the left ventricle. This can be seen in cases of volume overload or tachycardia. Maneuvers that increase venous return accentuate an S₃, whereas those that reduce venous return diminish the intensity. The fourth heart sound, S₄, is also a low-frequency sound, but in contrast to S₃, it is heard in late diastole, just before S₁. The S₄ gallop occurs as a result of active ejection of blood into a noncompliant left ventricle. Therefore, when atrial contraction is absent, such as in atrial fibrillation, an S₄ cannot be heard. This heart sound is also best recognized with the use of a bell at the apex. It can be heard in patients with left ventricular hypertrophy, acute myocardial infarction,

or hyperdynamic left ventricle. At times, an S₃ and an S₄ can be heard in the same patient. In tachycardic states, the two sounds can fuse in mid diastole to form a summation gallop.

S₃ and S₄ gallops are heard in mid diastole and late diastole, respectively. There are other abnormal sounds that can be heard during systole and early diastole. *Ejection sounds* are typically heard in early systole and involve the aortic and pulmonic valves. These are high-frequency sounds that can be heard with a diaphragm shortly after S₁.

Single S ₂	Widely Split S ₂ With Normal Respiratory Variation	Fixed Split S ₂	Paradoxically Split S ₂
Pulmonic stenosis	Right bundle branch block	Atrial septal defect	Left bundle branch block
Systemic hypertension	Left ventricular pacing	Severe right ventricular dysfunction	Right ventricular pacing
Coronary artery disease	Pulmonary embolism	Angina, myocardial infarction	Angina, myocardial infarction
Any condition that can lead to paradoxical splitting of S ₂	Idiopathic dilation of the pulmonary artery	Aortic stenosis	Hypertrophic cardiomyopathy
	Mitral regurgitation	Aortic regurgitation	
	Ventricular septal defect		

S₂, Second heart sound.

Fig. 3.3 Abnormal heart sounds can be related to abnormal intensity, abnormal presence of a gallop rhythm, or abnormal splitting of the second heart sound (S₂) with respiration. A₂, Component of S₂ caused by closure of aortic valve; ECG, electrocardiogram; P₂, component of S₂ caused by closure of pulmonic valve.

Fig. 3.4 The relationship of extra heart sounds to the normal first (S_1) and second (S_2) heart sounds. S_1 is composed of the mitral (M_1) and tricuspid (T_1) closing sounds, although it is frequently perceived as a single sound. S_2 is composed of the aortic (A_2) and pulmonic (P_2) closing sounds, which are usually easily distinguished. A fourth heart sound (S_4) is soft and low pitched and precedes S_1 . A pulmonic or aortic ejection sound (ES) occurs shortly after S_1 . The systolic click (C) of mitral valve prolapse may be heard in mid systole or late systole. The opening snap (OS) of mitral stenosis is high pitched and occurs shortly after S_2 . A tumor plop or pericardial knock occurs at the same time and can be confused with an OS or an S_3 , which is lower in pitch and occurs slightly later.

Ejection sounds are caused by the opening of abnormal valves to their full extent, such as with a bicuspid aortic valve or congenital pulmonic stenosis. They are frequently followed by a typical ejection murmur of aortic or pulmonic stenosis. Ejection sounds can also be heard with systemic or pulmonary hypertension, in which case the exact mechanism is not clear.

Midsystolic to late systolic sounds are called *ejection clicks*. They are most commonly associated with mitral valve prolapse. They are also high pitched and easily auscultated with the diaphragm. The click occurs because of maximal displacement of the prolapsed mitral leaflet into the left atrium and resultant tensing of chordae and redundant leaflets (Audio Clip 3.2, Mitral Valve Prolapse). The click is usually followed by a typical murmur of mitral regurgitation. Any maneuver that decreases venous return will cause the click to occur earlier in systole, whereas increasing ventricular volume will delay the click (see Table 3.4).

The opening of abnormal mitral or tricuspid valves can be heard in early diastole. This *opening snap* is most frequently associated with rheumatic mitral stenosis. It is heard if the valve leaflets remain pliable and is generated when the leaflets abruptly dome during diastole. The frequency, intensity, and timing of the click have diagnostic significance. For example, the shorter the interval between S_2 and the opening snap, the more severe the degree of mitral stenosis, because this is a reflection of higher left atrial pressure. The *pericardial knock* of constrictive pericarditis and *tumor plop* generated by an atrial myxoma also occur in early diastole and may be confused with an opening snap. They can typically be differentiated from an S_3 gallop because they are higher-frequency sounds.

Murmurs

Murmurs are a series of auditory vibrations generated by either abnormal blood flow across a normal cardiac structure or normal flow across an abnormal cardiac structure, both of which result in turbulent flow.

TABLE 3.7 Grading System for Intensity of Murmurs

Grade	Description
1	Barely audible murmur
2	Murmur of medium intensity
3	Loud murmur, no thrill
4	Loud murmur with thrill
5	Very loud murmur; stethoscope must be on the chest to hear it; may be heard posteriorly
6	Murmur audible with stethoscope off the chest

These sounds are longer than individual heart sounds and should be described on the basis of their location, frequency, intensity, quality, duration, shape, and timing in the cardiac cycle. The intensity of a given murmur is typically graded on a scale of 1 to 6 (Table 3.7). Murmurs of grade 4 or higher are associated with palpable thrills. The intensity or loudness of a murmur does not necessarily correlate with the severity of disease. For example, a murmur can be quite harsh when it is associated with a moderate degree of aortic stenosis. If stenosis is critical, however, the flow across the valve is diminished and the murmur becomes rather quiet. In the presence of a large atrial septal defect, flow is almost silent, whereas flow through a small ventricular septal defect is typically associated with a loud murmur.

The frequency of a murmur can be high or low; higher-frequency murmurs are more correlated with high velocity of flow at the site of turbulence. It is also important to notice the configuration or shape of a murmur, such as crescendo, crescendo-decrescendo, decrescendo, or plateau (Fig. 3.5). The quality of a murmur (e.g., harsh, blowing, rumbling) and the pattern of radiation are also helpful in diagnosis. Physical maneuvers can sometimes help clarify the nature of a particular murmur (see Table 3.4).

Murmurs can be divided into three different categories (Table 3.8). Systolic murmurs begin with or after S_1 and end with or before S_2 . Diastolic murmurs begin with or after S_2 and end with or before S_1 . Continuous murmurs begin in systole and continue through diastole. Murmurs can result from abnormalities on the left or right side of the heart or in the great vessels. Right-sided murmurs become louder with inspiration because of increased venous return. This can help differentiate them from left-sided murmurs, which are unaffected by respiration.

Systolic murmurs should be further differentiated based on timing (i.e., early systolic, midsystolic, late systolic, and holosystolic murmurs). Early systolic murmurs begin with S_1 , are decrescendo, and end typically before mid systole. Ventricular septal defects and acute mitral regurgitation may lead to early systolic murmurs. Midsystolic murmurs begin after S_1 and end before S_2 , often in a crescendo-decrescendo shape. They are typically caused by obstruction to left ventricular outflow, accelerated flow through the aortic or pulmonic valve, or enlargement of the aortic root or pulmonary trunk. Aortic stenosis, when less than severe in degree, causes a midsystolic murmur that may be harsh and may radiate to the carotids. Pulmonic stenosis leads to a similar murmur that does not radiate to the carotid arteries but may change with inspiration. The murmur of hypertrophic cardiomyopathy may be mistaken for aortic stenosis; however, it does not radiate to the carotids and becomes exaggerated with diminished venous return. Innocent or benign murmurs may also occur as a result of aortic valve sclerosis, vibrations of a left ventricular false tendon, or vibration of normal pulmonary leaflets. They are generally less

Fig. 3.5 Abnormal sounds and murmurs associated with valvular dysfunction displayed simultaneously with left atrial (LA), left ventricular (LV), and aortic pressure tracings. The shaded areas represent pressure gradients across the aortic valve during systole or across mitral valve during diastole; they are characteristic of aortic stenosis and mitral stenosis, respectively. AVO, Aortic valve opening; E, ejection click of the aortic valve; MVO, mitral valve opening; OS, opening snap of the mitral valve; S_1 , first heart sound; S_2 , second heart sound.

TABLE 3.8 Classification of Heart Murmurs

Class	Description	Characteristic Lesions
Systolic		
Ejection	Begins in early systole; may extend to mid or late systole Crescendo-decrescendo pattern Often harsh in quality Begins after S_1 and ends before S_2	Valvular, supra- and subvalvular aortic stenoses Hypertrophic cardiomyopathy Pulmonic stenosis Aortic or pulmonary artery dilation Malformed but nonobstructive aortic valve \uparrow Transvalvular flow (e.g., aortic regurgitation, hyperkinetic states, atrial septal defect, physiologic flow murmur)
Holosystolic	Extends throughout systole ^a Relatively uniform in intensity	Mitral regurgitation Tricuspid regurgitation Ventricular septal defect
Late	Variable onset and duration, often preceded by a nonejection click	Mitral valve prolapse
Diastolic		
Early	Begins with A_2 or P_2 Decrescendo pattern with variable duration Often high pitched, blowing	Aortic regurgitation Pulmonic regurgitation
Mid	Begins after S_2 , often after an opening snap Low-pitched <i>rumble</i> heard best with bell of stethoscope Louder with exercise and left lateral position Loudest in early diastole	Mitral stenosis Tricuspid stenosis \uparrow Flow across atrioventricular valves (e.g., mitral regurgitation, tricuspid regurgitation, atrial septal defect)
Late	Presystolic accentuation of mid-diastolic murmur	Mitral stenosis Tricuspid stenosis
Continuous		
	Systolic and diastolic components "Machinery murmurs"	Patent ductus arteriosus Coronary atrioventricular fistula Ruptured sinus of Valsalva aneurysm into right atrium or ventricle Mammary soufflé Venous hum

A_2 , Component of S_2 caused by closure of aortic valve; P_2 , component of S_2 caused by closure of pulmonic valve; S_1 , first heart sound; S_2 , second heart sound.

^aEncompasses both S_1 and S_2 .

harsh and shorter in duration. High-flow states such as those found in patients with fever, during pregnancy, or with anemia may also lead to midsystolic “flow” murmurs.

Holosystolic murmurs begin with S_1 and end with S_2 ; the classic examples are the murmurs associated with mitral regurgitation and tricuspid regurgitation. They may also occur with ventricular septal defects and patent ductus arteriosus. Late systolic murmurs begin in mid to late systole and end with S_2 . They can be characteristic of more severe aortic stenosis and are also typical of murmurs associated with mitral valve prolapse.

Diastolic murmurs are also classified by timing (i.e., early diastolic, mid diastolic, and late diastolic). Early diastolic murmurs begin with S_2 and can result from aortic or pulmonic regurgitation; they are usually decrescendo in shape. Shorter and quieter murmurs typically represent an acute process or mild regurgitation, whereas longer-lasting and louder murmurs are likely due to more severe regurgitation. Mid-diastolic murmurs begin after S_2 and are usually caused by mitral or tricuspid stenosis. They are low pitched and are often referred to as *diastolic rumbles*. Because they are of low frequency, they are better auscultated with the bell of the stethoscope. Similar murmurs can be heard with obstructing atrial myxomas. Severe chronic aortic insufficiency can lead to premature closure of the mitral valve, causing a mid-diastolic rumble called an Austin-Flint murmur. Late diastolic murmurs occur immediately before S_1 and reflect presystolic accentuation of the mid-diastolic murmurs resulting from augmented mitral or tricuspid flow after atrial contraction.

Continuous murmurs begin with S_1 and last though part or all of diastole. They are generated by continuous flow from a vessel or chamber with high pressure into a vessel or chamber with lower pressure. They are referred to as *machinery murmurs* and are caused by aortopulmonary connections such as a patent ductus arteriosus, AV malformations, or disturbances of flow in arteries or veins.

Other Cardiac Sounds

Pericardial rubs occur in the setting of pericarditis and are coarse, scratching sounds similar to rubbing leather. They are typically heard best at the left sternal border with the patient leaning forward and holding the breath at end-expiration. A classic pericardial rub has three components: atrial systole, ventricular systole, and ventricular diastole. One might also hear a pleural rub caused by localized irritation of surrounding pleura. Continuous venous murmurs, or *venous hums*, are almost always present in children. They can be heard in adults during pregnancy, in the setting of anemia, or with thyrotoxicosis. They are heard best at the base of the neck with the patient’s head turned to the opposite direction.

Prosthetic Heart Sounds

Prosthetic heart valves produce characteristic findings on auscultation. Bioprosthetic valves produce sounds that are similar to those of native heart valves, but they are typically smaller than the valves that they replace and therefore have an associated murmur. Mechanical valves have crisp, high-pitched sounds related to valve opening and closure. In most modern valves such as the St. Jude valve, which is a bileaflet mechanical valve, the closure sound is louder than the opening sound.

An ejection murmur is common. If there is a change in murmur or in the intensity of the mechanical valve closure sound, dysfunction of the valve should be suspected.

For a deeper discussion of this topic, please see Chapter 45, “Approach to the Patient with Possible Cardiovascular Disease,” in *Goldman-Cecil Medicine*, 26th Edition.

Diagnostic Tests and Procedures in the Patient With Cardiovascular Disease

Esseim Sharma, Alan R. Morrison

ELECTROCARDIOGRAPHY

The electrocardiogram (ECG) is one of the most basic yet powerful diagnostic tools in cardiovascular medicine. It is critical in the investigation of cardiac arrhythmias, myocardial infarction, and pericardial disease, and may provide additional insight into a variety of other cardiac and noncardiac conditions.

The ECG is a simple and noninvasive procedure that makes use of electrodes placed on the skin of the chest at specific locations in order to measure the electrical activity of the heart. The output is a scroll of wave forms represented as a temporal sequence of deflections on the ECG (Fig. 4.1). The horizontal axis of the graph paper represents time, and at a standard paper speed of 25 mm/second, which is also known as the sweep speed, each small box (1 mm) represents 0.04 seconds, and each large box (5 mm) represents 0.20 seconds. The vertical axis represents voltage or amplitude (1 mm = 0.1 mV). Because the standard ECG demonstrates a 10-second window of time, the heart rate can be calculated by simply counting the number of QRS complexes and multiplying by 6. Alternatively, the heart rate can be estimated by dividing the number of large boxes between complexes (i.e., R-R interval) into 300.

Lead Positioning

The standard ECG consists of 12 leads: six limb leads (I, II, III, aVR, aVL, and aVF) and six chest or precordial leads (V_1 to V_6) (Fig. 4.2). The limb leads view the electrical activity of the heart in the vertical plane, while the precordial leads view the horizontal plane. The electrical activity recorded in each lead represents the direction and magnitude (i.e., vector) of the electrical force as seen from that lead position. Electrical activity directed toward a particular lead is represented as an upward (positive) deflection, and electrical activity directed away from a particular lead is represented as a downward (negative) deflection. Accurate lead placement is essential to reliable interpretation of the ECG.

The limb leads consist of bipolar leads (I, II, and III) and unipolar or augmented leads (leads aVR, aVL, and aVF). The bipolar leads represent electrical forces between the two leads, while augmented leads represent the electrical forces towards the lead. Lead I measures electrical activity between the right and left arms (left arm positive), lead II between the right arm and left leg (left leg positive), and lead III between the left arm and left leg (left leg positive). A vector perpendicular to the limb leads would be isoelectric. In aVR, aVL, and aVF, the vector is positive if electrical forces are directed toward the right arm for aVR, left arm for aVL, and left leg for aVF. Taken together, the six limb leads form a frontal plane of 30-degree arc intervals (Fig. 4.3).

The six standard precordial leads (V_1 to V_6) are attached to the anterior chest wall and are also unipolar leads. Lead placement

should be as follows: V_1 : fourth intercostal space, right sternal border; V_2 : fourth intercostal space, left sternal border; V_3 : midway between V_2 and V_4 ; V_4 : fifth intercostal space, left midclavicular line; V_5 : level with V_4 , left anterior axillary line; V_6 : level with V_4 , left midaxillary line.

Nonstandard lead configurations can be used in specific clinical scenarios. In patients where there is concern for right ventricular infarction, standard V_1 and V_2 leads are switched, and V_{3R} to V_{6R} are placed at locations on the right chest wall in a mirror image of the standard left-sided chest leads. Posterior leads may be used to increase the sensitivity for diagnosing lateral and posterior wall infarction or ischemia—areas that are often deemed to be *electrically silent* on traditional 12-lead ECGs. To do this, six additional leads are placed in the fifth intercostal space continuing posteriorly from the position of V_6 . Shifting the right precordial leads (V_1 - V_3) superiorly to the second intercostal space can be used to unmask Brugada syndrome.

Electrocardiographic Intervals

In the normal heart, the electrical impulse originates in the sinoatrial (SA) node, located superiorly in the right atrium, and is conducted through the atria. Given that depolarization of the SA node is too weak to be detected on the surface ECG, the first, low-amplitude deflection on the surface ECG represents a summation atrial vector and is called the *P wave*. The P wave has an electrical axis that moves in sum toward the AV node, generally downward and to the left. The interval between the onset of the P wave and the next rapid deflection (QRS complex) is known as the *PR interval*. It primarily represents the time taken for the impulse to travel through the atrioventricular (AV) node. The normal PR segment ranges from 0.12 to 0.20 seconds. A PR interval greater than 0.20 seconds defines first-degree AV nodal block.

After the wave of depolarization has moved through the AV node, the ventricular myocardium is depolarized in a sequence of four phases. The interventricular septum depolarizes from left to right. This phase is followed by depolarization of the right ventricle and inferior wall of the left ventricle, then the apex and central portions of the left ventricle, and finally the base and the posterior wall of the left ventricle. Ventricular depolarization results in a high-amplitude complex on the surface ECG known as the *QRS complex*. The first downward deflection of this complex is the Q wave, the first upward deflection is the R wave, and the subsequent downward deflection is the S wave. In some individuals, a second upward deflection may occur after the S wave, and it is called *R prime* (R'). Normal duration of the QRS complex is less than 0.10 second. Complexes longer than 0.12 seconds in duration are usually secondary to some form of interventricular conduction delay, including right or left bundle branch block.

The isoelectric segment after the QRS complex is the ST segment, which represents a brief period during which relatively little electrical activity occurs in the heart. The junction between the end of the QRS complex and the beginning of the ST segment is the J point. The upward deflection after the ST segment is the T wave, which represents ventricular repolarization. The QT interval, which reflects the duration and transmural gradient of ventricular depolarization and repolarization, is measured from the onset of the QRS complex to the end of the T wave. The observed QT (QT_{ob}) interval varies with heart rate, but for rates between 60 and 100 beats/minute, the normal QT interval ranges from 0.35 to 0.44 seconds. For heart rates outside this range, the QT interval can be corrected (QT_c) using the following formula (with R-R interval in seconds):

$$QT_c = \frac{QT_{ob}}{\sqrt{R - R \text{ interval}}}$$

Importantly, patients with interventricular conduction delay due to the presence of bundle branch blocks or pacing will have prolonged QT intervals due to the dispersion of ventricular repolarization, which

Fig. 4.1 Normal electrocardiographic complex with labeling of waves and intervals.

is not necessarily pathologic. Adjustment of the QT interval in these cases remains controversial.

The TP segment is the isoelectric interval that follows the end of the T wave and lasts till the beginning of the P wave. Because it represents an electrically silent portion of the ECG, the TP segment can be used to measure excursions of other segments, such as the ST or PR segments, to determine the presence of elevation or depression. In some individuals, the T wave may be closely followed by a U wave (0.5 mm deflection, not shown in Fig. 4.1), which can be seen for a variety of reasons, including hypokalemia and central nervous system abnormalities.

Axis

The cardiac axis refers to the overall direction of myocardial depolarization measured in the vertical plane and provides clinically useful information. Though the axis can be calculated for any of the ECG segments mentioned above, the mean QRS axis is the most clinically useful.

Fig. 4.3 illustrates the axial reference system, a reconstruction of the Einthoven triangle, and the polarity of each of the six limb leads of the standard ECG. The normal QRS axis ranges from -30 to $+90$ degrees. An axis more negative than -30 defines left axis deviation, and an axis greater than $+90$ defines right axis deviation. Extreme axis deviation is present when the mean QRS axis is between -90 and $+180$ degrees. A positive QRS complex in leads I and aVF suggests a normal QRS axis between 0 and 90 degrees.

While the precordial leads are not useful in determining cardiac axis, they are helpful in determining the direction of cardiac activation in the horizontal plane. Normally, a small R wave occurs in lead V_1 , reflecting septal depolarization, along with a deep S wave, reflecting predominantly left ventricular activation. From V_1 to V_6 , the R wave becomes larger (and the S wave smaller) because the predominant forces directed at these leads originate from the left ventricle. The transition from a predominant S wave to a predominant R wave usually occurs between leads V_3 and V_4 . A delay in this transition is termed “poor R wave progression” and can be seen in patients with prior anterior myocardial infarctions, among other conditions. In patients with ventricular arrhythmias, the pattern of S and R waves in the precordial leads is essential in localizing the foci of the arrhythmia.

Fig. 4.2 Normal 12-lead electrocardiogram.

Fig. 4.3 Hexaxial reference figure for frontal plane axis determination, indicating values for abnormal left and right QRS axis deviations.

ABNORMAL ELECTROCARDIOGRAPHIC PATTERNS

Chamber Abnormalities and Ventricular Hypertrophy

Because of the downward and leftward vector direction, the P wave is normally upright in leads I, II, and aVF, inverted in aVR, and biphasic in V₁. Left atrial abnormality (i.e., enlargement, hypertrophy, or increased wall stress) is characterized by a wide P wave in lead II (0.12 second) and a deeply inverted terminal component in lead V₁ (able to contain one small box or 1 mm²). Right atrial abnormality is identified when the P waves in the limb leads are tall and peaked and at least 2.5 mm high and (able to contain two stacked small boxes).

Left ventricular hypertrophy may result in increased QRS voltage, slight widening of the QRS complex, late intrinsicoid deflection, left axis deviation, and abnormalities of the ST-T segments (Fig. 4.4A). Multiple criteria with various degrees of sensitivity and specificity for detecting left ventricular hypertrophy are available. The most frequently used criteria are given in Table 4.1.

Right ventricular hypertrophy is characterized by tall R waves in leads V₁ through V₃; deep S waves in leads I, aVL, V₅, and V₆; and right axis deviation (see Fig. 4.4B). The R wave is greater than 7 mm and the R-S ratio is greater than 1 in lead V₁. Other causes of a tall R-wave in V₁ must be excluded, including posterior wall myocardial infarction,

Fig. 4.4 (A) Left ventricular hypertrophy as seen on an electrocardiographic recording. Characteristic findings include increased QRS voltage in precordial leads (i.e., deep S in lead V₂ and tall R in lead V₅) and downsloping ST depression and T-wave inversion in lateral precordial leads (i.e., strain pattern) and leftward axis. (B) Right ventricular hypertrophy with tall R wave in right precordial leads, downsloping ST depression in precordial leads (i.e., RV strain), right axis deviation, and evidence of right atrial enlargement.

TABLE 4.1 Electrocardiographic Manifestations of Atrial Abnormalities and Ventricular Hypertrophy**Left Atrial Abnormality**

P-wave duration ≥ 0.12 second
 Notched, slurred P wave in leads I and II
 Biphasic P wave in lead V_1 with a wide, deep, negative terminal component

Right Atrial Abnormality

P-wave duration ≤ 0.11 second
 Tall, peaked P waves of ≥ 2.5 mm in leads II, III, and aVF

Left Ventricular Hypertrophy

Voltage criteria
 R wave in lead aVL ≥ 12 mm
 R wave in lead I ≥ 15 mm
 S wave in lead V_1 or V_2 + R wave in lead V_5 or V_6 ≥ 35 mm
 Depressed ST segments with inverted T waves in the lateral leads
 Left axis deviation
 QRS duration ≥ 0.09 second
 Left atrial enlargement

Right Ventricular Hypertrophy

Tall R waves over right precordium (R-to-S ratio in lead $V_1 > 1.0$)
 Right axis deviation
 Depressed ST segments with inverted T waves in leads V_1 to V_3
 Normal QRS duration (if no right bundle branch block)
 Right atrial enlargement

TABLE 4.2 Electrocardiographic Manifestations of Fascicular and Bundle Branch Blocks**Left Anterior Fascicular Block**

QRS duration ≤ 0.1 second
 Left axis deviation (more negative than -45 degrees)
 rS pattern in leads II, III, and aVF
 qR pattern in leads I and aVL

Right Posterior Fascicular Block

QRS duration ≤ 0.1 second
 Right axis deviation ($+90$ degrees or greater)
 qR pattern in leads II, III, and aVF
 rS pattern in leads I and aVL
 Exclusion of other causes of right axis deviation (e.g., chronic obstructive pulmonary disease, right ventricular hypertrophy)

Left Bundle Branch Block

QRS duration ≥ 0.12 second
 Broad, slurred, or notched R waves in lateral leads (I, aVL, V_5 , and V_6)
 QS or rS pattern in anterior precordium leads (V_1 and V_2)
 ST-T-wave vectors opposite to terminal QRS vectors

Right Bundle Branch Block

QRS duration ≥ 0.12 second
 Large R' wave in lead V_1 (rsR')
 Deep terminal S wave in lead V_6
 Normal septal Q waves
 Inverted T waves in leads V_1 and V_2

Wolff-Parkinson-White, right bundle branch block, muscular dystrophy, dextrocardia, and lead misplacement.

Interventricular Conduction Delays

The ventricular conduction system consists of two main branches, the right and left bundles. The left bundle further divides into the anterior and posterior fascicles. Conduction block can occur in either of the major branches or in the fascicles (Table 4.2).

Fascicular block results in a change in the sequence of ventricular activation but does not substantially prolong overall conduction time. Left anterior fascicular block abnormality is identified when extreme left axis deviation occurs (i.e., more negative than -45 degrees), when the R wave is greater than the Q wave in leads I and aVL, and when the S wave is greater than the R wave in leads II, III, and aVF. Left posterior fascicular block is relatively uncommon but is associated with right axis deviation (>90 degrees); small Q waves in leads II, III, and aVF; and small R waves in leads I and aVL. Fascicular blocks can be seen in conjunction with right bundle branch block (RBBB), and left or right axis deviations can indicate concurrent left anterior or posterior fascicular blocks, respectively.

Complete bundle branch blocks cause QRS prolongation greater than 120 milliseconds. A left bundle branch block (LBBB) can be indicative of underlying coronary or myocardial disease—most commonly fibrosis due to ischemic injury or hypertrophy. In LBBB, depolarization proceeds down the right bundle, across the interventricular septum from right to left, and then to the left ventricle. Characteristic electrocardiographic findings include a wide QRS complex; a broad R wave in leads I, aVL, V_5 , and V_6 ; a deep QS wave in leads V_1 and V_2 ; and ST depression and T-wave inversion opposite the terminal deflection of the QRS (Fig. 4.5A). Given the

abnormal sequence of ventricular activation and repolarization with LBBB, many ECG abnormalities, such as Q-wave myocardial infarction (MI) and left ventricular hypertrophy, are difficult to evaluate. Sgarbossa's criteria can help to identify the presence of MI in the setting of LBBB, though its sensitivity is limited. A new LBBB may be a sign of an acute myocardial infarction in the correct clinical setting (Fig. 4.6B).

With RBBB, the interventricular septum depolarizes normally from left to right, as this depolarization depends on the left bundle. Thus, the initial QRS deflection remains unchanged, and thus it is important to note that ECG abnormalities such as Q-wave MI can still be interpreted. After septal activation, the left ventricle depolarizes, followed by the right ventricle. The ECG is characterized by a wide QRS complex; a large R' wave in lead V_1 (R-S-R'); and deep S waves in leads I, aVL, and V_6 , representing delayed right ventricular activation (see Fig. 4.5B). Ventricular repolarization is still abnormal, and secondary ST and T wave changes will be present just as in LBBB. Although RBBB may be associated with underlying cardiac disease, it is quite common and may often reflect the fibrosis of aging.

Myocardial Ischemia and Infarction

Myocardial ischemia and myocardial infarction (MI) may be associated with abnormalities of the ST segment, T wave, and QRS complex. Myocardial ischemia primarily affects repolarization of the myocardium and is often associated with horizontal or downsloping ST-segment depression and T-wave inversion. These changes may be transient, such as during an anginal episode or an exercise-related stress, or they may be long-lasting in the setting of progressive angina or MI. T-wave inversion without ST-segment depression can be a nonspecific finding and must be correlated with the clinical findings

Fig. 4.5 (A) Left bundle branch block (LBBB). (B) Right bundle branch block (RBBB). Criteria for bundle branch blocks are summarized in [Table 4.2](#).

to invoke ischemia or injury. Diffuse T-wave inversions across the precordial leads are often seen in patients with acute cerebral disease, such as stroke or seizures.

ST-segment elevation of 2 mm or more in two or more contiguous leads suggests more extensive myocardial injury, and in the right clinical presentation, is often considered to be an acute MI until proven otherwise ([Fig. 4.6A](#)). Vasospastic or Prinzmetal angina may be associated with reversible ST-segment elevation without MI. ST-segment elevation may occur in other settings not related to acute ischemia or infarction. Persistent, localized ST-segment elevation in the same leads as pathologic Q waves is consistent with a ventricular aneurysm. Acute pericarditis is also associated with diffuse ST-segment elevation across multiple contiguous and noncontiguous leads but is also associated with PR depression relative to the TP interval. Diffuse J-point elevation in association with upward-coving ST segments is a normal variant common among young men and is often referred to as *early repolarization*.

A pathologic Q wave is one of the criteria used to diagnose MI. Infarcted myocardium is impaired at conducting normal electrical activity, and electrical forces are directed away from the surface electrode overlying the infarcted region, producing a Q wave on the surface ECG. A thorough understanding of contiguous leads allows for identification of each region of the myocardium relative to the surface lead, enabling the examiner to localize the area of infarction ([Table](#)

[4.3](#)). Pathologic Q waves are defined as follows: any Q wave 20 ms or greater or QS complex in leads V₂ to V₃, or a Q wave 30 ms or greater and 0.1 mV deep or greater or QS complex in leads I, II, aVL, aVF or V₄ to V₆ in any 2 leads of a contiguous lead grouping (I, aVL, V₆; V₄ to V₆; II, III, and aVF). Not all MIs result in the permanent formation of Q waves. Small R waves can return many weeks to months after an MI. Abnormal Q waves, or *pseudoinfarction* pattern, may be associated with nonischemic cardiac disease, such as ventricular preexcitation, cardiac amyloidosis, sarcoidosis, idiopathic or hypertrophic cardiomyopathy, myocarditis, and chronic lung disease.

Abnormalities of the ST Segment and T Wave

A number of drugs and metabolic abnormalities may affect the ST segment and T wave ([Fig. 4.7](#)). Hypokalemia may result in prominent U waves in the precordial leads along with prolongation of the QT interval. Hyperkalemia may result in tall, peaked T waves. Hypocalcemia typically lengthens the QT interval, whereas hypercalcemia shortens it. A commonly used cardiac medication, digoxin, often results in diffuse, scooped ST-segment depression. Cardiac pacing, LBBB, and RBBB affect ventricular repolarization and alter the ST segment and T-wave. Minor or *nonspecific* ST-segment and T-wave abnormalities may occur in many patients and have no definable cause. In these instances, the physician must determine the significance of the abnormalities based on clinical findings.

A

B

Fig. 4.6 (A) Evolutionary changes in a posteroinferior myocardial infarction (MI). Control tracing is normal. The tracing recorded 2 hours after onset of chest pain demonstrated development of early Q waves, marked ST-segment elevation, and hyperacute T waves in leads II, III, and aVF. A larger R wave, ST-segment depression, and negative T waves have developed in leads V₁ and V₂. These early changes indicate acute posteroinferior MI. The 24-hour tracing demonstrates further evolutionary changes. In leads II, III, and aVF, the Q wave is larger, the ST segments have almost returned to baseline, and the T wave has begun to invert. In leads V₁ to V₂, the duration of the R wave exceeds 0.04 seconds, the ST segment is depressed, and the T wave is upright. (In this example, electrocardiographic changes of true posterior involvement extend past lead V₂; ordinarily, only leads V₁ and V₂ may be involved.) Only minor further changes occur through the 8-day tracing. Six months later, the electrocardiographic pattern shows large Q waves, isoelectric ST segments, and inverted T waves in leads II, III, and aVF and shows large R waves, isoelectric ST segment, and upright T waves in leads V₁ and V₂, indicative of an old posteroinferior MI. (B) Electrocardiogram from a patient with an underlying left bundle branch block (LBBB) who experienced an acute anterior MI. Characteristic ST segment elevation and hyperacute T waves are seen in leads V₁ through V₆ and leads I and aVL despite the presence of the LBBB. This is not always the case, and a patient with typical symptoms, an LBBB, and no definite ischemic ST-segment elevations should be treated as if the individual is having a myocardial infarction or acute coronary syndrome.

TABLE 4.3 Electrocardiographic Localization of Myocardial Infarction

Infarct Location	Leads Depicting Primary Electrocardiographic Changes	Likely Vessel Involved ^a
Inferior	II, III, aVF	RCA
Septal	V ₁ , V ₂	LAD
Anterior	V ₃ , V ₄	LAD
Anteroseptal	V ₁ to V ₄	LAD
Extensive anterior	I, aVL, V ₁ to V ₆	LAD
Lateral	I, aVL, V ₅ to V ₆	CIRC
High lateral	I, aVL	CIRC
Posterior ^b	Prominent R in V ₁	RCA or CIRC
Right ventricular ^c	ST elevation in V ₁ ; more specifically, V ₄ R in setting of inferior infarction	RCA

CIRC, Circumflex artery; LAD, left anterior descending coronary artery; RCA, right coronary artery.

^aThis is a generalization; variations occur.

^bUsually in association with inferior or lateral infarction.

^cUsually in association with inferior infarction.

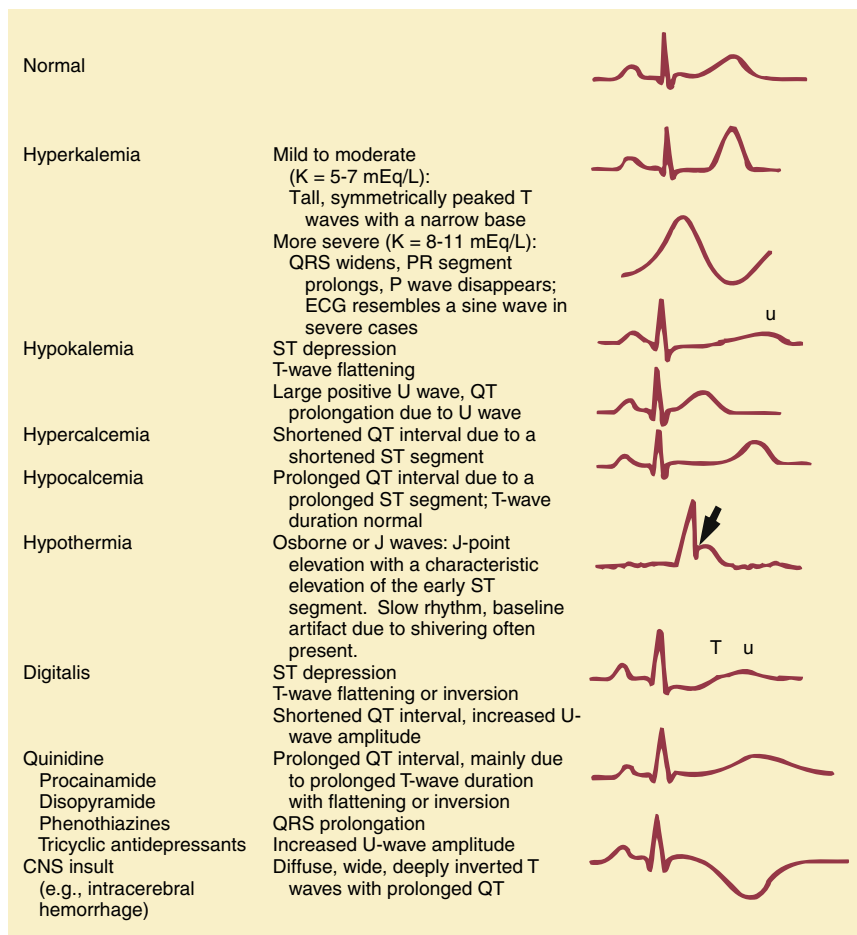

Fig. 4.7 Metabolic and drug influences on the electrocardiographic recording. CNS, Central nervous system; ECG, electrocardiogram.

AMBULATORY ELECTROCARDIOGRAPHIC RECORDING

Ambulatory ECG monitoring allows clinicians to monitor and capture the presence and frequency of cardiac arrhythmias over a specified

period of time. Multiple types of ambulatory recording modalities are available, and the decision to use one or the other largely depends on the duration of surveillance required. Determination of the surveillance duration is influenced by many factors, including the frequency of symptoms (daily, weekly, monthly, or longer), reason for the study

(i.e., quantifying arrhythmia burden vs. catching an arrhythmic event), and severity of symptoms (lightheadedness vs. stroke).

A Holter monitor collects ECG data from two or three surface leads on a recorder that the patient wears under their clothing, typically for 24 to 72 hours. The device stores all data over this period of time. Patients are asked to write their symptoms in a diary, so that symptoms can be correlated with the rhythm at that time. From these recordings, algorithms analyze and identify abnormal strips for clinician review. Holter monitors are most useful for patients with frequent, daily symptoms, or for quantifying arrhythmic burden such as frequent premature ventricular contractions. Electrocardiographic devices are more recent innovations that also provide continuous ECG recordings through small ECG sensors placed on the chest, usually over a period of two weeks, and can be used instead of Holter monitors.

For patients with more infrequent symptoms, an event recorder can be used to record data for up to a month. Like Holter monitors, surface leads are placed on the chest and connected to a recording device. Unlike Holter monitors, the device only maintains data for 30 to 60 second loops, after which it is erased. Data are only saved when algorithms identify ECG abnormalities, or when patients press a button indicating the presence of symptoms. Therefore, patients must be able to trigger the device. These data are usually uploaded to a monitoring center, where patients can be called for further questioning or counseling.

Implantable loop recorders (ILRs) are small recording devices that are implanted subcutaneously in the left parasternal chest wall. They can record symptoms for up to two years. Like event recorders, data are maintained on a loop, though for a much greater period of time (about thirty minutes). Data are stored either automatically or through a small magnetic activator that patients pass over the device. A device programmer is then used to extract the data in the office. ILRs are especially useful in patients with rare but serious symptoms, or when quantifying arrhythmic burden, such as atrial fibrillation, may be critical to informing the treatment plan.

In addition to clinician prescribed monitoring devices, there has been a recent surge in the use of personal wearable devices such as smartwatches that have the capacity to record and store single lead ECG tracings. Some of these devices may even alert patients to the presence of abnormal heart rhythms. Though the diagnostic utility of these devices is unclear at this time, clinicians are likely to encounter them at an increasing rate in practice, and abnormalities seen on these devices may be used to prompt further investigation.

CHEST RADIOGRAPHY

Chest radiography is one of the most ubiquitous and commonly performed diagnostic tests in the world. It is an integral part of the initial evaluation and work-up for patients presenting with a number of cardiovascular-related complaints, particularly chest pain, shortness of breath, and postprocedural complaints involving cardiac devices. Regardless of the clinical indication, chest radiography provides useful information regarding cardiac structures that may provide additional insight into a patient's condition.

Routinely, chest radiography is performed in the posteroanterior and lateral projections (Fig. 4.8). In the posteroanterior view, cardiac enlargement may be identified when the transverse diameter of the cardiac silhouette is greater than one half of the transverse diameter of the thorax. The heart may appear falsely enlarged when it is displaced horizontally, such as with poor inflation of the lungs or when the image is taken in an anteroposterior projection, which magnifies the heart shadow. The differential diagnosis for cardiac silhouette enlargement

on chest radiography includes cardiomegaly, pericardial effusion, prominent epicardial fat pad, or an anterior mediastinal mass.

Left atrial enlargement is suggested when the left-sided heart border is straightened or bulges toward the left. Right atrial enlargement may be confirmed when the right-sided heart border bulges toward the right. Left ventricular enlargement results in downward and lateral displacement of the apex. A rounding of the displaced apex suggests ventricular hypertrophy. Right ventricular enlargement is best assessed on the lateral view and may be diagnosed when the right ventricular border occupies more than one third of the retrosternal space between the diaphragm and thoracic apex.

The aortic arch and thoracic aorta may become dilated and tortuous in patients with severe atherosclerosis, long-standing hypertension, and aortic dissection. A widened mediastinum, which is defined as a width of greater than 8.0 centimeters at the level of the aortic knob, can be seen in acute aortic dissection, although it is not very sensitive or specific for acute dissection.

Pulmonary venous congestion due to elevated left ventricular end-diastolic pressure results in redistribution of blood flow in the lungs and prominence of the apical vessels, which can be seen on chest radiography. Transudation of fluid into the interstitial space may result in fluid in the fissures and along the horizontal periphery of the lower lung fields (i.e., Kerley B lines). As venous pressures further increase, fluid collects in the alveolar space, which early on collects preferentially in the inner two thirds of the lung fields, resulting in a characteristic butterfly appearance.

Chest radiography is also used to evaluate device and lead positioning after implantation of defibrillators or pacemakers. The posteroanterior view helps to evaluate for device and lead integrity as well as potential device placement complications such as pneumothorax. A lateral view is necessary to evaluate ventricular lead positioning. In the lateral view, a right ventricular lead will course anteriorly, while a left ventricular lead will course posteriorly. The shape of the pulse generator can help in determining the device manufacturer, which is necessary to know for device interrogation.

ECHOCARDIOGRAPHY

Echocardiography is a widely used, noninvasive technique in which sound waves are used to image cardiac structures and evaluate blood flow. Transthoracic echocardiography is safe, simple, fast, and relatively inexpensive. It can provide a wealth of information on a patient's cardiovascular status, including ventricular function, valvular function, chamber size, possible coronary artery disease, pericardial disease, congenital heart disease, aortopathy, cardioembolic sources, volume status, and hemodynamics, among many other things.

A piezoelectric crystal housed in a transducer placed on the patient's chest wall produces ultrasound waves. As the sound waves encounter structures with different acoustic properties, some of the ultrasound waves are reflected to the transducer and recorded. Steering the ultrasound beam across a 90-degree arc multiple times per second creates two-dimensional imaging (Fig. 4.9). The development of three-dimensional echocardiographic imaging techniques allows for greater accuracy in measurements of chamber volumes and mass, as well as the assessment of geometrically complex anatomy and valvular lesions. Video 4.1 shows a three-dimensional image.

Doppler echocardiography allows assessment of the direction and velocity of blood flow in the heart and great vessels. When ultrasound waves encounter moving red blood cells, the energy reflected to the transducer is altered. The magnitude of this change (i.e., Doppler shift) is represented as velocity on the echocardiographic display and can be used to determine whether the blood flow is normal or abnormal

Fig. 4.8 Schematic illustration of the parts of the heart, outlines of which can be identified on a routine chest radiograph. (A) Posteroanterior chest radiograph. (B) Lateral chest radiograph. Ao, Aorta; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle.

Fig. 4.9 Portions of standard two-dimensional echocardiograms show the major cardiac structures in a parasternal long-axis view (A) and apical four-chamber view (B). Video 4.3 shows a moving image of a two-dimensional echocardiogram. (Fig. 4.10). The velocity of a particular jet of blood can be converted to pressure, allowing assessment of pressure gradients across valves or between chambers. Color Doppler imaging allows visualization of blood flow through the heart by assigning a color to the red blood cells based on their velocity and direction (Fig. 4.11, Video 4.2). By convention, blood moving away from the transducer is represented in shades of blue, and blood moving toward the transducer is represented in red. Color Doppler imaging is particularly useful in identifying valvular insufficiency and abnormal shunt flow between chambers. The use of Doppler techniques to record myocardial velocities or strain rates can aid in the assessment of myocardial function and hemodynamics.

Ultrasound contrast agents composed of microbubbles can be used in patients who have poorly visualized cardiac structures, such as obese patients or those with chronic lung disease. Ultrasound contrast opacifies the endocardial cavity and aids in assessment of cardiac function (Fig. 4.12). Video 4.3 shows a dynamic contrast

echocardiographic image. These contrast agents are also necessary in the assessment of potential left ventricular thrombus. Agitated saline, commonly referred to as “bubbles,” can be used to assess for intra-cardiac shunts.

Transesophageal echocardiography (TEE) allows two-dimensional and Doppler imaging of the heart through the esophagus by having the patient swallow a gastroscope mounted with an ultrasound crystal in its tip. Given the proximity of the esophagus to the heart, high-resolution images can be obtained, especially of the left atrium, mitral valve apparatus, and aorta. TEE is particularly useful in diagnosing left atrial appendage thrombi, aortic dissection, endocarditis, prosthetic valve dysfunction, and left atrial masses (Fig. 4.13, Video 4.4). TEE has been used for decades intraoperatively during cardiac surgery, and it is now being used with increasing frequency to guide percutaneous cardiac procedures such as transcatheter aortic valve replacement, transcatheter mitral valve repair, and left atrial appendage occlusion.

Fig. 4.10 Doppler tracing in a patient with aortic stenosis and regurgitation. The velocity of systolic flow is related to the severity of obstruction.

Fig. 4.11 Color Doppler recording demonstrates severe mitral regurgitation. The regurgitant jet seen in the left atrium is represented in blue because blood flow is directed away from the transducer. The yellow components are the mosaic pattern traditionally assigned to turbulent or high-velocity flow. The arrow points to the hemisphere of blood accelerating proximal to the regurgitant orifice (i.e., proximal isovelocity surface area [PISA]). The size of the PISA can be used to help grade the severity of regurgitation. Video 4.2 shows a dynamic echocardiographic image in a patient with mitral regurgitation. LA, Left atrium; LV, left ventricle. (Image courtesy Sheldon E. Litwin, MD, Division of Cardiology, University of Utah, Salt Lake City, Utah.)

NUCLEAR CARDIOLOGY

The traditional radiotracer approach to assess ventricular function is equilibrium radionuclide angiography (ERNA), which uses technetium-99m-labeled red blood cells. Serial ERNA can be performed at rest and during various levels of exercise or pharmacologic perturbations to evaluate ventricular function and reserve. ERNA has high reproducibility because there are no geometric assumptions and there is much less operator dependence in the image acquisition. Diastolic parameters can be readily assessed from the ventricular volume curve, which may be very helpful in the assessment of diastolic dysfunction.

In radionuclide imaging of the heart, patients are injected with a radioactive tracer, which distributes throughout the myocardium in proportion to blood flow. Highly specialized cameras then capture the

distribution of the radioactive tracer, which allows for quantification of left ventricular size, systolic function, and myocardial perfusion, depending on the tracer used. The two main types of myocardial imaging used in cardiology, often in stress testing, are single-photon emission tomography (SPECT) and positron emission tomography (PET).

In SPECT imaging, images of the heart are obtained for qualitative and quantitative analyses at rest and after stress (i.e., exercise or pharmacologic vasodilation). Radionuclide tracers are injected prior to rest images and just prior to the completion of stress. The most frequently used radionuclide in SPECT imaging is technetium-99m sestamibi. In the normal heart, the radioisotope is equally distributed throughout the myocardium at rest and stress. In patients with ischemia, a localized area of decreased radiotracer uptake occurs after stress but may partially or completely reverse during rest. A persistent defect at peak exercise and rest (i.e., fixed defect) is consistent with MI or scarring.

The use of new approaches such as combined low-level exercise and vasodilators, prone imaging, attenuation correction, and computerized data analysis has improved the quality and reproducibility of the data from these studies. New camera technologies, including those with solid state detector arrays, have demonstrated improved image resolution and allow for reduced radiation exposure. Myocardial perfusion imaging may also be combined with ECG-gated image acquisition (gated SPECT) to allow simultaneous assessment of ventricular function and perfusion. Using this technique, regional wall motion can be evaluated to help assess potential perfusion defects (Video 4.5).

PET has been widely used in oncology for many years but has become increasingly popular in cardiology (Video 4.5). The commonly used tracers in cardiac PET imaging include rubidium-82 and fluorine-18 fluorodeoxyglucose (FDG). When compared to SPECT, PET has several technical advantages, including higher spatial and temporal resolution, less radiation exposure, and the ability to quantify absolute rather than relative coronary blood flow. These advantages mean that PET is more sensitive and specific compared to SPECT in diagnosing coronary disease, especially in the presence of multivessel disease. Additionally, because PET gives an absolute rather than relative quantification of coronary blood flow, it can be used to assess abnormal microvascular coronary circulation. Despite these clinical advantages of PET over SPECT, the lack of availability of PET cameras and radiotracers, as well as high costs and reimbursement issues, limits the widespread adoption of PET.

In patients with suspected cardiac sarcoidosis, FDG-PET is the imaging modality of choice for diagnosis. FDG-PET can also be used to detect myocardial viability by the use of perfusion and metabolic tracers. In patients with left ventricular dysfunction, metabolic activity in a region of myocardium supplied by a severely stenotic coronary artery suggests viable tissue that may regain more normal function after revascularization (Fig. 4.14).

CARDIAC MAGNETIC RESONANCE IMAGING

Cardiac magnetic resonance imaging (cMRI) is a noninvasive method that is increasingly used for studying the heart and vasculature and has, in fact, become the gold standard for measuring myocardial function, volumes, and scarring. cMRI offers high-resolution dynamic and static images of the heart that can be obtained in any plane, allowing quantification of left ventricular and valvular function. High-quality images can be obtained in a larger proportion of subjects than is typically possible with echocardiography. Obesity, claustrophobia, inability to perform multiple breath-holds of 10 to 20 seconds, and arrhythmias are causes of reduced image quality.

Fig. 4.12 Echocardiogram enhanced with intravenous ultrasound contrast agent: apical four-chamber view (A) and apical long-axis view (B). Highly echo-reflectant microbubbles make the left ventricular cavity appear white, whereas the myocardium appears dark. Video 4.3 shows a dynamic image of echocardiographic contrast. (Image courtesy Sheldon E. Litwin, MD, Division of Cardiology, University of Utah, Salt Lake City, Utah.)

Fig. 4.13 Transesophageal echocardiogram demonstrates a vegetation (*arrow*) adherent to the ring of a bileaflet, tilting-disk mitral valve prostheses. (A) In systole, the leaflets are closed with the vegetation seen in the left atrium. (B) In diastole, the leaflets are open, with the vegetation prolapsing into the left ventricle. Transesophageal echocardiography is the diagnostic test of choice for assessing prosthetic mitral valves because the esophageal window allows unimpeded views of the atrial surface of the valve. Video 4.4 shows a dynamic transesophageal echocardiographic image. LA, Left atrium; LV, left ventricle; MV, prosthetic mitral valve disks; V, vegetation. (Courtesy Sheldon E. Litwin, MD, Division of Cardiology, University of Utah, Salt Lake City, Utah.)

cMRI also offers significant advantages over other imaging techniques for the characterization of tissues (e.g., muscle, fat, scar). cMRI is useful in the evaluation of ischemic heart disease because stress-rest myocardial perfusion (Fig. 4.15A) and areas of prior infarction (see Fig. 4.15B to D) can be visualized with excellent spatial resolution. Delayed or late gadolinium enhancement (LGE) in the myocardium is characteristic of scar or permanently damaged tissue (Video 4.6). The greater the transmural extent of LGE is in a given segment, the lower the likelihood of improved function in that segment after revascularization. Because of the better spatial resolution, LGE can identify localized or subendocardial scars that are not detectable with nuclear imaging techniques.

MRI is excellent for evaluating a variety of cardiomyopathies (Fig. 4.16). In addition to morphology and function, characteristic patterns of LGE have been reported in myocarditis, cardiac amyloidosis, sarcoidosis, and hypertrophic cardiomyopathy (HCM). In patients with

HCM, specific patterns on MRI can help identify those patients at highest risk of sudden cardiac death who would require defibrillators. Similarly, MRI has also been used to help assess right ventricular morphology and function in patients with suspected arrhythmogenic right ventricular cardiomyopathy. The role of MRI in all aspects of cardiac imaging continues to grow.

STRESS TESTING

Stress testing is an important noninvasive tool for evaluating patients with known or suggested coronary artery disease (CAD). During exercise, the increased demand for oxygen by the working skeletal muscles is met by increases in heart rate and cardiac output. In patients with significant CAD, the increase in myocardial oxygen demand cannot be met by a proportional increase in coronary blood flow, and myocardial ischemia may produce chest pain and characteristic ECG

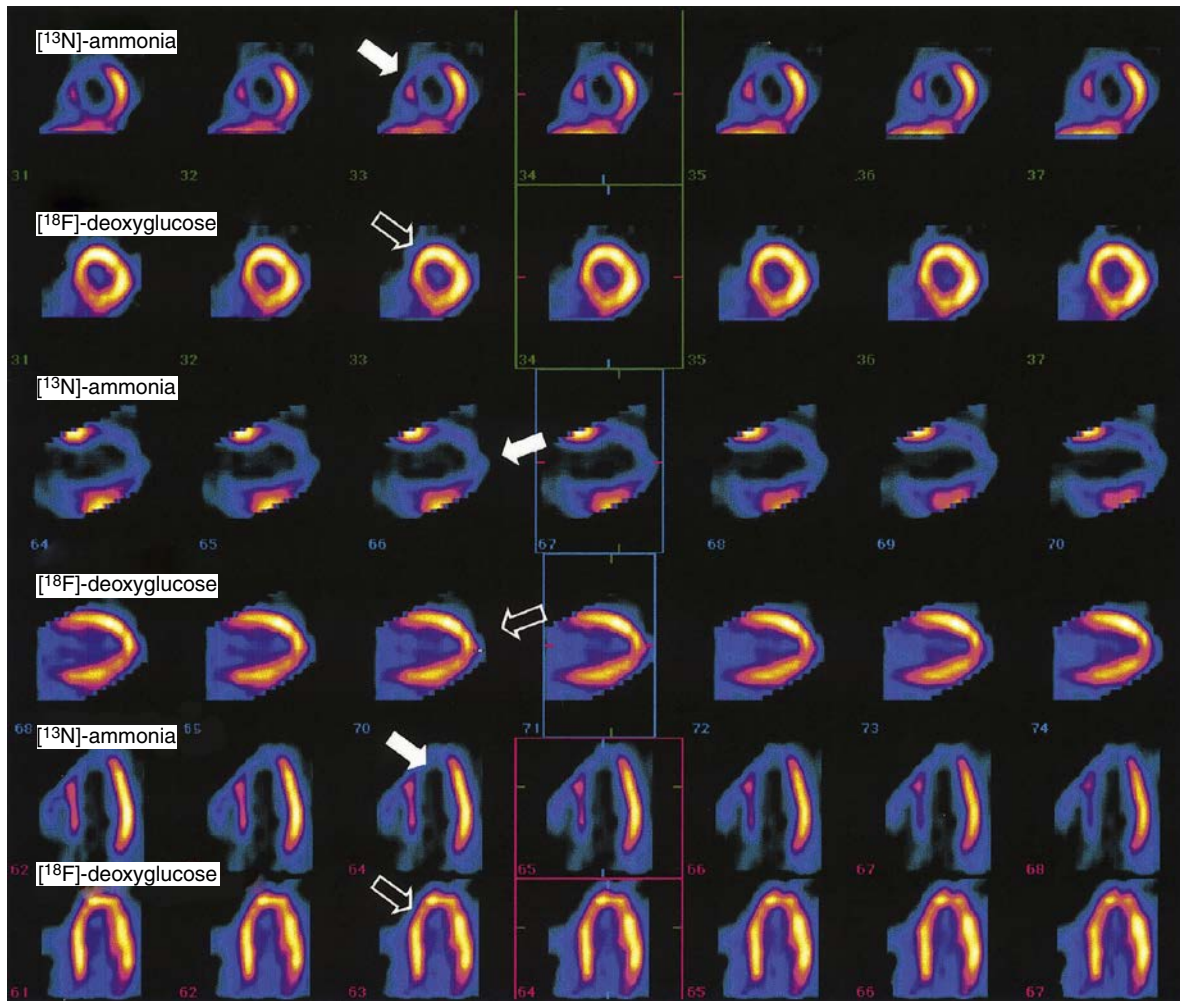

Fig. 4.14 Resting myocardial perfusion (obtained with $[^{13}\text{N}]$ -ammonia) and metabolism (obtained with $[^{18}\text{F}]$ -deoxyglucose) is seen in positron emission tomography images of a patient with ischemic cardiomyopathy. The study demonstrates a perfusion-metabolic mismatch (reflecting hibernating myocardium) in which large areas of hypoperfused (*solid arrows*) but metabolically viable (*open arrows*) myocardium involve the anterior, septal, and inferior walls and the left ventricular apex. Video 4.5 shows a dynamic image obtained with cardiac single-photon emission computed tomography imaging. (Courtesy Marcelo F. Di Carli, MD, Brigham and Women's Hospital, Boston, Mass.)

abnormalities. Combined with the hemodynamic response to exercise, these changes can give useful diagnostic and prognostic information for the patient with cardiac abnormalities. The most common indications for stress testing include establishing a diagnosis of CAD in patients with chest pain, assessing prognosis and functional capacity of patients with chronic stable angina or after an MI, evaluating exercise-induced arrhythmias, and assessing for ischemia after a revascularization procedure. Contraindications to stress testing include acute coronary syndromes, poorly controlled hypertension (blood pressure $>220/110$ mm Hg), severe aortic stenosis (valve area <1.0 cm^2), and decompensated congestive heart failure.

When to Stress Symptomatic Patients

Stress testing is most often used to evaluate symptoms concerning for flow-limiting coronary artery disease and make the diagnosis of CAD. The diagnostic accuracy of the stress test depends on several factors, including the pretest probability of CAD in a given patient, the sensitivity and specificity of the test results in that patient population, the adequacy of stress, and the criteria used to define a positive test. Stress

testing, when used to diagnose CAD, is one of the most useful and cost-effective tests in symptomatic patients who have an intermediate pretest probability of CAD, which is defined as a 10% to 90% risk. This is because in patients with a low pretest probability, a positive test does not significantly increase the post-test probability of CAD, and in patients with a high pretest probability, a negative test does not significantly decrease the post-test probability of CAD. The pretest probability of CAD can be calculated through a variety of scores but is most commonly done based on a patient's description of angina (Table 4.4).

Angina has three important components:

1. Substernal chest pain or discomfort
2. The pain or discomfort is provoked by exertion or emotional stress
3. The pain or discomfort is relieved by rest and/or nitroglycerin.

Patients with all three components are said to have *typical angina*. Those with any two of the three components have *atypical angina*, and patients with *nonanginal* chest pain have only one or none of these components.

Other factors that are not solely based on the description of chest discomfort may be present that would increase a patient's pretest

Fig. 4.15 Use of cardiac magnetic resonance imaging in the evaluation of chest pain or ischemic heart disease. (A) First-pass perfusion study during vasodilator stress shows a large septal perfusion defect (*arrow*). The hypoperfused area appears dark compared with the myocardium with normal perfusion. (B) Example of delayed enhancement imaging of an almost transmural infarction of the mid-inferolateral wall, including the posterior papillary muscle. Infarcted myocardium appears *white*, whereas normal myocardium is *black* (*arrow*). (C) Nontransmural (subendocardial) infarction of the septum and apex (*arrow*). (D) Patient with acute myocarditis mimicking an acute coronary syndrome. Midmyocardial, rather than subendocardial, delayed enhancement is characteristic of myocarditis (*arrow*).

probability of CAD. These include baseline ECG abnormalities suggestive of CAD and multiple CAD risk factors, such as diabetes, smoking, hypertension, dyslipidemia, or family history of premature CAD. These should be taken into consideration on an individual basis and may require an upward revision of pretest probability.

Stress Modalities

There are two essential components to any stress test: the type of stress and the imaging modality. Stress can either be exercise-induced or pharmacologic. Exercise level is deemed adequate if the patient achieves 85% of his or her maximal predicted heart rate. Submaximal stress tests can still be interpreted but may be limited in the ability to rule out disease due to decreased sensitivity. Indications for terminating a stress test include fatigue, severe hypertension (>220 mm Hg systolic), worsening angina during exercise, developing marked or widespread ischemic ECG changes, significant arrhythmias, or hypotension.

For patients who are able to exercise, the most commonly used exercise protocols are the Bruce and modified Bruce protocols. These protocols require a patient to walk on a treadmill as the speed and incline of the belt increases with each advancing stage. Any patient who can exercise should do so, as duration of exercise and provoked symptoms provide valuable clinical and prognostic information for the physician. The modified Bruce or similar protocols are ideal for older, overweight, unstable, or debilitated patients. Additionally, in patients

unable to exercise on a treadmill, bicycle or arm ergometer testing may also be used. In patients who cannot exercise or in those where exercise will interfere with image acquisition, pharmacologic agents may be used.

The most commonly used pharmacologic stress agents are dobutamine, adenosine, and regadenoson, an adenosine derivative and selective adenosine A_{2A} receptor agonist. Dobutamine is a synthetic sympathomimetic that stimulates alpha-1, beta-1, and beta-2 receptors, increasing inotropy and chronotropy, thereby increasing myocardial oxygen demand. It should be used cautiously in patients with a history of atrial or ventricular arrhythmias as it can exacerbate both. Regadenoson is an adenosine receptor agonist that induces coronary vasodilation and is more commonly used in radionuclide myocardial perfusion imaging. Its use is contraindicated in patients with asthma or COPD and active wheezing as well as patients with significant bradyarrhythmias without a pacemaker. It should be used with caution in patients with a history of seizures as it can lower the seizure threshold.

STRESS IMAGING

Exercise or pharmacologic stress testing must be combined with imaging modalities to assess for characteristic changes seen in flow-limiting coronary artery disease. The most basic form of imaging is an ECG, which can be combined with adjunctive echocardiography or radionuclide imaging to increase the diagnostic accuracy of the testing.

Fig. 4.16 Cardiac magnetic resonance imaging (MRI) is used in the evaluation of cardiomyopathies. (A) Severe left ventricular hypertrophy in a patient with hypertrophic cardiomyopathy. Diastolic frame shows open mitral valve (*arrow*). (B) Systolic frame shows systolic anterior motion of the mitral valve with flow disturbance in the left ventricular outflow tract (*arrow*). TABLE 4.4 Diamond and Forrester Pretest Probability of Coronary Artery Disease by Age, Sex, and Symptoms

Age (Years)	Sex	Typical/Definite Angina Pectoris	Atypical/Probable Angina Pectoris	Nonanginal Chest Pain
<39	Men	Intermediate	Intermediate	Low
	Women	Intermediate	Very low	Very low
40-49	Men	High	Intermediate	Intermediate
	Women	Intermediate	Low	Very low
50-59	Men	High	Intermediate	Intermediate
	Women	Intermediate	Intermediate	Low
≥60	Men	High	Intermediate	Intermediate
	Women	High	Intermediate	Intermediate

High: >90% pretest probability. Intermediate: between 10% and 90% pretest probability. Low: between 5% and 10% pretest probability. Very low: <5% pretest probability.

From Wolk MJ, Bailey SR, Doherty JU, et al: ACCF/AHA/ASE/ASNC/HFSA/HRS/SCAI/SCCT/SCMR/STS 2013 Multimodality Appropriate Use Criteria for the Detection and Risk Assessment of Stable Ischemic Heart Disease. *Journal of the American College of Cardiology* 63:380-406, 2014.

Stress Electrocardiography

The normal physiologic response to exercise is an increase in heart rate and systolic and diastolic blood pressures. The ECG maintains normal T-wave polarity, and the ST segment remains unchanged or, if depressed, has a rapid upstroke back to baseline. An ischemic ECG response to exercise is defined as 1.5 mm of upsloping ST-segment depression measured 0.08 second past the J point, at least 1 mm of horizontal ST depression, or 1 mm of downsloping ST-segment depression measured at the J point. Given the large amount of artifact on the ECG that may occur with exercise, these changes must be seen in at least three consecutive depolarizations. Other findings that suggest more extensive CAD include early onset of ST depression (6 minutes); marked, downsloping ST depression (>2 mm), especially if present in more than five leads; ST changes persisting into recovery for more than 5 minutes; and failure to increase systolic blood pressure to 120 mm Hg or more or a sustained decrease of 10 mm Hg or more below baseline.

The ECG is not diagnostically useful in the setting of left ventricular hypertrophy, LBBB, Wolff-Parkinson-White syndrome, or chronic digoxin therapy. In these instances, further imaging modalities such as echocardiography, nuclear imaging, or positron-emission tomography (PET) are needed to help diagnose ischemia.

Stress Echocardiography

Two-dimensional echocardiography and Doppler echocardiography are often used in conjunction with exercise or pharmacologic stress testing. The pharmacologic agent typically used is dobutamine. A baseline echocardiogram is performed at rest and during stress. Changes in wall motion are indicative of ischemia and coronary artery disease. In areas of the left ventricle that have wall motion abnormalities at rest, improvement of these wall motion abnormalities with exercise or low-dose dobutamine is indicative of viability.

Relative to myocardial perfusion imaging, the sensitivity of stress echocardiography is slightly lower whereas the specificity is slightly higher. A poor baseline echocardiogram due to limited acoustic windows will limit stress test results. The estimated cost-effectiveness of stress echocardiography is significantly better than nuclear perfusion imaging because of the overall lower cost.

Myocardial Perfusion Imaging (See Also Nuclear Cardiology Section)

Stress testing, using myocardial perfusion imaging with SPECT to compare relative coronary blood flow at stress and at rest, helps to identify areas of perfusion mismatch, indicative of ischemia. Like with other stress modalities, exercise or pharmacologic stress can be used. Commonly used pharmacologic agents include dipyridamole, adenosine, and regadenoson, which are all coronary vasodilators. It is important to note that patients with LBBB have to undergo pharmacologic stress when receiving myocardial perfusion imaging, even if they are able to exercise, as the abnormal septal motion caused by the LBBB can lead to a false perfusion defect during exercise.

Stress Cardiac Magnetic Resonance Imaging

Though either exercise or pharmacologic stress may be combined with cMRI, the contemporary use of stress cMRI usually refers to stress perfusion cMRI with gadolinium contrast that is performed with regadenoson. This technique allows for evaluation of wall motion, perfusion, scar, viability, and microvascular dysfunction, as well as chamber quantification and function, allowing for a comprehensive evaluation of the myocardium and myocardial function. Changes in late gadolinium enhancement between rest and stress has performance characteristics for diagnosing CAD that are at least as good and likely superior to

those of conventional stress tests using nuclear myocardial perfusion imaging or echocardiography, and on par with PET imaging.

COMPUTED TOMOGRAPHY OF THE HEART

Newer applications of computed tomography (CT) have greatly advanced our ability to diagnose cardiovascular disease noninvasively. The development of fast gantry rotation speeds and the addition of multiple rows of detectors (i.e., multidetector CT) have allowed unprecedented visualization of the great vessels, heart, and coronary arteries with images acquired during a single breath-hold lasting 10 to 15 seconds. CT is used to diagnose aortic aneurysm, acute aortic dissection, and pulmonary embolism, and it is useful for defining congenital abnormalities and detecting pericardial thickening or calcification associated with constrictive pericarditis. ECG-gated dynamic CT images have been used to quantify ventricular size, function, and regional wall motion (Video 4.7), and in contrast to echocardiography, CT is not limited by lung disease or chest wall deformity. However, obesity and implanted prosthetic materials (i.e., mechanical valves or pacing wires) may affect image quality.

The greatest excitement and controversy about cardiac CT relates to the evaluation of coronary atherosclerosis. Electron beam and multidetector CT scans can be used to quickly and reliably visualize and quantitate the extent of coronary artery calcification (Fig. 4.17). The presence of coronary calcium is pathognomonic of atherosclerosis, and the extent of coronary calcium (usually reported as an Agatston score) is a powerful marker of future cardiovascular events. The coronary calcium score adds substantial, independent improvement in risk prediction to the commonly employed clinical risk scores (e.g., Framingham risk score). Moreover, the calcium score is a good marker of the overall atherosclerotic burden. Indications for coronary calcium scoring continue to grow, especially in refining risk predictions in asymptomatic patients at intermediate risk for arteriosclerotic cardiovascular disease.

Contrast-enhanced coronary computed tomography angiography (CCTA) has improved dramatically in recent years. CCTA has a sensitivity of more than 95% in diagnosing significant coronary artery obstruction. Unlike myocardial perfusion imaging, CCTA is an anatomic test, and thus does not give information on perfusion or blood flow across a lesion. Thus, in patients with known coronary disease, CCTA cannot easily differentiate between ischemic and nonischemic chest pain. New technology is being developed to noninvasively determine the hemodynamic significance of a lesion through CCTA, similar to fractional flow reserve in coronary catheterization, though this technology still needs to be rigorously tested and standardized. Evaluation of coronary arteries with CCTA can be significantly limited in patients with extensive coronary calcifications, cardiac devices, or prior stents due to technical limitations.

Concerns that limit the widespread use of cardiac CT most frequently cite the risks of radiation and contrast exposure and the lack of prospective studies showing improvement in outcome with this testing modality. In early studies, the calculated radiation exposure of CCTA was about double that of a diagnostic invasive coronary angiogram, although with prospective ECG-gating, most studies are now equal to or less than a diagnostic angiogram. Contrast use is often higher in a CCTA than in a diagnostic invasive coronary angiogram. The role of CCTA in routine clinical practice continues to evolve.

CARDIAC CATHETERIZATION

Cardiac catheterization is an invasive technique in which fluid-filled catheters are introduced percutaneously into the arterial and/or venous circulation. This method allows direct measurement of intracardiac

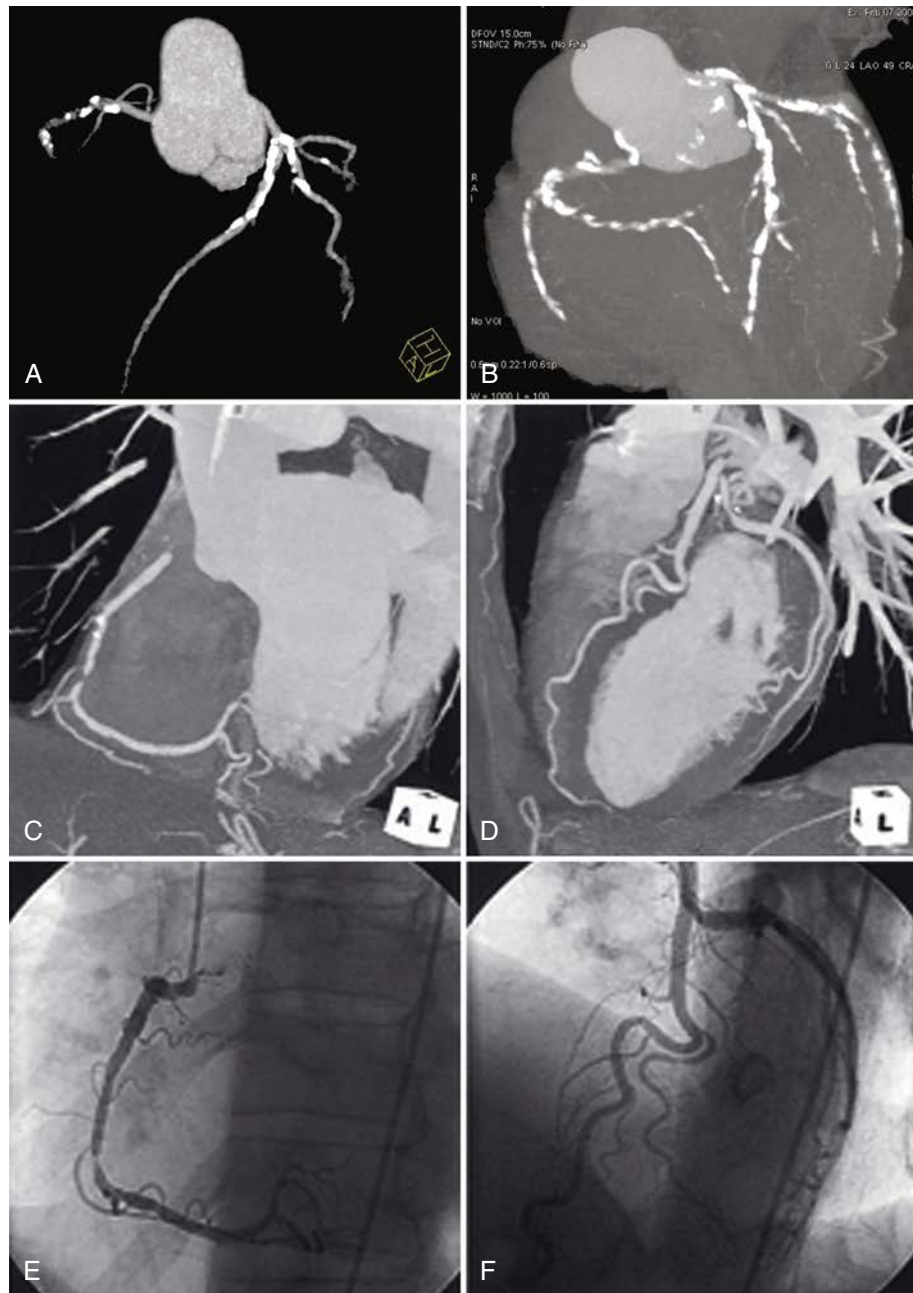

Fig. 4.17 Computed tomography coronary angiography compared with conventional radiographic contrast angiography. (A and B) Volume-rendering technique demonstrates stenosis of the right coronary artery and normal left coronary artery. (C and D) Maximal intensity projection of the same arteries demonstrates severe noncalcified plaque in the right coronary artery with superficial calcified plaque. (E and F) Invasive angiography of the same arteries. (From Raff GL, Gallagher MJ, O'Neill WW, et al: Diagnostic accuracy of noninvasive coronary angiography using 64-slice spiral computed tomography, *J Am Coll Cardiol* 46:552-557, 2005.)

pressures and oxygen saturation and, with the injection of a contrast agent, visualization of the coronary arteries, cardiac chambers, and great vessels. Cardiac catheterization is indicated when a clinically suggested cardiac abnormality requires confirmation and its anatomic and physiologic importance needs to be quantified. Coronary angiography for the diagnosis of CAD is the most common indication for this test.

Compared with catheterization, noninvasive testing with echocardiography is safer, often cheaper, and equally effective in the evaluation of most valvular and hemodynamic conditions. Most often, catheterization precedes some type of beneficial intervention, such as

coronary artery angioplasty, coronary bypass surgery, or valvular surgery. Although cardiac catheterization is usually safe (0.1% to 0.2% overall mortality rate), procedure-related complications such as vascular injury, renal failure, stroke, and MI can occur.

Left Heart Catheterization and Coronary Angiography

Left heart catheterization and coronary angiography first requires the introduction of wires and fluid-filled catheters into the arterial system of the body. In the past, femoral arterial access was the default route, but now, radial arterial access has become increasingly more common.

Fig. 4.18 Electrocardiographic tracing and left ventricular (LV) and aortic (AO) pressure curves in a patient with aortic stenosis. A pressure gradient occurs across the aortic valve during systole.

It has replaced femoral arterial access as the default access site in most centers. Radial arterial access is associated with less bleeding, fewer vascular complications, and increased patient comfort and early mobility after the procedure when compared with femoral arterial access. However, it is also associated with higher radiation exposure and increased procedural time.

After access is obtained, wires and fluid-filled catheters are advanced to the aortic root and through the aortic valve into the left ventricle under fluoroscopic guidance. Here, left ventricular size, wall motion, and ejection fraction can be accurately assessed by injecting contrast into the left ventricle (i.e., left ventriculography). Aortic and mitral valve insufficiency can be qualitatively assessed during angiography by observing the reflux of contrast medium into the left ventricle and left atrium, respectively. Left ventricular pressures can be directly measured and recorded, and the catheter can slowly be pulled back across the left ventricular outflow tract (LVOT) and aortic valve to directly assess for any pressure differential that would be consistent with aortic stenosis or LVOT obstruction (Fig. 4.18).

The coronary anatomy can be defined by injecting contrast medium into the coronary tree. Atherosclerotic lesions appear as narrowing of the internal diameter (lumen) of the vessel. A hemodynamically important stenosis is defined as 70% or more narrowing of the luminal diameter. However, the hemodynamic significance of a lesion can be underestimated by coronary angiography, particularly when the atherosclerotic plaque is eccentric or elongated. Intravascular ultrasound, optical coherence tomography, or miniaturized pressure sensors can be used during invasive procedures to help evaluate the severity or estimate the physiologic significance of intermediate lesions.

Right Heart Catheterization

Right heart catheterization is a useful invasive technique that can be performed at bedside or with fluoroscopic guidance. The pulmonary artery (Swan-Ganz) catheter, which is a balloon-tipped catheter used for right heart catheterization, can be left in a patient for a prolonged period of time in a critical care setting to provide continuous information on cardiovascular hemodynamics and filling pressures. Right heart catheterization can be helpful when used in appropriate situations, such as when differentiating noncardiogenic from cardiogenic

pulmonary edema, managing mixed shock, managing cardiogenic shock, and classifying and treating pulmonary hypertension.

Right heart catheterization is performed by first accessing the venous system. Common sites of entry for right heart catheterization include the internal jugular vein (usually the right), the right brachial vein, or the femoral veins. The procedure can be performed at the bedside or under fluoroscopic guidance with a balloon-tipped (Swan-Ganz) catheter. The catheter is advanced from the vein to the right atrium, right ventricle, and pulmonary artery, where pressures are measured and recorded. The catheter can then be advanced further until it wedges in the distal pulmonary artery. The transmitted pressure measured in this location originates from the pulmonary venous system and is known as the *pulmonary capillary wedge pressure*. In the absence of pulmonary venous disease, the pulmonary capillary wedge pressure reflects left atrial pressure, and if no significant mitral valve pathologic condition exists, it reflects left ventricular diastolic pressure. A more direct method of obtaining left ventricular filling pressures is through left heart catheterization, as described in the previous section. With these two methods of obtaining intracardiac pressures, each chamber of the heart can be directly assessed and the gradients across any of the valves determined (Fig. 4.19).

Cardiac output can be determined by one of two widely accepted methods: the Fick oxygen method and the indicator dilution technique. The basis of the Fick method is that total uptake or release of a substance by an organ is equal to the product of blood flow to that organ and the concentration difference of that substance between the arterial and venous circulation of that organ. If this method is applied to the lungs, the substance released into the blood is oxygen; if no intrapulmonary shunts exist, pulmonary blood flow is equal to systemic blood flow or cardiac output. The cardiac output can be determined by the following equation:

$$\text{Cardiac output} = \frac{\text{Oxygen consumption}}{(\text{Arterial oxygen content} - \text{Venous oxygen content})}$$

Oxygen consumption is measured in milliliters per minute by collecting the patient's expired air over a known period while simultaneously measuring oxygen saturation in a sample of arterial and mixed venous blood (i.e., arterial and venous oxygen content, respectively, measured in milliliters per liter). The cardiac output is expressed in liters per minute and then corrected for body surface area (i.e., cardiac index). The normal range of cardiac index is 2.6 to 4.2 L/min/m². Cardiac output can also be determined by the indicator dilution technique, which most commonly uses cold saline as the indicator. With this method, cold saline is injected into the blood, and the resulting temperature change *downstream* is monitored. This action generates a curve in which temperature change is plotted over time, and the area under the curve represents cardiac output.

Detection and localization of intracardiac shunts can be performed by sequential measurement of oxygen saturation in the venous system, right side of the heart, and two main pulmonary arteries. In patients with left-to-right shunt flow, an increase in oxygen *step-up* (i.e., saturation increase from one chamber to the successive chamber) occurs as arterial blood mixes with venous blood. By using the Fick method for calculating blood flow in the pulmonary and systemic systems, the shunt ratio can be calculated. Noninvasive approaches have largely supplanted catheterization laboratory assessment of shunts.

In the past, the Swan-Ganz catheter was routinely used in most patients with shock; however, randomized trials have since been published suggesting no improvement in outcomes in critically ill patients in whom pulmonary artery catheterization was performed.

Fig. 4.19 Electrocardiographic (ECG) (A) and Swan-Ganz flotation catheter (C) recordings are shown. The recordings of a catheter in the radial artery and Swan-Ganz floating catheter in the right atrium are shown in B and D, respectively. The left portion of tracing C was obtained with the balloon inflated, yielding the pulmonary arterial wedge pressure. The right portion of tracing C was recorded with the balloon deflated, depicting the pulmonary arterial pressure. In this patient, the pulmonary arterial wedge pressure (i.e., left ventricular filling pressure) is normal, and the pulmonary artery pressure is elevated because of lung disease.

Certainly, improvements in noninvasive imaging techniques have made the Swan-Ganz catheter much less important in diagnosing cardiac conditions such as cardiac tamponade, constrictive pericarditis, right ventricular infarction, and ventricular septal defect. This led to a decline in the routine use of Swan-Ganz catheters in intensive care units. However, the use of these catheters has resurged, likely due to the increased use of advanced heart failure therapies and mechanical support, where continuous hemodynamic monitoring is essential for optimal therapy titration (Table 4.5).

ENDOMYOCARDIAL BIOPSY

Biopsy of the right ventricular endomyocardium can be performed. With this technique, a biptome is introduced into the venous system through the right internal jugular vein and guided into the right

ventricle by fluoroscopy. Small samples of the endocardium are taken for histologic evaluation. The primary indication for endomyocardial biopsy is the diagnosis of rejection after cardiac transplantation and documentation of cardiac amyloidosis; however, endomyocardial biopsy may have some use in diagnosing specific etiologic agents responsible for myocarditis.

NONINVASIVE VASCULAR TESTING

Assessment for the presence and severity of peripheral vascular disease is an important component of the cardiovascular evaluation. Comparison of the systolic blood pressure in the upper and lower extremities is one of the simplest tests to detect hemodynamically important arterial disease. Normally, the systolic pressure in the thigh is similar to that in the brachial artery. An ankle-to-brachial pressure

TABLE 4.5 Differential Diagnosis Using a Bedside Balloon Flow-Directed (Swan-Ganz) Catheter

Disease State	Thermodilution Cardiac Output	PCW Pressure	RA Pressure	Comments
Cardiogenic shock	↓	↑	nl or ↓	↑ Systemic vascular resistance

ratio (i.e., ankle-brachial index) of less than or equal to 0.9 is abnormal. Patients with claudication usually have an index ranging from 0.5 to 0.8, and patients with rest pain have an index less than 0.5. In some patients, measuring the ankle-brachial index after treadmill exercise may help to determine the importance of borderline lesions. During normal exercise, blood flow increases to the upper and lower extremities with corresponding decreases in peripheral vascular resistance, whereas the overall ankle-brachial index remains unchanged. In the presence of a hemodynamically significant lesion, the reduced flow across the lesions causes a consequent pressure decrease, and as a result, the ankle-brachial index decreases in proportion to the severity of the stenosis. Some patients, especially those with diabetes or chronic kidney disease, may have falsely elevated ankle-brachial indices due to vascular stiffness (>1.3). In these patients, a toe-brachial index can be measured. In general, a toe-brachial index less than 0.6 indicates abnormal perfusion in the foot, though the site of the occlusive disease would have to be identified with further studies.

After significant vascular disease in the extremities has been identified, plethysmography can be used to determine the location and severity of the disease. With this method, a pneumatic cuff is positioned on the leg or thigh, and when inflated, temporarily obstructs venous return. Volume changes in the limb segment below the cuff are converted to a pressure waveform, which can be analyzed. The degree of amplitude reduction in the pressure waveform corresponds to the severity of arterial disease at that level.

Doppler ultrasound uses reflected sound waves to identify and localize stenotic lesions in the peripheral arteries. This test is particularly useful for patients with severely calcified arteries, for whom pneumatic compression is not possible and ankle-brachial indices are inaccurate. In combination with real-time imaging (i.e., duplex imaging), this technique is useful in assessing specific arterial segments and bypass grafts for stenotic or occlusive lesions.

Magnetic resonance angiography and CTA allow high-quality and comprehensive imaging of the entire peripheral arterial circulation in

a single study. The three-dimensional nature of these studies and the ability to perform extensive postprocessing views, including cross-sectional views, of all vessels, even those that are very tortuous, are attractive features of these modalities.

Heart Failure and Cardiomyopathy

Daniel J. Levine, Hyeon-Ju Ryoo Ali, Rayan Yousefzai

DEFINITION AND CLASSIFICATION

Heart failure (HF) is a clinical syndrome defined by inability of the heart to maintain output under normal filling pressures and/or impairment in relaxation of ventricles causing an increase in filling pressures. Patients experience fatigue and exercise intolerance if cardiac output is low and dyspnea and peripheral edema if the ventricular filling pressure is elevated. There are numerous ways to classify HF—by the type of cardiac impairment, causes of cardiomyopathy, patient’s symptoms, or hemodynamic profiles.

Ejection Fraction

Most patients with HF have disorders in both systolic and diastolic function. However, ejection fraction (EF) is an important distinguishing characteristic in most clinical trials and, therefore, in guidelines for therapy. By imaging, cardiac function can be categorized as reduced EF (<40%) or preserved EF (\geq 50%). Patients with midrange EF (40% to 50%) are treated similarly to patients with reduced EF. HF with reduced EF (HFrEF) is associated with significant morbidity and mortality, especially in the elderly and those with severely low EF (<30%). HF with preserved EF (HFpEF) is less well studied with fewer effective targeted therapies. Increasing awareness of HFpEF has led to recognition of its prevalence with associated morbidity and mortality and the need for more research into optimal management.

Causes

Table 5.1 lists the common causes of cardiomyopathy leading to HF. Ischemic cardiomyopathy is the most common cause of HF and is estimated to account for about 60% of all HF admissions in the United States. This serves as a basis for clinical practice. Patients who present with new cardiomyopathy may undergo cardiac catheterization to exclude underlying coronary artery disease (CAD). Common causes of nonischemic cardiomyopathy include hypertension, chemotherapy, substance use, familial cardiomyopathy, and systemic disorders affecting the heart, such as amyloidosis and hemochromatosis. Worldwide, infections are a common cause of nonischemic cardiomyopathy including Chagas disease (endemic in South America), tuberculosis, and HIV.

Additional nonmyocardial processes that lead to HF include primary pericardial disorders. Pericardial tamponade limits the compliance of the heart, resulting in elevated filling pressures. Other causes include radiation-induced pericarditis, viral pericarditis, postsurgical pericardial thickening, and idiopathic fibrosis of the pericardium.

Valvular pathology including regurgitant and stenotic lesions can also lead to signs and symptoms of HF. Undetected, they can lead to morphologic changes in ventricular size and function. Most studies of HF exclude patients with uncorrected valvular diseases. Diagnosis and

treatment of valvular heart disease is reviewed separately (see Chapter 7, “Valvular Heart Disease”).

Types of Cardiomyopathy

Historically, cardiomyopathy has been classified morphologically as “dilated,” “hypertrophic,” and “restrictive.” Dilated cardiomyopathy commonly leads to impairment in systolic function, or HFrEF. Common causes of dilated cardiomyopathy include myocardial infarction or infectious myocarditis.

Ventricular hypertrophy causes impairment in relaxation of ventricles, elevated filling pressures, and HFpEF. The most common cause of hypertrophy of ventricles is long-standing hypertension. Older women are at higher risk, as well as patients with diabetes, atrial fibrillation, obesity, hyperlipidemia, and CAD. Hypertrophic cardiomyopathy (HCM) is a genetic disorder in which a mutation in the sarcomeric proteins leads to thickening of ventricles and impaired filling. Patients with known family history of HCM should be tested by genetic analysis; current tests achieve a diagnostic yield of 30% to 60%. More than 130 genes associated with cardiomyopathy and arrhythmias have been identified. Genetic testing should be performed in centers with experienced geneticists and genetic counselors.

Restrictive cardiomyopathy also impairs ventricular relaxation and leads to HFpEF. This type of cardiomyopathy can be due to fibrosis as in radiation heart disease, or deposition of insoluble proteins as in amyloidosis. Restrictive cardiomyopathy is much less common than the other two types.

High-output HF is an under-recognized entity. It is characterized by an increased cardiac output that still fails to meet the metabolic and perfusion demands. Possible causes include obesity, anemia, hyperthyroidism, vitamin B1 deficiency, arteriovenous shunts and liver disease.

Functional Impairment

HF is a clinical syndrome with management strategies targeted to patients’ symptoms and function status. Thus, it is paramount to have a unified language to stratify patients’ degree of symptoms. Table 5.2 displays two classification methods: the “stages” as defined by the American College of Cardiology Foundation and the American Heart Association (ACCF/AHA) and the “classes” as defined by the New York Heart Association (NYHA).

ACCF/AHA Stages of HF

Patients in ACCF/AHA stage A have risk factors—such as hypertension, diabetes, metabolic syndrome, history of cardiac toxins, and family history of cardiomyopathy—without the diagnosis of CAD or cardiac remodeling. In stage B, patients may have prior history of MI or evidence of cardiomyopathy, but do not have symptoms. Stage C

TABLE 5.1 Causes of Cardiomyopathy

Myocardial infarction
Infection
HIV
Lyme
Chagas
Viral myocarditis
Tuberculosis
Iatrogenic
Chemotherapy: bleomycin, doxorubicin (Adriamycin)
Antiretroviral medications
Radiation
Phenothiazines
Chloroquine
Clozapine
Toxins

Cocaine
Methamphetamines
Cobalt, lead, lithium, mercury, carbon monoxide, beryllium
Endocrine and metabolic
Thyroid dysfunction
Thiamine deficiency
Pellagra
Hypophosphatemia, hypocalcemia, uremia
Inflammatory
Systemic lupus erythematosus
Scleroderma
Rheumatoid arthritis
Giant cell arteritis
Kawasaki disease
Infiltrative cardiomyopathy
Amyloidosis
Sarcoidosis
Hemochromatosis
Other structural
Valvular disease: progressive stenosis or regurgitation, acute chordae tendineae rupture, thrombosis of replaced valve
Infective endocarditis
Takotsubo cardiomyopathy
Idiopathic dilated cardiomyopathy
Idiopathic restrictive cardiomyopathy
Peripartum cardiomyopathy
Arrhythmogenic right ventricular dysplasia
Congenital heart disease
Fabry disease
Danon disease
Friedreich's ataxia
Myotonic dystrophy
Duchenne-Becker muscular dystrophy
Rhythm
Tachy-mediated cardiomyopathy
Pacing-mediated cardiomyopathy

constitutes clinical signs and symptoms of HF, while stage D encompasses patients whose HF is refractory to appropriate therapy.

NYHA Functional Classification of HF

The NYHA classification characterizes functional impairment of patients in symptomatic HF (ACCF/AHA stages C and D). Class I patients are

asymptomatic with ordinary activity and may also fall under stage B. Patients in class II have *some* limitation at *moderate* levels of physical activity while patients in class III have *any* limitations at *mild* levels of activity. Patients with symptoms at rest are categorized as class IV.

Hemodynamic Profiles

The impact of HF on circulatory physiology can be broadly categorized into four groups based on the degree of impairment of cardiac output and elevation of filling pressures (Fig. 5.1). Reduced cardiac output (cardiac index, CI ≤ 2.2 L/min/m²) leads to impairment in end-organ perfusion. Patients may complain of fatigue, dizziness, or diminished urine output. On physical exam, extremities are cool due to low cardiac output and the compensatory vasoconstriction of the capillary beds to maintain perfusion. This finding helps identify the “cold” patients in the low-output state.

Elevated filling pressures can cause hydrostatic pressure to increase beyond the oncotic pressure, leading to extravasation of fluid into the interstitial space. Fluid may be retained in the lungs causing dyspnea, in the gut causing loss of appetite or nausea, and in the extremities causing peripheral edema.

Most patients who present in acute HF exacerbation are “warm and wet.” Despite elevated filling pressures and congestion, they are still adequately perfused and can be treated with diuresis without hemodynamic support. “Cold and wet” patients are further decompensated. They require inotropic support to maintain adequate blood pressures and to perfuse the kidneys and permit effective diuresis. Some patients, despite diuresis, may remain in a poor perfusion state due to underlying cardiac disease. These patients are “cold and dry” and may require advanced therapies that will be described later.

PATHOPHYSIOLOGY

Frank-Starling Law

Under normal conditions, an increase in preload, or left ventricular end-diastolic pressure (LVEDP), increases stroke volume, as described by the Frank-Starling law (Fig. 5.2). In HF, the low cardiac output triggers an adaptive neurohormonal response that is designed to increase preload and stroke volume. However, due to the depressed myocardial contractility, the same increase in preload does not lead to increase in stroke volume or cardiac output. The consequence is dysregulation of an adaptive mechanism that leads to excessive filling pressures and fluid retention. Treatment consists of augmenting stroke volume by reducing afterload and increasing myocardial contractility with an inotrope. Diuresis can also reduce LVEDP, filling pressures, and congestive symptoms. Treatment of decompensated HF is discussed further in the section titled “Diagnosis and Management of Acute Decompensation.”

Adaptive Neurohormonal Response

Our understanding of HF has changed over the years. It is no longer sufficient to consider morphologic characteristics or hemodynamic profiles of this clinical syndrome. HF is a clinical syndrome marked by sympathetic activation and neurohormonal dysregulation. The neurohormonal dysregulation and adaptive response are important targets for HF management strategies.

In response to low cardiac output, the sympathetic nervous system is triggered, releasing epinephrine and norepinephrine. The adrenalins increase heart rate and cause ventricular relaxation. They also trigger the G-coupled receptor pathways, increasing cyclic adenosine monophosphate (cAMP) production. Increased cAMP concentration leads to calcium influx and augments myocardial contractility.

In the kidneys, the juxtaglomerular cells in afferent arterioles sense decreased blood flow and in turn release renin. The consequent activation of the renin-angiotensin-aldosterone system (RAAS) is a cascade

TABLE 5.2 ACCF/AHA Stages and NYHA Functional Classification of HF

ACCF/AHA Stages		NYHA Functional Classification	
A	Risk factors for HF without cardiomyopathy or HF symptoms	None	
B	Cardiomyopathy without HF symptoms	I	No HF symptoms
C	Cardiomyopathy with HF symptoms	I	No HF symptoms
		II	Some HF symptoms with moderate activity
		III	Any HF symptoms with mild activity
		IV	HF symptoms at rest
D	HF refractory to medical therapy	IV	HF symptoms at rest

ACCF, American College of Cardiology Foundation; AHA, American Heart Association; HF, heart failure; NYHA, New York Heart Association. Data from Yancy CW, Jessup M, Bozkurt B, et al: 2013 ACCF/AHA guidelines for the management of heart failure: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines, *J Am Coll Cardiol* 62:e147-e239, 2013.

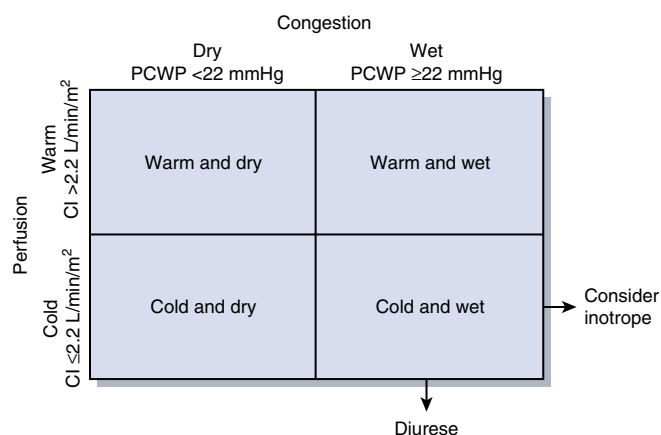

Fig. 5.1 Assessment of hemodynamic profiles in patients with heart failure. *CI*, Cardiac index; *PCWP*, pulmonary capillary wedge pressure. (Modified from Thibodeau JT, Drazner MH. The role of the clinical examination in patients with heart failure. *JACC Hear Fail.* 2019;6(7):544-551. <https://doi.org/10.1016/j.jchf.2018.04.005>.)

of enzyme activity that promotes end-organ perfusion by vasoconstriction, fluid retention at the level of the kidneys, and increased fluid intake by stimulating thirst.

Over time, these mechanisms become dysregulated. The adrenals augment chronotropy and inotropy, which increase wall stress and myocardial oxygen consumption. Angiotensin II causes vasoconstriction that places the myocardium under higher afterload. Initially, cardiac muscles become hypertrophied to compensate for the workload; however, ventricles eventually dilate and lose contractility. Aldosterone also exacerbates ventricular remodeling, leading to progressive decline in cardiac function and loss of myocytes with subsequent fibrosis in a process known as apoptosis.

Atrial natriuretic peptide and brain natriuretic peptide (BNP) are counterregulatory hormones that are released in response to myocardial stress. They promote natriuresis and arterial vasodilation. Neprilysin degrades BNP and thereby inhibits the counterregulatory mechanism and inhibits natriuresis. This pathway is the target of novel drug therapies described in the section titled “Guideline-directed Medical Therapy.”

DIAGNOSIS AND MANAGEMENT OF ACUTE DECOMPENSATION

Patients with HF frequently experience acute decompensation. Careful history and exam, as well as laboratory and imaging findings can help

Fig. 5.2 Frank-Starling curve. Pulmonary edema occurs when the left ventricular end-diastolic pressure (LVEDP) is elevated such that hydrostatic pressures in pulmonary vasculature exceed oncotic pressures. For most patients, this threshold is approximately LVEDP = 20 mm Hg. Diuresis or venodilation reduces the filling pressures and can shift patients along the same curve correlating with lower LVEDP. Inotropic agents or afterload reduction can improve the cardiac output and improve stroke volume, shifting the pressure-volume curve upwards and to the left, moving patients from point A to point B. Adding diuresis or venodilation can shift patients from point A to point C. Excessive diuresis or venodilation shifting from point A to point D may cause excessive decline in LVEDP. While these patients may be at lower risk of pulmonary edema, their stroke volume may be impaired and result in inadequate cardiac output.

distinguish HF from other causes of dyspnea, such as chronic obstructive pulmonary disease (COPD) exacerbation or pneumonia.

History Symptoms

HF is a clinical diagnosis. Thus, presenting symptoms, exam findings, and patients’ response to HF treatments help establish the diagnosis.

Most patients with HF exacerbation present with dyspnea. Patients may also experience orthopnea (shortness of breath while lying flat) or paroxysmal nocturnal dyspnea or PND (waking up with shortness of breath) due to redistribution of fluid from the periphery to the lungs. Orthopnea and PND are specific for HF (specificity = 74% to 77% for orthopnea and 80% to 84% for PND) and can help discriminate among different etiologies for dyspnea.

Elevation of venous pressures (preload to the right ventricle) cause symptoms of systemic venous congestion. Patients may complain of

decreased appetite, nausea, and abdominal fullness from intestinal edema of the gut. Transudation of fluid into the abdominal compartment may cause ascites and increased abdominal girth. Many patients complain of leg swelling or inability to fit into their shoes. Asking patients about sudden weight gain (e.g., 2-3 lb in a few days or 5 lb in a week) can also help assess the degree of fluid accumulation and identify targets for therapy.

Patients with inadequate cardiac output due to HF experience fatigue, exercise intolerance, or presyncope. Reduced end-organ perfusion can lead to altered mental status and diminished urine output. These symptoms are important clues to the hemodynamic profile of the patient and are critical for determining their need for inotropic support.

Precipitating Factors for Acute HF Exacerbation

Acute HF exacerbation may result from a new-onset primary cardiac dysfunction or decompensation of known chronic HF due to non-cardiac causes. Cardiac dysfunction causes of acute HF exacerbation include acute myocardial infarction, other primary nonischemic cardiomyopathy, conduction disorders, valvular pathology, or pericardial issues (see [Table 5.1](#) for a comprehensive list).

The most common noncardiac causes of heart failure exacerbation are diet indiscretion (increased salt intake or alcohol consumption) and medication noncompliance. Other common causes include infections (e.g., viral upper respiratory tract infection) or acute blood loss anemia. High blood pressure can also increase afterload acutely, increase filling pressures, and cause reduced cardiac output and/or worsening congestion.

Additional Information for New-Onset Cardiomyopathy

Once heart failure exacerbation diagnosis is established, additional history elements can help determine cause of cardiomyopathy. Questions should be focused on symptoms and risk factors of coronary artery disease, given that myocardial infarction is the most common cause of cardiomyopathy in the United States. Other helpful information includes past medical history including valvular disease, arrhythmias, autoimmune diseases, congenital heart disease, cancer, radiation, or cardiotoxic therapy, such as anthracycline derivatives. Social history should include duration and quantity of alcohol intake and cocaine use. Symptoms suggestive of other systemic disorders affecting the heart, such as neuropathy in amyloidosis, may be helpful and relevant for treatment options. Family history may be important in cases such as early-onset coronary artery disease, autoimmune disorders, congenital heart disease, and familial cardiomyopathies.

Exam Findings

Exam findings should be focused on signs of elevated filling pressures and reduced cardiac output to establish the diagnosis of heart failure. Other exam maneuvers not reviewed here include those relevant to myocardial ischemia, valvular disease, and arrhythmias that are reviewed in [Chapters 7, 8, and 9](#).

Edema, JVD, and HJR

Elevated filling pressures in the heart are detected by several physical exam cues. Pulmonary auscultation may demonstrate rales, rhonchi, or even wheezing. Edema may be found in the lower extremities, but also in the abdomen in the form of ascites.

Jugular venous distension (JVD) is assessed with the patient situated at 30 to 45 degrees and breathing quietly. The vertical distance between the sternal notch and top of the JVD meniscus is the jugular venous height to which 5 cm should be added for true central venous pressure (normal range = 5-9 cm H₂O). Hepatojugular reflux (HJR) is

elevation of filling pressures by more than 3 cm H₂O while compressing the right upper quadrant for at least 10 seconds. Valvular disease, specifically tricuspid regurgitation, may falsely elevate the JVD meniscus and make these exam findings less reliable.

Cardiac Examination: S₃ and S₄

The point of maximal impulse (PMI) may be displaced (below the fifth intercostal space and lateral to the midclavicular line) suggestive of cardiomegaly. On auscultation of the heart, a third heart sound (S₃) may be heard in early diastole. The sound is the result of blood passively traveling from the atrium into an already filled ventricle. This is typically associated with left ventricular systolic dysfunction and incomplete ejection of blood during systole. S₄ is heard in late diastole and results from the atrial kick pushing the remaining fluid into a stiffened ventricle. S₄ suggests diastolic dysfunction.

Bendopnea

Bendopnea is a recently described simple stress maneuver that can be used if the aforementioned exams are not helpful in discriminating among the many causes of dyspnea. Patients are asked to bend forward while sitting in a chair for 30 seconds, which increases filling pressures. Patients may develop dyspnea or “bendopnea,” particularly if they have a low cardiac index. This maneuver has been associated with increased 6-month mortality, composite end point of death, heart failure–related admission, and need for advanced therapies.

Square Wave Response

Another stress maneuver to assess the left ventricular filling pressure is the square wave response. This is particularly useful when the JVD and HJR are limited due to body habitus or tricuspid regurgitation. The blood pressure cuff is inflated to the point of hearing the first Korotkoff sound. Then the patient is asked to Valsalva (i.e., bear down) in order to reduce the preload and decrease pulmonary venous return to the left ventricle. In normal patients, the Korotkoff sound disappears due to a drop in blood pressure. In patients with pulmonary congestion, the pulmonary intravascular volume maintains forward flow during Valsalva, and the Korotkoff sound remains the same. The persistence of Korotkoff sound, therefore, is a positive test and is suggestive of elevated left ventricular pressures and pulmonary congestion.

Laboratory Data and Imaging

Patients who have symptoms and signs concerning for acute heart failure exacerbation should all receive an electrocardiogram (ECG) and a chest radiograph. An ECG may show evidence of new ischemia or old infarct suggesting MI as the potential cause for cardiomyopathy. A chest radiograph may demonstrate signs of pulmonary edema, such as Kerley B lines and pleural effusions ([Fig. 5.3](#)). The BNP is often elevated, although it is neither sensitive nor specific. In fact, BNP is most useful for its negative predictive value. A low BNP (or NT-pro-BNP) can exclude HF in patients with combined cardiopulmonary disease who present acutely with dyspnea. The troponin may be elevated in acute myocardial infarction or demand ischemia. Laboratory testing should include a basic metabolic panel to establish baseline electrolytes and kidney function. The liver function test results help assess the degree of congestion and cardiohepatic syndrome. The complete blood count can give clues to the etiology, such as leukocytosis in the setting of acute infection or anemia.

All patients with new-onset heart failure should have an echocardiogram. It may reveal wall motion abnormalities consistent with CAD, valvular stenosis or regurgitation, or pericardial effusion. Ventricular wall thickness and chamber sizes can also be assessed. Thickened ventricles may raise concerns for genetic hypertrophic cardiomyopathy,

Fig. 5.3 (A) Posteroanterior chest radiograph demonstrating pulmonary edema. Notice the increased interstitial markings, more prominent in central zones, and Kerley B lines, which are horizontal markings at the lung periphery. There is also a prominent horizontal line in left lung, suggestive of fluid layering in the major fissure. Both costovertebral angles are obscured, suggesting bilateral pulmonary effusion. (B) Lateral chest radiograph demonstrating pulmonary edema. Fluid is layering in the lower lung zones suggestive of pulmonary effusion.

long-standing hypertension hypertrophic heart, or infiltrative disease such as amyloidosis (Fig. 5.4). Newer techniques including strain imaging can be used to evaluate for infiltrative disease as well as early changes due to toxic chemotherapeutic agents.

Additional Testing to Determine Etiology

Appropriate patients with symptoms, signs, ECG, and/or troponin results concerning for myocardial infarction causing heart failure exacerbation should undergo coronary angiography and revascularization. Some patients presenting with new heart failure diagnosis have a history of coronary artery disease but do not have typical anginal symptoms. For these patients, the Surgical Treatment for Ischemic Heart Failure (STITCH) trials demonstrated that myocardial viability assessment with nuclear stress testing does not, in fact, improve mortality. However, the ACCF/AHA 2013 guidelines make weak recommendations to obtain noninvasive imaging such as nuclear stress test or stress echocardiogram prior to proceeding with revascularization. Evidence of ischemia and significant myocardial viability may be one of the factors to be considered for catheterization.

If the above work-up is negative, additional testing for nonischemic cardiomyopathy can be pursued. A cardiac MRI can reveal specific patterns of enhancement that are indicative of infiltrative disorders (e.g., cardiac amyloidosis and sarcoidosis). Additional laboratory testing may include thyroid function test, human immunodeficiency virus (HIV) test, iron studies, and hepatitis C virus antibodies.

Prompt recognition and work-up for cardiac amyloidosis has become more important as novel therapies have become available that are important to initiate early in the disease progression. Features concerning for amyloidosis include low voltage on ECG, left ventricular hypertrophy, and evidence of other organ manifestation such as gastrointestinal symptoms (diarrhea, nausea), neuropathy, and chronic kidney disease. Laboratory testing should include levels of serum and urine protein electrophoresis (SPEP and UPEP) along with serum and/or urine immunofixation. Imaging techniques

include echocardiography, specifically strain imaging that tends to spare the apex, and nuclear imaging called pyrophosphate (PYP) scan. The latter is sensitive and specific for transthyretin, or wild-type amyloidosis. Definitive diagnosis is achieved with direct visualization of the amyloid deposits in tissue samples. Biopsy can be done on the abdominal fat pad, cardiac muscle, rectal mucosa, salivary gland, and liver.

Right heart catheterization is another diagnostic tool for assessment of acute HF exacerbation. The routine use of pulmonary artery catheters (PACs) for patients with HF exacerbation has not been shown to improve mortality, length of stay, or rehospitalization rates (the Evaluation Study of Congestive Heart Failure and Pulmonary Artery Catheterization Effectiveness, ESCAPE). The ACCF/AHA 2013 guidelines still recommend use of PACs with patients who do not respond to standard therapies and when there is a degree of uncertainty regarding the patient's volume status despite routine clinical assessment. Right heart catheterization is also used to estimate cardiac output, assess candidacy for advanced therapy, and perform cardiac biopsy.

Acute Management Diuresis

The mainstay treatment for acute HF exacerbation is intravenous (IV) loop diuretics. Intravenous administration of diuretics should be equal to or exceed the dose of home oral medications. Oral diuretics may be less effective in this setting due to bowel edema which can impair absorption via the gut. Diuresis should be targeted toward symptom management, improvement in vital signs, resolution of acute kidney injury (AKI), change in weight, and net output of urine. Some patients with prolonged diuretic use can develop resistance to loop diuretics. These patients may benefit from thiazide administration to block fluid reabsorption in the distal convoluted tubules. Patients who do not respond to maximal diuretic regimen can be considered for ultrafiltration.

Fig. 5.4 Examples of hypertrophic cardiomyopathy on (A) long axis view and (B) short axis view. The posterior wall “P” and interventricular septum, “S” are markedly thickened. Examples of dilated cardiomyopathy on (C) long axis view and (D) short axis view. The left ventricular cavity “LV” and left atrium “LA” are enlarged.

Afterload Reduction

Patients may be hypertensive in the setting of HF exacerbation. Acutely lowering the blood pressure can quickly reduce the afterload, lower ventricular filling pressures, and reduce the degree of pulmonary vascular congestion. Patients in respiratory distress may experience prompt relief of their symptoms with afterload reduction. Intravenous therapy options for acute afterload reduction include nitroglycerin, nitroprusside, and nesiritide.

Cardiogenic Shock Management

Some patients in acute HF exacerbation present in “cold” hemodynamic profiles and have significantly reduced cardiac output. These patients may require inotropic support for end-organ perfusion. The use of inotropes can improve perfusion of kidneys and patients’ response to diuresis. More information regarding the different types of inotropes and their use is detailed in the section titled “Inotropic Support.”

Guideline-Directed Medical Therapy

In the current age, the goal in heart failure therapy is to not only control symptoms and slow progression of disease, but also to recover some cardiac function. New pharmacotherapies have become available

that not only improve functional status but lower mortality and reduce hospitalizations. Thus, it is imperative to understand and follow guideline-directed medical therapy (GDMT) for all patients with HF (Fig. 5.5).

All patients with HF should be advised to make lifestyle modifications to reduce the risk of development or progression of cardiac disease. Blood pressure control, weight loss, and management of diabetes can significantly reduce the risk of CAD and ventricular remodeling. Patients with any stage of heart failure, regardless of whether they have symptoms, should be treated with ACE inhibitors or aldosterone receptor II blockers (ARBs), as well as statins if there is evidence of coronary artery disease or the atherosclerotic cardiovascular disease (ASCVD) risk score is greater than 7.5%.

For patients with HFrEF stage C (i.e., patients with any symptoms), several medications have been shown to reduce mortality and improve quality of life. All patients should be treated with specific β -blockers known to improve mortality in HFrEF patients, as well as a medication for afterload reduction (ACE inhibitors, ARBs, or angiotensin receptor blocker–neprilysin inhibitors, i.e., ARNIs). The other therapies described in the following sections have been proven effective for only certain subpopulations.

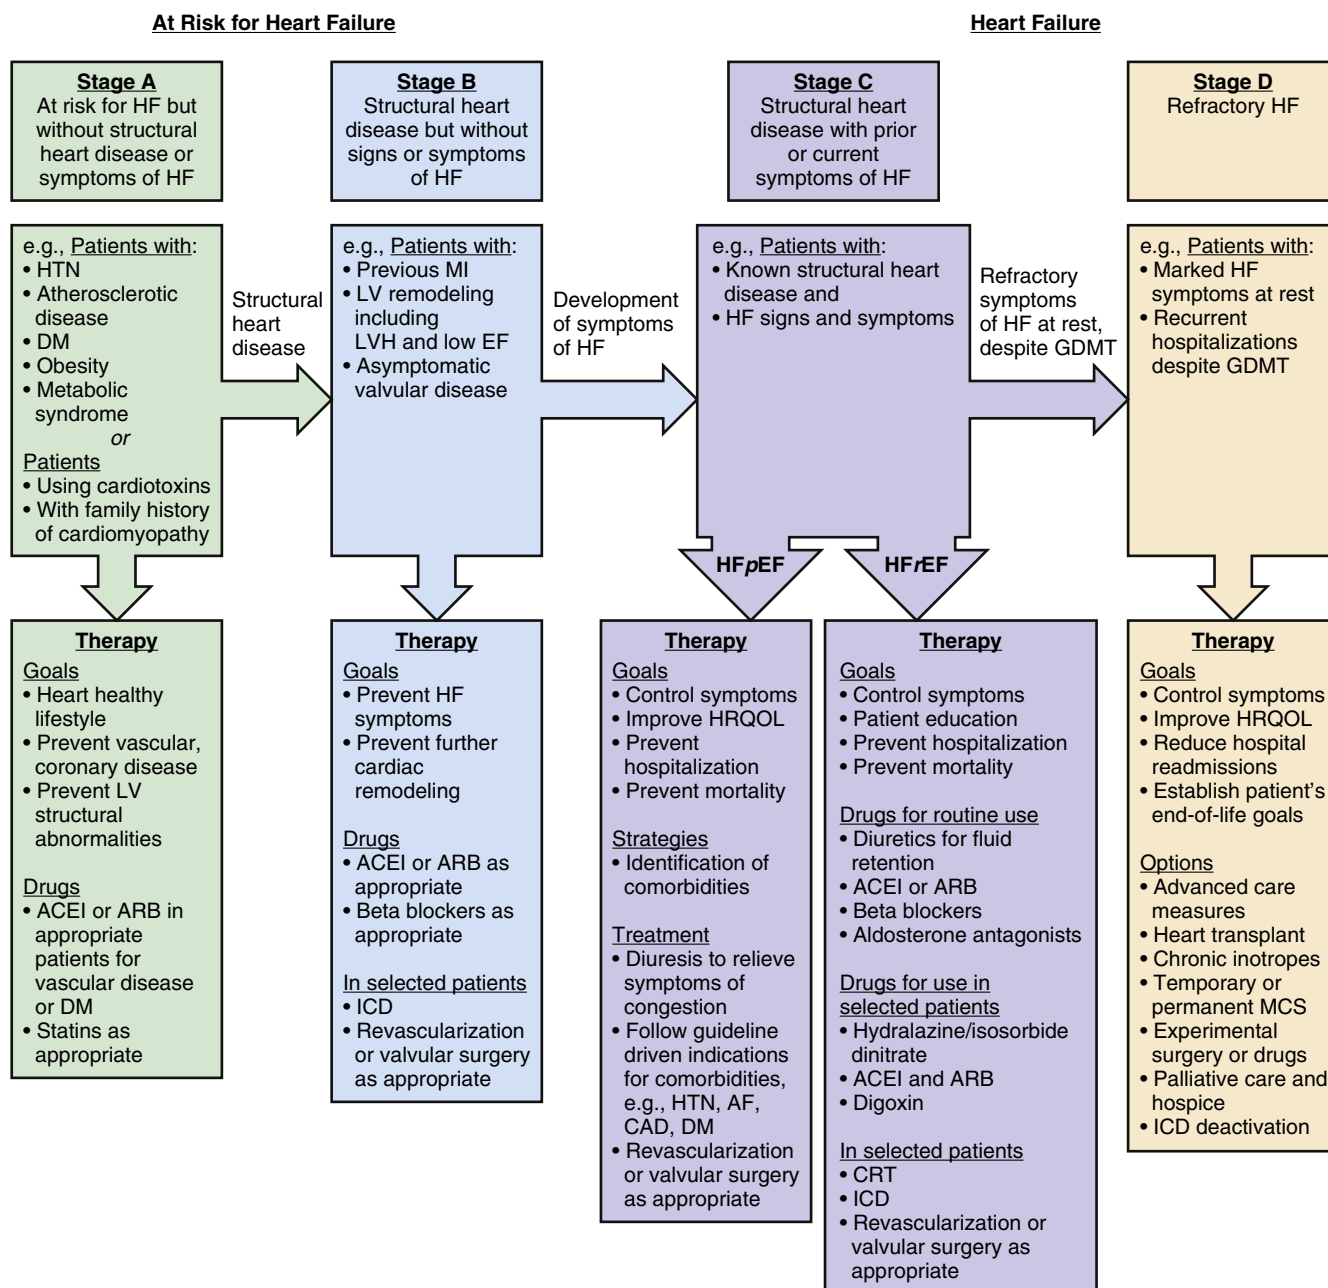

Fig. 5.5 Clinical overview by HF stage A-D. ACEI, Angiotensin-converting enzyme inhibitor; AF, atrial fibrillation; ARB, angiotensin receptor blocker; CAD, coronary artery disease; CRT, cardiac resynchronization therapy; DM, diabetes mellitus; EF, ejection fraction; GDMT, guideline-directed medical therapy; HF, heart failure; HRQOL, health-related quality of life; HTN, hypertension; ICD, implantable cardiac defibrillator; LV, left ventricular; LVH, left ventricular hypertrophy; MCS, mechanical circulatory support. (Adapted from ACCF/AHA 2013 Guidelines.)

ACE Inhibitor, ARB, and ARNI

All patients with stage C HFrEF, regardless of symptom burden, should be on an ACE inhibitor, an ARB, or an ARNI. By inhibiting RAAS, ACE inhibitors and ARBs reduce afterload and inhibit fibrosis. Multiple trials from the 1980s to the early 2000s including CONSENSUS, SOLVD, Val-HeFT, and CHARM demonstrated an improvement in mortality (by 16% to 40%) and reduced hospitalizations for HF exacerbations in patients treated with ACE inhibitors or ARBs.

The ARNI is a novel medication that combines the ARB, valsartan, with a neprilysin inhibitor called sacubitril. Neprilysin is an

endopeptidase that breaks down vasoactive peptides such as BNP and bradykinin. By inhibiting neprilysin, the sacubitril promotes the action of the BNP, which increases diuresis. In the PARADIGM randomized controlled trial (RCT) ARNIs were found to be superior to ACE inhibitors (number needed to treat, NNT = 21 for composite end point of HF admissions or mortality). The PIONEER study also demonstrated ARNIs could be safely started during hospitalization and readmission due to HF exacerbations. The 2017 American College of Cardiology and American Heart Association (ACC/AHA) updates to the guidelines recommend patients on ACE inhibitors or ARBs should be

switched to ARNIs. Patients on ACE inhibitors should have a wash-out period of 36 hours after ACE inhibitors are discontinued to avoid angioedema secondary to bradykinin accumulation.

The therapeutic potential of ACE inhibitors and ARBs for the HFpEF patient population has been investigated by several RCTs, including PEP-CHF, CHARM-preserved, and I-PRESERVE. These studies unfortunately showed ACE inhibitors and ARBs do not significantly reduce cardiovascular mortality or heart failure exacerbations in this patient group. The Prospective Comparison of ARNI with ARB Global Outcomes in HFpEF (PARAGON-HF) also demonstrated no significant risk reduction of mortality or HF-related hospitalizations for ARNIs. Guidelines currently do not recommend initiation of ACE inhibitors, ARBs, or ARNIs for HFpEF patients.

Beta-Blockers

The three types of β -blockers found to be effective in Stage C HFrEF are bisoprolol, carvedilol, and metoprolol succinate. β -Blockers inhibit the sympathetic nervous system, reduce myocardial work, improve endothelial integrity, and ultimately reduce ventricular remodeling. Numerous studies—MERIT-HF, CAPRICORN, COPERNICUS, COMET, and CIBIS-II—have demonstrated a significant reduction in mortality (31% to 40%) and the composite end point of mortality and heart failure exacerbation admissions. The trials on HFpEF patients are small and inadequately powered, but many show a trend toward improving mortality.

Aldosterone Antagonist

Patients with stage C HFrEF, NYHA class II-IV already on β -blockers and afterload reduction with an ACE inhibitor, ARB, or ARNI should be started on aldosterone receptor antagonists assuming creatinine clearance greater than 30 and normal potassium levels. The direct inhibition of aldosterone further reduces ventricular fibrosis and remodeling. The RALES trial showed a 30% reduction in all-cause mortality, sudden cardiac death, and HF hospitalizations for patients with NYHA class II-IV symptoms. EMPHASIS-HF also showed a 37% reduction in the composite end point of death and HF readmissions.

Patients with HFpEF may also benefit from aldosterone receptor antagonists. The Treatment of Preserved Cardiac Function Heart Failure with an Aldosterone Antagonist (TOPCAT) was an international, placebo-controlled, randomized study for patients with EF 45% or greater. The study showed a small effect size of spironolactone reducing HF hospitalizations (12.0% vs. 14.2%). However, subsequent analyses showed a significant regional variation, suggesting that North American participants may have been more compliant with the medications and likely may have derived greater benefit.

Ivabradine

Patients with symptomatic HFrEF (stage C, NYHA class II-IV) with high resting heart rate (≥ 70 beats per minute) despite treatment with a high dose of β -blocker may benefit from the addition of ivabradine. Ivabradine works by inhibiting I_f —the “funny channel”—at the sinus node. The SHIFT trial demonstrated that patients in NYHA II-IV class with EF 35% or less already on GDMT treated with ivabradine experienced a 5% absolute risk reduction in heart failure exacerbations and 2% absolute reduction in cardiovascular mortality.

Hydralazine and Nitrates

Vasodilators such as hydralazine and nitrates reduce afterload, myocardial work, and in theory, reduce ventricular remodeling. Their efficacy, however, has only been shown among African Americans with HFrEF stage C and NYHA III-IV symptoms already on GDMT. For patients with HFpEF, nitrates have been shown to improve exercise tolerance but do not improve mortality (NEAT-HFpEF, 2015). The

ACC/AHA 2017 updates to the guidelines do not yet recommend vasodilators for HFpEF patients.

Digoxin

Digoxin increases myocardial contractility by inhibiting sodium-potassium exchange, which increases intracellular calcium. Digoxin is associated with a decrease in HF hospitalizations, improvement in quality of life, and increase in exercise tolerance. The DIG trials, however, showed no impact on mortality. Digoxin also has an unfavorable side effect profile. It can cause arrhythmias (ectopic, re-entrant cardiac rhythms, and heart block), GI side effects (nausea, anorexia), and neurologic side effects (visual effects, disorientation, confusion). Patients who are elderly and have low body mass index or renal dysfunction are at higher risk. Many medications can increase the digoxin level and increase the risk of toxicity (clarithromycin, erythromycin, itraconazole, amiodarone, dronedarone, cyclosporine, propafenone, verapamil, and quinidine). Given these risks and benefits, patients with stage C HFrEF could benefit from digoxin.

Diuretics

For patients with chronic heart failure, diuretics are used to maintain euvolemia and target symptom management. Loop diuretics are most commonly used, but some patients develop resistance over time. Distal convoluted tubules become hypertrophied and water becomes reabsorbed past the loop of Henle, reversing the effect of loop diuretics. Small doses of thiazide and metolazone, which impact the distal nephrons, can significantly increase diuresis. Their use requires close and careful monitoring of serum electrolytes and renal function.

Device Therapy

Cardiomyopathy confers an increased risk of ventricular arrhythmias and sudden cardiac death (SCD). Patients with low EF of 35% or less and NYHA class II-III symptoms should receive an implantable cardiac defibrillator (ICD) for primary prevention (Fig. 5.6). Numerous trials—SCD-HeFT, CARE-HF, MADIT-CRT, and REVERSE—have demonstrated reduction in SCDs that outweigh the risk of device-related complications for HFrEF patients.

Patients with ischemic cardiomyopathy are at higher risk for SCDs due to the scar tissue that can be a nidus for ventricular arrhythmias. Thus, patients with ischemic cardiomyopathy (EF $\leq 30\%$) should also receive an ICD even if they do not have symptoms (NYHA class I). The evidence behind device therapy for HFpEF patients, however, is less clear. The DANISH trials demonstrated 3% mortality benefit but 1.5% device-related complications.

Device therapy in the form of cardiac resynchronization therapy (CRT), also termed “biventricular pacing,” has also been shown to improve functional capacity, reduce HF rehospitalizations, and improve all-cause mortality. Patients derive their benefit from improved contractility and increased forward flow due to ventricular synchrony. Additional benefits include improvement in blood pressure, making it possible to intensify therapy with ACE inhibitors, ARBs, and ARNIs. Patients with HFrEF and a widened QRS of 150 ms or greater with a left bundle branch block pattern should be considered for CRT implantation.

Management of Atrial Fibrillation

HF patients with atrial fibrillation (AF) are at higher risk of stroke, HF exacerbations, and mortality. The AFFIRM trial demonstrated similar outcomes between rate and rhythm control strategies; however, patients with HFrEF were underrepresented. Theoretically, restoring sinus rhythm allows preservation of the atrial kick and improvement in A-V synchrony, which could reduce filling pressures and improve cardiac output. Recently, CASTLE-AF demonstrated that patients with HFrEF

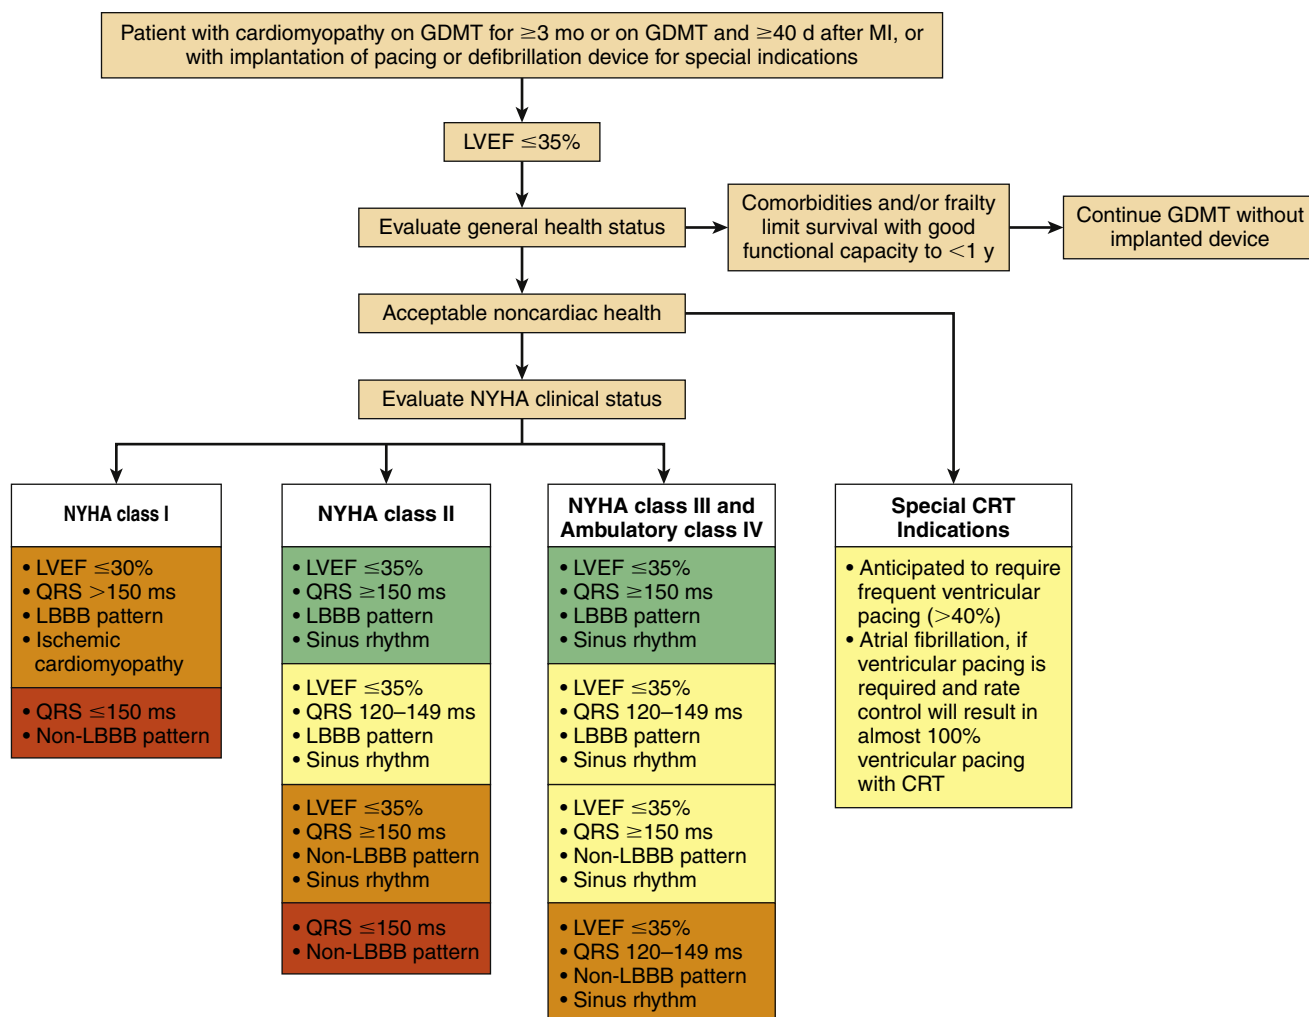

Fig. 5.6 Recommendations for implanted cardiac defibrillator (ICDs) and cardiac resynchronization therapy (CRT) depend on the ejection fraction (EF) and New York Heart Association (NYHA) functional class. *Green* indicates class I recommendations (evidence or agreement that treatment is useful and effective), *yellow* indicates class IIa recommendations (weight of evidence or opinion in favor of treatment), *orange* indicates IIb recommendations (usefulness/efficacy is less well established), and *red* indicates class III recommendations (evidence or general agreement that treatment is not useful/effect and in some cases may be harmful). *GDMT*, Guideline-directed medical therapy; *LBBB*, left bundle branch block; *MI*, myocardial infarction. (Adapted from ACCF/AHA 2013 guidelines.)

NYHA class II-IV experienced significant reduction in death (11.6%) and heart failure exacerbation (15.2%) after catheter ablation to restore sinus rhythm. Although not yet reflected in the guidelines, patients with HFrEF who are symptomatic should be considered for AF ablation.

Invasive Hemodynamic Monitoring of Ambulatory Patients

For patients with recurrent heart failure exacerbations, ambulatory monitoring devices can allow for early detection of increase in filling pressures and timely interventions. CardioMEMS is an implantable device placed in the pulmonary artery that communicates real-time hemodynamics measurements remotely to trained health care professionals. Multiple RCTs have demonstrated their effectiveness. In COMPASS-HF patients with NYHA class III monitored with CardioMEMS experienced a 36% reduction of HF hospitalizations. Similarly, CHAMPION-HF demonstrated CardioMEMS could achieve up to 37% relative risk reduction in HF exacerbations in the first 17 months. Device-related or systems-related complications were found to be exceedingly rare (freedom from complications estimated to be 98.6%). Currently, the device is FDA-approved for patients with heart failure with NYHA class III symptoms

who have been hospitalized in the past year. The GUIDE-HF trial is an ongoing investigation to determine the impact of CardioMEMS in the NYHA class II and IV patient population and patients with elevated BNP. Many ICDs now have the capacity to monitor physiologic parameters including heart rate variability and intrathoracic impedance, which may be helpful for patient assessment and management.

Advanced Therapy

Patients with HFrEF stage D, who are refractory to medical therapy, are challenging to manage. Appropriate patients with stage D symptoms despite optimal medical therapy should be referred to centers that provide advanced circulatory support. Recent advances in mechanical support technology have made possible implantation of durable pumps as destination therapy in patients ineligible for other therapy.

INTERMACS Profiles

Patients in HFrEF stage D can be further characterized with profiles developed by the Interagency Registry of Mechanically Assisted Circulatory Support (INTERMACS). The INTERMACS profiles

TABLE 5.3 INTERMACS Profiles

INTERMACS Profile	Description	Urgency of Interventions
1: Cardiogenic shock	“Crash and burn”: critical cardiogenic shock despite increasing doses of inotropes confirmed with rising lactate or acidosis	Within hours
2: Progressive decline	“Sliding on inotropes”: end-organ hypoperfusion evidenced by worsening renal failure and inability to maintain euolemia despite inotropic support	Within days
3: Stable but inotrope dependent	“Dependent stability”: adequate end-organ perfusion and symptom control while on inotropic support or temporary circulatory support device, but unable to wean from inotropes	Within weeks to months
4: Resting symptoms	Symptoms of congestion occur at rest	Within weeks to months
5: Exertion intolerant	“Housebound”: comfortable at rest and basic activities of daily living but any other activity causes limiting symptoms	Depends upon nutrition, organ function, activity
6: Exertion limited	“Walking wounded”: fatigues after a few minutes of activity. Could confirm cardiac impairment with hemodynamic measures or cardiopulmonary stress test	Depends upon nutrition, organ function, activity
7: Advanced NYHA III	Mild physical exertion is tolerable, but moderate activity causes symptoms	Not yet indicated

INTERMACS, Interagency Registry of Mechanically Assisted Circulatory Support; NYHA, New York Heart Association.

Data from Stevenson LW, Pagani FD, Young JB, et al. INTERMACS profiles of advanced heart failure: the current picture. *J Heart Lung Transplant.* 2009;28(6):535-541.

describe the range of symptoms from advanced NYHA class III (profile 7) to critical cardiogenic shock (profile 1) and can help assess the urgency to evaluate for mechanical circulatory support or transplants (Table 5.3). Patients in INTERMACS profiles 5 through 7 can be monitored without immediate plan for advanced heart failure therapy. Patients with resting symptoms (profile 4) or receiving inotropic support (profile 3) may need circulatory support sooner. Patients who are “sliding on inotropes” (profile 2)—demonstrating poor end-organ perfusion despite inotropic support—should be considered for immediate support within days and potentially transferred to a left ventricular assist device (LVAD) and transplant center. Patients in critical cardiogenic shock (profile 1) take precedence in mechanical circulatory support or heart transplant, which may be needed within hours.

Inotropic Support

Patients who have persistent symptoms despite GDMT and volume optimization, found to have elevated filling pressures and/or low cardiac output, may be appropriate candidates for ambulatory inotropic support. Ambulatory inotropes can be used for either bridge to durable mechanical support or palliation of symptoms. The current evidence suggests that ambulatory inotropes compared to GDMT do not improve mortality but may improve heart failure symptoms (improvement in NYHA class by 0.6 more than GDMT).

Inotropes commonly used include milrinone and dobutamine. Milrinone inhibits phosphodiesterase and thereby causes vasodilation. Hemodynamics improve due to reduction in afterload, decrease in pulmonary vascular resistance, and increase in cardiac contractility. Dobutamine is a sympathomimetic agent; it is an agonist for α -1, β -1, and β -2 receptor. This leads to an increase in myocardial contractility and stroke volume as well as decrease in total peripheral resistance, or afterload. Adverse effects include arrhythmias and significant hypotension due to vasodilation. If patients are hypotensive, norepinephrine (α -1 and β -1 receptor agonists) and dopamine (β -1 receptor agonist at medium doses and α -adrenergic receptor agonists at high doses) are preferred agents because they can vasoconstrict and increase blood pressure in addition to increasing myocardial contractility.

Mechanical Circulatory Support

In the setting of acute cardiogenic shock, several options are available for short-term mechanical support.

The intra-aortic balloon pump (IABP) is a counterpulsation pump placed in the aorta and synchronized to native cardiac beats. It reduces the afterload by deflating during systole and improves coronary perfusion pressure by inflating during diastole. The IABP-SHOCK II trials demonstrated no difference in 30-day mortality between patients treated with inotropes alone and those with IABP. Compared to other short-term mechanical supports, IABP provides only a small augmentation in cardiac output (500-600 mL/min/m²). Potential complications include limb ischemia, thrombosis, and vascular complications.

The Impella ventricular support system is an axial-flow pump that pulls blood from the left ventricle through an inlet area near the tip and expels blood from the catheter into the ascending aorta. There are different sizes of Impella including 2.5 or CP, which are designed for percutaneous peripheral insertion, as well as Impella 5.0 or LD, which are designed for surgical insertion. Depending on the type of Impella, it can provide 2.5 to 5 L/min/m² of augmentation. The ISAR-SHOCK and IMPRESS trials, however, have demonstrated no improvement in mortality. In addition to limb ischemia and vascular complications, the rotor in the pump can lyse red blood cells, causing significant hemolytic anemia.

Venous arterial extracorporeal membrane oxygenation (VA-ECMO) is a heart-lung bypass via venous and arterial cannulas that pump the blood from the body through an external oxygenator. Venous blood is drained from the right atrium and returned to the distal arterial system providing near complete temporary circulation support.

In addition to concerns of limb ischemia, hemolysis, and vascular injury due to the cannulas, the north-south syndrome is a feared complication. In this syndrome, only the lower body receives oxygenated blood through the arterial cannula, and the “north”—or the brain and upper body—receives perfusion with the deoxygenated blood. This may occur due to the position of the cannulas or the recovery of native heart function. VA-ECMO is considered as a last resort and is available at only select centers with the surgeons and infrastructure capabilities.

The advancement in durable mechanical circulatory support devices has now made it possible for HF patients in cardiogenic shock to be discharged and managed in ambulatory settings. Since the first heart lung machine in 1953, the durable circulatory supports have undergone significant transformation to reduce their size, noise, and device-related complications (Table 5.4). In order to reduce pump thrombosis, devices have evolved from axial-flow to centrifugal-flow.

TABLE 5.4 Parameters of Left Ventricular Assist Device

	HeartMate II	HeartMate III	HVAD
Flow configuration	Axial	Centrifugal	Centrifugal
Impeller bearings	Mechanical	Magnetic levitation	Hybrid
Weight	250 grams	220 grams	160 grams
Variation in speed	No	Yes	No
Implantation site	Chest and abdomen	Pericardial	Pericardial

In the latter configuration, impellers are perpendicular to the flow of the blood to reduce the risk of clot formation. Although older devices required mechanical bearings for the pumps, the latest designs employ magnetic levitation, further reducing thrombotic risks and improving durability. The newest FDA-approved device, HeartMate III, combines continuous flow with frequent variation in the speed, which can further reduce hemostasis and clot formation.

The prospective, multicenter RCT with the HeartMate III demonstrated up to 78% stroke-free 2-year survival rate. With these superior outcomes for the latest LVADs, advanced heart failure patients who are otherwise not candidates for heart transplants can now receive durable circulatory support as destination therapy. In fact, LVADs are now FDA-approved for patients with INTERMACS profiles 1 through 6. Patients who demonstrate signs of cardiorenal syndrome, intolerance to GDMT due to hypotension, and are persistently in NYHA functional classes III to IV despite GDMT should be referred to an advanced heart failure specialist for further evaluation.

Heart Transplant

Heart transplant remains an option for select patients with refractory HF. In recent years, the list of candidates for heart transplantation continues to grow without concurrent increase in available heart donors. Due to the scarcity of organs and high waitlist mortality, particularly in certain geographic areas, the United Network for Organ Sharing (UNOS) released a new set of allocation criteria in order to prioritize the sickest patients (Fig. 5.7). Those in status 1 or 2 will have access to organs that become available in a larger geographic area of up to 500 miles from the donor site.

Patients' survival after heart transplantation has improved but gains are mostly limited to the first year, with 1-year survival estimated to be 85%. The median survival is estimated to be 11 years; those who survive the first year have a longer median survival of 13 years. Survival may be improved by preoperative care including LVAD implantation as bridge to transplant, reducing allograft ischemic time intraoperatively, and optimization of postoperative immunosuppressants and cardiac rehabilitation. Patients are on multiple immunosuppressants, which places them at increased risk of developing opportunistic infections and malignancy. Inadequate immunosuppression can increase the risk of graft failure. These patients undergo close surveillance for the first year and continued monitoring for the rest of their lives.

Palliative Care

Despite advances in HF treatment and prevention, rates of hospitalization for acute decompensation, 30-day readmission, and mortality rates remain high. Only 50% of patients survive after 5 years and 29% die within the first year. Indicators of poor prognosis include functional status, low EF, pulmonary vascular and right ventricular remodeling due to left ventricular failure, cardiorenal and hepatic syndromes, and presence of arrhythmias.

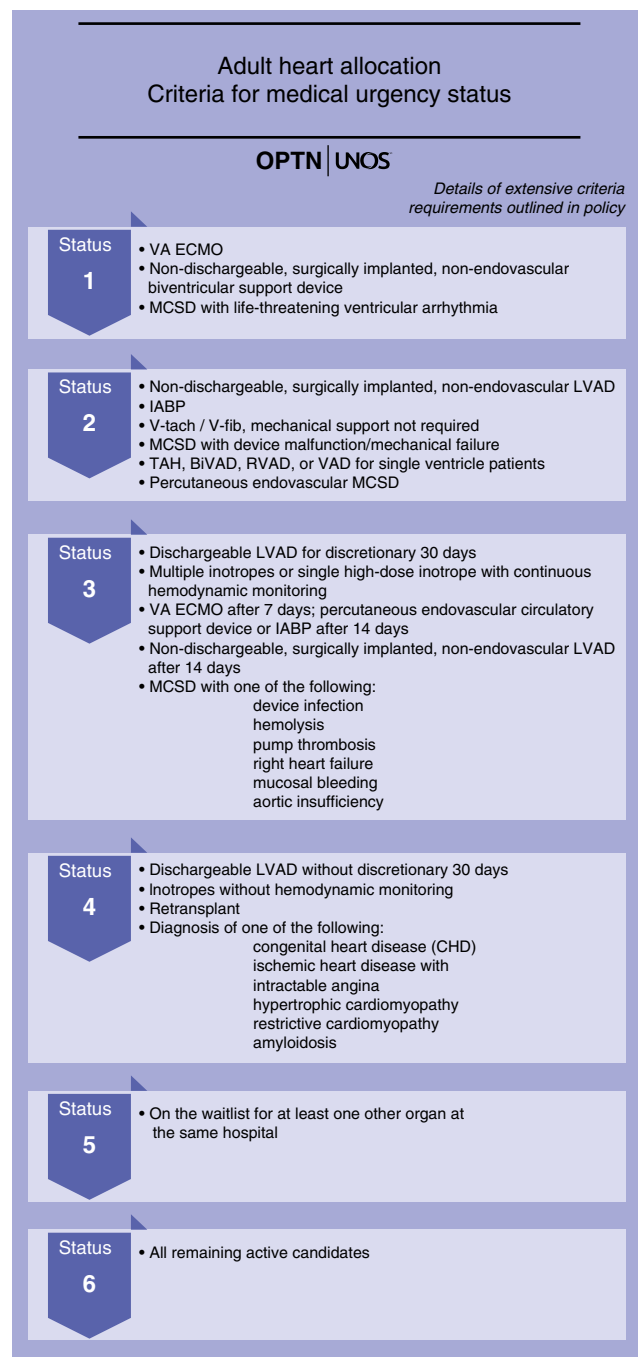

Fig. 5.7 Adult heart allocation criteria. (Adapted from UNOS, <https://optn.transplant.hrsa.gov/learn/professional-education/adult-heart-allocation/>.)

Toward the end of life, patients with HF have significant symptom burden that leads to loss of function and independence. Palliative care provides an interdisciplinary approach to meet the physical and emotional needs of the patient. Patients experience significant improvement in symptom burden, rates of anxiety and depression, as well as reduced hospitalization readmission rates. Palliative care can also assist with end-of-life transition and introduction of hospice care to patients and their families. Palliative care is a class I recommendation for stage D HFrEF patients. The optimization of HF symptom management and increasing access to palliative care are critical for improving care for advanced HF patients.

FUTURE DIRECTIONS

Prevention is still the key to success in treating HF. Treating hypertension and diabetes remain major public health objectives. Recent advances in pharmacologic and device therapies have improved HF-associated mortality and morbidity. Replacement of ACE inhibitors and ARBs with ARNIs has been shown to reduce mortality. CardioMEMs reduce 30-day readmission rates by more than 50%. Patients with advanced HF who are poor candidates for heart transplants can now receive LVADs as destination therapy. In addition, there is promising research and development in diagnosis and treatment of previously underrecognized conditions, such as HFpEF and amyloidosis.

However, access to care remains challenging in the modern health care environment. Currently, costs of novel therapies like ARNIs, cardioMEMs, and LVADs can be prohibitive. There is still limited access to palliative care services for advanced HF patients, even though this “low tech” intervention improves symptom management and reduces costs due to excessive acute care service utilization. Collaboration among health care providers, patient advocates, and policymakers can lead to improvement not only in survival and quality of life but reducing the financial burden to the society and the individual.

Congenital Heart Disease

Scott Cohen, Michael G. Earing

INTRODUCTION

Congenital heart defects are the most common group of birth defects, occurring in approximately 9 of 1000 live births. Without treatment, most patients die in infancy or childhood, with only 5% to 15% surviving into adulthood. Advancements in surgical and medical practices have resulted in survival of approximately 90% of these children to adulthood. Estimates suggest that more adults than children are living with congenital heart disease in the United States and that there is a 5% increase in the size of the adult congenital heart disease population every year.

Most adults living with congenital heart disease have had interventions performed (Table 6.1). Although most children who undergo surgical intervention survive to adulthood, total correction usually is not the rule. Adult patients with congenital heart disease are surviving longer than ever before, and it is becoming apparent that even the simplest lesions can be associated with long-term cardiac complications (i.e., arrhythmias and conduction abnormalities, ventricular dysfunction, residual shunts, valvular lesions, hypertension, and aneurysms) and noncardiac complications (i.e., renal dysfunction, restrictive lung disease, neurocognitive deficits, anxiety, depression, and liver dysfunction). Most adults with congenital heart disease need lifelong follow-up.

ACYANOTIC HEART DISEASE

Atrial Septal Defects

Definition and Epidemiology

Atrial septal defects (ASDs) are communications between the atria that allow shunting of blood from one atrium to the other. They are among the most common congenital anomalies seen in adolescents and young adults, occurring in 1 of 1500 live births and constituting 6% to 10% of all congenital heart defects.

There are four main types of ASDs. Ostium secundum defects are the most common, accounting for 75% of all ASDs. This defect occurs in the region of the fossa ovalis and results from excessive absorption of the septum primum or insufficient development of the septum secundum, or both.

Ostium primum defects represent about 20% of all ASDs and represent a form of atrioventricular septal defect (i.e., partial or incomplete atrioventricular canal). These defects are located in the inferior aspect of the atrial septum adjacent to the mitral and tricuspid valves. The defects result from lack of closure of the ostium primum by the endocardial cushions, which are embryologic swellings in the heart that form the primum atrial septum, the inlet portion of the ventricular septum, and parts of the mitral and tricuspid valve. The lesions often are associated with clefts in the mitral and tricuspid valves.

Sinus venosus ASDs represent 5% of all ASDs and are located at the entry of the superior vena cava or inferior vena cava into the right atrium. Frequently, there is associated partial anomalous drainage of the right upper pulmonary vein with the superior sinus venosus defect. This type of defect results from resorption of the wall between the vena cava and pulmonary veins.

An unroofed coronary sinus is a rare form of ASD, representing less than 1% of all ASDs. The coronary sinus is in apposition to the posterior aspect of the left atrium, but the orifice is in the right atrium. When a defect exists in the roof of the coronary sinus, a communication between the left atrium and right atrium exists, allowing shunting.

Pathology

All four types of ASDs allow oxygenated blood to pass from the left atrium into the right atrium, resulting in volume overload of the right atrium and right ventricle (Fig. 6.1). The degree of shunting is determined by the size of the ASD and the compliance of the left and right cardiac chambers. Comorbidities that increase left-sided filling pressures (i.e., left ventricular [LV] diastolic dysfunction, myocardial infarction, and mitral stenosis) may result in an increased left-to-right shunt. Over time, significant left-to-right shunting can cause enlargement of the right atrium and right ventricle, eventually leading to right ventricular (RV) systolic dysfunction and failure. Pulmonary hypertension may occur in approximately 26% of patients with a secundum ASD. However, significant elevation in pulmonary vascular resistance is rare.

Clinical Presentation

Although most individuals with an ASD are diagnosed during childhood after a murmur is noticed, a few patients have symptoms for the first time as adults. Most patients are asymptomatic during the first and second decades of life. In the third decade, increasing numbers of patients develop exercise intolerance, palpitations due to atrial arrhythmias, and cardiac enlargement on the chest radiograph. In patients with ASDs, the RV impulse at the left lower sternal border often has increased force compared with normal. On auscultation, the second heart sound typically is widely split and fixed (i.e., does not vary with inspiration).

All patients have a systolic ejection murmur, which is best heard at the left upper sternal border and is related to increased flow across a usually normal pulmonary valve. When there is a large left-to-right shunt, a mid-diastolic murmur can be heard at the left lower sternal border; it is related to increased flow across a normal tricuspid valve. When a mid-diastolic murmur is identified, the degree of left-to-right shunt is considered to be 1.5 times normal. In the setting of a primum

TABLE 6.1 Most Common Congenital Heart Defects Surviving to Adulthood Without Surgery or Interventional Catheterization

Mild pulmonary valve stenosis
Bicuspid aortic valve
Small to moderate size atrial septal defect
Small ventricular septal defect
Small patent ductus arteriosus
Mitral valve prolapse
Partial atrioventricular canal (ostium primum atrial septal defect and cleft mitral valve)
Marfan syndrome
Ebstein's anomaly
Congenitally corrected transposition (atrioventricular and ventriculoarterial discordance)

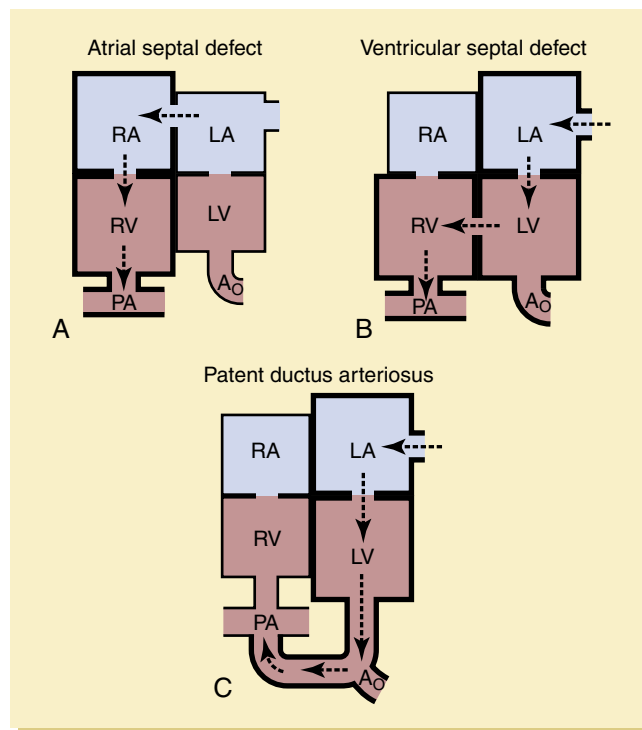

Fig. 6.1 The diagram shows three types of shunt lesions that commonly survive until adulthood and their effects on chamber size. (A) Uncomplicated atrial septal defect with left-to-right shunt flow across the interatrial septum, resulting in dilation of the right atrium (RA), right ventricle (RV), and pulmonary artery (PA). (B) Uncomplicated ventricular septal defect, resulting in dilation of the RV, left atrium (LA), and left ventricle (LV). (C) Uncomplicated patent ductus arteriosus, resulting in dilation of the LA, LV, and PA. Ao, Aorta. (From Liberthson RR, Walkdman H: Congenital heart disease in the adult. In Kloner RA, editor: Guide to cardiology, ed 3, Greenwich, Conn., 1991, Le Jacq Communications, pp 24-27.)

ASD, an additional holosystolic murmur at the apex may be caused by a cleft in the anterior leaflet of the mitral valve, resulting in mitral regurgitation.

Diagnosis

On the electrocardiogram (ECG), the features of ASD depend on the size and type of defect. In the setting of a large ostium secundum, sinus

venosus, or unroofed coronary sinus defect, the ECG typically demonstrates evidence of right atrial (RA) enlargement, RV hypertrophy, and right axis deviation. In the setting of an ostium primum ASD, like other forms of atrioventricular defects, there is a superior axis. The chest radiograph is helpful for evaluating the degree of left-to-right shunting. With a small shunt, the radiograph will be normal. As the shunt increases in size, the heart size and pulmonary vascular markings also increase.

The diagnosis of an ASD and its location are confirmed by transthoracic echocardiography in most cases. A sinus venosus ASD is the exception. In this setting, transesophageal echocardiography may be necessary. Cardiac catheterization is rarely performed to diagnose an ASD. CT scan or cardiac MRI may be useful in defining the pulmonary venous anatomy especially in defects associated with anomalous pulmonary veins.

Treatment

The treatment of ASDs involves surgical or transcatheter device closure and is indicated in the setting of impaired functional capacity, right atrial and/or right ventricular enlargement or a Qp:Qs (pulmonary to systemic blood flow) ratio of 1.5:1 or greater. Individuals with an ASD and a PA systolic pressure greater than two-thirds of systemic, pulmonary vascular resistance greater than two-thirds of systemic, and/or a net right to left shunt should not undergo ASD closure. However, individuals with significantly elevated PA systolic pressure or pulmonary vascular resistance can be assessed for reversibility during a hemodynamic catheterization (usually with nitric oxide) and if found to have reversible pulmonary vascular disease they can be considered for repair. Those that are not reversible can be placed on pulmonary hypertension targeted therapy and undergo a hemodynamic reassessment after 6 months. A reduction in pulmonary vascular resistance of greater than 20% is associated with a favorable prognosis after ASD closure, and closure with a pulmonary vascular resistance of 6.5 Wood units or less has been associated with improved RV function. For a secundum ASD, surgical closure and transcatheter device closure are accepted treatment options. Device closure is the most commonly used technique for closure of secundum defects. This technique, however, requires an adequate rim of septal tissue around the entire defect to allow for device stabilization. For ostium primum, sinus venosus, and unroofed coronary sinus forms of ASDs, surgical closure remains the only option.

Prognosis

Most patients who have undergone early closure of a defect have excellent long-term survival rates with low morbidity rates if repair is undertaken before 25 years of age. Older age at repair is associated with decreased late survival rates and an associated increased risk of atrial arrhythmias, thromboembolic events, and pulmonary hypertension. After the age of 40 years for patients with unrepaired ASDs, the mortality rate increases by 6% per year, and more than 20% of patients develop atrial fibrillation. By 60 years of age, the number of patients with atrial fibrillation increases to more than 60%. In asymptomatic patients, it is reasonable to close a hemodynamically significant ASD in the absence of significant pulmonary hypertension; however, comorbidities (especially in older adults) may impact the benefit of ASD closure on improving symptoms and functional capacity. Long-term rates of late complications and survival after transcatheter device closure remain unknown.

Ventricular Septal Defects

Definition and Epidemiology

Ventricular septal defects (VSDs) occur in 1.5 to 3.5 of 1000 live births. They constitute 20% of congenital heart defects.

There are four types of VSD: perimembranous, muscular, supracristal, and inlet. Perimembranous VSDs are the most common, comprising 70% of all VSDs. The membranous septum is relatively small and sits directly under the aortic valve. Perimembranous VSDs involve the membranous septum and typically extend into the muscular tissue adjacent to the membranous septum. If not large, these defects may close spontaneously by tissue from the septal leaflet of the tricuspid valve.

Muscular VSDs are the second most common VSD and account for 5% to 20% of all VSDs. Multiple muscular VSDs commonly are found at the time of diagnosis. Muscular VSDs have the highest rate of spontaneous closure.

Supracristal VSDs represent 5% to 8% of all VSDs. These defects are located superior to the crista supraventricularis (i.e., within the RV outflow tract directly below the right cusp of the aortic valve). These defects are associated with prolapse of the right aortic cusp, which can lead to progressive aortic regurgitation. In some cases, the prolapsed right aortic cusp may restrict the defect, but rarely do they spontaneously close.

Inlet VSDs are located in the posterior ventricular septum, just inferior to the tricuspid and mitral valve. They account for 5% to 8% of all VSDs and never close spontaneously.

Pathology

Shunting through a VSD is typically left to right and can cause overcirculation of the pulmonary vasculature and increased pulmonary venous return, resulting in left-sided chamber enlargement (see Fig. 6.1). The degree of shunting depends on the size of the defect and the pulmonary vascular resistance. Small defects (i.e., restrictive defects) typically have a small degree of shunting and normal pulmonary artery pressure. Moderate-sized defects have enough left-to-right shunting to cause mildly elevated pulmonary artery pressures and some left-sided chamber enlargement. Large defects (i.e., nonrestrictive defects) allow LV systolic pressures to be transmitted to the pulmonary circulation. This can cause irreversible obstructive pulmonary vascular disease early in childhood. Eventually, if the pulmonary vascular resistance exceeds the systemic vascular resistance, the shunt may reverse to right to left (i.e., Eisenmenger's physiology).

Clinical Presentation

The physical findings for a patient with a VSD depend on the size of the VSD, magnitude of the shunt, and the level of pulmonary artery hypertension. For patients with a small VSD, the apical impulses of the right ventricle and left ventricle typically have normal intensity on palpation, but there may be a palpable thrill. The first and second heart sounds typically are normal, and in most cases, there is a holosystolic murmur of moderate intensity at the left lower sternal border.

Patients with Eisenmenger's syndrome have cyanosis and secondary erythrocytosis. The RV impulse usually is increased at the left lower sternal border, and the pulmonary component of the second heart sound may be palpable. Typically, no systolic murmur is detected, but a diastolic murmur is often heard at the left upper sternal border due to a severely dilated main pulmonary artery and resultant pulmonary regurgitation.

Diagnosis

The ECG should be normal for patients with small VSDs. For those with Eisenmenger's syndrome, the ECG usually demonstrates RV hypertrophy with right axis deviation. Patients with a small VSD have a normal chest radiograph. Patients with Eisenmenger's syndrome may have mild cardiac enlargement with enlarged proximal pulmonary arteries and peripheral pruning with oligemic lung fields. Echocardiography

allows confirmation of the diagnosis, localization of defect, identification of long-term complications, and estimation of pulmonary artery pressure. Cardiac catheterization allows direct measurement of the degree of left-to-right shunting, pulmonary artery pressure, and pulmonary vascular reactivity.

Treatment

Because the majority of adult patients with an isolated VSD have no significant hemodynamic abnormalities, closure of the VSD is typically not needed. Closure of a VSD is indicated if there is evidence of left ventricular volume overload and a hemodynamically significant shunt ($Q_p:Q_s > 1.5$). Small VSDs that are asymptomatic should be followed conservatively. Because of the long-term risks, they need intermittent follow-up for life to monitor for the development of late complications. The exceptions to this rule are those with small supracristal or perimembranous VSDs with associated prolapse of the aortic cusp into the defect that results in progressive aortic regurgitation. These patients should be considered for surgical repair at the time of diagnosis to prevent progressive aortic valve damage.

Prognosis

Although isolated VSDs are common forms of congenital heart disease, the diagnosis of a VSD in an adult is rare. Most patients with a hemodynamically significant VSD have undergone repair in childhood or died earlier in life. As a result, the spectrum of isolated VSDs in adults is limited to those with small restrictive defects, those with Eisenmenger's syndrome, and those who had their defects closed in childhood.

For patients with small restrictive VSDs, long-term survival is excellent, with an estimated 25-year survival rate of 96%. The rate of long-term morbidity for patients with a restrictive VSD also appears to be low. However, the clinical course is not completely benign. Reported long-term complications include endocarditis, progressive aortic regurgitation due to prolapse of aortic valve into the defect (i.e., highest risk for the supracristal type but can occur with a perimembranous defect), and the development of right and left outflow tract obstruction from a double-chamber right ventricle or a subaortic membrane.

For patients who develop Eisenmenger's syndrome, survival into the third decade is common. However, with increasing age, the long-term complications of right heart failure, paradoxical emboli, and erythrocytosis usually result in a progressive drop in survival, with an average age of death of 37 years. Adults with previous VSD closure and without pulmonary hypertension or residual defects have a normal life expectancy.

Complete Atrioventricular Septal Defects

Definition and Epidemiology

Complete atrioventricular septal defects (AVSDs) consist of several cardiac malformations that result from abnormal development of the endocardial cushions. AVSDs account for 4% to 5% of congenital heart defects. Down syndrome is a common association; 40% of Down syndrome patients have congenital heart disease, and 40% of these have some form of AVSD.

AVSDs are categorized as partial (or incomplete) or complete. Both forms share common structural abnormalities—ostium primum ASD, inlet VSD, and cleft anterior mitral and septal tricuspid leaflet—in various combinations.

Pathology

A combination of the previously described defects results in interatrial and interventricular shunts, LV-to-RA shunt, and atrioventricular regurgitation. Because these defects include deficiency of the inlet portion of the ventricular septum, the LV outflow tract is lengthened and may be narrowed, producing the characteristic goose-neck deformity.

The natural history for patients with complete AVSD is characterized by the early development of pulmonary vascular disease, leading to irreversible damage that often occurs by 1 year of age, particularly for patients with Down syndrome. Surgery needs to be undertaken early if it is to be successful. Patients who are diagnosed in adulthood can be categorized in two groups: those with Eisenmenger's syndrome and those who had their defects closed in childhood.

Clinical Presentation

On physical examination, most previously repaired patients are cardiovascularly normal. However, patients with significant left atrioventricular (AV) valve regurgitation have a grade 3 or 4 (of 6) holosystolic regurgitant murmur at the apex. For the rare patient with subaortic stenosis, a grade 2 or 3 systolic murmur can be detected at the left mid-sternal border and radiating to the neck. The physical examination findings for patients with Eisenmenger's syndrome are similar to those for patients with unoperated VSDs.

Diagnosis

On the ECG, first-degree heart block is a common finding for patients with AVSD. All patients have a superior, leftward QRS axis. For those with Eisenmenger's syndrome, the chest radiograph demonstrates cardiomegaly, large proximal pulmonary arteries, and small peripheral pulmonary arteries (i.e., peripheral pruning). Patients who underwent previous repair and have significant systemic left AV valve regurgitation have cardiomegaly with increased vascular markings.

Treatment

Patients who underwent previous repair with significant left AV valve regurgitation causing symptoms, atrial arrhythmias, or deterioration in ventricular function should undergo elective repair or replacement. Previously repaired patients who develop significant subaortic stenosis (i.e., peak cardiac catheterization or echo gradient of ≥ 50 mm Hg or less in the presence of heart failure or moderate to severe mitral regurgitation) should undergo surgical repair.

Prognosis

Overall, for patients who underwent early repair before the development of pulmonary vascular disease, the long-term prognosis is good. The most common long-term complication is left AV valve regurgitation, with approximately 5% to 10% of patients requiring surgical revision for left AV valve repair or replacement during follow-up. The second most common long-term complication for this group is subaortic stenosis, occurring in up to 5% of patients after repair. Other long-term complications include residual atrial- or ventricular-level shunts, complete heart block, atrial and ventricular arrhythmias, and endocarditis.

Patients with Eisenmenger's syndrome are symptomatic with exertional dyspnea, fatigue, palpitations, edema, and syncope. Survival is similar to that for other forms of Eisenmenger's syndrome, with a mean age at death of 37 years. In retrospective studies, strong predictors for death included syncope, age at presentation of symptoms, poor functional class, low oxygen saturation ($\leq 85\%$), increased serum creatinine and serum uric acid concentrations, and Down syndrome.

Coarctation of the Aorta

Definition

Coarctation of the aorta is an abnormal narrowing of the aortic lumen. It constitutes 5% of congenital heart defects. Coarctation of the aorta may occur anywhere along the descending aorta, even below the diaphragm, but in more than 95% of cases, the narrowing is just below the takeoff of the left subclavian artery. In 50% to 85% of cases, there

is an associated bicuspid aortic valve. Other associated lesions include VSDs, subaortic stenosis, and mitral valve stenosis.

Pathology

Coarctation of the aorta is an aortopathy of the entire aorta rather than a localized abnormality. In the young, significant coarctation can decrease blood flow to the kidneys, gut, and lower extremities, resulting in severe acidosis and shock requiring immediate treatment. Unrepaired coarctation of the aorta can be seen in adults, but it is rare. Affected individuals develop extensive arterial collateralization to maintain distal perfusion. Most patients seen in adulthood are patients who have had previous coarctation of the aorta repair using a variety of different techniques.

Even after successful repair to relieve the obstruction, multiple studies have demonstrated that patients have persistent abnormalities in the media of the aorta proximal and distal to the coarctation repair site. The stiff aortic wall is characterized by decreased distensibility and endothelial and vascular dysfunction. These can result in resting and exercise-induced hypertension, increased carotid intimal thickness, and abnormal peripheral arterial responses to augmented blood flow and nitroglycerin.

Clinical Presentation

The clinical presentation of coarctation of the aorta depends on the severity of obstruction and the associated anomalies. Unrepaired coarctation of the aorta typically manifests with symptoms before adulthood. Symptoms include headaches related to hypertension, leg fatigue or cramps, exercise intolerance, and systemic hypertension. Untreated patients surviving to adulthood typically have only mild coarctation of the aorta.

Cardinal clinical features in the setting of a significant coarctation of the aorta include upper body hypertension, weak and delayed femoral pulses, and a blood pressure gradient between the right arm and right leg determined by blood pressure cuff. On auscultation, the aortic valve closure sound is usually loud; in the setting of a bicuspid aortic valve, an ejection click, often with a crescendo-decrescendo systolic murmur, is heard at the right upper sternal border. Often, a continuous systolic murmur is heard over the left scapula. It is related to continuous flow across the coarctation of the aorta.

Diagnosis

Patients with significant coarctation of the aorta typically show various degrees of left atrial (LA) and LV enlargement on an ECG. The chest radiograph typically demonstrates normal heart size with dilation of the ascending aorta and kinking or double contouring in the region of the descending aorta in the area of the coarctation, producing the characteristic figure-3 sign.

Most adult patients have rib notching. It is caused by the dilated intercostal collateral arteries eroding the undersurface of the ribs. Echocardiography is used to identify site, structure, and degree of stenosis or restenosis. Echocardiography is valuable for identifying other lesions, LV systolic function, and degree of LV hypertrophy.

Magnetic resonance imaging (MRI) and CT angiography are quite good for imaging the coarctation, defining the arch vessel anatomy, and identifying collaterals. Cardiac catheterization remains the gold standard for determining the anatomy and absolute degree of stenosis.

Treatment

Patients with hypertension and a significant native or residual coarctation of the aorta (i.e., upper extremity/lower extremity resting peak to peak gradient >20 mm Hg or mean Doppler systolic gradient >20 mm Hg, upper extremity/lower extremity gradient >10 mm Hg or mean

Doppler gradient >10 mm Hg plus either decreased LV systolic function of aortic regurgitation, upper extremity/lower extremity gradient >10 mm Hg or mean Doppler gradient >10 mm Hg with collateral flow) should be considered for surgical repair or catheter intervention with balloon angioplasty with or without stent placement. Surgical repair in the adult patient is technically difficult and is associated with high rates of morbidity. As a result, catheter-based intervention has become the preferred method in most experienced congenital heart disease centers, and balloon angioplasty for a native or recurrent coarctation of the aorta should be considered if stent placement or surgery is not an option.

Prognosis

After surgical repair, long-term survival is good but directly correlates with the age at repair. Those repaired after 14 years of age have a lower 20-year survival rate than those repaired earlier (79% vs. 91%). Long-term outcome data for catheter-based treatment is limited, but studies suggest that stented patients have lower acute and long-term complications at 60 months (25% for surgery vs. 12.5% for stents). Irrespective of the type of repair, the most common long-term complication is persistent or new systemic hypertension at rest or during exercise. Other long-term complications include aneurysms of the ascending or descending aorta (especially after Dacron patch repair), recoarctation at the site of previous repair, coronary artery disease, aortic stenosis or regurgitation (in the setting of a bicuspid aortic valve), and endarteritis. Intracranial aneurysms are seen in approximately 10% of patients with a coarctation, and increasing age and hypertension have been identified as risk factors.

Patent Ductus Arteriosus

Definition and Epidemiology

Patent ductus arteriosus (PDA) represents 9% to 12% of congenital heart defects. It is patent in the fetus but normally closes within several days of birth. However, it remains open in about 1 of 2500 to 5000 births. In infants born prematurely, the incidence is even higher, occurring in 8 of 1000 live births. The incidence of PDA is 30 times greater for babies born at high altitudes than for those born at sea level.

Pathology

A PDA allows transit of blood from the aorta into the pulmonary artery and recirculation through the pulmonary vasculature and the left side of the heart. This can result in left-sided chamber enlargement (see Fig. 6.1). As with VSDs, the size of the defect is the primary determinant of the clinical course in the adult patient. PDAs can be clinically categorized as silent PDAs; small, hemodynamically insignificant PDAs; moderate-size PDAs; large PDAs; and previously repaired PDAs.

Clinical Presentation

A silent PDA is a tiny defect that cannot be heard by auscultation and is detected only by other nonclinical means such as echocardiography. Life expectancy is always normal for this population, and the risk of endocarditis is extremely low.

Patients with a small PDA have an audible, long-ejection or continuous murmur that is heard best at the left upper sternal border and radiating to the back. They have normal peripheral pulses. Because there is negligible left-to-right shunting, these patients have normal LA and LV sizes and normal pulmonary artery pressure. Like those with silent PDAs, these patients are asymptomatic and have a normal life expectancy. However, they do have a higher risk of endocarditis.

Patients with moderate-size PDAs may be diagnosed during adulthood. These patients often have wide, bouncy peripheral pulses and an

audible, continuous murmur. They have significant volume overload and develop some degree of LA and LV enlargement and some degree of pulmonary hypertension. These patients are symptomatic with dyspnea, palpitations, and heart failure. Patients with large PDAs typically have signs of severe pulmonary hypertension and Eisenmenger's syndrome. By adulthood, the continuous murmur is typically absent, and there is differential cyanosis (i.e., lower extremity saturations are lower than the right arm saturation).

Diagnosis

Patients with silent and small PDAs appear normal by echocardiography and chest radiography. Calcifications may be seen on the postero-anterior and lateral films of an older patient with a PDA. In patients with significant left-to-right shunting, there typically is dilation of the central pulmonary arteries with increased pulmonary vascular markings. On an ECG, broad P waves and tall QRS complexes suggest LA and LV volume overload. A tall R wave in lead V_1 with a right axis deviation suggests significant pulmonary hypertension. Measurement of oxygen saturation should be performed in feet and both hands in adults with moderate or large PDAs to assess for the presence of right to left shunting. Echocardiography is important to estimate the size of the defect, degree of LA or LV enlargement, and degree of pulmonary artery hypertension.

Treatment

PDA closure is recommended if there is left atrial or left ventricular enlargement present that is attributable to a PDA with left-to-right shunting. Patients with a PDA and severe, irreversible pulmonary hypertension should not have their PDA closed. Catheter device closure is the preferred method in most centers. Surgical closure is reserved for patients with PDAs too large for device closure and for distorted anatomy such as a large ductal aneurysm. Because patients with clinical evidence of a PDA are at increased risk for endocarditis and the low risk of catheter-based device closure, a small audible PDA should be considered for device closure.

Prognosis

Patients with a large PDA who have developed Eisenmenger's syndrome have a prognosis similar to that of other patients with Eisenmenger's syndrome. Patients who underwent PDA repair before the development of pulmonary hypertension have a normal life expectancy without restrictions.

Pulmonary Valve Stenosis

Definition and Epidemiology

Pulmonary valve stenosis occurs in approximately 4 of 1000 live births and constitutes 5% to 8% of congenital cardiac defects. It is one of the most common adult forms of unoperated congenital heart disease. It can occur in isolation or with other congenital heart defects, such as an ASD.

Pathology

In congenital pulmonary valve stenosis, the pulmonary valve leaflets are often fused or thickened, which obstructs blood flow out of the right ventricle. The obstruction elevates RV pressure, and compensatory RV hypertrophy develops. Pulmonary stenosis is often tolerated better than aortic stenosis. Over time, RV dilation and dysfunction may occur.

Clinical Presentation

Most patients with pulmonary valve stenosis are asymptomatic and have a cardiac murmur at presentation. Most unoperated adults with

severe stenosis have jugular venous distention, and on palpation, an RV lift at the left lower sternal border and a thrill at the left upper sternal border can be identified. On auscultation, the second heart sound is widely split, and a systolic ejection click may or may not be heard, depending on the mobility of the pulmonary valve leaflets. In most cases, there is a harsh, crescendo-decrescendo systolic ejection murmur, which is heard best at the left upper sternal border; it radiates to the back and varies with inspiration.

Diagnosis

With moderate to severe pulmonary valve stenosis, the ECG demonstrates right axis deviation, RV hypertrophy, and RA enlargement. The ECG is usually normal for patients with mild pulmonary valve stenosis. On the chest radiograph, a prominent main pulmonary artery caused by poststenotic dilatation is a common finding regardless of the degree of stenosis. In patients with severe pulmonary valve stenosis, cardiomegaly due to RA and RV enlargement is often seen.

Echocardiography is the diagnostic method of choice. It allows visualization of the valve anatomy and degree of stenosis and enables estimation of the valve gradient.

Treatment

Survival into adult life and the need for intervention directly correlate with the degree of obstruction. In the Second Natural History Study of Congenital Heart Disease, patients with trivial stenosis (i.e., peak gradient ≤ 25 mm Hg) who were followed for 25 years remained asymptomatic and had no significant progression of obstruction over time. For those with moderate pulmonary valve stenosis (i.e., peak gradient between 25 and 49 mm Hg), there was an approximately 20% chance of requiring intervention by 25 years of age. Most patients with severe stenosis (i.e., peak gradient of ≥ 50 mm Hg) require intervention (i.e., surgery or balloon valvuloplasty) by age 25 years. Patients with moderate to severe pulmonary stenosis may be considered for intervention even in the absence of symptoms.

Since 1985, percutaneous balloon valvuloplasty has been the accepted treatment for patients of all ages. Before 1985, surgical valvotomy had been the gold standard. Today, adults with moderate or severe valvular pulmonary stenosis and otherwise unexplained symptoms of heart failure, cyanosis from interatrial right to left shunting, or exercise are recommended to undergo balloon valvuloplasty if feasible; otherwise surgical valvotomy is recommended (if the valve is extremely dysplastic or calcified).

Prognosis

After surgical valvotomy for isolated pulmonary stenosis, long-term survival is excellent. However, with longer follow-up the incidence of late complications and the need for reintervention do increase. The most common indication for reintervention is pulmonary valve replacement for severe pulmonary regurgitation. Other long-term complications include recurrent atrial arrhythmias, endocarditis, and residual subpulmonary obstruction.

Aortic Valve Stenosis

Definition and Epidemiology

Aortic valve stenosis is a common abnormality in adults with congenital heart disease. It is usually caused by a bicuspid aortic valve, which occurs in 1% to 2% of adults and is three times more common in males. It typically is an isolated lesion but can be associated with a dilated ascending aorta and other defects such as coarctation of the aorta or VSD.

Pathology

Aortic valve stenosis results in pressure overload of the left ventricle, which increases wall stress and causes compensatory LV hypertrophy. Diastolic dysfunction and oxygen delivery-demand mismatch ensues. The patient may remain well compensated and asymptomatic for many years, but compensatory mechanisms eventually begin to fail and LV dysfunction can develop. Patients with a bicuspid aortic valve have abnormal structure of the aortic wall that often leads to ascending aortic dilation.

Clinical Presentation

Most patients with aortic valve stenosis are asymptomatic and are diagnosed after a murmur is detected. The severity of obstruction at the time of diagnosis correlates with the pattern of progression. Symptoms are rare until patients have severe aortic valve stenosis (i.e., mean gradient by echocardiography of ≥ 40 mm Hg). Symptoms include chest pain, exertional dyspnea, near-syncope, and syncope. With any of these symptoms, the risk of sudden cardiac death is very high, and surgical intervention is mandated.

Patients with moderate to severe stenosis typically have decreased peripheral pulses, an increased apical impulse, and a palpable thrill at the base of the heart. On auscultation, these patients have an ejection click followed by a crescendo-decrescendo systolic murmur, which is heard best at the left midsternal border and radiating to the right upper sternal border and the neck. Correlation between the degree of stenosis and the intensity of the murmur is not good. However, it is rare for a murmur of 2/6 or less to be associated with severe stenosis. Some patients with aortic stenosis also have aortic regurgitation, in which case a decrescendo diastolic murmur at the left midsternal border that radiates to the apex is detected at presentation.

Diagnosis

Many patients with significant aortic stenosis have LV hypertrophy identified on the ECG. However, the correlation between the severity of stenosis and the finding of LV hypertrophy on the ECG is unreliable. On chest radiography, most patients with severe aortic stenosis have a normal heart size unless there is concurrent aortic regurgitation. Post-stenotic dilation of the ascending aorta is common irrespective of degree of stenosis, and ascending aorta dilation is a common finding. It appears on the chest radiograph as a widened mediastinum.

Echocardiography is the gold standard for evaluation of the severity of aortic valve stenosis and the anatomic morphology of the aortic valve. Cardiac catheterization is primarily indicated to evaluate coronary artery disease before surgical intervention, because approximately one-half of adults with symptomatic aortic valve stenosis have concurrent coronary artery disease.

Treatment

Patients with severe aortic stenosis and symptoms or asymptomatic patients with severe aortic valve stenosis and reduced LV systolic function ($< 50\%$) should be considered for intervention. Treatment involves manipulating the valve to reduce stenosis. This can be accomplished by transvenous balloon dilation of the valve, open surgical valvotomy, or surgical or catheter-based valve replacement. In absence of significant aortic regurgitation, most centers favor balloon dilation or surgical valvotomy for children who have pliable valves with fusion of the commissures. In adults, aortic valve replacement is the treatment of choice. Aortic valve replacement may be done with a mechanical valve, bioprosthetic valve, or the Ross procedure (placing the pulmonary autograft in the aortic position and putting a new valve in the pulmonary position). The ascending aorta may be replaced if it is 5.5 cm (5.0 cm in the setting of high-risk features, such as growth > 0.5 cm/year or family history of dissection) or 4.5 cm at the time of an aortic valve replacement.

Prognosis

The natural history of aortic valve stenosis in adults varies but is characterized by progressive stenosis over time. By 45 years of age, approximately 50% of bicuspid aortic valves have some degree of stenosis. Most patients requiring surgical valvotomy to relieve the stenosis before adulthood do well. However, by the 25-year follow-up, up to 40% of patients required a second operation for residual stenosis or regurgitation.

CYANOTIC HEART DISEASE

Tetralogy of Fallot

Definition and Epidemiology

Tetralogy of Fallot (TOF) is the most common cyanotic heart disease seen in adulthood, and it represents 10% of congenital heart defects. It consists of a large VSD, pulmonary stenosis (which may be valvular, subvalvular, and or supra-valvular), an aorta that overrides the VSD, and RV hypertrophy.

Pathology

Newborns with TOF are cyanotic because of the right-to-left shunt through the VSD and decreased pulmonary blood flow. The amount of pulmonary blood flow depends on the severity of the obstruction through the RV outflow tract. By the time TOF patients reach adulthood, most have had complete repair or palliative surgery.

Many adults with repaired TOF have had a transannular patch (i.e., synthetic patch across the pulmonary annulus) placed to relieve the RV outflow tract obstruction. This patch causes obligatory free pulmonary regurgitation. Free pulmonary regurgitation can be well tolerated by the right ventricle for many years, but usually in the third or fourth decades, the right ventricle begins to dilate, and it may become dysfunctional. Significant RV dilation and dysfunction can lead to LV dysfunction, significant tricuspid regurgitation, and atrial or ventricular arrhythmias. Almost 29% of adults with repaired TOF also have a dilated ascending aorta due to increased blood flow through the aorta before repair.

Clinical Presentation

Patients with repaired TOF typically have normal oxygen saturation levels. On palpation, there often is an RV lift at the left lower sternal border. On auscultation, there typically is a widely split second heart sound with a to-and-fro murmur in the pulmonary area due to significant pulmonary regurgitation or, less commonly, aortic regurgitation. A holosystolic murmur due to tricuspid regurgitation may be heard at the left lower sternal border. Symptoms in the adult with repaired TOF may include exertional dyspnea, palpitations, syncope, and sudden cardiac death.

Diagnosis

The ECG almost universally reveals a right bundle branch block pattern in patients who underwent repair of TOF. The QRS duration from the standard surface ECG correlates with the degree of RV dilation and dysfunction. A maximum QRS duration of 180 milliseconds or more is a highly sensitive and relatively specific marker for sustained ventricular tachycardia and sudden cardiac death. Patients with significant pulmonary regurgitation often have cardiomegaly with dilated central pulmonary arteries identified on the chest radiograph. A right aortic arch occurs in 25% of cases, and it can be detected by close observation of the chest radiograph. An echocardiogram is useful for evaluating the RV outflow tract (e.g., pulmonary regurgitation, residual stenosis), biventricular size and function, tricuspid valve function, and ascending aortic size. MRI is the gold standard for assessing RV size and function

(Fig. 6.2). It can also give an accurate assessment of the degree of pulmonary insufficiency and branch pulmonary artery anatomy.

Treatment

Treatment for TOF is surgical repair. Repair is typically performed between 3 to 12 months of age and consists of patch closure of the VSD and relief of the pulmonary outflow tract obstruction by patch augmentation of the RV outflow tract or pulmonary valve annulus, or both. Reintervention is necessary in approximately 10% of adults with repaired TOF after 20 years of follow-up. With longer follow-up, the incidence of reintervention continues to increase. The most common indication for reintervention is pulmonary valve replacement in patients with moderate or greater pulmonary valve regurgitation and symptoms. Pulmonary valve replacement is also reasonable for preservation of ventricular size and function in asymptomatic patients with repaired tetralogy of Fallot and ventricular enlargement or dysfunction and moderate or greater pulmonary regurgitation. Pulmonary valve replacement can be performed surgically, or in some patients, percutaneously. Patients with repaired tetralogy of Fallot may be considered for an ICD for primary prevention if multiple risk factors for sudden death are present, including LV systolic or diastolic dysfunction, nonsustained ventricular tachycardia, QRS greater than 180 ms, extensive right ventricular scarring or inducible sustained ventricular tachycardia at an electrophysiologic study.

Prognosis

In the developed world, the unoperated adult with TOF has become a rarity because most patients undergo palliation (i.e., stenting) or repair in childhood. Survival of the unoperated patient to the seventh decade has been described but is rare. Only 11% of unrepaired patients are alive at 20 years of age and only 3% at 40 years.

Late survival after repair of TOF is excellent. Survival rates at 32 and 35 years are 86% and 85%, respectively, compared with 95% for age- and sex-matched controls. Importantly, most patients live an unrestricted life. However, many patients over time develop late symptoms related to numerous, long-term complications after TOF repair. Late complications include endocarditis, aortic regurgitation with or without aortic root dilation (typically due to damage of the aortic valve during VSD closure or to an intrinsic aortic root abnormality), LV dysfunction (from inadequate myocardial protection during previous repair or chronic LV volume overload due to long-standing palliative arterial shunts), residual pulmonary obstruction, residual pulmonary valve regurgitation, RV dysfunction (due to pulmonary regurgitation or pulmonary stenosis), atrial arrhythmias (typically atrial flutter), ventricular arrhythmias, and heart block.

Transposition of the Great Arteries

Definition and Epidemiology

Transposition of the great arteries (TGA) represents 3.8% of all congenital heart disease. In complete TGA, the aorta arises from the right ventricle and the pulmonary artery from the left ventricle. As a result, the systemic venous flow (i.e., blood with low oxygen content) is returned to the right ventricle and is then pumped to the body through the aorta without passing through the lungs for gas exchange. The pulmonary venous flow (i.e., oxygenated blood) returning to the left ventricle is then pumped back to the lungs. As a result, the systemic and pulmonary circulations run in parallel. Oxygenation and survival depend on mixing between the systemic and pulmonary circulations at the atrial, ventricular, or PDA level. In 50% of cases, there are other anomalies: VSD (30%), pulmonary stenosis (5% to 10%), aortic stenosis, and coarctation of the aorta ($\leq 5\%$).

The first definitive operations for TGA (i.e., atrial switch procedures) were described by Senning in 1959 and Mustard in 1964. In these procedures, the systemic and pulmonary venous returns are

Fig. 6.2 Short axis magnetic resonance images of the right and left ventricles with epicardial and endocardial tracings of both ventricular cavities. There are a predefined number of slices through the heart with a constant thickness. The volumes of the left and right ventricles in each slice are calculated and summed together in end diastole and end systole to determine the total right and left ventricular volumes (i.e., Simpson's method).

rerouted in the atrium by constructing baffles. The systemic venous return from the superior and inferior vena cavae is directed through the mitral valve and into the left ventricle, which is connected to the pulmonary artery. The pulmonary venous return is then directed through the tricuspid valve into the right ventricle, which is connected to the aorta. These procedures leave the left ventricle as the pulmonary ventricle and the right ventricle as the systemic ventricle.

Over the past 20 years, the arterial switch procedure has gained popularity. During the procedure, the great arteries are transected and reanastomosed to the correct ventricle (i.e., left ventricle to the aorta and right ventricle to the pulmonary artery) along with coronary artery transfer. Operative survival after the arterial switch procedure is very good, with a surgical mortality rate of 2% to 5%.

Pathology

Most infants who do not have surgical intervention die in the first few months of life. For adults born with complete TGA who have had an atrial switch procedure, the right ventricle continues to be the systemic ventricle, and the left ventricle is the subpulmonic ventricle. Long-term follow-up series have demonstrated that the right ventricle can function as the systemic ventricle for 30 to 40 years, but with longer follow-up, systemic ventricular dysfunction continues to increase. At the 35-year follow-up, approximately 61% of patients have developed moderate or severe RV dysfunction.

Another common postoperative problem is the tricuspid valve. After the atrial switch procedure, the tricuspid valve remains the systemic atrioventricular valve and must tolerate systemic pressures. Due to changes in RV morphology and abnormal chordal attachments, the tricuspid valve is prone to become dysfunctional and develop significant regurgitation.

Significant coronary lesions, such as occlusions or stenoses, occur in 6.8% of patients who have had the arterial switch procedure. These lesions are likely related to suture lines or kinking at the time of reimplantation of the coronary arteries into the neo-aorta. Systemic LV function is usually normal. LV dysfunction is associated with coronary anomalies.

Clinical Presentation

In the repaired adult with an atrial switch procedure, the physical examination may reveal a murmur consistent with tricuspid valve insufficiency and a prominent second heart sound due to the anterior

position of the aorta. Patients who have had an atrial switch procedure tend to have worsening functional status as the length of follow-up increases. They often have resting sinus bradycardia or a junctional rhythm. Palpitations due to atrial arrhythmias are common, occurring in up to 48% of patients 23 years after the atrial switch procedure.

In those who undergo the arterial switch procedure, the physical examination may reveal a murmur of neo-aortic or neo-pulmonic regurgitation. These patients usually have normal function status, but because of denervation of the heart, myocardial ischemia may manifest as atypical chest discomfort.

Diagnosis

After the atrial switch procedure, the ECG may show a loss of sinus rhythm with evidence of RV hypertrophy. Ambulatory monitors are important to monitor for bradyarrhythmias, sinus node dysfunction, and atrial arrhythmias. Chest radiographs may show an enlarged cardiac silhouette in those with a dilated systemic right ventricle. An echocardiogram can demonstrate qualitative systemic RV size and function and the degree of tricuspid regurgitation. MRI is often used to accurately quantify systemic RV size and function, tricuspid valve function, and atrial baffle anatomy.

After the arterial switch, echocardiography is used to assess pulmonary artery and branch pulmonary artery stenosis, neo-aortic and neo-pulmonic valve regurgitation, and ventricular function. MRI or computed tomography may be used to assess the anatomy of the branch pulmonary arteries. An exercise stress test is often used to evaluate myocardial ischemia.

Treatment

Treatment options are limited for adults with complete TGA repaired by atrial switch who have failing systemic right ventricles or significant tricuspid regurgitation, and evidence of significant benefit is lacking. However, potential treatments include medical therapy, revision of atrial baffles, pulmonary artery banding, resynchronization therapy, ventricular assist devices, and possible transplantation. Medical therapy, including consideration of anticoagulation, in patients with atrial tachyarrhythmias is recommended.

After the arterial switch procedure, catheter-based or surgical reintervention for pulmonary artery stenosis may be required in 5% to 25% of patients. Coronary artery revascularization is rarely required (0.46% of patients), as is neo-aortic valve repair or replacement (1.1%

of patients). Guideline-directed recommendations for aortic valve replacement are reasonable to follow for patients with d-TGA and severe neo-aortic valve regurgitation.

Prognosis

Long-term follow-up studies after the atrial switch procedure show a small but ongoing attrition rate, with numerous intermediate- and long-term complications. Long-term complications include systemic RV dysfunction and tricuspid valve regurgitation, loss of sinus rhythm with the development of atrial arrhythmias (50% incidence by age 25), endocarditis, baffle leaks, baffle obstruction, and sinus node dysfunction requiring pacemaker placement. Intermediate-term complications related to the arterial switch procedure include coronary artery compromise, pulmonary outflow tract obstruction (at the supra-valvular level or takeoff of the peripheral pulmonary arteries), neo-aortic valve regurgitation, endocarditis, and neo-aorta dilation.

As a result of the long-term complications associated with the atrial switch procedure, the arterial switch operation has been the procedure of choice since 1985. Long-term data on the survival after the arterial switch operation do not exist, but intermediate-term results are promising: 88% at 10 and 15 years.

Valvular Heart Disease

Christopher Song

INTRODUCTION

In developing countries, rheumatic heart disease (RHD) remains a common cause of valvular heart disease (VHD). In industrialized countries, the burden of rheumatic disease has significantly decreased, and the most common etiology is degenerative disease. The prevalence of VHD in the US adult population is 2.5%. Prevalence increases with age to as high as 13.3% in those 75 years and older. Moderate or severe VHD is associated with excess mortality. Therefore, with an aging population, valvular heart disease is and will continue to be a major public health problem.

The “2014 AHA/ACC Guideline for the Management of Patients with Valvular Heart Disease” provides a classification of the progression of VHD with 4 stages, A through D (Table 7.1). Timing of intervention for most VHD is guided by the onset of symptoms, severity of VHD, and evidence of adverse cardiac remodeling. Therefore, a thorough history and physical examination along with a comprehensive transthoracic echocardiogram (TTE) are essential in the evaluation of patients with known or suspected VHD. Other cardiac testing modalities can help to determine the severity of VHD and the presence of symptoms. Once intervention is contemplated, each individual patient’s surgical risk should be assessed. If surgical risk is high or prohibitive, transcatheter approaches may be an option.

AORTIC STENOSIS

Definition and Etiology

Valvular aortic stenosis (AS) is defined by restriction in leaflet motion resulting in left ventricular (LV) outflow obstruction. Less common causes of LV outflow obstruction include lesions at the supra- or subvalvular level. There are three primary etiologies of valvular AS: congenital, rheumatic, and calcific disease.

The etiology often dictates age at presentation. Patients with congenital aortic stenosis and unicuspid aortic valves usually present before the age of 30. Those with a bicuspid aortic valve or rheumatic valve disease typically present between the age of 40 and 60. Patients with calcific trileaflet valve typically present after age 70. However, patients with Paget disease or end-stage renal disease may present at a younger age.

Pathophysiology

The initiation phase of calcific aortic valve disease is similar to atherosclerosis. The process is thought to begin with mechanical stress and endothelial damage leading to inflammation and lipid deposition. The propagation phase is dominated by calcification leading to progressive restriction of the valve leaflets and eventual LV outflow obstruction.

In bicuspid aortic valves there is an associated increase in mechanical stress which leads to accelerated calcification of the valve leaflets. Bicuspid aortic valve occurs in about 1% of the population and it is twice as common in males as in females. Patients with a bicuspid aortic valve often have an associated aortopathy such as coarctation or aortic aneurysm.

Once AS becomes hemodynamically significant, it leads to resistance in LV ejection and an increase in LV systolic pressure and wall stress. In order to maintain normal wall stress, wall thickness increases resulting in concentric hypertrophy. The left ventricle can remain in this compensated state for a prolonged period. However, as valvular stenosis and hypertrophy progress, LV end-diastolic pressure increases and, eventually, LV dilation and systolic dysfunction ensue.

Natural History and Clinical Presentation

Patients with AS are usually asymptomatic for a prolonged period. Symptom onset occurs when valve obstruction is severe and usually prior to the onset of LV systolic dysfunction. In fact, LV chamber size and systolic function can remain normal until the AS is end-stage. The onset of symptoms in AS indicates a significant increase in mortality risk. This was first described by Ross and Braunwald in their seminal paper in 1968. They also found that specific symptoms were associated with different survival rates. The average survival of patients with symptoms of angina, syncope, and heart failure was 5, 3, and 2 years, respectively (Fig. 7.1).

These “classic” symptoms are now thought to be symptoms of end-stage disease. With the advent of echocardiography and close follow-up of patients, the most common presenting symptoms are dyspnea on exertion or decreased exercise tolerance, exertional dizziness, and exertional angina. Given the nonspecific nature of these symptoms along with the prognostic and therapeutic implications of diagnosing a patient with severe symptomatic AS, one must be thorough in screening patients for these symptoms but also be cautious in attributing these symptoms to AS.

Physical Examination

The physical examination is useful in the initial detection of AS and correlates with severity (Table 7.2). However, no physical examination findings can reliably exclude severe AS.

When palpating the carotid artery, a delayed, low amplitude pulse may be appreciated (*pulsus parvus et tardus*). With precordial palpation, a heaving and sustained apical impulse may be noted due to LV hypertrophy or systolic dysfunction. A fourth heart sound (S_4) can be palpable in the setting of a noncompliant left ventricle. In addition, a

TABLE 7.1 Stages of Progression of VHD

Stage	Definition	Description
A	At risk	Patients with risk factors for development of VHD
B	Progressive	Patients with progressive VHD (mild-moderate severity and asymptomatic)
C	Asymptomatic severe	Asymptomatic patients who have the criteria for severe VHD: C1: asymptomatic patients with severe VHD in whom the left and right ventricle remain compensated C2: asymptomatic patients with severe VHD with decompensation of the left or right ventricle
D	Symptomatic severe	Patients who have developed symptoms as a result of VHD

Fig. 7.1 Natural history of severe aortic stenosis without surgery once symptoms develop. (Data from Ross J Jr, Braunwald E: Aortic stenosis, Circulation 38:61, 1968.)

precordial thrill may be appreciated due to turbulent blood flow across a stenotic aortic valve.

The findings on cardiac auscultation are reflective of reduced mobility and delayed closure of the aortic valve leaflets and resistance to flow. The aortic component (A_2) of the second heart sound (S_2) becomes delayed to occur simultaneously with the pulmonic component (P_2) forming a single S_2 . In severe AS, A_2 may become inaudible or paradoxical S_2 can be observed. An aortic ejection click can be heard in mild to moderate AS, when the leaflets are stiff but still mobile. The classic murmur AS is described as a harsh crescendo-decrescendo systolic murmur that is best heard at the right upper sternal border that radiates to the carotid arteries. The murmur begins after the first heart sound (S_1) and ends before S_2 . Like the carotid pulse, the timing of the murmur correlates with severity of AS. An early peaking murmur is indicative of mild or moderate AS whereas a late peaking murmur is typically a sign of severe AS. The murmur may also radiate to the apex where a distinct musical quality can be appreciated. This is known as Gallavardin's phenomenon and often mistaken as the presence of concomitant mitral regurgitation (MR).

Diagnosis

An electrocardiogram (ECG) and chest radiograph are commonly obtained and can have nonspecific findings such as LV hypertrophy or cardiomegaly, respectively. The primary tool for diagnosing AS is echocardiography. TTE can accurately assess the aortic valve structure, the severity of AS, and the effects of AS on the cardiac chambers. Doppler imaging can be used to estimate the gradients across a stenotic aortic valve and calculate an aortic valve area. Criteria for mild, moderate, and severe AS are well established (Table 7.3).

In most cases the severity of AS by TTE correlates with the clinical evaluation. If there is a discrepancy, further testing can be considered.

An exercise treadmill study can be done to objectively assess functional capacity. A cardiac catheterization with hemodynamic measurements provides an alternative assessment of the severity of AS. Computed tomography can quantify aortic valve calcium, which has been shown to correlate with AS severity by TTE and with clinical outcomes.

In patients with LV systolic dysfunction, it may be unclear if a patient has true severe AS or pseudosevere AS. A low-dose dobutamine stress echocardiogram can help to differentiate between the two. In true severe AS the valve area is fixed, regardless of dobutamine. In pseudosevere AS the aortic valve opening is limited by the low LV outflow and the valve area will increase with dobutamine. This test can also provide information about the contractile reserve of the left ventricle, which has prognostic implications when considering valve replacement.

Treatment

The management of asymptomatic AS involves close monitoring, early detection of symptoms, and treatment of cardiovascular risk factors and comorbidities such as hypertension, hyperlipidemia, and coronary artery disease. No treatments have been shown to prevent the progression of AS.

Once a patient develops severe symptomatic AS, medical therapy has limited benefit and aortic valve replacement (AVR) is recommended. Medical therapy should focus on preventing and optimizing concomitant cardiovascular conditions and treating symptoms. Nonetheless, AVR has been shown to improve symptoms and survival and it is the only effective treatment in severe symptomatic AS. Those with severe asymptomatic AS may also meet indications for AVR if they have concurrent LV systolic dysfunction, very severe AS, rapidly progressing AS, or if they are undergoing another cardiac surgery.

There are two broad approaches to AVR: surgical and transcatheter. For decades, surgical AVR was the mainstay of therapy for severe AS. With surgical AVR, either a mechanical or bioprosthetic valve can be considered. With favorable flow characteristics, mechanical valves can last for the patient's lifetime (Fig. 7.2). However, these valves require anticoagulation with warfarin. While bioprosthetic valves, made from bovine or porcine material, do not require anticoagulation, they are less durable and typically require re-replacement after 10 to 20 years (Fig. 7.3).

Rather than an open procedure requiring sternotomy, transcatheter aortic valve implantation (TAVI) most commonly involves accessing the femoral artery and using a catheter to deliver a bioprosthetic valve into position by expanding a balloon and effectively crushing the native aortic valve against the aortic wall (Fig. 7.4). Less common approaches include transapical, transaortic, and subclavian. The role of TAVI was initially established in patients with severe symptomatic AS and prohibitive surgical risk. TAVI led to significant mortality benefit

TABLE 7.2 AS Exam Findings by Severity

Exam Finding	Mild	Moderate	Severe
Carotid pulse	Normal	Slow rising	Parvus et tardus
Apical impulse	Normal	Heaving	Heaving and sustained
S ₄ gallop	Absent	May be present	Present
Systolic ejection click	Present	May be present	Absent
Systolic murmur peak	Early systole	Mid systole	Mid or late systole
S ₂	Normal	Normal or single	Single or paradoxical

TABLE 7.3 Measures of AS Severity on Echocardiography

Indicator	Normal	Mild	Moderate	Severe
Aortic valve area (cm ²)	>2.0	1.5-2.0	1.0-1.5	<1.0
Mean gradient (mm Hg)		<25	25-40	>40
Peak jet velocity (m/s)	<2.0	2-3	3-4	>4

in this patient population when compared to standard therapy. Since the landmark trial in 2010, TAVI has emerged as an effective therapy for severe symptomatic AS in patients across the entire spectrum of surgical risk, from extreme risk to low risk.

Patients being considered for AVR should undergo a thorough individualized evaluation by a multidisciplinary heart valve team. The patient's life expectancy, surgical risk, comorbidities, frailty, anatomy, quality of life, values, and preferences should all be considered before making an informed shared decision on treatment strategy.

MITRAL STENOSIS

Definition and Etiology

Mitral stenosis (MS) is defined by the restriction of blood flow from the left atrium (LA) to the left ventricle during diastole. RHD is by far the most common cause of MS. In developed nations, rheumatic MS has become less common with the decreasing incidence of rheumatic fever. However, in developing nations, RHD remains a significant

public health problem. Less common causes of MS include mitral annular calcification, radiation exposure, congenital, or mechanical obstruction from an atrial myxoma, vegetation, or thrombus.

Pathophysiology

Rheumatic fever is the result of an abnormal immune response usually occurring after 10 days to 3 weeks after untreated group A streptococcal pharyngitis. It typically affects children between the ages of 6 and 15 years. The diagnosis can be made based on clinical manifestations and the revised Jones criteria (Table 7.4).

In RHD, there is inflammatory process thought to be due to cross-reactivity between streptococcal antigen and valve tissue. This along with chronic turbulent flow through a deformed valve results in thickening and calcification of the mitral leaflets, thickening and shortening of the chordae tendineae, and fusion of the leaflet commissures (Fig. 7.5). This ultimately leads to a reduced orifice through which blood can flow from the LA to the left ventricle during diastole.

Polyarthritits	Arthralgia
Chorea	Previous rheumatic fever or known rheumatic heart disease
Erythema marginatum	
Subcutaneous nodules	

^aRheumatic fever is diagnosed based on the presence of two major criteria or one major and two minor criteria after a recent documented group A streptococcal infection.

Fig. 7.5 Commissural fusion in mitral stenosis. (A) Left atrial aspect. (B) Left ventricular aspect. (From Cardiovascular Pathology, Fourth Ed, Elsevier, 2016.)

The hemodynamic consequences of MS primarily affect the pulmonary capillary bed, pulmonary artery, and right ventricle. In pure MS, the left ventricle remains unaffected. With resistance to left atrial emptying during diastole, left atrial pressure (LAP) increases. This pressure is reflected back to the capillary bed and pulmonary artery, which can result in pulmonary edema and pulmonary hypertension. This can lead to pressure overload of the right ventricle with subsequent right ventricle hypertrophy (RVH), tricuspid regurgitation (TR), and eventual right ventricular (RV) failure.

Natural History and Clinical Presentation

In developed countries, rheumatic MS is usually a slow progressive disease with a prolonged asymptomatic period of up to several decades. In developing countries, the disease course can be more rapid with symptoms in young adults and children. Symptom onset occurs once the mitral valve area is less than 1.5 cm². Once symptom onset occurs, the prognosis becomes worse. Mortality has been linked to New York Heart Association (NYHA) functional class. The presence of atrial fibrillation (AF) and pulmonary hypertension has also been established as a poor prognostic indicator.

Patients often present with dyspnea on exertion and decreased exercise tolerance. This is a consequence of elevated LAP and pulmonary pressures. Additionally, with exertion, an increase in heart rate leads to a decrease in diastolic filling time and increase in the diastolic gradient across the mitral valve.

Elevated LAP leads to left atrial dilation and AF. This can often precipitate or exacerbate the symptoms of MS in two possible ways. First, in AF, there is the loss of atrial contraction which further impedes diastolic flow across a stenotic mitral valve. Second, AF often leads to high heart rates and decreases diastolic filling time. Also, with AF associated with MS, there is an increased thromboembolic risk. If the LA becomes severely dilated, it can compress the recurrent laryngeal nerve and cause hoarseness (Ortner syndrome) or coughing.

Increases in pulmonary pressures and vascular congestion can lead to hemoptysis. As pulmonary hypertension progresses, it affects the right heart and right-sided filling pressures, ultimately leading to symptoms of right heart failure such as ascites and peripheral edema.

Symptoms can be provoked with any state causing an increase in cardiac output or heart rate such as exertion, stress, illness, infection, or arrhythmia. Symptoms may be unmasked in previously asymptomatic women with MS who become pregnant given the increase in heart rate and cardiac output associated with pregnancy.

Physical Examination

Several components of the physical examination need to be carefully assessed when evaluating patients with MS. The patient should be examined in a quiet room and positioned in the left lateral decubitus position because certain characteristic findings of MS may be difficult to appreciate.

S₁ is loud early on in the disease as elevated LAP leads to increased excursion of the mitral leaflets. However, as the disease progresses and the leaflets become calcified and rigid, S₁ diminishes. The S₂ is initially normal but P₂ can increase in intensity as pulmonary pressures rise. Eventually a single S₂ can result. S₃ is typically not heard but S₄ can be heard due to right ventricular hypertrophy (RVH).

A diastolic opening snap (OS) can be heard due to the initial rapid opening of the mitral leaflets followed by an abrupt halt due to fusion of the leaflet tips. The interval between S₂ and OS varies inversely with the severity of MS. The earlier in diastole the OS occurs, the more severe the MS as this is reflective of higher LAP.

The murmur appreciated in MS is a low-pitched diastolic rumble best heard at the apex and at end expiration using the bell of the stethoscope. In mild MS, the murmur may be heard only in late diastole. As

MS progresses the murmur may be heard throughout diastole, and if the MS is very severe the murmur may be very soft or absent due to slow flow across the mitral valve.

Patients with symptomatic MS may have signs of heart failure such as rales, jugular venous distension, hepatomegaly, and peripheral edema. If there is significant pulmonary hypertension, a parasternal lift or RV heave may be appreciable.

Diagnosis

ECG and chest radiograph can have nonspecific findings. ECG can show left atrial enlargement, AF, or RVH. Chest radiograph may demonstrate pulmonary vascular congestion, RV dilation, pulmonary artery dilation, or left atrial enlargement (“double density” sign).

TTE is the diagnostic test for MS. TTE is also used to evaluate the severity of MS, assess the effects of the MS on the cardiac chambers and pulmonary pressures, assess for concomitant valvular disease, and assess for suitability of valve anatomy for percutaneous mitral balloon valvotomy (PMBV). On TTE, the mitral leaflets appear thickened and deformed. In rheumatic MS, leaflet motion during diastole is restricted and results in a characteristic “hockey stick” appearance. Doppler interrogation can provide an estimation of mitral valve area and pulmonary artery pressure. The TTE can also assess for the other findings associated with MS such as left atrial dilation, RVH or RV dilation, and TR. With the findings on TTE and the patient’s symptoms, MS severity can be staged (Table 7.5).

When there is a discrepancy between the TTE findings and clinical findings, exercise stress echocardiography can be performed to evaluate the mitral valve gradients and pulmonary pressures during exercise. Alternatively, cardiac catheterization can be considered to obtain direct measurements of the cardiac chambers and mitral gradients.

Treatment

There is a limited role for medical therapy in the treatment of MS. If patients have symptoms of heart failure, diuretics can be used to alleviate symptoms. Slowing the heart rate with β -blockers or calcium-channel blockers will increase diastolic filling time and decrease mitral gradients. Rate control is particularly important in AF. Anticoagulation with a vitamin K antagonist is recommended in patients with MS and AF, prior embolic event, or left atrial thrombus. Direct oral anticoagulants have not been approved for this indication.

The decision to proceed with an intervention of the mitral valve depends on the severity of MS and the presence of symptoms, AF, and pulmonary hypertension. Valve morphology, presence of concomitant MR, presence of left atrial thrombus, and the patient’s surgical risk will guide whether the patient undergoes a surgical mitral valve replacement or PMBV. Contraindications for PMBV include the presence of left atrial thrombus and more than moderate MR. TTE can be used to assess the suitability for PMBV by assessing the mobility, thickening, and calcification of the mitral leaflets and the degree of subvalvular thickening. Refer to Table 7.6 for a summary of the recommendations for mitral valve intervention described in the 2014 AHA/ACC valve guidelines.

PULMONIC STENOSIS

Definition and Etiology

Pulmonic stenosis (PS) is defined by a restriction in leaflet motion resulting in RV outflow obstruction and a pressure gradient between the right ventricle and main pulmonary artery. The etiology of PS is almost always congenital and usually occurs as an isolated lesion. However, it can also be associated with other congenital conditions such as tetralogy of Fallot, congenital rubella syndrome, and Noonan syndrome.

TABLE 7.5 Stages of MS

Stage	Definition	Valve Anatomy	Hemodynamic Consequences	Symptoms
A	At risk of MS	Doming of mitral leaflets during diastole	None	None
B	Progressive MS	Rheumatic valve changes with commissural fusion and diastolic doming of the mitral leaflets	Mild to moderate LA enlargement Normal pulmonary pressure at rest	None
C	Asymptomatic severe MS	MVA >1.5 cm ² Rheumatic valve changes with commissural fusion and diastolic doming of the mitral leaflets	Severe LA enlargement Elevated pulmonary artery pressure	None

TABLE 7.6 Summary of Recommendations for Mitral Valve Intervention in MS

Recommendation	Class of Recommendation
PMBV is recommended for symptomatic patients with severe MS (MVA ≤1.5 cm ² , stage D) and favorable valve morphology in the absence of contraindications	I
MVR is indicated in severely symptomatic patients (NYHA class III/IV) with severe MS (MVA ≤1.5 cm ² , stage D) who are not high risk for surgery and who are not candidates for or failed previous PMBV	I
Concomitant MVR is indicated for patients with severe MS (MVA ≤1.5 cm ² , stage C or D) undergoing other cardiac surgery	I
PMBV is reasonable for asymptomatic patients with very severe MS (MVA ≤1.0 cm ² , stage C) and favorable valve morphology in the absence of contraindications	IIa
MVR is reasonable for severely symptomatic patients (NYHA class III/IV) with severe MS (MVA ≤1.5 cm ² , stage D), provided there are other operative indications	IIa
PMBV may be considered for asymptomatic patients with severe MS (MVA ≤1.5 cm ² , stage C) and favorable valve morphology who have new onset of AF in the absence of contraindications	IIb
PMBV may be considered for symptomatic patients with MVA >1.5 cm ² if there is evidence of hemodynamically significant MS during exercise	IIb
PMBV may be considered for severely symptomatic patients (NYHA class III/IV) with severe MS (MVA ≤1.5 cm ² , stage D) who have suboptimal valve anatomy and are not candidates for surgery or at high risk for surgery	IIb
Concomitant MVR may be considered for patients with moderate MS (MVA 1.6 to 2.0 cm ²) undergoing other cardiac surgery	IIb
MVR and excision of the left atrial appendage may be considered for patients with severe MS (MVA ≤1.5 cm ² , stages C and D) who have had recurrent embolic events while receiving adequate anticoagulation	IIb

Modified from Nishimura R, Otto C, Bonow RO, et al: 2014 AHA/ACC guideline for the management of patients with valvular heart disease. *J Am Coll Cardiol* 2014;63:e57-e185.

Pathophysiology

In PS, the valve is typically trileaflet with thickening and fusion of the commissures resulting in restricted leaflet opening during systole. Post-stenotic dilation of the main pulmonary artery can occur due to eccentric flow through the stenotic valve. Over time, RVH can occur due to increased afterload.

Natural History and Clinical Presentation

Isolated PS is generally well tolerated and survival is comparable to the general population. Patients with mild PS are asymptomatic and may not be diagnosed with PS until adulthood. Moderate PS is usually identified in childhood and patients are usually symptomatic due to RV pressure overload. Decreasing right-sided cardiac output leads to

symptoms of dyspnea on exertion and fatigue. In more advanced disease, patients can have RV failure and cyanosis.

Physical Examination

On physical examination, patients with PS can have a parasternal lift as a result of RVH. The jugular veins may demonstrate prominent *a* waves. The murmur of PS is a systolic ejection murmur best heard at the left upper sternal border radiating to the back with the duration correlating with severity. A late peaking murmur indicates more severe disease. A systolic ejection click may be heard in mild to moderate PS. S₂ can have wide splitting due to prolonged ejection time of the right ventricle. Fixed splitting of S₂ occurs in severe disease when the RV output becomes fixed.

Diagnosis

TTE can be used to diagnose PS, assess the severity of PS, and evaluate the right ventricle. Using Doppler measurements, the gradients across a stenotic pulmonic valve can be estimated. If TTE is inconclusive or for patients with complex anatomy, cardiac magnetic resonance imaging (CMR) can be considered as an alternative imaging modality to assess the severity of valve disease and quantitatively measure RV size and function.

Treatment

Intervention is guided by the valve anatomy, gradients measured on TTE, and the presence of symptoms. Percutaneous balloon valvotomy is recommended in asymptomatic patients with a peak gradient of greater than 60 mm Hg or a mean gradient of 40 mm Hg, or in symptomatic patients with a peak gradient of 50 mm Hg or a mean gradient of 30 mm Hg. A surgical approach is usually recommended for dysplastic valves, in the presence of severe pulmonic regurgitation, or if there is another indication for surgery.

TRICUSPID STENOSIS

Definition and Etiology

In tricuspid stenosis (TS), there is restriction of blood flow between the right atrium and right ventricle. The etiology of TS is most commonly rheumatic and is generally associated with MS. Isolated TS is rare but can be seen in congenital tricuspid valve atresia, right heart tumors, carcinoid syndrome, and endocarditis.

Pathophysiology

TS causes flow obstruction at the level of the tricuspid valve resulting in a diastolic pressure gradient between the right atrium and right ventricle. This leads to elevated right atrial pressure (RAP) and systemic venous congestion. With exertion or tachycardia, diastolic filling time decreases and the diastolic pressure gradient increases. With inspiration, the decrease in intrathoracic pressure results in increased venous return which also increases the pressure gradient across the tricuspid valve. Conversely, expiration leads to a decrease in the pressure gradient.

Natural History and Clinical Presentation

The natural history of patients with TS is variable. Most patients with rheumatic TS have concomitant significant aortic and/or mitral valve disease. Tricuspid valve atresia is managed with multiple surgeries starting in the neonatal period into early childhood.

Patients present with signs and symptoms of systemic venous congestion including ascites, peripheral edema, and hepatomegaly. Patients may report a fluttering sensation in the neck from prominent *a* waves.

Physical Examination

With an increase in RAP there is jugular venous distension. A prominent *a* wave can often be appreciated. A rise in jugular venous pressure with inspiration (Kussmaul sign) may also be seen. Other signs of systemic venous congestion can be present including hepatomegaly, ascites, peripheral edema, and anasarca. The murmur of TS is described as a low-frequency, diastolic murmur best heard at the left lower sternal border. There may also be an opening snap. These sounds are difficult to distinguish from the murmur and opening snap of MS. However, with right-sided murmurs, the intensity of the TS murmur should increase with inspiration (Carvallo sign).

Diagnosis

TS can be diagnosed using TTE. In rheumatic TS, as seen in MS, the leaflets are restricted, thickened, and calcified. TTE is also used to assess for concomitant valve disease and to estimate the right atrial size

and pressure. Using Doppler, the diastolic pressure gradients can be measured across the tricuspid valve and the tricuspid valve area can be estimated. A valve area of 1.0 cm² or less is considered to be severe TS.

Treatment

There are limited data to guide treatment in TS. Options include medical therapy such as diuretics to help with systemic venous congestion, surgical intervention, or percutaneous balloon valvotomy. The decision for surgical versus percutaneous approach should be individualized and based on valve anatomy, surgical risk, and operator experience. A surgical approach is typically reserved for symptomatic patients with severe TS or asymptomatic patients with severe TS requiring cardiac surgery for another indication.

AORTIC REGURGITATION

Definition and Etiology

Aortic regurgitation (AR) is the result of inadequate coaptation of the aortic valve leaflets during diastole leading to regurgitant flow of blood from the aorta to the left ventricle. The ability of the left ventricle to accommodate this additional volume is dependent on the chronicity of the disease. Therefore, acute severe AR and chronic AR should be considered as separate disease processes.

The two most common causes of acute severe AR in a native aortic valve are endocarditis and aortic dissection. Endocarditis can lead to leaflet destruction, leaflet perforation, or perivalvular abscess that can rupture into the left ventricle. Aortic dissection can result in AR by dilation of the sinuses, involvement of the commissures or leaflets, or prolapse of the dissection flap across the aortic valve.

In developing countries, chronic AR is usually due to rheumatic heart disease. In developed countries, aortic root dilation, calcific degeneration, and bicuspid aortic valve are the most common causes. However, many other disease processes can affect the aortic valve or the ascending aorta and lead to chronic AR (Table 7.7).

Pathophysiology

In acute severe AR, a large regurgitant volume enters an unprepared left ventricle which results in a decrease in effective stroke volume and rapid increase in LV end-diastolic pressure with subsequent pulmonary edema, cardiogenic shock, and possible hemodynamic collapse.

In chronic AR, the left ventricle is able to make compensatory changes to maintain cardiac output. The regurgitant flow from the aorta into the left ventricle results in an increase in LV end-diastolic volume and wall stress. In response, there is eccentric hypertrophy, chamber dilation, and an increase in ventricular compliance. Therefore, LV end-diastolic pressure can remain normal despite a significant increase in LV volume. In addition, these compensatory changes can lead to an increase in total stroke volume, which results in an elevation in systolic pressure. During diastole, there is rapid equalization of pressures between the aorta and left ventricle resulting in a low diastolic pressure. This accounts for the wide pulse pressure and several of the characteristic physical examination findings seen in chronic AR.

Natural History and Clinical Presentation

Patients with acute severe AR often present with pulmonary edema and cardiogenic shock. Other presenting symptoms will depend on the etiology, which is usually aortic dissection or endocarditis.

In contrast, there is a prolonged asymptomatic period in chronic AR. Even with severe AR, exercise tolerance can be preserved as an increase in heart rate during exercise leads to shorter diastolic filling times, and thus less AR. However, with progressive LV dilation,

TABLE 7.7 Causes of Chronic Aortic Regurgitation

Mechanism	Etiology
Congenital/leaflet abnormalities	Bicuspid, unicuspid, or quadricuspid aortic valve Ventricular septal defect
Acquired leaflet abnormalities	Senile calcification Infective endocarditis Rheumatic disease Radiation-induced valvulopathy Toxin-induced valvulopathy: anorectic drugs, 5-hydroxytryptamine
Congenital/genetic aortic root abnormalities	Annuloaortic ectasia Connective tissue disease: Loeys Dietz, Ehlers-Danlos, Marfan syndrome, osteogenesis imperfecta
Acquired aortic root abnormalities	Idiopathic aortic root dilation Systemic hypertension Autoimmune disease: systemic lupus erythematosus, ankylosing spondylitis, reactive arthritis Aortitis: syphilis, Takayasu arteritis Aortic dissection Trauma

Modified from: Zoghbi W, Adams D, et al: Recommendations for noninvasive evaluation of native valvular regurgitation. *JASE* 2017;30:303-371.

patients can develop LV systolic dysfunction and symptoms of heart failure.

Physical Examination

Patients with acute severe AR will have physical examination findings consistent with cardiogenic shock and pulmonary edema such as hypotension, pallor, peripheral vasoconstriction, and rales. Wide pulse pressures and the characteristic findings seen in chronic AR are typically not appreciated.

With regards to the heart sounds in acute severe AR, A_2 may be diminished, P_2 is more prominent due to pulmonary hypertension, and S_3 can be heard. The murmurs heard in acute AR include an early, low-pitched, diastolic murmur and a soft systolic murmur due to increased flow across the aortic valve. The presence of both results in a characteristic “to-and-fro” murmur. However, depending on the diastolic gradient between the aorta and left ventricle, these murmurs may be inaudible.

The wide pulse pressure seen in chronic AR can lead to several physical findings (Table 7.8). The murmur of chronic AR is a blowing early diastolic murmur best heard at the left upper sternal border with the patient sitting up, leaning forward, and at end-expiration. As AR progresses, this murmur can become holodiastolic and harsher in quality. In very severe AR, the murmur can become soft or even absent.

An Austin-Flint murmur, a mid to late diastolic rumble best heard at the apex in severe AR and due to vibration of the anterior mitral leaflet as it is struck by the jet of AR, may also be appreciated. Additionally, a short midsystolic ejection murmur radiating to the neck can be heard as a result of increased stroke volume.

Diagnosis

In both acute and chronic AR, echocardiography can evaluate the presence, severity, and mechanism of AR, the effect of AR on the other cardiac chambers, and the presence of concomitant valve disease. In the case of acute severe AR with suspected aortic dissection or endocarditis, a transesophageal echocardiogram (TEE) should be considered over TTE given its superior sensitivity and specificity for these diagnoses. Computed tomography (CT) imaging has similar sensitivity and specificity for diagnosing aortic dissection. However, TEE also allows for concomitant evaluation of the aortic valve structure, AR, and the other cardiac structures.

In the assessment of chronic AR, when the TTE results are inconclusive or discrepant from clinical findings, alternative imaging modalities can be considered. TEE generally provides superior image quality compared to TTE. CMR can accurately quantify the severity of AR as well as chamber sizes and LV systolic function. Aortography and cardiac catheterization may also be considered to evaluate AR, aortic root, and left-sided filling pressures. However, their role has diminished because of the availability and accuracy of noninvasive imaging.

Treatment

In acute severe AR, emergent or urgent surgical intervention is usually indicated in the setting of aortic dissection or infective endocarditis. Prior to surgery, the mainstay of medical therapy is afterload reduction. This can be achieved with intravenous nitroprusside. Diuretics and inotropic agents may be helpful in the setting of cardiogenic shock and pulmonary edema. Beta-blockers, while helpful for aortic dissection, can lead to further hemodynamic deterioration as the increase in diastolic filling time leads to more AR. Vasopressors and intra-aortic balloon pumps are contraindicated in this setting.

With chronic AR, there is a limited role for medical therapy. Vasodilators such as hydralazine, angiotensin-converting enzyme (ACE) inhibitors, and calcium-channel blockers can be used in patients who are asymptomatic and hypertensive. There is conflicting evidence for their use to delay surgery. AVR is recommended once a patient has severe symptomatic AR or severe asymptomatic AR with a LV systolic dysfunction (left ventricular ejection fraction (LVEF) of less than 50%) or chamber dilation (LV end systolic diameter (LVESD) of greater than 50 mm or LV end diastolic diameter (LVEDD) of greater than 65 mm). AVR is also indicated in patients with severe asymptomatic AR if there is another indication for cardiac surgery.

The options for mechanical and biologic prostheses are similar to those for surgical AVR for AS. However, a percutaneous approach is not available.

MITRAL REGURGITATION

Definition and Etiology

Mitral regurgitation (MR) is defined by the inadequate coaptation of the mitral leaflets during systole resulting in regurgitant flow from the left ventricle to the left atrium. Similar to AR, MR leads to LV volume overload

TABLE 7.8 Signs of Chronic Aortic Regurgitation

Name	Description
Corrigan pulse	Rapid upstroke and collapse of pulses; “water hammer pulses”
Musset sign	Head bob with each heartbeat
Traube sign	Systolic and diastolic sounds heard over femoral arteries; “pistol shot pulse”
Duroziez sign	Systolic and diastolic bruit heard with compression of femoral artery
Quincke pulses	Capillary pulsations
Mueller sign	Pulsation of uvula
Becker sign	Pulsation of retinal arteries and pupils
Hills sign	Popliteal systolic cuff pressure exceed brachial pressure by >20 mm Hg
Mayne sign	>15 mm Hg decrease in diastolic blood pressure with arm elevation
Rosenbach sign	Pulsations of liver
Gerhard sign	Pulsations of spleen

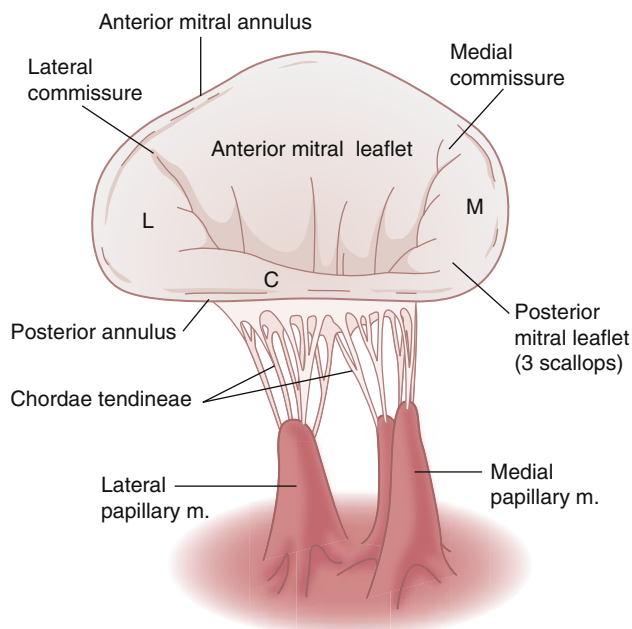

Fig. 7.6 Mitral apparatus. (From Otto C: Textbook of Clinical Echocardiography, 6th ed., Elsevier, 2018.)

and the ability of the left ventricle to compensate for this additional volume is dependent upon chronicity. Therefore, like AR, acute severe MR and chronic MR should be considered as two distinct disease processes.

The mitral apparatus consists of the left atrial wall, mitral annulus, anterior and posterior leaflets, chordae tendineae, papillary muscles, and the LV myocardium underlying the papillary muscles (Fig. 7.6). Disturbance to any component of the mitral apparatus can result in MR.

Acute MR can be caused by ischemic and nonischemic etiologies. Papillary muscle rupture or displacement can be seen in the setting of an acute myocardial infarction or ischemia. Nonischemic causes include infective endocarditis, ruptured chordae tendineae, trauma, RHD, and dynamic LV outflow obstruction.

Given the complexity of the mitral apparatus, it is useful to categorize the causes of MR as primary or secondary (Table 7.9). Primary MR is due to an intrinsic abnormality of the mitral leaflets. Secondary MR is a result of distortion of the mitral annulus in the setting of ventricular remodeling. Distinguishing between primary and secondary MR is important because the management and outcomes differ. Alternatively, MR can be classified based on leaflet motion using the Carpentier classification (Fig. 7.7).

Pathophysiology

The pathophysiology of MR and the differences in the pathophysiology between acute and chronic MR are illustrated in Fig. 7.8. In acute severe MR, there is a sudden increase in preload and decrease in afterload. This leads to an increase in the total stroke volume (TSV) and LVEF. However, the forward stroke volume (FSV) decreases resulting in reduced cardiac output. Simultaneously, there is an acute rise in LAP causing pulmonary edema. This ultimately leads to cardiogenic shock.

In chronic compensated MR, the progressive rise in LV preload leads to increased wall stress. In response, there is eccentric hypertrophy of the left ventricle and an increase in the LV end diastolic volume. This not only increases LVEF and TSV, but it also allows for the maintenance of a normal FSV. However, as MR progresses, LV systolic dysfunction and dilation occur. In this setting, LVEF, TSV, and FSV all decrease, resulting in chronic decompensated MR.

In chronic MR, the compliant left atrium is able to accommodate a large regurgitant volume from the left ventricle. However, this eventually results in left atrial dilation and pulmonary hypertension.

Natural History and Clinical Presentation

Patients with acute severe MR are acutely ill and often in cardiogenic shock. Along with hemodynamic instability, patients may have symptoms related to the etiology of MR. For example, in the setting of an acute myocardial infarction with papillary muscle rupture, a patient may present with chest pain along with ischemic ECG changes and elevated cardiac enzymes. Patients with infective endocarditis may have fevers, positive blood cultures, vascular phenomena, immunologic phenomena, or a predisposing condition such as intravenous drug use.

With chronic MR, the natural history and clinical presentation are quite different because the left ventricle has time to remodel and compensate via the mechanisms noted above. Often times, patients have a prolonged asymptomatic phase. Over time, as the left-sided filling pressures increase, patients may develop fatigue or decreased exercise tolerance. Eventually, patients can have signs and symptoms of congestive heart failure (CHF) such as dyspnea on exertion, orthopnea, paroxysmal nocturnal dyspnea, and/or peripheral edema. With left atrial dilation, patients may develop AF.

Physical Examination

Patients with acute severe MR are often in pulmonary edema and cardiogenic shock. Physical examination may be remarkable for pallor, cool extremities due to peripheral vasoconstriction, rales, jugular venous distension, and diminished peripheral pulses. The murmur of acute severe MR is usually soft, low-pitched, decrescendo, and early systolic. However, in about half of the patients, no murmur may be appreciated due to the low-pressure gradient between the left ventricle and the left atrium. Therefore, the absence of a systolic murmur does not necessarily rule out acute severe MR.

In chronic MR, S_1 is diminished due to inadequate coaptation of the mitral leaflets. S_2 is widely split with a reduced forward stroke volume leading to an early A_2 and pulmonary hypertension delaying P_2 . An S_3 can also be appreciated with the increased diastolic flow across the mitral valve into a left ventricle. The murmur of chronic MR is

TABLE 7.9 Mechanisms of Mitral Regurgitation

Valvular Abnormality	
Primary Mitral Regurgitation	
Degenerative	Mitral valve prolapse, thickening/calcification
Rheumatic	Leaflet thickening/restriction
Infectious endocarditis	Vegetations, tissue destruction, leaflet perforation
Systemic inflammatory conditions	Libman-Sacks lesions
Malignancy associated	Marantic endocarditis
Genetic connective tissue disorders (Marfan syndrome, Ehlers-Danlos syndrome)	Elongated, redundant leaflet tissue
Irradiation	Diffuse leaflet thickening/calcification
Drug-induced (anorexigen, ergotamine)	Diffuse leaflet thickening
Congenital	Cleft/parachute mitral valve
Secondary Mitral Regurgitation	
	Ventricular distortion of mitral apparatus (coronary artery disease, cardiomyopathy)
	Mitral annular dilation (usually with atrial fibrillation)

Modified from Otto C: Practice of Clinical Echocardiography, Fifth Edition. Philadelphia, Elsevier, 2017.

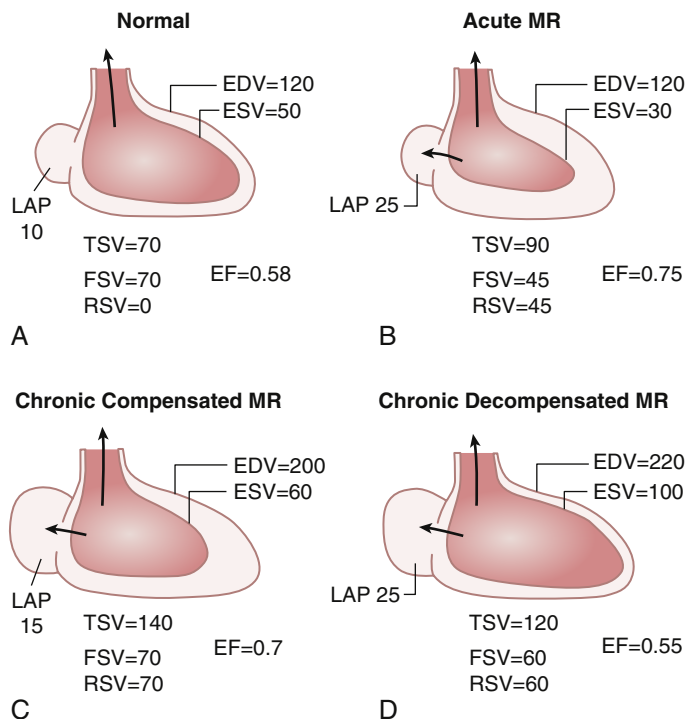

Fig. 7.8 Pathophysiology of mitral regurgitation. (From Otto C: Textbook of Clinical Echocardiography, 5th ed., Elsevier, 2013.)

most commonly a blowing, high-pitched, holosystolic murmur best heard at the apex. Depending on the direction of the MR jet, the murmur may radiate toward the axilla or the neck. In MR due to mitral valve prolapse, a midsystolic click can be heard followed by a mid or late systolic murmur.

Diagnosis

An electrocardiogram (ECG) and chest radiograph may have nonspecific findings such as left atrial enlargement or cardiomegaly, respectively. Pulmonary edema can be seen on chest radiograph in the setting of CHF. However, the diagnosis of MR is ultimately made by TTE, which can assess for the presence and severity of MR, the effect of MR on the other cardiac chambers, the presence of concomitant valve disease, and possibly the etiology of MR. If TTE is inadequate, there are other imaging modalities that are useful. CMR can be used to accurately

quantify the chamber sizes, LVEF, and the severity of MR. TEE can provide superior image quality to TTE, including three-dimensional imaging, and help to clarify the severity and anatomic mechanism of MR. In the case of acute severe MR, if the level of suspicion is high and the TTE does not show significant MR, a TEE can be performed. Alternatively, a right heart catheterization can be considered. In the presence of significant MR, the pulmonary capillary wedge waveform would have prominent *v* waves from the regurgitant flow from the left atrium. Finally, in patients who have symptoms that are out of proportion to the severity of MR, exercise echocardiography can be considered to assess for changes in MR and pulmonary artery pressure with exercise.

Treatment

In acute severe MR, emergent or urgent surgical intervention is usually indicated. Until surgery can be performed, afterload reduction is essential. This is achieved with an intra-aortic balloon pump which not only reduces afterload but also improves cardiac output and coronary blood flow. Nitroprusside can also be given to reduce afterload and inotropic agents can be given for hemodynamic support. In the absence of hypotension, diuretics can be given to treat pulmonary edema.

There is no clear role for medical therapy in treating the primary process of chronic MR. The use of vasodilators in normotensive patients with normal LV systolic function is not recommended. Hypertensive patients can be treated with standard antihypertensive therapy which may limit worsening of MR. Patients with LV systolic dysfunction can be given guideline-directed medical therapy (ACE inhibitors/angiotensin-receptor blockers/angiotensin receptor–neprilysin inhibitor, β -blocker, aldosterone antagonist, and diuretics).

The indication for mitral valve intervention depends on several factors. If a patient has severe symptomatic MR, mitral valve surgery is recommended. If a patient has severe asymptomatic MR and LVEF between 30% and 60%, LVESD 40 mm or greater, or if there is a progressive decrease in LVEF or increase in LVESD, then mitral valve surgery is also recommended. Also, in patients with severe asymptomatic MR with new onset AF or pulmonary hypertension, mitral valve repair can be considered if the likelihood of successful repair is greater than 95% and the expected mortality is less than 1%. In general, there is a higher chance of successful repair in primary MR involving the posterior leaflet. Mitral valve repair is preferred over mitral valve replacement, when possible.

For patients with prohibitive surgical risk, transcatheter mitral valve repair (TMVR) can be considered (Figs. 7.9 and 7.10). Patients with prohibitive surgical risk, at least moderate to severe primary MR with NYHA class III or IV symptoms despite optimal medical therapy, favorable anatomy, and reasonable life expectancy (≥ 2 years), should be referred to a heart valve team for evaluation for TMVR. Trials assessing the benefit of TMVR in secondary MR have yielded conflicting results. Nonetheless, TMVR has been approved for moderate to severe or severe secondary MR.

PULMONIC REGURGITATION

Definition and Etiology

Pulmonic regurgitation (PR) is a result of inadequate coaptation of the pulmonic leaflets resulting in diastolic flow from the pulmonary artery to the right ventricle. Physiologic to mild PR is common in normal adults. Primary PR is due to an abnormality of the valve leaflets. Causes of primary PR include iatrogenic, endocarditis, RHD, carcinoid syndrome, and congenital. Secondary PR occurs in the setting of normal valve leaflets and can be seen in patients with pulmonary artery dilation or severe pulmonary arterial hypertension. Severe PR is most

Fig. 7.9 Mitralclip delivery system. (Modified from Abbott Vascular.)

Fig. 7.10 Transcatheter mitral valve repair. (From *Interventional Cardiology Clinics*, Volume 5, Issue 1, 2016.)

commonly seen in patients with tetralogy of Fallot who underwent surgical valvotomy or balloon valvuloplasty.

Pathophysiology

Regurgitant diastolic flow from the main pulmonary artery to the right ventricle leads to RV volume overload. Eventually, patients may develop RV dilation, RV dysfunction, and TR.

Natural History and Clinical Presentation

Patients with PR typically have a prolonged asymptomatic phase. As RV systolic function declines, cardiac output decreases and patients can develop fatigue or decreasing exercise tolerance. With RV dilation, TR and elevated right-sided filling pressure may develop along with signs and symptoms of right-sided heart failure such as ascites, peripheral edema, and hepatosplenomegaly.

Physical Examination

The murmur of PR is an early diastolic murmur best heard over the left upper sternal border that increases in intensity with inspiration. A systolic ejection murmur may also be heard with more significant amounts of PR due to increased RV flow. With concomitant pulmonary hypertension, a high frequency, blowing, diastolic murmur (Graham-Steell murmur) may be present. On examination of the neck veins, a prominent *a* wave can be seen in pulmonary hypertension and a prominent *v* wave in TR.

Diagnosis

ECG may have nonspecific findings such as RVH or arrhythmias. A right bundle branch block with intraventricular conduction delay can be observed in patients with a history of tetralogy of Fallot repair and severe PR. RV dilation may be seen on chest radiograph.

TTE can confirm the diagnosis of PR and also evaluates the severity, etiology, and, hemodynamic effects of PR, as well as concomitant valvular disease or pulmonary hypertension. CMR can also provide a quantitative assessment of PR and RV size and function.

Treatment

Medical therapy of secondary PR should target the underlying cause. Patients with right-sided heart failure can be given diuretics. However, surgical intervention is recommended for severe symptomatic PR. Surgery can also be considered for patients with severe asymptomatic PR with RV dilation or dysfunction, symptomatic arrhythmias, or progressive TR. In general, patients with native PR undergo surgical valve replacement. Due to the risk of prosthesis regurgitation and device embolization, a percutaneous approach is rarely recommended for native PR. Alternatively, for those with prosthetic PR, percutaneous valve replacement is an option.

TRICUSPID REGURGITATION

Definition and Etiology

TR is defined by the inadequate coaptation of the tricuspid leaflets during systole resulting in regurgitant flow from the right ventricle to the right atrium. Physiologic TR is present in about 70% of healthy adults.

Primary TR, a result of an abnormality of the valve structure, is rare. Possible causes include iatrogenic direct valve injury, chest wall trauma or deceleration injury, endocarditis, RHD, carcinoid syndrome, ischemic heart disease (causing papillary muscle dysfunction), myxomatous degeneration, Marfan syndrome, or drug-induced (fenfluramine, phentermine). The most common congenital heart disease affecting the tricuspid valve is Ebstein's anomaly.

Secondary TR occurs in the setting of normal valve anatomy and is much more common. TR is most often a result of RV dilation, annular dilation, or leaflet tethering. This can occur in any condition with increased right-sided filling pressures or pulmonary hypertension such as left-sided heart failure, mitral valve disease, stenosis of the pulmonary valve or pulmonary artery, primary pulmonary disease, left-to-right shunting, and Eisenmenger syndrome.

Pathophysiology

With regurgitant systolic flow into the right atrium, there is a progressive increase in RAP and RV volume. This leads to signs and symptoms of right-sided heart failure and low cardiac output due to RV systolic dysfunction.

Natural History and Clinical Presentation

Since the right atrium is a compliant chamber, it is able to accommodate the regurgitant volume when TR is mild or moderate. Therefore, patients are usually asymptomatic. Once severe, patients may have symptoms of venous congestion and right-sided heart failure such as hepatosplenomegaly, ascites, and peripheral edema. Patients with significant pulmonary hypertension may have signs of reduced cardiac output such as fatigue and dyspnea on exertion.

Physical Examination

TR leads to elevated RAP. This is demonstrated on physical examination by distended jugular veins. A prominent *c-v* wave due to the regurgitant flow may be observed. Kussmaul sign, a paradoxical rise in jugular venous pressure with inspiration, can be seen in the setting of RV dysfunction. With right-sided heart failure, peripheral edema, ascites, anasarca, and painful hepatosplenomegaly may be present.

On cardiac exam, wide splitting of S_2 and a loud P_2 can be heard with pulmonary hypertension. S_3 or S_4 may also be present in the setting of RV dilation or hypertrophy. The murmur of TR is holosystolic and best heard at the mid left sternal border. The intensity of the murmur will increase with maneuvers that increase venous return such as inspiration, leg raise, and hepatic compression. An RV heave may be appreciated on palpation in the setting of RV dilation.

Diagnosis

TR is diagnosed by TTE. Echocardiography can help to determine the severity and etiology of TR and RV size and function. In addition, Doppler can be used to estimate the pulmonary artery systolic pressure. If the TTE is inconclusive, CMR can quantify TR, RV size, and RV function. Right heart catheterization can provide direct measurements of right-sided pressures, pulmonary pressures, and pulmonary vascular resistance.

Treatment

Medical therapy for severe TR and right-sided heart failure consists of diuretics to treat volume overload. If possible, the primary disease process should be treated such as in ischemic heart disease, left-sided heart failure, mitral valve disease, and pulmonary arterial hypertension.

Isolated tricuspid valve surgery is only recommended in patients with severe symptomatic primary TR or severe asymptomatic TR with progressive RV dysfunction. If a patient is undergoing left-sided valve surgery, tricuspid valve surgery is recommended for those with concomitant severe TR or at least mild functional TR with tricuspid annular dilation or right-sided heart failure.

Coronary Heart Disease

David E. Lewandowski, Michael P. Cinquegrani

DEFINITION AND EPIDEMIOLOGY

The term *coronary heart disease* (CHD) describes a number of cardiac conditions that result from the presence of atherosclerotic lesions in the coronary arteries. The development of atherosclerotic plaque within the coronary arteries can result in obstruction to blood flow, producing ischemia, which can be acute or chronic in nature. Atherosclerosis is a disease process that starts at a young age and can be present for years in an asymptomatic form until the degree of vessel obstruction leads to ischemic symptoms. Obstructive atherosclerotic lesions can cause chronic symptoms of exercise- or stress-related angina; or, in the case of plaque rupture and acute thrombosis, sudden death, unstable angina, or myocardial infarction (MI) may ensue.

In the United States, more than 18 million people experience some form of CHD. Approximately 10 million suffer from symptoms of angina, and at least 360,000 deaths occur each year from acute MI or CHD-related sudden death. Despite progress in therapy and overall reductions in CHD-related mortality, CHD remains the number one cause of death in both men and women, accounting for 27% of deaths in women (more than deaths due to cancer). The incidence of CHD increases with age for both men and women. There are at least 1.3 million MIs per year in the United States and many more cases of unstable angina. CHD frequently results in lifestyle-limiting symptoms due to angina or impairment of left ventricular (LV) function. The cost of care related directly to CHD and indirectly to lost productivity from CHD is in the range of \$156 billion per year. CHD remains a major life-threatening disease process associated with significant economic impact.

RISK FACTORS FOR ATHEROSCLEROSIS

There are a number of well-known risk factors for coronary artery disease (CAD), some of which are modifiable (Table 8.1). Although women ultimately also carry a significant atherosclerotic burden, men develop CAD at younger ages, and the prevalence of the disease also increases as men age. Another potent risk factor for the development of CAD is a family history of premature CAD. This speaks to a non-modifiable, genetically based risk. Commonly, multiple family members develop symptomatic CAD before the age of 55 years (65 years for women). Risks are additive, making it very important to appreciate the modifiable risk factors such as hyperlipidemia, hypertension, diabetes mellitus, metabolic syndrome, cigarette smoking, obesity, sedentary lifestyle, and heavy alcohol intake. Patients are risk-stratified for the likelihood of developing clinically significant coronary artery disease through the ASCVD (atherosclerotic cardiovascular disease)

score. Taking into account multiple patient-specific factors, the score estimates the patient's 10-year probability of experiencing an adverse event such as nonfatal MI, cardiovascular death, or stroke. The score can help guide blood pressure goals, the need for statin therapy, and other key preventative measures against CAD.

Metabolic syndrome deserves particular attention given that up to 25% of the adult US population may satisfy the definition of the disorder as laid out by the National Cholesterol Education Program Adult Treatment Panel. The definition of metabolic syndrome requires the presence of at least three of the following five criteria: waist circumference greater than 102 cm in men or 88 cm in women, triglyceride level 150 mg/dL or higher, high-density lipoprotein (HDL) cholesterol level lower than 40 mg/dL in men or 50 mg/dL in women, blood pressure 130/85 mm Hg or higher, and fasting serum glucose level 110 mg/dL or higher. The features of metabolic syndrome are largely modifiable risk factors for CAD.

Hyperlipidemia, in particular elevated levels of low-density lipoprotein (LDL) cholesterol, plays a pivotal role in the development and evolution of atherosclerosis. HDL-cholesterol is believed to be protective, likely due to its role in transporting cholesterol from the vessel wall to the liver for degradation. Increased levels of HDL are inversely proportional to the risk of CAD-related problems. The interplay among circulating lipids is complex. Elevated levels of triglycerides are a risk factor for CAD and are frequently associated with reduced levels of protective HDL. Hyperlipidemia is highly modifiable, and clinical trials have shown that drug treatment directed at lowering LDL-cholesterol significantly reduces the risk of CAD-related complications or death.

As with hyperlipidemia, hypertension contributes to the risk of CAD-related complications. Hypertension, probably through sheer stress, causes vessel injury that supports the development of atherosclerotic plaque. Increasing severity of hypertension is associated with greater risk of CAD. Control of hypertension is associated with a reduced risk of CAD. Recent guidelines advise more aggressive blood pressure goals for patients at high risk for coronary artery disease. Antihypertensive medications are advised for patients with a blood pressure greater than 130/80 and diabetes, chronic kidney disease, or an ASCVD 10-year risk of greater than 10%.

Diabetes mellitus is a prominent risk factor for CAD, and the disease is becoming epidemic. Diabetes mellitus typically is associated with other risk factors, such as elevated triglycerides, reduced HDL, and hypertension, which accounts for the enhanced risk of CAD-related problems in diabetic patients. It is not clear that control of hyperglycemia in diabetic patients translates into a reduced risk of CAD, but the presence of diabetes mellitus drives the need to ensure good treatment

TABLE 8.1 Risk Factors and Markers for Coronary Artery Disease**Nonmodifiable Risk Factors**

of other modifiable risk factors. Although metformin remains the first-line agent for glycemic control, the new sodium-glucose cotransporter-2 (SGLT-2) inhibitors and the glucagon-like peptide-1 (GLP-1) receptor agonists have shown improvements in ASCVD outcomes in patients with diabetes and established CAD.

Chronic kidney disease (CKD) is increasingly being recognized as a unique risk factor in the development of CAD. Although not recognized as a CAD risk equivalent to diabetes, patients with CKD, particularly end-stage renal disease (ESRD) on dialysis, have dramatically elevated risks of CAD compared to the general population. In addition, outcomes of acute coronary syndrome (ACS) in CKD patients are worse compared to the general population.

Cigarette smoking has long been known as a significant risk factor for both CAD and lung cancer. Cigarette smoking is associated with increased platelet reactivity and increased risk of thrombosis, as well as lipid abnormalities. This addictive habit is modifiable, and smoking cessation can lead to a decrease in CAD event rates by 50% in the first 2 years of cessation.

Similar to diabetes mellitus, obesity (body mass index >30 kg/m²) is associated with risk factors such as hypertension, hyperlipidemia, and glucose intolerance. Although multiple risk factors are frequently present in obese people, obesity itself carries some independent risk for CAD. The location and type of adipose tissue appear to influence CAD risk, with abdominal obesity posing a greater risk for CAD in men and women.

Numerous clinical studies have shown the benefit of regular aerobic exercise in decreasing the risk for CAD-related problems, both in the people without known CAD and in those with the disease. Sedentary lifestyles carry an increased risk that is modifiable through exercise.

Another common attribute of life, alcohol consumption, can influence the risk of CAD in both directions. One to two ounces of alcohol per day may reduce the risk for CAD-related events, but more than 2 ounces of alcohol per day is associated with an increased risk of events. Lower levels of alcohol consumption can increase HDL levels, although it is not clear that this is the mechanism of benefit. In contrast, excessive alcohol consumption is associated with hypertension, a definite risk for CAD, although other effects of high-dose alcohol may also be at play.

Additional factors that may have some role in adding CAD risk include lipoprotein(a) and homocysteine. Lipoprotein(a) is structurally similar to plasminogen and may interfere with the activity of plasmin, thus contributing to a prothrombotic state. Hyperhomocysteinemia has been associated with increased vascular risks, including coronary, cerebral, and peripheral vascular disease. It is not clear that a causal link exists, and the use of folic acid supplementation to lower homocysteine levels has not been shown to reduce the risk of MI or stroke.

C-reactive protein (CRP) is a marker of systemic inflammation, and it indicates an increased risk for coronary plaque rupture. High-sensitivity assays for CRP (hsCRP) have measured elevated levels that correlate with risk for MI, stroke, peripheral vascular disease, and sudden cardiac death. Another marker for the presence of CAD is coronary calcification. The process of atherosclerosis is often associated with deposition of calcium within the plaque.

Coronary artery calcification can be detected by fluoroscopy during cardiac catheterization as well as by computed tomography (CT) scanning using multidetector computed tomography (MDCT). CT technology allows for a quantitative measure of coronary calcium deposits that correlates with the probability of having significant obstructive lesions. Advantages to this method include low cost and relatively low radiation exposure. This technology can be used in conjunction with ASCVD score stratification to identify patients at elevated risk for MI. Patients in whom coronary calcification is identified should be approached with aggressive risk-factor modification.

Historically, low-dose aspirin therapy (75-162 mg daily) has been recommended for patients deemed “high-risk” for CAD for the prevention of CAD-related adverse events. More recently, several trials looking at aspirin use for patients without CAD (primary prevention) failed to find a mortality benefit. Furthermore, in patients over age 70 there was a significantly increased risk of bleeding associated with aspirin use that outweighed any small reduction in ASCVD events. Given these findings, the use of aspirin for patients without established CAD is no longer routinely recommended. Aspirin use in patients with established CAD (secondary prevention) is still highly recommended.

PATHOLOGY

The process of atherosclerosis is known to begin at a young age. Autopsies of teenagers frequently demonstrate the presence of atherosclerotic changes in coronary arteries. Atherosclerosis is a process linked to the subintimal accumulation of small lipoprotein particles that are rich in LDL. Subintimal deposits of LDL are oxidized, setting off a cascade of events that culminate in not only the development of atherosclerotic plaque but also vascular inflammation. Vascular inflammation drives progression of atherosclerosis as well as the potential rupture of plaque leading to vessel occlusion. The process of lipoprotein uptake by the vessel wall is enhanced by vascular endothelial injury, which may be triggered by hypercholesterolemia, the toxic effects of cigarette smoking, sheer stresses associated with hypertension, or vascular effects of diabetes mellitus.

Oxidized LDL aggregates trigger the expression of endothelial cell surface adhesion molecules, including vascular adhesion molecule-1, intracellular adhesion molecule-1, and selectins, which results in the binding of circulating macrophages to the endothelium. In response to cytokines and chemokines released by endothelial and smooth muscle cells, macrophages migrate into the subintimal region, where they ingest oxidized LDL aggregates. These LDL-laden macrophages are also called foam cells (based on the microscopic appearance),

and the accumulation of foam cells represents the development of atherosclerosis.

Foam cells break down, releasing pro-inflammatory substances that promote ongoing accumulation of both macrophages and T lymphocytes. This process potentiates the development of atherosclerotic plaque. Growth factors are also released that promote smooth muscle cell and fibroblast proliferation. The net result is the development of a fibrous cap, which covers a lipid-rich core.

Important contributors to the pathologic evolution of atherosclerotic plaque include impaired endothelial synthesis of nitric oxide and prostacyclin, both of which play major roles in vascular homeostasis. The loss of these vasodilators leads to abnormal regulation of vascular tone and also plays a role in evolving a local prothrombotic state. Platelets adhere to areas of vascular injury and are not only prothrombotic but also release growth factors that help drive the aforementioned proliferation of smooth muscle cells and fibroblasts. A key structural constituent of the fibrous cap is collagen, and its synthesis by fibroblasts is inhibited by cytokines elaborated by accumulating T lymphocytes. Foam cell degradation also releases matrix metalloproteinases that break down collagen, leading to weakening of the fibrous core and making it prone to rupture. T lymphocytes tend to accumulate at the border of plaque, which is the frequent site of plaque rupture.

As the fibrous cap thins through collagen degradation and eventually ruptures, blood is exposed to the thrombogenic triggers of collagen and lipid. In this setting, platelets are activated and begin to aggregate at the site of rupture. Platelets release vasoconstrictor substances thromboxane and serotonin, but more importantly, they serve as the trigger for thrombin formation, which leads to local thrombosis. Thrombin accumulation along with ongoing platelet activation can lead to rapid accumulation of thrombus in the vessel lumen. The combination of platelet-mediated thrombus accumulation and vasoconstriction can significantly limit blood flow, leading to myocardial ischemia. The degree of ischemia and its duration can culminate in MI. Complete vessel occlusion by thrombus leads to the greatest degree of myocardial ischemia and infarction, typically resulting in an ST elevation myocardial infarction (STEMI). Incomplete vessel occlusion limits blood flow enough to cause symptomatic myocardial ischemia and lesser degrees of MI, resulting in the syndromes of unstable angina or non-ST segment elevation myocardial infarction (NSTEMI).

MI is the most profound consequence of atherosclerotic plaque pathology, but significant disability can also develop when atherosclerotic plaques expand in size, leading to obstruction of blood flow and resultant myocardial ischemia. Plaque growth, driven by smooth muscle cell proliferation, initially causes the vessel to expand toward the adventitia (Glagov remodeling). Once a limit of lateral expansion is reached, the enlarging plaque encroaches on the vessel lumen. Typically, when the diameter of the lumen is decreased by at least 70%, myocardial ischemia and symptoms of angina can develop under conditions of increasing demand for blood flow. In the case of exercise, increases in heart rate and blood pressure lead to increasing myocardial oxygen demand; when flow-limiting atherosclerotic lesions are present, oxygen demand may not be met by supply and myocardial ischemia ensues. The greater the degree of vessel obstruction, the more likely it is that myocardial ischemia and angina will occur at low workloads, even to the point of angina at rest. [Fig. 8.1](#) shows an angiogram demonstrating a coronary artery obstruction before and after angioplasty. Other forms of stress, such as emotional stress or cold exposure, can also cause symptoms of angina in patients with significant obstructive plaque through mechanisms such as hypertension (increased myocardial oxygen demand) or sympathetically mediated vasoconstriction and tachycardia.

CLINICAL PRESENTATIONS OF CORONARY ARTERY DISEASE

The clinical syndromes that patients experience due to the presence of CAD principally relate to the occurrence of myocardial ischemia. Myocardial ischemia develops when there is a mismatch of oxygen delivery and oxygen demand. Given that extraction of oxygen by the myocardium is very high, any increase in oxygen demand must be met with an increase in coronary blood flow. Oxygen demand is directly related to increases in heart rate, myocardial contractility, and wall stress (which are related to blood pressure and cardiac dimensions). There is a reflex increase in myocardial oxygen demand driven by these factors as the heart is required to deliver more systemic blood flow in the face of various stresses, the most common of which is increased exertion. Coronary blood flow also depends on the vascular tone of arterioles that are under the control of vasodilators derived from normal functioning endothelium and autonomic tone.

Coronary blood flow increases to meet an increase in myocardial oxygen demand through endothelium-mediated vasodilation. In the face of atherosclerosis, endothelial dysfunction may develop, resulting in reduced endothelium-mediated vasodilation. Endothelial dysfunction coupled with a flow-limiting stenosis sets the stage for the development of myocardial ischemia. The coronary vessel distal to a flow-limiting stenosis tends to be maximally dilated. As myocardial oxygen demand increases, the myocardium distal to a flow-limiting stenosis is no longer able to augment flow by additional dilation. An overall limitation in the ability to increase coronary blood flow due to flow-limiting stenosis and endothelial dysfunction results in supply/demand mismatch and myocardial ischemia.

The major clinical manifestation of myocardial ischemia is chest discomfort (angina pectoris), which is usually described as a pressure or sensation of midsternal tightness. It may be quite pronounced in intensity or relatively subtle. Myocardial ischemia produces not only the sensation of angina pectoris but also a number of derangements in myocyte function. As in any tissue, inadequate oxygen delivery leads to a transition to anaerobic glycolysis, increased lactate production causing cellular acidosis, and abnormal calcium homeostasis. The net consequences of these cellular abnormalities include reductions in myocardial contractility and relaxation. Decreased myocardial contractility results in systolic wall motion abnormalities in the area of ischemia, and the abnormality of relaxation causes reduced ventricular compliance. These changes cause an increase in LV filling pressures above the normal range. The cellular abnormalities related to myocardial ischemia also translate into changes in cellular electrical activity that appear as abnormalities in the electrocardiogram (ECG). Myocardial ischemia may result in either ST depression or ST elevation, depending on the duration, severity, and location of the ischemia. The cellular, mechanical, and electrical abnormalities caused by ischemia typically precede the patient's perception of angina.

Myocardial dysfunction due to ischemia may recover quickly to normal if the duration of ischemia is brief. Prolonged myocardial ischemia can lead to conditions of myocardial stunning or myocardial hibernation. In the case of stunning, the mechanical dysfunction induced by prolonged ischemia persists for hours or days until function returns to normal. In the face of chronic ischemia, myocyte viability may be maintained, but because of ischemia, mechanical dysfunction persists; in this condition, known as hibernation, restoration of blood flow can result in recovery of myocardial function.

The heart's conduction system is less prone to ischemic injury, but ischemia can lead to impaired conduction. Ischemic disruption of myocyte electrical homeostasis also sets the stage for potentially life-threatening arrhythmias.

Fig. 8.1 Angiograms of the right coronary artery. (A) Discrete stenosis is observed in the middle segment of the artery (*arrow*). (B) The same artery is shown after successful balloon angioplasty of the stenosis and placement of an intracoronary stent (*arrow*).

Angina Pectoris and Stable Ischemic Heart Disease

Definition

Angina pectoris is a clinical manifestation of obstructive CAD, which in turn is usually the result of atherosclerotic plaque formation over a number of years. The term *angina pectoris* refers to the symptom of chest discomfort that may be described by the patient as a sensation of chest tightness or burning. Of the 18,000,000 adults in the United States with heart disease, as many as 9,400,00 have angina pectoris. It is estimated that 785,000 people experience a new ischemic episode annually, and recurrent events occur in at least 470,000 Americans each year.

Pathology

As a symptom, angina pectoris is experienced when myocardial ischemia develops. Myocardial ischemia and angina pectoris may occur in the face of obstructive atherosclerotic plaque that limits blood flow in the face of increased demand such as exertion or emotional excitement. Myocardial oxygen demand is directly related to increases in heart rate and blood pressure; these variables, in turn, can be manipulated with medical therapy to reduce the demand. Restricted oxygen supply, in the form of reduced blood flow, can also induce myocardial ischemia. Blood flow reduction is a prominent feature of acute presentations of CAD such as NSTEMI and STEMI, but atherosclerosis-mediated coronary vasoconstriction, or coronary vasospasm, is also a potential cause of flow limitation leading to myocardial ischemia. Another example of supply limitation is anemia, whereby reduced oxygen-carrying capacity coupled with obstructive lesions leads to myocardial ischemia and symptoms of angina pectoris. The term *stable* angina pectoris refers to myocardial ischemia caused by either plaque-mediated flow limitation in the face of excess demand or supply limitation due to coronary vasospasm.

Clinical Presentation

Angina pectoris may manifest in either stable or unstable patterns (Table 8.2), but the symptom expression is similar. Typically, patients complain of retrosternal discomfort that they may describe as pressure,

tightness, or heaviness. The symptom can be subtle in its presentation, and inquiry as to the presence of “chest pain” may lead to a negative response in a patient experiencing angina pectoris. When taking a history aimed at discerning angina pectoris, one needs to seek answers to these more nuanced descriptions of symptoms. In addition to chest discomfort, patients may have associated discomfort in the arm, throat, back, or jaw. They also may experience dyspnea, diaphoresis, or nausea associated with angina pectoris.

There is a good deal of variability in the expression of symptoms related to myocardial ischemia, although each person tends to have a unique signature of symptoms. Some have no chest discomfort but only radiated arm, throat, or back symptoms; dyspnea; or abdominal discomfort. Myocardial ischemia can also manifest in a “silent” form, particularly in the elderly and in patients with long-standing diabetes mellitus. The duration of angina pectoris varies, probably depending on the magnitude of the underlying myocardial ischemia. Exertion-related angina pectoris, the hallmark of stable obstructive CAD, typically resolves with rest or with decreased intensity of exercise. In stable angina pectoris, the duration of events is usually in the range of 1 to 3 minutes. Prolonged symptoms in the 20- to 30-minute range are indicative of a more serious problem such as NSTEMI or STEMI.

The physical examination of patients with CAD is typically normal. However, if the patient is physically examined during an episode of myocardial ischemia, either at rest or after exertion, significant changes may be present. As with any form of discomfort, there may be a reflex increase in heart rate and blood pressure. Elevated heart rate and blood pressure may act to sustain the duration of angina by increasing myocardial oxygen demand in the face of supply-limiting coronary stenosis. Acute mitral regurgitation can develop if the distribution of myocardial ischemia includes a papillary muscle, the supporting structure of the mitral valve. The physical examination in such cases would demonstrate a new systolic murmur consistent with mitral regurgitation. If severe enough in degree, this mitral regurgitation will cause decreased LV compliance and, consequently, an acute elevation in left atrial and pulmonary vein pressure leading to pulmonary congestion. In this setting, the patient will have not only

TABLE 8.2 Angina Pectoris

Type	Pattern	ECG	Abnormality	Medical Therapy
Stable	Stable pattern, induced by physical exertion, exposure to cold, eating, emotional stress	Baseline often normal or non-specific ST-T changes	≥70% Luminal narrowing of one or more coronary arteries from atherosclerosis	Aspirin Sublingual nitroglycerin
	Lasts 5-10 min Relieved by rest or nitroglycerin	Signs of previous MI ST-segment depression during angina		Anti-ischemic medications Statin
Unstable	Increase in anginal frequency, severity, or duration	Same as stable angina, although changes during discomfort may be more pronounced	Plaque rupture with platelet and fibrin thrombus, causing worsening coronary obstruction	Aspirin and clopidogrel Anti-ischemic medications
	Angina of new onset or now occurring at low level of activity or at rest May be less responsive to sublingual nitroglycerin	Occasional ST-segment elevation during discomfort		Heparin or LMWH Glycoprotein IIb/IIIa inhibitors
Prinzmetal or variant angina	Angina without provocation, typically occurring at rest	Transient ST-segment elevation during pain Often with associated AV block or ventricular arrhythmias	Coronary artery spasm	Calcium-channel blockers Nitrates

AV, Atrioventricular; ECG, electrocardiography; LMWH, low-molecular-weight heparin; MI, myocardial infarction.

the symptom of angina pectoris but also the symptom of dyspnea and the physical finding of rales. Ischemia-induced increases in LV filling pressure due to diminished compliance also can occur independently of ischemia-induced mitral regurgitation. Decreased LV compliance can produce the abnormal heart sound S_4 ; in the case of severe diffuse myocardial ischemia causing LV systolic dysfunction, an S_3 may also be perceived. Resolution of myocardial ischemia results in not only a cessation of angina pectoris but also a return to the patient's baseline physical examination status.

Diagnosis and Differential Diagnosis

Three basic forms of testing have played major roles in assessing patients with chest discomfort possibly due to CAD. All of these tests capitalize on the effect of myocardial ischemia on various aspects of cardiac physiology. First, myocardial ischemia induced by exercise or by spontaneous coronary occlusion results in subendocardial ischemia, which appears on an ECG as diffuse ST depression (Fig. 8.2). Once ischemia resolves, the ECG returns to normal. Second, myocardial ischemia typically affects a segment of heart muscle, and that territory develops a wall motion abnormality that can be detected by either echocardiography or nuclear scintigraphy. Third, the basis for myocardial ischemia is a decrease in coronary and myocardial blood flow. This abnormality can be detected by assessing the distribution of radioactive tracers such as thallium 201 or technetium sestamibi using specialized detectors for imaging myocardial perfusion. All stress test techniques used in diagnosing patients with possible CAD rely on these means of detecting the impact of myocardial ischemia on cardiac electrical activity, mechanical function, or myocardial perfusion.

Stress testing in its various forms frequently plays a pivotal role in the assessment of patients with possible CAD. In using stress testing, it is important to understand the significance of pretest probability of CAD in interpreting the results of any stress test method. For a patient with a high pretest probability of CAD, a positive test is highly predictive of underlying CAD, and a negative test carries the weight of being falsely negative. The opposite is true in a patient with a low pretest probability of CAD: A negative test is associated with a high negative predictive value for the presence of CAD, but a positive test is likely to be falsely positive.

Stress testing is useful not only as a diagnostic tool but also in the long-term management of established CAD. Exercise stress testing, through its ability to quantify exercise capacity, can monitor the

effectiveness of medical therapy directed at reducing myocardial ischemia. The findings of an exercise stress test also have predictive value in that patients with ischemia induced at low workloads are more likely to have extensive multivessel disease, whereas those who achieve high workloads are less prone to ischemic complications of CAD. A higher risk for poor outcomes related to CAD is implied by (1) ECG changes of ST depression early during exercise and persisting late into recovery; (2) exercise-induced reduction in systolic blood pressure; and (3) poor exercise tolerance (<6 minutes on the Bruce stress test protocol).

Patients with a normal resting ECG can reliably be assessed by standard exercise stress testing with ECG monitoring (Fig. 8.3). The specificity of ST changes with exertion is significantly reduced in the face of baseline ECG abnormalities related to LV hypertrophy, left bundle branch block (LBBB), preexcitation, or use of digoxin. Various imaging techniques (echocardiography, nuclear scintigraphy, magnetic resonance imaging) have been developed to overcome the impact of baseline ECG abnormalities on the validity of stress testing. Because women also have lower specificity for ECG changes during exercise testing than men, an imaging technique is frequently used in the assessment of women. Overall, the addition of an imaging technique to stress testing significantly improves the sensitivity, specificity, and predictive value of the stress test but also greatly increases its cost.

Radionuclide stress testing is a common form of imaging-based stress test. Near peak exertion, a radionuclide tracer (thallium-201, technetium-99, or tetrofosmin) is administered intravenously. The tracer is distributed to the myocardium in a quantity directly proportional to blood flow. This type of image testing relies on a disparity of tracer uptake to detect an area of ischemia. Thallium-201 redistributes over 4 hours to viable myocardium, allowing for comparison of stress-induced ischemia to a baseline state. The other tracers do not share this redistribution feature, and tests using technetium-99 or tetrofosmin require both "rest" and "stress" injections of tracer to differentiate ischemic myocardium. Patients with normal perfusion studies have a low risk of coronary events (<1%/year). The presence of a positive perfusion study confers a risk of about 7%/year for coronary events, with the risk increasing relative to the extent of perfusion abnormality.

An alternative means of imaging for exercise testing is the use of echocardiography to detect ischemia-induced wall motion abnormalities. This form of testing is increasingly favored because there is no

A

B

Fig. 8.2 Electrocardiogram obtained during angina (A) and after the administration of sublingual nitroglycerin and subsequent resolution of angina (B). During angina, transient ST-segment depression and T wave abnormalities are present.

radiation associated with its use, whereas radionuclide tracers expose the patient to a significant dose of radiation. Stress echocardiography carries with it the same enhancement in sensitivity, specificity, and predictive value as radionuclide imaging. An additional benefit of echocardiography imaging is more discrete anatomic data on valve function. If it is coupled with Doppler flow imaging, information regarding exercise-induced mitral regurgitation can be obtained.

Another means of assessing for exercise-induced wall motion abnormalities is the use of radionuclide ventriculography or multigated acquisition scanning (MUGA). This technique is usually included as part of the interpretation of an exercise stress radionuclide

study. This imaging technique does not provide the anatomic detail associated with echocardiography, and it has the negative feature of significant radiation exposure.

An additional imaging technique for stress testing is the use of magnetic resonance imaging. Radiation is not a concern, and cardiac structural imaging can match echocardiography (or exceed it in patients with poor images on echocardiography). The technique is not as easy to execute as echocardiography and is not as frequently utilized.

Not all patients who require noninvasive testing for CAD are able to exercise to a degree sufficient to induce ischemia, and for some patients exercise testing is not an option at all. For these patients,

Fig. 8.3 Treadmill exercise test demonstrates a markedly ischemic electrocardiogram (ECG) response. The resting ECG is normal. The test was stopped when the patient developed angina at a relatively low workload, accompanied by ST-segment depression in lead II and ST-segment elevation in lead V_2 . These changes worsened early in recovery and resolved after administration of sublingual nitroglycerin. Only leads II and V_2 are shown; however, ischemic changes were seen in 10 of the 12 recorded leads. Severe atherosclerotic disease of all three coronary arteries was documented at subsequent cardiac catheterization.

pharmacologic stress testing has evolved as a viable alternative to exercise testing. The prognostic benefit of exercise workload is not available from this form of testing, but information regarding the presence of ischemia-inducing atherosclerosis is obtainable. One common form of pharmacologic testing relies on inducing coronary vasodilation (as with dipyridamole, adenosine, or regadenoson), which produces a disparity of myocardial blood flow based on the presence of coronary stenosis. Radionuclide administered during the infusion of the coronary vasodilator allows for detection of myocardial ischemia similar to that observed with exercise testing. An alternative pharmacologic approach uses the inotropic and chronotropic effects of dobutamine to increase myocardial oxygen demand and induce segmental ischemia. Echocardiography is commonly used to detect dobutamine-induced wall motion abnormalities with this approach, although radionuclide or magnetic resonance imaging could also be used.

All of the stress testing techniques discussed here are able to assess for the presence of inducible myocardial ischemia associated with CAD. The presence of CAD can also be determined by assessment of coronary calcification using either EBCT or the now more common MDCT. Coronary calcification is present only because of underlying CAD. Although detecting its presence does not directly indicate the presence of obstructive CAD as would an abnormal imaging stress test, studies have shown a direct correlation between the amount of coronary calcification and the probability that a 70% stenosis is present.

Multidetector computed tomography (MDCT) scanners can reliably perform coronary angiography with the use of intravenous contrast agents and specifically timed imaging protocols. This can provide insight into coronary anatomy that stress testing cannot. When this technique is coupled with newer techniques such as CT fractional flow reserve (FFR), it can provide a functional assessment as well. The PLATFORM trial demonstrated that in patients with stable chest pain, CTA + FFR guiding the need for invasive coronary angiography (ICA) resulted in similar outcomes but with lower costs compared to standard of care. A negative study carries a high negative predictive value for the occurrence of coronary events and thus is useful in patients

with low-intermediate pretest probability for coronary artery disease. MDCT is also valuable in defining coronary anomalies.

Invasive coronary angiography (ICA) has been considered the “gold standard” for detecting the extent and severity of underlying CAD. This approach carries a small risk of MI, stroke, or death, so it must not be taken lightly. In the case of patients with positive stress tests, particularly those with high-risk features, coronary angiography adds more discrete information regarding the underlying disease and guides the potential use of revascularization techniques (i.e., percutaneous coronary intervention or coronary artery bypass surgery) versus medical therapy to treat CAD (Table 8.3). Additional tools, such as pressure wires used to perform FFR, add to the diagnostic power of invasive catheterization by allowing one to discriminate between physiologically significant lesions and those not likely to cause ischemia. Revascularization is not indicated for lesions that do not cause ischemia.

The physician must also be cognizant of the fact that not all chest discomfort is related to CAD. Other causes of chest discomfort include esophageal disease (esophageal reflux may mimic typical angina pectoris), chest wall–related pain, pulmonary embolism, pneumonia, and trauma. The clinical presentation of the patient usually points in one direction or another, but patients with chest discomfort commonly undergo an evaluation for CAD, typically with the use of stress testing. Once CAD is reliably ruled out, the physician needs to consider alternative causes of the symptom. In the acute setting of severe chest discomfort, particularly in a hemodynamically unstable patient, the differential diagnosis includes acute MI, pulmonary embolism, and aortic dissection. Prompt and accurate diagnostic evaluation, commonly with the use of invasive or CT angiography, can be lifesaving in this situation.

Treatment

Medical management of stable angina. The treatment of CAD and angina pectoris is multifaceted. The presence of CAD with or without angina requires the physician to recommend risk factor modification, frequently associated with lifestyle changes. For

angina pectoris, pharmacologic therapy is typically used to control symptoms, allowing for maintenance of reasonable exercise tolerance. Revascularization is commonly used to control symptoms to a degree better than what can be achieved with medications alone, but only a small group of patients with CAD benefit from revascularization in terms of increased longevity.

Other medical conditions can lower the threshold for angina, causing worsening symptoms and affecting quality of life. Anemia is a common medical problem that, when addressed, can significantly reduce the frequency of angina pectoris. Hyperthyroidism, with its increased metabolic demand and tachycardia, can increase the frequency of angina pectoris. Uncompensated congestive heart failure lowers the anginal threshold through the effects of LV dilation and filling pressure elevation on myocardial oxygen demand. Chronic obstructive pulmonary disease (COPD) and obstructive sleep apnea leading to hypoxemia can trigger angina pectoris. The use of illicit substances such as cocaine can also lead to angina through increased metabolic demand as well as coronary vasospasm.

Attention to the major modifiable risk factors for CAD is a cornerstone of therapy. Poorly controlled diabetes mellitus, hypertension, hyperlipidemia, and ongoing smoking all drive the progression of CAD and increase the risk for catastrophic events such as MI or sudden death. The wealth of clinical research on preventing death and disability from CAD has led to the development of evidence-based

guidelines that form the basis of contemporary therapy for CAD (Table 8.4). Complete smoking cessation is a must for patients with CAD regardless of the presence of symptoms. Control of hypertension is also important. The use of statin medications to reduce LDL cholesterol has revolutionized the therapy for CAD and remains the cornerstone of lipid therapy. Statins have been shown to reduce the risk of MI in patients with proven CAD (goal LDL <70 mg/dL) and in those at significant risk (goal to lower LDL levels by >30% in intermediate risk patients and >50% in high-risk patients). If LDL levels do not reach the goal with statin monotherapy, ezetimibe can be utilized as an adjunctive agent. A new class of drug, PCSK-9 inhibitors (alirocumab and evolocumab), can have a dramatic impact on a patient's lipid profile but are somewhat cost-prohibitive. These are considered for secondary prevention in patients who have refractory hyperlipidemia to statin therapy as well as patients with familial hyperlipidemia syndromes who are at extreme risk for developing clinical ASCVD. There is also interest in low HDL levels, which appear to confer increased risk for coronary events. Exercise increases HDL levels and may confer protective effects through other mechanisms. Pharmacologic strategies to elevate HDL including niacin have not been proven to be beneficial.

Antiplatelet therapy is known to reduce the risk of MI in those who have known CAD. Patients should be instructed to take aspirin, 75 to 162 mg/day (clopidogrel 75 mg/day may be used in those who are aspirin intolerant or allergic). Angiotensin-converting enzyme (ACE) inhibitors reduce the risk of recurrent MI and are also beneficial for patients with diabetes mellitus or reduced LV function. Angiotensin receptor blockers (ARBs) can be substituted in those who experience significant side effects from ACE inhibitors.

Regular aerobic exercise can benefit patients with CAD by reducing their risk for complications related to the disease. Aerobic exercise also increases exercise tolerance and may reduce the frequency of exercise-related angina pectoris. Positive benefits also accrue from weight loss related to exercise and improved blood pressure control. In sedentary individuals, isometric activities such as snow shoveling can trigger MI and should be avoided. There may be some benefits to judicious weight training in patients with CAD.

TABLE 8.3 Indications for Coronary Angiography in Patients With Stable Angina Pectoris

Unacceptable angina despite medical therapy (for consideration of revascularization)
Noninvasive testing results with high-risk features
Angina or risk factors for coronary artery disease in the setting of depressed left ventricular systolic function
For diagnostic purposes, in the individual in whom the results of noninvasive testing are unclear

TABLE 8.4 Goals of Risk Factor Modification

Risk Factor	Goal
Dyslipidemia	
Elevated LDL-cholesterol level	
Patients with CAD or CAD equivalent ^a	LDL <70 mg/dL
Without CAD, ≥2 risk factors ^b	LDL <130 mg/dL (or <100 mg/dL ^c)
Without CAD, 0-1 risk factors ^c	LDL <160 mg/dL
Elevated TG	TG <200 mg/dL
Reduced HDL-cholesterol level	HDL >40 mg/dL
Hypertension	Systolic blood pressure <140 mm Hg Diastolic blood pressure <90 mm Hg
Smoking	Complete cessation
Obesity	<120% of ideal body weight for height
Sedentary lifestyle	30-60 min moderately intense activity (e.g., walking, jogging, cycling, rowing) five times per week

CAD, Coronary artery disease; CRP, C-reactive protein; HDL, high-density lipoprotein; hsCRP, high-sensitivity C-reactive protein; LDL, low-density lipoprotein; TG, triglycerides.

^aCAD equivalents include diabetes mellitus, noncoronary atherosclerotic vascular disease, or >20% 10-year risk for a cardiovascular event as predicted by the Framingham risk score.

^bRisk factors include cigarette smoking, blood pressure ≥140/90 mm Hg or taking antihypertensive medication, HDL-cholesterol level <40 mg/dL, family history of premature coronary atherosclerosis (male, <45 yr; female, <55 yr).

^cTarget of 100 mg/dL should be strongly considered for men ≥60 yr and for individuals with a high burden of subclinical atherosclerosis (coronary calcification >75th percentile for age and sex), hsCRP >3 mg/dL, or metabolic syndrome.

TABLE 8.5 Medications for Angina Pectoris

Drug Class	Examples	Antianginal Effect	Physiologic Side Effects	Comments
Nitroglycerin	Sublingual Topical Intravenous Oral	Decreased preload and afterload Coronary vasodilation Increased collateral blood flow	Headache Flushing Orthostasis	Tolerance develops with continuous use
β -Adrenergic blocking agents	Metoprolol Atenolol Propranolol Nadolol	Decreased heart rate Decreased blood pressure Decreased contractility	Bradycardia Hypotension Bronchospasm Depression	May worsen heart failure and AV conduction block; avoid in vasospastic angina
Calcium-channel blocking agents (non-dihydropyridine)	Phenylalkylamine (verapamil) Benzothiazepine (diltiazem)	Decreased heart rate Decreased blood pressure Decreased contractility Coronary vasodilation	Bradycardia Hypotension Constipation with verapamil	May worsen heart failure and AV conduction
Calcium-channel blocking agents	Dihydropyridine (nifedipine, amlodipine)	Decreased blood pressure Coronary vasodilation	Hypotension, reflex tachycardia Peripheral edema	Short-acting nifedipine is associated with increased risk for cardiovascular events.
Late sodium current blocking agents	Ranolazine	Inhibits cardiac late I_{Na} Prevents calcium overload	Dizziness Headache Constipation Nausea	No effects on blood pressure or heart rate Modest QTc prolongation

AV, Atrioventricular; I_{Na} , sodium current.

In addition to antiplatelet therapy, the commonly employed medications to control angina pectoris include β -blockers, nitrates, and calcium-channel blockers. These agents work by correcting supply/demand blood flow mismatch that is the cause of myocardial ischemia and angina pectoris (Table 8.5). Interestingly, these drugs principally control symptoms in chronic stable angina pectoris, but they do not reduce mortality risk as therapy with aspirin or statins does.

Nitrates in various forms have a long history of use in patients with symptomatic CAD and can be very effective in controlling exertion-related angina. Nitrates work by venodilating large-capacitance veins and thus shifting blood out of the heart, reducing preload and myocardial oxygen demand. Nitrates are also potent coronary vasodilators and can reverse coronary spasm, allowing for improved perfusion. Short-duration but quick-acting sublingual nitroglycerin has been a mainstay both for treatment of an anginal episode and for prophylaxis against angina in situations where it is likely to occur. Patients who respond well to nitrates are frequently treated with long-acting oral or topical preparations. Both methods can effectively prevent angina pectoris, but continued use can induce tolerance. There is a recognized need for patients to have a nitrate-free period of about 8 hours every day to prevent tolerance. This usually involves cessation of use during sleep. Intravenous nitroglycerin administered by continuous drip is reserved for patients with unstable angina or acute MI.

β -Blocker therapy is very effective at reducing the likelihood of exertion-related angina. β -Blockers bind to cell surface β -receptors and by so doing reduce heart rate, contractility, and blood pressure, all of which tip the balance in favor of reduced oxygen demand and less angina. The use of β -blockers can be limited by the degree of bradycardia they induce or by baseline atrioventricular (AV) conduction abnormalities. In patients with higher degrees of AV block, β -blockers can induce complete heart block. These drugs also vary in their β -receptor selectivity. Blockade of β_2 -adrenergic receptors can lead to bronchospasm and vasoconstriction. Even selective β_1 -adrenergic antagonists such as atenolol and metoprolol have some β_2 activity at higher doses. Intolerance of β -blockers can limit their use in patients with significant COPD or peripheral vascular disease. β -Blockers may also add to glucose intolerance and may affect lipids by increasing

triglycerides or reducing HDL. In general, these effects do not preclude their use if they prove effective in controlling angina pectoris.

Calcium-channel blocking drugs can decrease myocardial oxygen demand by causing arterial vasodilation, bradycardia, and decreased contractility. The magnitude of these effects varies according to the class of agent used. Dihydropyridines such as nifedipine and amlodipine cause arterial vasodilation leading to a blood pressure-lowering effect. In the dose ranges administered, they have no significant effect on contractility or heart rate. In contrast, verapamil, a phenylalkylamine, has significant effects on heart rate, AV conduction, and contractility. Benzothiazepine agents such as diltiazem manifest less vasodilation than dihydropyridines and less effect on contractility than phenylalkylamine drugs. The net effect of calcium-channel blocking drugs is reduced myocardial oxygen demand resulting in less angina pectoris. Diltiazem should be used with caution in patients who are also taking a β -blocker, because severe bradycardia or heart block can occur. Verapamil should not be co-administered with a β -blocker.

A newer class of antianginal drug is represented by ranolazine. This drug is a selective inhibitor of late sodium current and reduces sodium-induced calcium overload in myocytes. Although it has no effect on heart rate or blood pressure, ranolazine demonstrates antianginal properties. It is typically used when other medical therapy is insufficient in controlling angina.

Revascularization therapy for chronic stable angina pectoris.

Revascularization therapy is an option to be considered when medical therapy is not sufficiently controlling symptoms leading to impaired lifestyle. It is also frequently pursued in the face of high-risk situations such as unstable angina, STEMI, heart failure complicated by angina, arrhythmias associated with angina, or the presence of large areas of myocardial ischemia documented by noninvasive imaging. The two types of revascularization procedures are coronary bypass grafting (CABG) and percutaneous coronary intervention (PCI).

Percutaneous transluminal coronary angioplasty was the initial mode of catheter-based revascularization introduced in the late 1970s (see video, Angioplasty, <http://www.heartsite.com/html/ptca.html>). In this technique, a guidewire is placed through a stenotic segment of artery, after which a balloon-tipped catheter is threaded over the

wire to the area of stenosis and then inflated. Angioplasty of this form enlarges the vessel lumen in an irregular geometry through disruption of the plaque and injury to the vessel intima. Plain old balloon angioplasty (POBA), as the procedure later became known, was effective at improving myocardial perfusion and reducing exercise-related angina. However, because of plaque disruption, there was a 2% to 5% risk of abrupt vessel closure frequently leading to MI. In addition, there was a high incidence of injury-mediated restenosis (up to 50%) during the first 3 to 6 months after the procedure. The process of restenosis involved intimal hyperplasia and remodeling, yielding a recurrent stenosis sometimes more severe in nature than the original lesion.

The innovation of coronary stents pioneered through the 1980s and clinically available in the early 1990s represented a significant advance in PCI (see video, Intracoronary Stenting, <http://www.heartsite.com/html/stent.html>). Coronary stents are expandable metallic mesh tubes that are mounted on an angioplasty balloon, allowing delivery to an area of stenosis, where balloon inflation expands the stent into the vessel wall. The stent becomes permanently embedded in the vessel wall and scaffolds the artery to keep it open. This procedure not only reduces the risk of abrupt vessel occlusion to 1% or less, but it is also associated with a significant reduction in restenosis risk (20% to 25%, compared with 50% for POBA). The benefit of stenting for a patient is clear in terms of less risk of procedure-related acute MI and less need for repeat procedures. Vessels smaller than 2 mm in diameter are not good targets for stenting, because the smallest-diameter stent is 2 mm. Stents do have a risk of thrombosis, necessitating lifelong aspirin therapy and the use of clopidogrel for 4 weeks to 1 year after the procedure (there may be some advantage to longer-duration clopidogrel for 1 year).

Despite the reduction achieved with coronary stents, there was still a significant risk of restenosis, leading investigators to search for a means to lower that risk. Drug-eluting stents (DES) were found to significantly reduce the risk of restenosis compared to bare metal stents. The first DES, released for use in 2003, was coated with either sirolimus or paclitaxel, both of which inhibited the hyperplastic response in the vessel wall triggered by PCI. The current generations of DES are coated with either zotarolimus or everolimus, both very effective at reducing restenosis. The predicted restenosis rate for current-generation DES is in the range of 5% to 10%. Vessel diameter affects restenosis risk, with larger-diameter vessels demonstrating less restenosis. The benefit of inhibiting tissue overgrowth within the stent is also associated with delayed endothelialization of the stent, which increases the risk of stent thrombosis for a longer time than with bare metal stents. For this reason P2Y₁₂ inhibitors, in conjunction with aspirin, are prescribed to patients with stents to prevent stent thrombosis. If a situation arises in which the P2Y₁₂ inhibitor must be discontinued the minimum time post-stent implantation at which it can safely be held depends on the type of stent implanted: 1 month for a bare metal stent (BMS) and 3 to 6 months for a drug-eluting stent. The decision regarding whether to implant a DES or a BMS is based on patient characteristics such as risk of bleeding or need for urgent surgical procedure. However, the use of BMS has declined over recent years as the safety and effectiveness of newer generation DES has been demonstrated. Aspirin should be continued indefinitely, to minimize the risk of late stent thrombosis.

A host of other devices to treat stenotic coronary arteries have come and gone over time. In this era, rotational atherectomy plays a role in treating calcified lesions in about 5% of patients. Routine use of catheter-based aspiration of thrombus led to an increased incidence of stroke and thus is no longer recommended on a routine basis. Intravascular ultrasound is an important imaging adjunct that can be helpful in interrogating lesions or defining the end result of stent placement.

CABG emerged in the 1970s as an effective means of coronary revascularization for the control of angina. Bypass grafts take the form of saphenous vein from the leg, free radial artery segments, or intact left or right internal mammary artery grafts. The vein or radial artery grafts are placed on the ascending aorta and then anastomosed to the coronary vessels distal to the site of obstruction. In contrast, left or right internal mammary arteries are left intact at their origins and anastomosed distal to the obstruction. The left internal mammary artery is typically placed onto the left anterior descending coronary artery. This is the most important vessel to graft because of its size and distribution, and the left internal mammary artery is ideal given an expected patency rate of 90% at 10 years. Saphenous vein grafts degenerate over time, leading to episodes of symptomatic abrupt occlusion and a 50% patency rate at 10 years. Free radial artery grafts perform better than vein grafts but less well than intact mammary artery grafts. CABG is a major cardiac surgical procedure, but in skilled hands the mortality rate is expected to be 1% to 2%, with a similar risk of stroke. Periprocedural MI rates are in the range of 5% to 10%. There has been controversy over whether the use of the heart-lung machine to support CABG causes more problems for patients than “beating heart” surgery does. Recent studies suggest there is no long-term difference in outcomes, such as death, MI, or stroke, for patients undergoing CABG, either on- or off-pump.

Most CABG procedures are performed for symptom control and are not likely to enhance longevity. The categories of patients likely to have life prolonged by CABG include those with a left main coronary artery more than 50% narrowed, those with severe three-vessel obstructive disease associated with a decrease in ejection fraction (EF, 35% to 50%), and those with two- or three-artery disease whose proximal left anterior descending artery is severely stenosed.

Clinical trials comparing CABG and PCI have consistently shown that patients undergoing CABG require fewer repeat procedures during the first 2 years after surgery. In the first 2 years, it is more likely that patients with PCI will experience symptomatic restenosis than that patients with CABG will have graft failure. Over time, this advantage is lost as vein grafts begin to fail 5 to 10 years after surgery. However, there is evidence that a survival advantage exists for diabetic patients with multivessel CAD who undergo CABG as opposed to PCI. A recent study also demonstrated long-term survival benefit for CABG over PCI in the face of multivessel CAD. Some of the survival advantages in favor of CABG may be linked to the use of the left internal mammary artery as a graft.

Despite the use of either revascularization technique, patients remain prone to progressive atherosclerotic disease with the potential to form plaque at previously unaffected sites. This necessitates aggressive long-term medical therapy and risk factor modification to achieve the lowest possible risk of symptomatic progression or MI. Retreatment with CABG is possible but is fraught with higher risk, and the outcome of repeat stenting for in-stent restenosis is never as good as for de novo lesions.

In a small group of patients, PCI and/or CABG fails and the patient has refractory angina. Once medical therapy has been maximized, few truly effective options remain. Transmyocardial laser revascularization in areas of ischemia has been used to reduce symptoms, but this technique is now of uncertain value. External counterpulsation is a technique whereby blood pressure cuffs are placed on each leg, inflated during diastole and deflated during systole. Patients typically have a 1-hour session that may be repeated 35 times. Angina relief has been reported with this procedure and may reflect some beneficial effect on endothelial function. Spinal cord stimulation using electrodes placed in the C7-T1 dorsal epidural space can reduce anginal symptoms in the short term, although the long-term role needs definition.

Fig. 8.4 Continuous electrocardiogram recording in a patient with Prinzmetal (variant) angina. The spontaneous onset of chest discomfort began during the top strip, accompanied by transient ST-segment elevation. By the bottom strip, several minutes later, both discomfort and ST-segment elevation had resolved.

Other Anginal Syndromes

Variant angina. Whereas typical angina pectoris is usually triggered by physical or emotional stress, some patients experience a syndrome termed variant angina. Variant angina was first described in 1959 by Prinzmetal and colleagues, who observed patients with chest discomfort at rest, not triggered by physical or emotional stress, and associated with ST-segment elevation (Fig. 8.4). Episodes of AV block and ventricular ectopy were observed, but MI was not a common feature. These patients typically did not have the common CAD risk factors other than smoking. Coronary angiography demonstrated these patients to be experiencing transient coronary vasospasm. The vasospasm tended to occur in an area of atherosclerotic plaque, but some patients had spasm in angiographically normal segments of coronary artery.

In the course of investigating the pathophysiology of variant angina, a number of provocative tests were developed to induce coronary spasm in susceptible individuals. Intracoronary ergonovine or acetylcholine can induce spasm in patients with variant angina, probably as a result of underlying endothelial dysfunction. Other spasm-inducing provocations include the cold pressor test (placing a hand in an ice bath), the induction of alkalosis (hyperventilation or intravenous bicarbonate), and histamine infusion. Provocative testing to induce coronary vasospasm has fallen out of favor in the routine assessment of patients with angina.

Coronary vasospasm usually resolves promptly with the administration of nitroglycerin (sublingual, intravenous, or intra-arterial). The combination of oral nitrates and calcium-channel blockers is often used to prevent spasm. β -Blockers may aggravate coronary spasm by inhibiting the action of vasodilating β_2 -receptors, allowing for unopposed α -receptor induced vasoconstriction. Rare patients do not respond to vasodilator medical therapy and may benefit from coronary stent placement in spasm-prone atherosclerotic lesions.

Microvascular angina with normal coronary arteries. Angina can occur in some patients in the face of normal-appearing coronary arteries and no provokable spasm. Decreased endothelium-dependent vasodilation may be the underlying pathophysiology of microvascular angina. Patients with this condition may demonstrate an increase in coronary resistance and an inability to increase coronary blood flow sufficiently when challenged by increases in myocardial oxygen

demand. Women are more likely to be affected with microvascular angina, and the symptoms not uncommonly occur at rest or with emotional stress. Exercise can also trigger angina.

A host of diagnostic tests can detect the presence of ischemia in patients with microvascular angina. In the case of stress testing, ST changes of ischemia can be detected as well as nuclear perfusion defects and transient wall motion abnormalities on echocardiography. More sophisticated invasive testing may demonstrate the presence of stress-induced metabolic abnormalities characteristic of ischemia and endothelial dysfunction.

Exercise-related ischemic symptoms may respond to β -blocker therapy. Microvascular angina also tends to respond well to nitrates, both short-acting sublingual nitroglycerin and long-acting oral nitrates. Calcium-channel antagonists are sometimes used together with nitrates to control angina related to microvascular ischemia.

Silent myocardial ischemia. Not all episodes of myocardial ischemia are associated with angina. Some patients may only experience episodes of silent myocardial ischemia as evidenced by transient ST depression with ECG monitoring. Such patients can also have silent MI. It is also possible, and probably not uncommon, for patients to have both silent myocardial ischemia episodes and typical angina; this is termed mixed angina. Episodes of silent myocardial ischemia can be observed in all settings of CAD: chronic stable angina, unstable angina, and coronary vasospasm. Silent ischemia is more common in diabetic patients. Medical therapy directed at controlling symptomatic angina also reduces the number of episodes of silent ischemia.

Prognosis

Contemporary therapies for stable ischemic heart disease have significantly reduced the risks of cardiac events and mortality. The annual rate of major ischemic events such as MI is in the range of 1% to 2%, and the yearly mortality rate is 1% to 3%. CAD is frequently associated with systemic vascular disease, making these patients prone to a host of other events. Patients with stable ischemic heart disease have a yearly combined outcome risk for cardiovascular death, MI, or stroke in the range of 4.5%.

Despite advances in medical and revascularization therapies, up to 30% of patients face some limiting symptoms of recurrent angina.

Revascularization does not abolish the need for ongoing antianginal medical therapy in 80% of patients.

Patients with stable ischemic heart disease should first be treated with medical therapy appropriate to reduce the risk of ischemic events (aspirin, statins) and to control symptoms of angina (nitrates, β -blockers, calcium-channel antagonists). Revascularization therapy with either PCI or CABG is an option for patients who continue to have lifestyle-limiting symptoms despite the use of medical therapy and risk factor modification. The goal of all therapies for patients with stable ischemic heart disease should be individualized, taking advantage of information from controlled trials and directed at improving overall lifestyle and reducing the risk of death and disability due to progressive CAD or systemic vascular disease.

Acute Coronary Syndrome: Unstable Angina and NSTEMI

Definition

Asymptomatic CAD or chronic stable angina may undergo transition to a more aggressive stage of disease called acute coronary syndrome (ACS). ACS comprises a spectrum of clinical presentations, ranging from unstable angina to NSTEMI or STEMI. Unstable angina represents the new onset of angina at rest or on exertion, or an increase in frequency of previously stable anginal symptoms, particularly at rest. ACS manifesting as MI, either NSTEMI or STEMI, is differentiated from unstable angina on the basis of prolonged symptoms, characteristic ECG changes, and the presence of biomarkers in blood. Unstable angina may be a harbinger of either NSTEMI or STEMI, and the diagnosis of unstable angina identifies a patient who requires careful assessment and treatment.

Epidemiology

The occurrence of ACS represents a significant clinical event in up to 1.3 million Americans annually. One third of those categorized as having ACS are diagnosed with NSTEMI. More than half of patients with NSTEMI are 65 years of age or older, and approximately one half are women. NSTEMI is more common in patients with diabetes, peripheral vascular disease, or chronic inflammatory disease (e.g., rheumatoid arthritis).

Primary ACS is the most common form of the disease and reflects underlying plaque rupture leading to intracoronary thrombus formation and limitation of blood flow. This is in contrast to demand ischemia that reflects imbalances in myocardial oxygen supply and demand leading to myocardial ischemia. Examples of decreased oxygen supply include profound anemia, systemic hypotension, and hypoxemia. Increased demand occurs in the face of severe systemic hypertension, fever, tachycardia, and thyrotoxicosis. Demand ischemia not uncommonly unmasks previously asymptomatic obstructive CAD, but it may also occur in the absence of CAD. Treatment of demand ischemia is directed at correcting the underlying medical condition.

Pathology

Most patients who experience NSTEMI do so as a result of plaque rupture with subsequent thrombosis causing subtotal occlusion of the coronary artery. The limitation of coronary blood flow in this situation leads to subendocardial ischemia in the distribution of the affected coronary artery. The same pathology underlies STEMI, although in that case complete vessel occlusion occurs, leading to more extensive MI. It is possible for patients with obstructive CAD to develop collateral support of the affected artery, and in that case plaque rupture with complete vessel occlusion may lead to NSTEMI as opposed to STEMI.

A smaller percentage of patients have ACS due to coronary vasospasm, which, if severe and prolonged, can lead to myocardial necrosis. Vasospasm may occur in regions of endothelial dysfunction induced by atherosclerotic plaque, or it may be triggered by exogenous vasoconstrictors such as cocaine ingestion, the use of serotonin agonists (for migraine therapy), or chemotherapeutic agents (e.g., 5-fluorouracil). A less common cause of ACS is coronary vasculitis.

An alternative coronary artery pathology that can lead to MI is spontaneous coronary artery dissection (SCAD). Less is known about the underlying pathology of SCAD in contrast with MI due to plaque rupture, but its recognition is critical to appropriate treatment. SCAD has a predilection for a younger patient population with a strong bias toward females and is associated in particular with pregnancy and in patients with fibromuscular dysplasia. Rapid diagnosis can be challenging given that the patient population is one with few risk factors for CAD, and so a high index of suspicion is critical. Treatment differs from traditional MI in that a conservative approach is more often taken owing to increased complexity of percutaneous coronary intervention (PCI) on coronary dissection. Medical therapy for SCAD is similar to plaque rupture MI.

Atherosclerotic plaques rich in LDL are prone to develop inflammation, which in turn degrades the collagen-rich fibrous cap, leading to rupture and thrombosis as described previously. Systemic inflammatory conditions may also play a role in plaque rupture in some patients. It is possible to have multiple sites of plaque ulceration or rupture.

Plaque rupture leads to platelet adherence and subsequent activation at the site of rupture. As platelets aggregate, the thrombosis cascade is triggered, leading to progressive accumulation of intravascular thrombus. The severity of myocardial ischemia and MI depends on the degree to which thrombus occludes the vessel. It is also possible for ACS to occur as a result of embolization of platelet aggregates or thrombus.

Clinical Presentation

ACS may manifest as a first symptom of angina pectoris in a previously asymptomatic patient. Alternatively, patients with preexisting angina pectoris experience more frequent angina, angina at lower levels of exertion, or angina at rest. Patients who have developed ACS commonly experience their typical symptom of angina in terms of location and radiation but with increased intensity and duration. Patients with subtotal or total occlusion of a coronary artery may be much less responsive or completely unresponsive to the effects of nitroglycerin.

Physical examination during myocardial ischemia may reveal a patient who is clearly anxious and uncomfortable and who may also be experiencing dyspnea, nausea, or vomiting. Sinus tachycardia and hypertension is a common response to the discomfort of ACS, but in some instances sinus bradycardia and varying degrees of heart block may be observed. Bradyarrhythmias may also be associated with hypotension. Auscultation may reveal the presence of an S_4 , reflecting diminished LV compliance, or an S_3 if there is extensive LV dysfunction. In the case of ischemia-induced papillary muscle dysfunction, the systolic murmur of mitral regurgitation can be heard. Patients with large areas of ischemic myocardium develop elevated LV filling pressures leading to pulmonary congestion, dyspnea, and the physical finding of rales on lung auscultation.

Diagnosis

Patients presenting with ACS require urgent care directed at rapid diagnosis and treatment. The ECG is critically important in early diagnosis of presumed ACS. The finding of ST elevation in multiple leads (Fig. 8.5) is diagnostic of STEMI and portends a more extensive MI

Fig. 8.5 Acute anterolateral myocardial infarction. Leads I, aVL, and V_2 to V_6 demonstrate ST-segment elevation. Reciprocal ST-segment depression is seen in leads II, III, and aVF. Deep Q waves have developed in leads V_2 and V_3 .

and the need for prompt revascularization. The distribution of ST elevation reflects the region of myocardium affected by thrombotic coronary occlusion. For example, ST elevation in leads II, III, and aVF reflects an inferior MI due to occlusion of the right coronary artery (or circumflex coronary artery in some cases). ST elevation in leads V_2 through V_6 (see Fig. 8.5) reflects an anterior MI caused by obstruction of the left anterior descending coronary artery.

Unstable angina or NSTEMI is caused by subtotal vessel occlusion by thrombus leading to reduced coronary blood flow. This results in subendocardial ischemia and the characteristic ECG changes of ST depression (Fig. 8.6). It is important to recognize that up to half of patients with acute MI do not have significant ECG abnormalities on the initial study. Sequential ECGs are frequently required to establish a diagnosis. If there is a high index of suspicion for MI and ECGs are persistently nondiagnostic, the use of leads extending to the patient's back (V_7 to V_9) may demonstrate ST changes related to posterior LV ischemia (usually a circumflex coronary artery occlusion). Echocardiography showing regional wall motion abnormalities can also help to establish the diagnosis of acute MI.

Serum biomarkers also play an important role in the diagnosis of acute MI. Myocardial necrosis leads to the release of biomarkers that can be measured in serial fashion to document the occurrence of MI. The presence of specific biomarkers is definitive evidence of MI, and they are particularly helpful to provide prognostic significance when symptoms are mild and ECG changes are minimal. Common biomarkers include creatine kinase (CK), troponin I, troponin T, lactate dehydrogenase (LDH), and aspartate aminotransferase (AST). Sequential measurement of biomarkers demonstrates their various time courses for abnormal elevation after an acute MI (Fig. 8.7). This information can be helpful in retrospectively timing the occurrence of an event. In contemporary practice, troponin has become the most frequently measured biomarker. LDH, CK, and AST are no longer routinely measured for the diagnosis of MI. Some centers are adopting the "high-sensitivity troponin," which can detect more subtle degrees of myocardial injury than its predecessors. In principle this allows for more rapid triaging of patients presenting with chest pain while maintaining high sensitivity as the test will pick up on troponin release very early in the course of ACS.

Troponins I and T are the most sensitive and most specific markers of myocardial necrosis, and as a consequence, they have become the standard in the biochemical diagnosis of acute MI. The myocardial-specific isozyme CK-MB may be in the normal range while concomitant measurement of troponin I or T reveals the presence of myocardial necrosis. Troponins I and T begin to rise within 4 hours of myocardial necrosis and remain elevated for 7 to 10 days after the MI event. Confounding elevations of troponin T occur in patients with renal failure and congestive heart failure not related to ACS. Troponin release also occurs in the case of demand ischemia not related to coronary thrombosis. This requires careful attention to the entire clinical presentation in discerning the likelihood of underlying ACS due to coronary thrombosis.

In the absence of clear evidence of NSTEMI (i.e., normal examination, ECG findings, and biomarkers), patients who present with the diagnosis of unstable angina should undergo stress testing. A negative exercise stress test is very helpful for distinguishing those patients who require more aggressive diagnostic testing (e.g., catheterization) from those who can be monitored as outpatients. Some centers have embraced the use of CT coronary angiography in the assessment of low-risk patients. This technique has a high negative predictive value for ACS by demonstrating the absence of obstructive CAD.

Echocardiography can be helpful in patients with equivocal ECG findings for ischemia and normal biomarkers. The presence of regional wall motion abnormalities, particularly if they correlate with the distribution of ECG abnormalities, raises the risk for underlying CAD as a cause of symptoms. The echocardiogram may also show evidence of other abnormalities as causes of chest discomfort, such as pericarditis, pulmonary embolism, or aortic dissection.

Patients with a high risk for future coronary events should be directed toward coronary angiography. In the absence of contraindications, coronary angiography is indicated for patients with clear evidence of NSTEMI based on clinical presentation of symptoms, ECG changes, and positive biomarkers. Patients undergoing evaluation for unstable angina who have significant stress test abnormalities are also candidates for coronary angiography. Some patients who have ambiguous stress test findings or ongoing symptoms in the absence of other

Boston University Hospital

Fig. 8.6 Marked ST-segment depression in a patient with prolonged chest pain resulting from an acute non-ST segment elevation myocardial infarction. Between 1 and 3 mm of ST-segment depression is seen in leads I, aVL, and V₄ to V₆. The patient was known to have had a previous inferior myocardial infarction.

Fig. 8.7 Typical time course for the detection of enzymes released after myocardial infarction. *AST*, Serum aspartate aminotransferase; *CK*, creatine kinase; *cTnI*, cardiac troponin I; *cTnT*, cardiac troponin T; *LDH*, lactate dehydrogenase.

findings of NSTEMI require coronary angiography to resolve the issue as to whether underlying CAD is present.

Up to 15% of patients undergoing coronary angiography for NSTEMI have no significant obstructive CAD. In a number of patients, there will be a clear “culprit” lesion showing the earmarks of plaque rupture with ulceration, associated thrombus, or reduced coronary

flow. Lesions that may have played a role in symptoms, ECG findings, or biomarker release that are not clearly stenotic may be assessed for physiologic significance with the use of a fractional flow reserve (FFR) study using a pressure wire device.

Patients who have new-onset chest pain require careful monitoring in an appropriate care setting that allows for rhythm monitoring as well as repeat evaluations of ECG findings and biomarker measurements. Risk assessment is aided by the use of risk scores calculated with either the Thrombolysis in Myocardial Infarction (TIMI) or the Global Registry of Acute Coronary Events (GRACE) algorithms (see Chapter 63, “Acute Coronary Syndrome: Unstable Angina and Non-ST Elevation Myocardial Infarction,” in *Goldman-Cecil Medicine*, 26th Edition). The overall assessment in cases of new symptoms of chest discomfort aims to triage patients based on risk for coronary events. Low-risk patients can be spared aggressive anticoagulation protocols and coronary angiography, whereas high-risk patients are likely to benefit from these approaches. The use of appropriate therapies in high-risk patients (medical therapy or revascularization or both) leads to a 20% to 40% decrease in recurrent ischemic events and a 10% reduction in mortality.

Differential Diagnosis

The initial assessment of patients with possible ACS should include consideration of other potentially life-threatening conditions such as pulmonary embolism and aortic dissection. These considerations are particularly important if the patient’s presentation does not entirely fit that of ACS. Pulmonary embolism can be associated with ECG changes and troponin elevation, and such findings lead to early use of coronary angiography. If there is no CAD-related explanation of the patient’s presentation, prompt investigation for pulmonary embolism is warranted. If the patient has findings suggestive of aortic dissection, that diagnosis should be aggressively pursued with appropriate imaging techniques, given the high risk of mortality associated with that disease. Valvular heart diseases such as aortic stenosis or regurgitation and hypertrophic cardiomyopathy can manifest with symptoms and ECG findings suggestive of ACS. Physical examination should aid in

consideration of these conditions. Pericarditis and myopericarditis can also present diagnostic dilemmas related to chest pain, ECG abnormalities (ST and T wave changes mimicking ischemia), and positive biomarkers. Stress cardiomyopathy (takotsubo syndrome) also manifests with chest pain, T wave inversion, and positive biomarkers. Patients with this diagnosis frequently undergo urgent catheterization to assess for CAD. The absence of a culprit lesion and findings of characteristic wall motion abnormalities establish the diagnosis.

Treatment

Patients with chest pain suggestive of ACS need urgent evaluation for evidence of ischemia (serial ECGs) and myocardial necrosis (serial biomarkers). Serial biomarker measurements, in the current era usually troponin, establish the diagnosis of MI. Continuous ECG monitoring is important given the risk of ischemia-mediated arrhythmias, and serial ECGs establish a pattern of ST changes consistent with ischemia. Patients are also placed on activity limitations up to and including bedrest for patients with particularly difficult to control angina. Supplemental oxygen is provided to patients who are hypoxemic, but routine administration of supplemental oxygen to patients with ACS has not been shown to provide any benefit. Those with a high index of suspicion for ACS require hospital admission for observation and appropriate diagnostic testing. Chest pain lends itself well to diagnosis and treatment algorithms that guide the clinician through decision trees based on expert opinion and evidence-based medicine (see Chapter 63, “Acute Coronary Syndrome: Unstable Angina and Non-ST Elevation Myocardial Infarction,” in *Goldman-Cecil Medicine*, 26th Edition). STEMI is typically diagnosed at the time of initial presentation. Those without evidence of ST elevation can be risk stratified, as discussed earlier, using the guidance of recurrent symptoms, ECG changes, or abnormal biomarker levels. Treatment of patients who are categorized as having unstable angina or NSTEMI is directed by their allocation to either low- or high-risk status.

Once recognized as having ACS, patients require antiplatelet therapy because plaque rupture and thrombosis is a frequent underlying pathology, and antiplatelet therapy significantly reduces mortality risk in patients with NSTEMI. Patients should be given aspirin (75 to 162 mg per day) and a P2Y₁₂ inhibitor (either clopidogrel or ticagrelor). Given prasugrel and ticagrelor’s increased strength and rapidity of platelet inhibition compared to clopidogrel they are favored in the ACS setting. Note that prasugrel is reserved for patients undergoing PCI and is contraindicated in patients with a history of stroke or transient ischemic attack.

The use of these more potent antiplatelet agents must be weighed against an increased risk of bleeding that accompanies this effect. The aspirin/P2Y₁₂ inhibitor combination is indicated as ongoing therapy in the year following diagnosis of NSTEMI.

Symptoms of chest discomfort can be treated with nitrates (sublingual, topical, or intravenous drip) and β -blockers. The latter therapy slows heart rate and reduces blood pressure, effects that translate into reduced myocardial oxygen demand in the face of limited supply. It is important not to give nitrates to patients who have taken phosphodiesterase-5 inhibitors (sildenafil, tadalafil, or vardenafil) within the previous 24 to 48 hours. Attention to this detail minimizes the risk for nitrate-induced hypotension. Calcium-channel antagonists may be used in lieu of β -blockers, particularly if there is a need for blood pressure control, but they should be avoided in patients with reduced EF or overt heart failure. The dihydropyridine calcium-channel blocker nifedipine can be effective in controlling blood pressure and promoting coronary vasodilation, but it should be given in conjunction with a β -blocker because of the potential for the drug to induce reflex tachycardia and thereby increase myocardial oxygen demand.

Glycoprotein IIb/IIIa inhibitors block platelet aggregation and can reduce ischemic events in patients undergoing PCI as treatment for NSTEMI. These drugs are usually reserved for high-risk patients at the time of PCI. They require intravenous administration and are given for 12 to 24 hours after PCI. The use of this class of drugs for PCI has decreased in light of data suggesting advantages of bivalirudin, a direct thrombin inhibitor, over the glycoprotein IIb/IIIa inhibitors.

Heparin, given in its unfractionated form or as a low-molecular-weight (LMW) preparation, has been shown to reduce the risk of ischemic complications in patients with NSTEMI. Heparin acts by activating antithrombin and thereby inhibiting the formation and activity of thrombin. The anti-ischemic effect of heparin is additive to that of aspirin. Unfractionated heparin is given by continuous intravenous drip for up to 48 hours. It is usually not continued after revascularization. Heparin may be associated with mild thrombocytopenia, and 1% to 5% of patients experience profound antibody-mediated thrombocytopenia. These patients usually have been exposed to heparin in the past, and a known diagnosis of heparin-induced thrombocytopenia necessitates the use of alternative antithrombin therapy.

LMW heparins are fragments of unfractionated heparin that are more predictable in their antithrombin activity and are associated with reduced risks for thrombocytopenia and bleeding complications. The drug should be avoided in patients who have a history of heparin-induced thrombocytopenia. Clinical studies of patients with NSTEMI have shown superiority of LMW heparin over unfractionated heparin in reducing the end point of death or MI during hospitalization. LMW heparin, either enoxaparin or dalteparin, is administered subcutaneously for up to 8 days after hospitalization. As with unfractionated heparin, LMW heparin is not continued after revascularization. Dosing of LMW heparin is based on renal function status, age, and weight. LMW heparin has a long duration of action and cannot be reversed with protamine. Unfractionated heparin has a shorter duration of action and is reversible with protamine, making unfractionated heparin the preferred anticoagulant for patients who may require CABG.

Fondaparinux is a selective factor Xa inhibitor that does not induce thrombocytopenia. It can reduce ischemic events in patients with NSTEMI and is associated with a lower risk of bleeding than is seen with enoxaparin. There is an increased risk of catheter-related thrombosis in patients treated with fondaparinux who are undergoing coronary angiography. This drug is reserved for cases that will be managed noninvasively and where there is a higher risk for heparin-related bleeding.

Bivalirudin, a direct thrombin inhibitor, is an alternative to heparin for patients who are undergoing PCI. It is as effective as the combination of heparin and glycoprotein IIb/IIIa inhibitor in reducing the risk of ischemic complications related to PCI, and it is associated with a reduced risk of postprocedure bleeding. Bivalirudin is used preferentially in patients with a history of heparin-induced thrombocytopenia.

Statin therapy is also indicated in patients with NSTEMI at presentation. Statins act to stabilize plaque and improve endothelial function. These drugs should be initiated at the time of admission to the hospital and continued after discharge. There is evidence that high-dose atorvastatin (80 mg/day) given to patients with NSTEMI reduces the risk of subsequent ischemic events.

Risk stratification is important in appropriately evaluating patients with ACS. Low-risk patients (age <75 years, normal troponin levels, 0 to 2 TIMI risk factors) should be evaluated with noninvasive testing, either exercise or pharmacologic stress testing before hospital discharge. Those whose tests are positive for ischemia should be considered for predischarge coronary angiography. This approach leads to selective use of invasive testing and subsequent revascularization. Patients with high-risk ACS profiles (age >75 years, elevated troponin

levels, ≥ 3 TIMI risk factors) are candidates for coronary angiography and, when appropriate, revascularization. The high-risk ACS patient group will have fewer subsequent ischemic events when approached in this way. Risk stratification occurs early after admission for possible ACS. An early invasive strategy (coronary angiography within 24 hours of admission) for high-risk patients has been shown to reduce the combined end point of death, MI, or stroke compared with a delayed invasive approach. The occurrence of acute heart failure, hypotension, or ventricular arrhythmias in the face of ACS prompts urgent coronary angiography to identify patients with high-risk coronary anatomy that requires urgent revascularization (see video, Cardiac Cath, http://www.heartsite.com/html/cardiac_cath.html).

Invasive coronary angiography always carries with it a risk of bleeding complications that is no doubt enhanced by the concomitant use of potent antiplatelet and antithrombin therapies. Those at increased risk for bleeding complications include patients with female gender, low body weight, diabetes mellitus, renal insufficiency, low hematocrit, and hypertension. The risks of bleeding as well as vascular complications are lower via radial artery catheterization compared to a femoral artery approach at the cost of some increased difficulty in catheter manipulation. Utilization of a radial approach is becoming more commonplace and has become the preferred method of access for a large number of interventional cardiologists.

Prognosis

The extent and magnitude of ST depression noted on ECG in patients with NSTEMI predicts mortality risk. Patients who exhibit 2 mm or more of ST depression in multiple leads have a 10-fold increased mortality rate at 1 year. The degree of elevation in troponin also identifies patients with an increased risk of mortality during the following year. It has also been observed that the combined measurement of troponin, hsCRP, and B-type natriuretic peptide (BNP) predicts an increased mortality risk better than any individual biomarker.

Contemporary practice significantly reduced the risk of mortality for patients with ACS at presentation. Risk stratification with appropriate revascularization and use of antiplatelet therapy, statins, and overall coronary risk factor reduction also contribute to this decrease in mortality risk. Whereas the immediate mortality risk for patients with NSTEMI is lower than for patients with STEMI (5% vs. 7%), those with NSTEMI are more prone to subsequent recurrent coronary events. The cumulative mortality rate for STEMI and NSTEMI is similar at 6 months after presentation (12% vs. 13%). NSTEMI identifies a patient group with significant long-term mortality risk who require aggressive attention to modifiable coronary risk factors.

Acute STEMI and Complications of Myocardial Infarction

Definition and Epidemiology

Sustained myocardial ischemia, regardless of its cause, can result in myocardial necrosis, which underlies the clinical syndrome of MI. MI represents a spectrum of myocardial necrosis, from relatively small amounts of muscle in the case of demand ischemia, to more extensive subendocardial MI that characterizes NSTEMI, to typically large transmural MIs commonly manifesting as STEMI. The current accepted definition of acute MI accounts for clinical setting and mechanism. STEMI represents the range of large MIs that are almost always caused by total occlusion of an epicardial coronary artery resulting in extensive transmural myonecrosis (Fig. 8.8). In contrast, NSTEMI reflects subtotal coronary occlusion leading to subendocardial myonecrosis. Whereas both NSTEMI and STEMI are life-threatening, their different underlying mechanisms mandate different therapeutic strategies and affect the urgency with which they are applied.

One half of all deaths in the United States and developed countries are related to cardiovascular disease. In the United States, there are over one million nonfatal or fatal MIs each year. CAD plays a role in 360,000 deaths each year, and 110,000 deaths are caused by acute MI. One half of patients with acute MI at presentation die within 1 hour of onset, before therapy can be instituted. Of the 5 million patients who come to emergency rooms with chest pain, 1.3 million are admitted to hospital with ACS. In this group of patients, the presence of ST elevation on ECG or an LBBB indicates the diagnosis of STEMI and the need for prompt intervention to open an occluded coronary artery. STEMI accounts for 30% of all MIs, but this mechanism of MI is associated with the highest immediate mortality risk, prompting the need for urgent therapeutic intervention.

Pathology

Lipid-rich coronary plaques are subject to inflammation incited by the response to oxidation of LDL-cholesterol within the plaque. A sequence of inflammatory events leads to macrophage accumulation and the elaboration of metalloproteinases that degrade collagen in the fibrous cap of the plaque. Thinning of the fibrous cap makes the plaque vulnerable to rupture and exposure of blood to thrombogenic stimuli, resulting in platelet aggregation and activation, thrombin generation, and the evolution of fibrin-based thrombus. If the occlusion is total, transmural myocardial ischemia and necrosis ensue and the ECG demonstrates ST elevation. In contrast, partially occlusive thrombus can result in unstable angina or NSTEMI (subendocardial MI). The presence of coronary collaterals can limit the extent of ischemia and necrosis in either scenario. Both STEMI and NSTEMI can set the stage for arrhythmias and LV dysfunction. Whereas coronary thrombosis is the cause of most MIs, there are patients who develop MI related to coronary embolization, coronary vasospasm, vasculitis, coronary anomalies, dissection of the aorta or a coronary artery, or trauma.

One key feature of the pathology of MI is its time-dependent nature. Experimental and clinical studies have documented that coronary occlusion leads to ischemia and myonecrosis in a wavefront manner, from endocardium to epicardium. Restoration of flow to the vessel within 6 hours after occlusion is associated with limitation of infarct size and a favorable effect on mortality risk. The principle of time dependency of MI drives the need to aggressively reperfuse occluded coronary arteries, and this is the cornerstone of contemporary therapy for STEMI.

Clinical Presentation

Patients with acute MI usually have a combination of chest discomfort, ECG changes (ST elevation in contiguous leads or LBBB), and elevation in biomarkers such as CK-MB and troponin. The high sensitivity and high specificity of troponin have made it the preferred biomarker in the diagnosis of MI. The chest discomfort associated with MI is similar to angina pectoris but more severe in nature. It is usually described as substernal pressure, tightness, or fullness. Patients may have symptoms of discomfort that radiate to the neck, jaw, one or both arms, or the back. Not uncommonly, patients with symptoms of acute MI also experience nausea, vomiting, diaphoresis, apprehension, dyspnea, or weakness. In contrast to angina pectoris associated with stable CAD, acute MI symptoms last longer than 20 to 30 minutes (up to hours).

Occasionally, patients only have symptoms in the non-chest areas usually associated with radiation. Up to 20% of patients, particularly the elderly and diabetics, do not have typical chest discomfort at presentation. The index of suspicion for acute MI should be high in these groups if the patient exhibits profound weakness, acute dyspnea or pulmonary edema, nausea, vomiting, ventricular arrhythmias, or hypotension. The differential diagnosis for patients with chest

Fig. 8.8 Right coronary artery angiogram in a patient with acute inferior myocardial infarction. The left panel demonstrates total occlusion of the right coronary artery. The right panel depicts restoration of flow 90 minutes after the intravenous administration of tissue-type plasminogen activator.

discomfort suspicious for acute MI includes aortic dissection, pulmonary embolism, chest wall pain, esophageal reflux, acute pericarditis, pleuritis, and panic attacks. Given the life-threatening nature of aortic dissection and pulmonary embolism, these diagnoses should always be paramount, along with acute MI, in patients presenting with chest discomfort.

Physical examination. A comprehensive examination should be undertaken if acute MI is suspected. Attention must be paid to vital signs, because patients may be either hypertensive or hypotensive during the course of an MI. In some cases, such as inferior MI, profound bradycardia may be present. Auscultation of the heart may reveal an S_4 . In the case of a large MI, the patient may have symptoms and signs of heart failure such as dyspnea, rales, elevated central venous pressure, and an S_3 . Severe heart failure may lead to cardiogenic shock with hypotension and vasoconstriction causing the extremities to be cool to touch. Patients with acute MI are also subject to mechanical problems such as mitral regurgitation due to papillary muscle dysfunction.

Electrocardiogram. The ECG is an important tool in the diagnosis of acute MI. ST elevation of 1 mm or greater in contiguous leads is seen in most patients with acute MI. The initial ECG may be nondiagnostic, so it is important to obtain serial tracings no more than 20 minutes apart to detect the evolutionary changes characteristic of STEMI. The first stage of ECG presentation is ST elevation that subtends the region of the heart affected by transmural ischemia. ST depression may be present in opposing leads, and these are termed reciprocal changes (see Chapter 64, “ST Elevation Acute Myocardial Infarction and Complications of Myocardial Infarction,” in *Goldman-Cecil Medicine*, 26th Edition). The presence of reciprocal changes may indicate a larger and more threatening MI. As the MI progresses, ST elevation gives way to T wave inversion. Varying degrees of resolution of ST and T wave changes occur over time, but patients with transmural MI develop pathologic Q waves in the leads subtending the infarcted muscle. Other causes of ST elevation include pericarditis and a chronic repolarization finding of “early repolarization.” The presence of either cause of ST elevation can confound the early ECG diagnosis of acute MI.

Approximately 30% of acute MIs originate from the circumflex coronary artery on the posterior wall of the heart. This type of MI appears on the ECG as precordial ST depression. The presence of precordial ST depression should raise suspicion of the presence of “true posterior MI,” and additional leads placed through the axilla to the back may reveal the presence of posterior ST elevation. Echocardiography

demonstrating posterior hypokinesis is also useful in discriminating true posterior MI. Acute inferior MI due to occlusion of the right coronary artery can also be associated with right ventricular infarction if the right coronary artery’s acute marginal branch is compromised. Right ventricular infarction can lead to some challenging management issues, and its diagnosis is aided by the use of right precordial leads to detect ST elevation.

LBBB or ventricular pacing can mask ST elevation due to acute MI. Patients with clinical features of acute MI who have an LBBB (particularly a new LBBB) should be presumed to have STEMI and treated appropriately. Right bundle branch block (RBBB) does not mask the ST elevation of STEMI.

Differential Diagnosis

The diagnosis of STEMI is usually straightforward based on symptoms and ECG findings, but a number of conditions can mimic the ST elevation of STEMI and confound the diagnosis. The ECG changes of early repolarization, takotsubo syndrome, acute myocarditis, or pericarditis can be difficult or impossible to distinguish from those of STEMI. In the face of ST elevation and chest discomfort, it may be necessary to perform coronary angiography in patients who ultimately are diagnosed with a condition other than STEMI so as to not miss this critical diagnosis.

Diagnostic testing. Cardiac troponins (cTnI and cTnT) are sarcomere proteins that, when measured in blood, are specific for myocardial injury. The troponin level becomes elevated 2 to 4 hours after the onset of injury, and the abnormal elevation can persist for up to 2 weeks after the event. The CK-MB isomer is not as specific for heart injury as troponin, but it can still be useful in documenting the presence of MI. CK-MB is found elevated within 4 hours after an acute MI, but it clears more rapidly than troponin. In the case of persistently elevated troponin, a measurable increase in CK-MB may herald another episode of myocardial necrosis. Chronic renal insufficiency is associated with false-positive elevations of troponin T, more so than troponin I. In addition to biomarkers of myocardial injury, other laboratory studies obtained in patients with acute MI include a complete blood count, blood chemistries, lipid panel, prothrombin time (PT), and partial thromboplastin time (PTT). Leukocytosis is a common finding in acute MI, reflecting the inflammatory nature of myocardial necrosis.

At the time of admission, chest radiographs are obtained to assess for the presence of pulmonary edema or mediastinal widening

suspicious for dissection. Echocardiography is important in delineating the extent of MI and assessing EF. In cases of diagnostic ambiguity, early use of echocardiography can demonstrate the presence of regional wall motion abnormalities consistent with acute MI. Echocardiography with color Doppler is also helpful in diagnosing complications of acute MI such as infarct-related mitral regurgitation or ventricular septal defect (VSD), pericardial effusion, or evidence of pseudoaneurysm as a result of myocardial rupture. Follow-up echocardiography in the months after acute MI can also reveal recovery of LV function. Radionuclide tracer studies are not useful in diagnosing acute MI. CT, cardiac MRI, and transesophageal echocardiography are all useful in diagnosing aortic dissection when there is an increased index of suspicion. Cardiac MRI can also distinguish myopericarditis.

Treatment

Acute STEMI is caused by occlusion of the epicardial coronary artery by thrombus after rupture of a vulnerable plaque. The process of myocardial necrosis is time dependent, so diagnosis and treatment of STEMI to preserve myocardium must occur as quickly as possible. More than half of deaths occur within 1 hour after onset of symptoms, before the patient can be reached for emergency care. Patients often delay seeking care for symptoms of acute MI despite efforts to alert the public to the risk of ignoring symptoms of chest discomfort. Emergency medical personnel who respond to patients with possible MI begin to institute initial therapy in the field. Patients are monitored with ECG for rhythm disturbances such as ventricular tachycardia (VT) or ventricular fibrillation (VF) that require prompt cardioversion or defibrillation. Oxygen is administered via nasal cannula, and intravenous access is established. Aspirin (162 to 325 mg) is administered to the patient, and sublingual nitroglycerin may also be given in an attempt to relieve chest discomfort. Some emergency response systems perform 12-lead ECGs and telemeter the results to the emergency department, allowing for early diagnosis of STEMI and early decision making regarding revascularization strategies.

Once the patient arrives in the emergency department, an ECG, if not already available, will be performed within 5 minutes. If the ECG is nondiagnostic, a second study is obtained no more than 20 minutes after presentation. A diagnosis of STEMI triggers decision making regarding reperfusion strategies that are used by the particular institution (see Chapter 64, "ST Elevation Acute Myocardial Infarction and Complications of Myocardial Infarction," in *Goldman-Cecil Medicine*, 26th Edition). Hospitals that are capable of performing emergency cardiac catheterization for the purpose of reperfusion therapy have an established rapid response system to activate the catheterization laboratory for this urgent therapy. There is evidence that primary PCI therapy for STEMI is superior to fibrinolytic therapy, but its use depends on the timely availability of a well-trained catheterization team. The quality of primary PCI is signified by a so-called door-to-balloon time of less than 90 minutes. Likewise, the standard for fibrinolytic therapy is a door-to-needle time of less than 30 minutes. Regardless of the means of reperfusion, it is important for the hospital treating patients with STEMI to have a structured protocol for timely diagnosis, decision making, and initiation of therapy.

In addition to aspirin, the patient should be given a loading dose of a P2Y₁₂ inhibitor (ticagrelor 180 mg, clopidogrel 600 mg or prasugrel 60 mg), assuming he or she will be treated with primary PCI. Unfractionated heparin in a dose of 60 IU/kg should be administered (no more than 4000 IU bolus) with a drip rate of 12 IU/kg/hour (maximum dose, 1000 IU/hour). LMW heparin may also be used (enoxaparin 30 mg IV bolus with 1 mg/kg subcutaneously every 12 hours for patients younger than 75 years of age who have normal renal function). Other agents such as glycoprotein IIb/IIIa inhibitors or bivalirudin

are administered depending on the protocols of the catheterization laboratory.

Patients are commonly given sublingual nitroglycerin 0.4 mg (repeat every 5 minutes for no more than three total doses), which often helps to diminish chest discomfort. Intravenous nitroglycerin may be helpful for control of both persistent pain and hypertension if present. Intravenous morphine (2 to 4 mg, repeated every 5 to 15 minutes as needed) is also frequently used for pain control. Although there has been no consensus statement on the use of morphine in ACS, recently there have been several studies that have suggested an increased risk of in-hospital mortality associated with its use presumed secondary to reduced antiplatelet activity of P2Y₁₂ inhibitors. Intravenous β -blockers such as metoprolol (5-mg bolus every 10 minutes for a total dose of 15 mg) are indicated in the treatment of STEMI but should be avoided in the face of heart failure, severe COPD, hypotension, or bradycardia. β -Blockers (metoprolol, propranolol, atenolol, timolol, and carvedilol) have been shown to significantly reduce the risk of future MI and cardiovascular mortality. Statin therapy, as mentioned for NSTEMI, is recommended for all patients with STEMI as a presenting symptom regardless of their history of hypercholesterolemia. Other adjunctive measures include bedrest for the first 12 hours, ongoing oxygen by nasal cannula with pulse oximeter monitoring, continuous rhythm monitoring, anxiolytic agents as needed, and stool softeners. Atropine is kept in reserve for the treatment of hemodynamically significant bradycardia, which may occur with inferior MI.

ACE-inhibitor therapy also plays an important role in the long-term survival of patients after STEMI. ACE-inhibitor therapy has been shown to reduce the incidence of heart failure, recurrent MI, and long-term mortality after STEMI. ACE inhibitors commonly used for this purpose include lisinopril, captopril, enalapril, and ramipril. The decision to initiate ACE-inhibitor therapy is directed by the patient's tolerance. Care is warranted early after STEMI, because the patient may be prone to hypotension related to ACE-inhibitor therapy. A low dose should be administered first, with gradual upward titration.

Aldosterone receptor blockade with eplerenone (25 to 50 mg/day) reduces cardiovascular mortality after MI in patients with heart failure and a reduced EF of less than 40% or diabetes. Spironolactone also reduces mortality in patients with heart failure and a history of remote MI.

Reperfusion therapy. Timely reperfusion therapy, either thrombolytic therapy or primary PCI, is critical to limiting the extent of MI and reducing the risks of future morbidity and mortality. Primary PCI has been shown to have advantages over thrombolytic therapy, with higher immediate and long-term vessel patency. Primary PCI depends on the availability of cardiac catheterization facilities and staff to conduct the reperfusion procedure quickly (see earlier discussion). If the patient has not had access to a catheterization facility for longer than 2 hours after presentation, thrombolytic therapy is a reasonable alternative.

In the randomized, placebo-controlled Gruppo Italiano per lo Studio della Streptochinasi nell'Infarto (GISSI) study, thrombolytic therapy with intravenous streptokinase was shown to reduce the risk of mortality in patients with STEMI if it was administered early after presentation. The time-dependent nature of therapy was also demonstrated, in that patients treated more than 12 hours after the onset of symptoms had no measurable benefit from thrombolysis. The next generation of thrombolytic agents, recombinant tissue-type plasminogen activators (rt-PA), improved on mortality reduction when compared with streptokinase (30-day mortality rate, 7.3% with streptokinase vs. 6.3% with rt-PA). The advantage of rt-PA appeared to be related to enhanced vessel patency at 90 minutes after administration (80% with rt-PA vs. 53% to 60% with streptokinase). Subsequent forms of rt-PA,

although easier to administer, did not further reduce mortality. The major attribute of thrombolytic therapy is its ease of administration, but there is a significant risk (0.5% to 1%) of catastrophic bleeding complications in the form of intracerebral hemorrhage. Age older than 75 years, female gender, hypertension, and concomitant use of heparin increase the risk of this complication. In the case of failed thrombolytic therapy, rescue PCI may be pursued.

Primary PCI has been shown to be superior to thrombolytic therapy based on lower overall mortality rates and reduced risk of recurrent nonfatal MI. It is also associated with higher vessel patency rates and a low risk of intracranial hemorrhage. Primary PCI is frequently performed by mechanical aspiration of thrombus and placement of a coronary stent. Balloon angioplasty may or may not be needed during this procedure. Patients should receive preprocedure P2Y₁₂ inhibitor (ticagrelor 180 mg, clopidogrel 600 mg or prasugrel 60 mg). For patients who are not able to take oral medications, whose platelet inhibition may not be at therapeutic levels at the time of stent placement, or who are at high risk for life-threatening bleeding requiring cessation of antiplatelet therapy, cangrelor (an intravenous P2Y₁₂ inhibitor given at 30 mcg/kg bolus followed by infusion of 4 mcg/kg/minute) may be considered given its rapid onset and offset of platelet inhibition.

Bivalirudin was shown in a clinical trial of primary PCI to be superior to both heparin- and glycoprotein IIb/IIIa-based anticoagulation with lower post-MI mortality and fewer bleeding complications. Centers that are dedicated to primary PCI as the preferred therapy are likely to have the best outcomes when operators are sufficiently skilled and the institution cares for this patient population on a regular basis. Primary PCI is the best option for patients in cardiogenic shock (within 18 hours after onset of shock), for patients with prior CABG (graft occlusion is not amenable to thrombolysis), and for patients older than 70 years of age (conferring a reduced risk of intracerebral hemorrhage compared with thrombolysis).

Complications of Myocardial Infarction

Recurrent Chest Pain

MI is associated with a number of possible problems related to the extent of injury (Table 8.6). Patients can experience post-infarction angina that may reflect re-occlusion of the infarct related vessel. This can occur either in patients who underwent primary PCI with stent placement (stent thrombosis) or thrombolysis. Post-infarction angina usually requires cardiac catheterization for appropriate diagnosis and treatment. Patients with transmural MI are also subject to pericarditis 2 to 4 days after the event. This diagnosis is usually established by the symptom nature and pattern (worse with inspiration or supine position, improved with sitting), which is different from their initial presentation with acute MI. A less common event is the development of pericarditis due to Dressler syndrome up to 10 weeks after acute MI. This is likely an immune-mediated phenomenon. Pericarditis is treated with aspirin or nonsteroidal anti-inflammatory drugs.

Arrhythmias

The highest risk of life-threatening arrhythmias is during the first 24 to 48 hours after the onset of acute MI. Ischemic myocardium is susceptible to arrhythmia generation, probably based on micro-reentry associated with ischemic myocardium. The significant mortality risk in the early hours of acute MI is largely attributed to arrhythmias such as VF or VT. The risk of VF is about 3% to 5% in the early hours of MI and diminishes over 24 to 48 hours. One of the benefits of rhythm monitoring during the first 48 hours after presentation is prompt recognition and treatment of life-threatening ventricular arrhythmias.

TABLE 8.6 Complications of Acute Myocardial Infarction

Functional
Left ventricular failure
Right ventricular failure
Cardiogenic shock
Mechanical
Free-wall rupture
Ventricular septal defect
Papillary muscle rupture with acute mitral regurgitation
Electrical
Bradyarrhythmias (first-, second-, and third-degree atrioventricular blocks)
Tachyarrhythmias (supraventricular, ventricular)
Conduction abnormalities (bundle branch and fascicular blocks)

Accelerated idioventricular rhythm occurs early in the course of MI and may be associated with reperfusion. This arrhythmia is well tolerated and does not require specific therapy.

Ventricular arrhythmias occurring late (>48 hours) after acute MI usually are associated with large underlying MIs and heart failure. Late episodes of VF or VT portend a poor prognosis. Immediate therapy for VF is electrical defibrillation. VT that causes hemodynamic embarrassment is treated with synchronized electrical cardioversion. β -Blocker therapy may help to suppress arrhythmias in patients who are prone to them, as may the use of amiodarone. Correction of residual ischemia may also play a role in controlling VF or VT events. Patients with late VF or hemodynamically significant VT are candidates for an implantable cardioverter defibrillator device (ICD). An ICD can also improve survival in asymptomatic patients with a persistently reduced EF less than 30% at 40 days after their acute MI. ICD therapy is also indicated if the EF is less than 35% at 40 days after MI in a patient with symptomatic heart failure.

Atrial fibrillation (AF) occurs in 10% to 15% of patients after MI. Those more prone to AF include patients with older age, large MI, hypokalemia, hypomagnesemia, hypoxia, or increased sympathetic activity. Rate control with β -blockers (e.g., metoprolol), digoxin, calcium-channel blockers (e.g., diltiazem) or some combination of these agents is warranted, as is the use of intravenous heparin to reduce the risk of systemic embolization. Cardioversion is warranted in the face of rapid rates that cause ischemia, heart failure, or hypotension. Amiodarone is sometimes used to help maintain sinus rhythm for the first few months after MI-related AF.

Sinus bradycardia or AV block due to increased vagal tone is common in cases of inferior MI (30% to 40%). Reperfusion of the right coronary artery may be associated with significant bradycardia (Bezold-Jarisch reflex). Atropine (0.5 to 1.5 mg IV) can resolve severe inferior MI-related bradycardia. In contrast, heart block and wide-complex escape rhythms associated with anterior MI suggest an infra-AV node block. This may be worsened by the use of atropine.

Advanced degrees of heart block may require the placement of a permanent pacemaker. Intermittent second-degree or third-degree AV block associated with bundle branch block or symptomatic AV block are indications for a permanent pacemaker. Type I AV block (Wenckebach) is usually not persistent and rarely causes symptoms that warrant a permanent pacemaker.

Heart Failure and Low-Output States

MI involving 20% to 25% of the left ventricle can result in significant heart failure manifesting with dyspnea due to pulmonary congestion

and findings of LV dysfunction such as an S_3 or S_4 . Cardiogenic shock is associated with loss of 40% of the myocardium. This condition carries a very high risk of mortality. In the era of widespread use of reperfusion therapy, the incidence of post-MI heart failure or cardiogenic shock has declined. Early use of reperfusion therapies limits infarct size and the risk of complications related to heart failure. When acute heart failure occurs with MI, therapeutic interventions including oxygen, intravenous morphine, and diuretics can help stabilize the patient. Nitroglycerin can also help by reducing the elevated preload. Long-term therapy for heart failure related to reduced EF after acute MI includes the use of ACE inhibitors (or ARBs), appropriate β -blockers, aldosterone receptor antagonists such as eplerenone or spironolactone, and diuretics as needed.

The acutely infarcted ventricle requires an increased filling pressure and volume to optimize its performance. Patients with acute MI may become relatively fluid depleted due to nausea, vomiting, or decreased fluid intake, leading to reduced LV volume and a fall in cardiac output. This can translate into hypotension that is best treated by judicious administration of fluids.

Acute inferior MI is usually associated with a low mortality risk once the early arrhythmia-prone hours have passed. Occlusion of the right coronary artery and a significant acute marginal branch can lead to right ventricular infarction. Approximately 10% to 15% of patients with inferior MI have associated right ventricular infarction. This condition produces a significant increase in mortality risk (in-hospital mortality, 25% to 30% vs. <6%). Hallmarks of right ventricular infarction include elevated jugular venous pressure with Kussmaul sign and hypotension. Right ventricular function frequently recovers, but it may be necessary to administer sufficient volume to maintain right heart output. Short-term inotropic support with dobutamine is sometimes needed, and venodilators and diuretics should be avoided. High-degree AV block, usually transient with inferior MI, may worsen hemodynamics and necessitate temporary AV sequential pacing. AF may not be tolerated and may require cardioversion.

Cardiogenic Shock

Cardiogenic shock is a clinical syndrome associated with extensive loss of myocardium, which leads to a reduced cardiac index (<1.8 L/min/ m^2) in the face of elevated LV filling pressures (pulmonary capillary wedge pressure >18 mm Hg), resulting in systemic hypotension and reduced organ perfusion. This shock state is associated with mortality rates in the range of 70% to 80%. Aggressive diagnosis with hemodynamic monitoring and appropriate support with an inotropic agent and invasive mechanical support as indicated can help to stabilize the patient. Mechanical circulatory support includes the intra-aortic balloon pump (IABP), Impella ventricular assist device (VAD), and extracorporeal membrane oxygenation (ECMO). One benefit of the IABP is that it can quickly be placed in the cath lab to both augment cardiac output as well as diastolic filling of the coronary arteries. IABP therapy is at best temporizing, and the patient's survival depends on the presence of reversible factors such as ischemia that respond to revascularization or correction of a mechanical complication of MI (e.g., mitral regurgitation or VSD). IABP therapy cannot be used in the face of significant aortic insufficiency and may not be feasible in the presence of significant peripheral vascular disease. Despite the hemodynamic support it provides, the IABP has never been proven in a randomized trial to improve mortality, and thus its use is based on clinician decision making rather than routine use. Some centers now are opting for more advanced levels of support in particularly ill patients including the Impella or ECMO as a bridge to recovery or long-term VAD/transplant.

In patients with cardiogenic shock secondary to acute MI it is key to reestablish perfusion to affected areas of the heart as able. More recent theories have suggested that rather than the "door to balloon time" emphasized in STEMI, the emphasis in patients in shock should be to achieve early improvement in perfusion with mechanical support as needed and then address revascularization. If multivessel disease is discovered in a patient in shock, the culprit lesion should be addressed, and other high-grade diseases can be addressed at a later time.

Mechanical Complications

Mechanical complications of acute MI include mitral regurgitation (due to ischemic papillary muscle dysfunction or rupture), VSD, free wall rupture, and LV aneurysm formation. These problems usually occur during the first week after MI, and they account for as much as 15% of MI-related mortality. A new murmur, sudden onset of heart failure, or hemodynamic collapse should also raise suspicion of a mechanical complication of MI. Patients who either were not reperfused or were reperfused late after onset of MI are most at risk for these problems. Echocardiography usually identifies the mechanical problem, and hemodynamic assessment with right heart catheterization can aid the diagnosis. Surgical correction of the defect is usually required.

Papillary muscle rupture or dysfunction leading to acute severe mitral regurgitation results in severe heart failure and up to 75% mortality within 24 hours after onset. Afterload reduction with intravenous nitroprusside and the use of IABP can help to stabilize the patient, but surgical valve repair or replacement will be needed to provide some chance of survival. Surgery is associated with a 25% to 50% mortality risk, but that still is better than the risk with medical or IABP therapy only.

Elderly patients, particularly those with hypertension, are more prone to MI-related VSD. Thrombolytic therapy may also place patients at risk for this complication. Acute VSD with resultant left-to-right shunting can produce severe hemodynamic instability. As with acute mitral regurgitation, afterload reduction and IABP may help to stabilize the patient, but ultimately surgical repair will be required. Moderate to large VSDs are not well tolerated and are associated with significant mortality risk. VSDs related to anterior MI may offer a better opportunity for surgical repair than those resulting from inferior MI. Some patients have been helped by the use of percutaneous closure devices, which can afford an opportunity to delay surgery until there is better tissue healing in the infarct area.

LV free wall rupture is similar to VSD in terms of risk for occurrence and underlying myocardial pathology. Free wall rupture is usually associated with sudden death due to cardiac tamponade. On occasion, a pseudoaneurysm forms and the patient can be treated surgically.

Thromboembolic Complications

In earlier years, thromboembolism in the form of either cardioembolic stroke or pulmonary embolism contributed to 25% of post-MI in-hospital mortality, and clinical events were diagnosed in 10% of patients. The risk of thromboembolism is linked to the presence of LV mural clot, which is more likely to be found in anterior MI with associated apical akinesis and deep venous thrombosis due to prolonged bedrest. Contemporary methods of care for acute MI have greatly reduced the risk of post-MI thromboembolism.

Reperfusion therapy, when applied in a timely fashion, results in less extensive MI and less impairment of LV function. Patients with anterior MI treated with reperfusion therapy are less likely to have extensive apical akinesis, which is the breeding ground for mural thrombus. It is advised that patients treated for acute MI have an echocardiogram to assess for overall LV function; in the case of anterior MI, the presence of apical mural thrombus can be detected by echocardiography.

If LV mural thrombus is present, the patient should receive therapeutic anticoagulation with unfractionated or LMW heparin while oral anticoagulation with warfarin is initiated. Warfarin therapy should be continued for 6 months after MI when LV apical mural thrombus is detected. Early ambulation after MI, along with the use of compression stockings and subcutaneous heparin prophylaxis (unfractionated or LMW) for deep venous thrombosis, has greatly diminished the threat of pulmonary embolism.

PROGNOSIS

Risk Stratification After Myocardial Infarction

Key to understanding an individual patient's risk for future coronary events or mortality related to MI is a thorough assessment of drivers for those risks: status of LV function and its impact on clinical functional status, residual myocardial ischemia, and spontaneous or exercise-induced arrhythmias. Appropriate predischARGE assessments provide a comprehensive picture of the patient's risk status and prognosis.

Electrocardiographic Monitoring

Patients are routinely monitored by telemetry systems that capture arrhythmic events in the first 48 hours after MI. Late ventricular arrhythmias such as VF or sustained VT identify patients who are likely to benefit from ICD therapy. This is particularly true if EF is reduced to less than 40%. ICD implantation is also indicated for patients with persistently reduced EF (<30%).

Cardiac Catheterization and Noninvasive Testing

PredischARGE risk stratification may involve cardiac catheterization, submaximal predischARGE exercise stress testing (on days 4 to 6), or maximal exercise stress testing after dischARGE (at 2 to 6 weeks). The presence or absence of high-risk coronary anatomy is demonstrated for patients who have undergone primary PCI at the time of presentation. Many patients who have been treated with thrombolytic therapy undergo coronary angiography before dischARGE to determine the extent and severity of underlying CAD as well as the status of the culprit lesion. If coronary angiography is not performed, predischARGE submaximal exercise testing (up to 70% of maximal predicted heart rate) is done to identify those who are at increased risk for postdischARGE coronary ischemic events. Patients who undergo submaximal exercise stress testing in lieu of coronary angiography frequently have a follow-up maximal exercise stress test within 2 to 6 weeks after dischARGE. During stress testing, positive results that suggest the need for coronary angiography include exercise-induced angina, ST changes of ischemia (ST depression), exercise-induced hypotension, exercise-induced ventricular arrhythmias, and low functional capacity. The sensitivity and specificity of stress testing after MI is enhanced by the use of imaging modalities such as stress echocardiography or nuclear perfusion imaging. All patients should have their EF assessed, typically by echocardiography, before dischARGE.

Secondary Prevention, Patient Education, and Rehabilitation

The goal of secondary prevention is to reduce the risk of recurrent MI and cardiovascular mortality. Risk factor modification is key to the secondary prevention strategy. All patients should have their lipid status assessed at the time of admission, but statin therapy is warranted in patients with acute MI at presentation. The target LDL level is less than 100 mg/dL, preferably closer to 70 mg/dL. Smoking cessation is of critical importance because it can reduce the risk of reinfarction, and ongoing smoking can double the risk of recurrent MI or mortality in the first year after MI. Structured smoking cessation programs and the

use of pharmacologic aids (e.g., nicotine patches or gum, bupropion, varenicline) can increase the success of smoking cessation efforts.

Antiplatelet therapy with aspirin (75 to 162 mg/day) is given indefinitely to all patients after MI. Regardless of whether primary PCI has been performed, patients will benefit from the additional use of a P2Y₁₂ inhibitor for the first year after MI. Those patients who have received a stent during primary PCI should continue clopidogrel 75 mg/day, ticagrelor 90 mg twice daily, or prasugrel 10 mg/day for one year. There are some data suggesting that if the patient is tolerating dual-antiplatelet therapy (DAPT) well and has a low bleeding risk, there may be additional benefit to continuing DAPT even for up to three years.

The use of anticoagulation is indicated for patients with systemic or pulmonary thromboembolism, as well as persistent or paroxysmal AF, guided by their CHADS-2 score (congestive heart failure, hypertension, age \geq 75 years, diabetes mellitus, and stroke). Patients who are at high risk for thromboembolism after acute MI, such as those with low EF related to anterior MI, can also be considered for prophylactic anticoagulation; however, there is no strong randomized data for this indication.

The high prevalence of patients who have both AF and the need for stent placement creates a conundrum involving the need for both anticoagulation and antiplatelet agents leading to a significantly increased risk of bleeding. Warfarin (target international normalized ratio [INR], 2.0 to 3.0) has been the historical choice for anticoagulation. Its use in conjunction with patients having undergone stenting was evaluated in several clinical trials that suggested that therapy with warfarin and clopidogrel had similar outcomes for ischemic or embolic events compared to "triple therapy" (warfarin, clopidogrel, and aspirin) but afforded a lower risk of bleeding. Since then, newer anticoagulant medications have been developed for nonvalvular AF that have merited their own series of trials, including the thrombin inhibitor dabigatran and the direct factor Xa inhibitors apixaban, edoxaban, and rivaroxaban. These drugs were also demonstrated to be effective when paired with clopidogrel with a lower bleeding risk compared to triple therapy. None of the trials referenced above utilized any other P2Y₁₂ inhibitors aside from clopidogrel. Ultimately the decision regarding antithrombotic therapy length and composition will be provider dependent but should be based upon an assessment of the patient's bleeding and ischemic risk.

Acute anterior MI that has resulted in significant injury to the ventricle with an EF of less than 40% places the patient at risk for future negative remodeling of the left ventricle and potential heart failure. ACE-inhibitor therapy has been shown to reduce the risk of negative remodeling and the occurrence of heart failure in such patients. This group of patients also experiences a reduction in future recurrent MI risk with the use of ACE-inhibitor therapy. This observation does not appear to carry over to patients with stable CAD. ACE-inhibitor therapy (captopril, ramipril, lisinopril) is indicated for all patients after MI. The use of ARBs (e.g., valsartan, losartan) is reasonable for patients who are intolerant of ACE-inhibitor therapy. The aldosterone receptor antagonist eplerenone (25 mg/day, titrated to 50 mg/day) is indicated as additive therapy to ACE or ARB in MI patients who have reduced EF (<40%) or diabetes. Careful monitoring of serum potassium is required after initiation of eplerenone together with ACE or ARB.

β -Blocker therapy reduces mortality risk in patients who have reduced EF post-MI. This therapy should be avoided in patients with uncompensated heart failure early after MI or the presence of other contraindications. Metoprolol succinate (25 mg/day titrated up to 200 mg/day) or carvedilol (3.125-6.25 mg titrated to 25 mg twice each day) should be initiated at low doses and titrated upward as tolerated. The role of β -blockers in patients with no residual myocardial ischemia, arrhythmias, or normal EF is not clear.

Nitrates, either short-acting sublingual nitroglycerin or long-acting versions, may be useful in the treatment of stable angina. Calcium-channel blocking drugs should be avoided in patients with reduced EF (<40%). In patients with normal EF, either diltiazem or verapamil may be useful as a substitute in patients who are intolerant of β -blockers when either antianginal therapy or rate control for AF is needed. The dihydropyridine, amlodipine, may be a useful adjunct for control of hypertension or treatment of angina. It should be used with caution in the face of reduced EF.

After acute MI, women should refrain from initiating hormone therapy with estrogen or estrogen/progesterone preparations; these agents do not decrease the risk of recurrent MI but do increase the risk of thromboembolic events. The ongoing use of hormone therapy in women already receiving treatment should be individualized, with a bias toward discontinuing therapy. Diabetic patients need attention to their degree of glycemic control, with a target of hemoglobin A_{1c} less than 7%. Vitamin supplements have no clear role in therapy for MI patients. Fish oil supplements do not appear to benefit patients who have experienced acute MI.

Patient Education and Cardiac Rehabilitation

It is important to begin the education of patients early after acute MI so that they understand the value of their various prescribed medical therapies and the need for risk factor modification. Cardiac rehabilitation programs are very useful in the ongoing education of patients; they reinforce positive lifestyle changes and provide exercise training in the post-MI period. Such programs not only educate patients but also help them to regain confidence in their ability to perform the tasks of daily living and other activities they enjoy. Early follow-up with the physician after discharge is also important to ensure clinical stability and tolerance of medical therapy and to monitor the progress of lifestyle changes.

Cardiac Arrhythmias

Marcie G. Berger, Jason C. Rubenstein, James A. Roth

BASIC CELLULAR ELECTROPHYSIOLOGY

Cardiac myocytes actively maintain a negative resting membrane potential (E_m) through the differential distribution of ions between intracellular and extracellular compartments, which is an energy-dependent process that relies on ion channels, pumps, and exchangers. Transmembrane differences in voltage and ionic concentration create electrical and chemical forces that drive charged ions in and out of cells.

The resting E_m of cardiac myocytes is controlled by potassium ions (K^+). Active K^+ transport by the sodium-potassium adenosine triphosphatase pump (Na^+ , K^+ -ATPase) produces a transmembrane ionic gradient, with the intracellular concentration of K^+ exceeding the extracellular concentration. This favors the net efflux of K^+ from cells, down the chemical concentration gradient, yielding a resting negative charge within the cardiac myocytes. K^+ continues to flow from the intracellular to the extracellular compartment until the negative intracellular charge counterbalances the transmembrane K^+ concentration gradient at a potential called the *equilibrium potential* for K^+ . This potential, at which the net K^+ current is zero, is close to the resting E_m of nonpacemaker cardiac myocytes. Pacemaker cells (i.e., sinoatrial and atrioventricular [AV] nodal cells) are characterized by a resting E_m of -50 to -60 mV. The resting E_m of atrial and ventricular myocytes is typically -80 to -90 mV.

The depolarization of a cardiac myocyte to threshold potential triggers a sequence of ionic movements resulting in a cardiac action potential (Fig. 9.1). The action potential is divided into five phases. Phase 0 is the rapid depolarization of nonpacemaker myocytes resulting from rapid sodium ion (Na^+) entry through fast Na^+ channels. These channels have three conformational states: closed (resting state), open (conducting Na^+ current), and inactivated, from which recovery is voltage dependent. Phase 1 is early, rapid, partial repolarization of the cell mediated by K^+ efflux. During phase 2, the plateau phase, there is a small net current flow, with inward calcium ion (Ca^{2+}) flow balanced by outward K^+ flow.

During phase 3, repolarization is mediated by an increase in K^+ efflux and a decline in Ca^{2+} influx. The dominant repolarizing current is I_{Kr} , the rapidly activating delayed rectifier K^+ current, a channel encoded by the *KCNE2* gene (also called *HERG*). The I_{Ks} current, or slowly activating delayed rectifier K^+ current, also contributes to repolarization. Phase 3 determines to a large degree the cellular refractory period. Importantly, I_{Kr} is inhibited by a large number of drugs that prolong the action potential duration.

Phase 4 is particularly significant in cardiac pacemaker cells because slow depolarization occurs from the resting membrane potential to the threshold potential. The resting E_m , rate of spontaneous phase 4 depolarization, and rate of phase 0 depolarization differentiate

slow-response from fast-response cardiac myocytes. Slow-response cells, located in the sinoatrial node and AV node, normally display automaticity or spontaneous depolarization during phase 4. Resting E_m in slow-response cells is less negative, and Ca^{2+} current mediates phase 0 depolarization. Conduction in these pacemaker cells is slow, and recovery from inactivation is time dependent. The fast-response cells found in atrial myocytes, ventricular myocytes, and the His-Purkinje system display slow phase 4 depolarization and do not typically display automaticity. Their resting E_m is more negative, and the fast Na^+ current drives rapid phase 0 depolarization and rapid conduction. Recovery from inactivation in these cells is voltage dependent.

The sinus node typically displays the fastest phase 4 depolarization. Other cardiac tissues have the capacity to depolarize spontaneously, and subsidiary pacemakers may take over when sinus rates slow and under conditions of increased automaticity. Typically, the AV node, located above the AV ring, serves as the heart's secondary pacemaker, with a spontaneous rate of depolarization of 40 to 50 beats per minute. Automaticity of cardiac myocytes is increased when the slope of phase 4 depolarization increases, with a shift of threshold potentials to more negative values, or in the presence of more positive maximal diastolic potentials.

The sinus node is the primary intrinsic pacemaker, and spontaneous depolarization leads to action potential generation, with normal resting rates of 60 to 100 beats per minute. Depolarization then spreads through the atria to the AV node, where conduction slows, introducing a delay between atrial and ventricular activation, and then to the His-Purkinje system fibers, which originate at the AV node with the bundle of His and split to form the left bundle branch and the right bundle branch, rapidly conducting depolarization to the ventricular myocardium. Cardiac myocytes are joined by electrical synapses called *gap junctions*, which permit the flow of intracellular current from cell to cell.

Classification of Arrhythmias

Mechanistically, cardiac arrhythmias can be broadly divided into disorders of action potential formation and disorders of impulse conduction. Clinically, arrhythmias are classified as bradycardias and tachycardias, with further categorization according to arrhythmia origin. This information is used to guide evaluation and management strategies.

Electrophysiologic Mechanisms of Arrhythmias

Automaticity is a normal function of pacemaker cells, occurring during phase 4 depolarization. *Enhanced automaticity* occurs when pacemaker cells depolarize at a faster rate due to an increased slope of phase 4 depolarization, a shift of threshold potential to a more negative value,

Fig. 9.1 Electrophysiologic basis of the cardiac cellular action potential. (A) Fast-response cells found in working myocardium and the specialized infranodal conduction system maintain a strongly negative resting membrane potential and a brisk phase 0 upstroke mediated by rapid sodium influx at the start of the action potential. (B) In contrast, slow-response cells found in the sinus node and atrioventricular nodal tissue exhibit less-negative resting membrane potentials, slower calcium-channel-dependent action potential upstrokes, and phase 4 depolarization.

or a shift of the maximal diastolic potential to a more positive value. These changes may occur with sympathetic stimulation. Enhanced automaticity may be normal (e.g., appropriate sinus tachycardia) or abnormal (e.g., inappropriate sinus tachycardia). Spontaneous depolarization occurring in nonpacemaker cardiac myocytes is called *abnormal automaticity*. Conditions such as ischemia, electrolyte abnormalities, and sympathetic stimulation may produce abnormal automaticity. Premature atrial and ventricular depolarizations, atrial tachycardia, and ventricular tachycardia (VT) may result.

Triggered activity occurs when secondary cardiac depolarizations are initiated by prior depolarizations. If these secondary depolarizations reach threshold potential, they may generate action potentials during or immediately after phase 3 of the action potential. *Early afterdepolarizations* (EADs) are observed when triggered depolarization occurs during phase 3 of the action potential. Inciters of EADs include QT-prolonging drugs, hypokalemia, and bradycardia. Patients with congenital long QT syndrome (LQTS) are prone to develop EADs, resulting in *torsades de pointes* (TdP).

When triggered activity occurs during phase 4, *delayed afterdepolarizations* (DADs) result. DADs are exaggerated at rapid heart rates and observed with digoxin toxicity and high-level catecholamine

Fig. 9.2 Mechanism of reentry. Reentry requires two distinct pathways with different refractoriness and a region of slowed conduction. One pathway (A) has normal rapid conduction but a long refractory period. The second pathway (B) has slowed conduction but a relatively shorter refractory period. To initiate reentry, conduction must fail down one pathway in the antegrade direction but then permit later retrograde reactivation of this pathway. This is referred to as a *unidirectional block*. A fixed or functional obstacle must maintain separation of the two pathways. Although drawn schematically as a circular loop, the anatomy of circuits is often complex and circuitous and is different in different arrhythmia mechanisms. (A) In normal rhythm, the circuit is activated in an antegrade direction down both pathways. However, because of slowed conduction in the B limb, distal activation is mediated by the faster A pathway, which arrives first and may activate the slowly conducting pathway in a retrograde direction. This retrograde conduction is electrocardiographically concealed (invisible), collides with the antegrade wave front, and is extinguished, and no tachycardia results. (B) Reentry is usually initiated by a premature beat originating independently of the circuit. The premature beat fails to propagate down the rapidly conducting A limb due to differential refractoriness of the two limbs, but it is able to propagate down the slowly conducting B pathway, where it may encounter substantial delay due to increased conduction time with prematurity (i.e., decremental conduction), allowing recovery of the previously blocked rapidly conducting A limb. This permits the rapidly conducting A limb to act as a return path and for ultimate reentrant reactivation of the slowly conducting B pathway, initiating sustained reentrant tachycardia in the circuit.

states, conditions that are associated with intracellular calcium overload. DADs are thought to be the chief arrhythmic mechanism underlying catecholaminergic polymorphic VT (CPVT).

Reentry is the dominant mechanism underlying clinical tachyarrhythmias. Reentry describes the reexcitation of a localized region of cardiac tissue by the same impulse, requiring bifurcating conduction pathways with different velocities and refractory periods. To permit reentry, unidirectional block in one pathway and slowed conduction in the other are required. Reentry is further categorized as anatomic, circling around a fixed anatomic obstacle, or functional, in which the unexcitable center of a reentrant circuit is not fixed but functionally refractory. Fig. 9.2 illustrates reentry as an arrhythmic mechanism. The two pathways join proximally and distally. Pathway A conducts rapidly but has a long refractory period. Pathway B is slowly conducting but has a shorter refractory period. A normally timed impulse enters the two pathways through the proximal common pathway, conducting rapidly down A and slowly down B. As the impulse from pathway A reaches the distal common pathway, while continuing distally, it may also turn around to activate B retrogradely. This impulse collides with the slowly conducting antegrade impulse in pathway B, extinguishing the impulse. However, a sufficiently premature stimulus

TABLE 9.1 Singh–Vaughan Williams Classification of Antiarrhythmic Drugs

Class	Physiologic Effect ^a	Examples
I	Blocks sodium channels; predominantly reduces the maximum velocity of the upstroke of the action potential (phase 0)	
IA	Intermediate-potency blockade	Quinidine, procainamide, disopyramide
IB	Least-potent blockade	Lidocaine, tocainide, mexiletine, phenytoin
IC	Most-potent blockade	Flecainide, propafenone, moricizine
II	β -Adrenergic receptor blockade	Propranolol, metoprolol, atenolol
III	Potassium-channel blockade: predominantly prolongs action potential duration	Amiodarone, sotalol, bretylium, ibutilide, dofetilide, dronedarone
IV	Calcium-channel blockade	Verapamil, diltiazem

^aSeveral agents have physiologic effects characteristic of more than one class.

may enter the proximal common pathway, finding pathway *A* with its long refractory period unexcitable, traveling slowly down pathway *B*, and finally reaching the distal common pathway. Due to the slow conduction velocity in pathway *B*, pathway *A* may no longer be refractory, and the impulse may successfully travel retrograde up pathway *A*, potentially repeatedly activating the circuit. Reentry is the most common mechanism producing supraventricular tachycardia (SVT) and VT.

❖ For a deeper discussion on this topic, please see Chapter 55, “Principles of Electrophysiology,” in *Goldman-Cecil Medicine*, 26th Edition.

GENERAL APPROACH TO MANAGEMENT

Diagnostic Procedures

Electrocardiography

The baseline 12-lead electrocardiogram (ECG) is essential for the initial evaluation of patients with arrhythmic symptoms. The baseline ECG may indicate underlying structural heart disease, with Q waves or fractionated QRS complexes suggesting prior myocardial infarction (MI). Slow sinus rates or AV conduction abnormalities may point to susceptibility to symptomatic bradycardia. Delta waves confirm an accessory pathway and direct the evaluation of arrhythmic symptoms toward the diagnosis of Wolff-Parkinson-White (WPW) syndrome while localizing the accessory pathway.

Evidence for hereditary cardiomyopathies and cardiac ion channel disorders that predispose to sudden death may be detected on a baseline ECG. Patients with arrhythmogenic right ventricular (RV) dysplasia may have epsilon waves and inverted T waves in the right precordial leads. QT interval prolongation or shortening may indicate congenital or acquired long QT or short QT syndrome, respectively. Brugada syndrome can be diagnosed based on coved ST-segment elevation in leads V_1 and V_2 .

A 12-lead ECG obtained during arrhythmic symptoms can establish the cause of a patient's symptoms. The specific mechanism underlying bradycardia and tachycardia can often be inferred from the ECG. Documentation of QRS morphology during VT or accessory pathway-mediated tachycardia on a 12-lead ECG aids in localizing the site of origin and guiding catheter ablation.

Ambulatory Monitoring

Although a 12-lead ECG obtained during arrhythmic symptoms is ideal, it is difficult to obtain in practice because of the transient and intermittent nature of these symptoms. Ambulatory recording devices permit electrocardiographic monitoring over longer periods to establish symptom-rhythm correlations.

Three types of monitoring devices are available. *Holter monitors* typically provide continuous electrogram storage for 24 to 48 hours.

Holter monitoring is helpful for patients with frequent symptoms. The comprehensive rhythm record obtained during this sampling period provides useful information about heart rate variability, rate control with atrial fibrillation (AF), AF burden, asymptomatic arrhythmias, and the frequency of ventricular ectopy.

External event monitors or loop recorders, which can be worn for 30 days, store electrograms when triggered by patients for symptoms. Additionally, loop monitors employ algorithms to automatically detect tachycardia, bradycardia, and atrial fibrillation. Episode storage varies from seconds to minutes. After events are recorded, patients transmit the data by telephone. External loop recorders are intended to identify cardiac rhythm disturbances underlying infrequent symptoms.

For patients with arrhythmia symptoms occurring less than once per month, *implantable loop recorders* may be useful. These small devices implanted in a subcutaneous pocket in the left chest record patient-triggered and auto-triggered ECGs based on heart rate and AF detection criteria. With a 3-year anticipated battery longevity, implantable loop recorders are valuable in establishing the cause of recurrent infrequent syncope and arrhythmic symptoms. Implantable loop recorders, with a reported 98% sensitivity for AF detection, are useful both for AF management and AF surveillance in the setting of cryptogenic stroke, resulting in higher utilization of appropriate oral anticoagulation following stroke.

Electrophysiologic Testing

To perform electrophysiologic studies, temporary transvenous pacing catheters are positioned in multiple locations in the heart, permitting pacing and recording of intracardiac electrograms. Catheters are typically placed in the right atrium, the right ventricle, close to the bundle of His, and in the coronary sinus for left atrial recording and pacing. Electrophysiologic studies can define the mechanism of tachyarrhythmias and guide therapy. In patients with prior MI, induction of VT may assist in determining patient susceptibility to life-threatening arrhythmias and inform decisions regarding defibrillator implantation. Electrophysiologic testing also can evaluate sinus node function and AV conduction.

Pharmacologic Therapy

Antiarrhythmic drugs are traditionally divided according to the Singh–Vaughan Williams classification, which categorizes agents based on their primary physiologic effect (Table 9.1). When this classification system was first proposed, knowledge of electrophysiologic mechanisms was limited. Although the simplicity of categorizing antiarrhythmic drugs according to Singh–Vaughan Williams classes I through IV is appealing, the system has many limitations. A hybrid classification system, class I and III agents block ion channels, and class II and IV drugs block receptors. Some drugs cross classes and have several

TABLE 9.2 Selected Characteristics of Antiarrhythmic Drugs

Drug	Effect on Surface ECG	Effect on LV Function	Important Drug Interactions	Effect on Pacing and Defibrillation Thresholds	Major Route of Elimination
Quinidine	Prolongs QRS and QT	Negative inotrope	Increases digoxin level and warfarin effect Cimetidine increases quinidine level Phenobarbital, phenytoin, and rifampin decrease quinidine level	Increases PT and DT at high doses	Liver (CYP3A4) and kidney
Procainamide	Prolongs PR, QRS, and QT	Negative inotrope	Cimetidine, alcohol, and amiodarone increase procainamide level	Increases PT at high doses	Liver and kidney
Disopyramide	Prolongs QRS and QT	Negative inotrope	Phenobarbital, phenytoin, and rifampin decrease disopyramide level	Increases PT at high doses	Liver (CYP3A4) and kidney
Lidocaine	Shortens QT	None	Propranolol, metoprolol, and cimetidine increase lidocaine level	Increases DT	Liver (CYP2D6)
Mexiletine	Shortens QT	None	Increases theophylline level Phenobarbital, phenytoin, and rifampin decrease mexiletine level	Various effects	Liver (CYP2D6)
Flecainide	Prolongs PR and QRS	Negative inotrope	Increases digoxin level	Increases PT; variable effect on DT	Liver (CYP2D6) and kidney
Propafenone	Prolongs PR and QRS	Negative inotrope	Increases digoxin, theophylline, and cyclosporine levels; increases warfarin effect Phenobarbital, phenytoin, and rifampin decrease propafenone level Cimetidine and quinidine increase propafenone level	Increases PT; variable effect on DT	Liver (CYP2D6)
Dronedaron	Prolongs PR and QT; slows sinus rate	Negative inotrope	CYP3A4 inhibitors (ketoconazole, clarithromycin, calcium-channel blockers) increase dronedaron levels; additive effect with drugs that prolong QT (macrolides, class I and III antiarrhythmics) increasing risk of TdP; increases dabigatran levels	Little effect	Liver (CYP3A4)
Amiodarone	Prolongs PR and QT; slows sinus rate	None	Increases digoxin and cyclosporine levels; increases warfarin effect	Increases DT	Liver (CYP3A4)
Sotalol	Prolongs PR and QT; slows sinus rate	Negative inotrope	Additive effects with other β -blockers	Decreases DT	Kidney
Ibutilide	Prolongs PR and QT	None	Additive effect on QT prolongation with class IA and other class III antiarrhythmic agents	Decreases DT	Liver
Dofetilide	Prolongs QT	None	Verapamil, diltiazem, Cimetidine, and ketoconazole increase dofetilide level	Decreases DT	Liver and kidney

DT, Defibrillation threshold; ECG, electrocardiogram; LV, left ventricle; PT, pacing threshold; TdP, torsades de pointes.

mechanisms of action. There are drugs with antiarrhythmic action that are excluded from the classification, such as digitalis and adenosine. The system categorizes drugs based on their in vitro electrophysiologic effects in normal cardiac tissues.

Available antiarrhythmic drugs have limited efficacy and carry the risk of adverse events, including proarrhythmic potential. Knowledge of drug metabolism, interactions, electrophysiologic effects, and side effects is essential. Certain antiarrhythmics may suppress left ventricular systolic function and may impact pacing and defibrillation thresholds. Excepting β -blockers, none of the antiarrhythmics has been demonstrated to reduce mortality rates. In fact, the use of antiarrhythmic agents may confer an increased risk of cardiovascular mortality, particularly in heart failure patients. Tables 9.2 and 9.3 summarize major characteristics and side effects of commonly used antiarrhythmic drugs.

Class I Antiarrhythmic Agents

Class I antiarrhythmic drugs include sodium-channel blockers that bind fast sodium channels in their open and inactivated states and dissociate from sodium channels during their resting state. Blocking voltage-gated fast sodium channels slows phase 0 depolarization and conduction velocity. Class I agents demonstrate use-dependent blockade, and their effect is potentiated at faster heart rates. The drug dissociation rate from sodium channels during phase 4 of the action potential determines the degree to which these agents depress cardiac conduction velocity.

Class IA agents have a slow rate of drug dissociation from sodium channels, conferring moderate potency. In addition to blocking voltage-gated fast sodium channels, class IA drugs block delayed rectifier potassium channels. Slowing of conduction velocity and action potential prolongation are observed. All are antimuscarinic, especially

TABLE 9.3 Common Side Effects of Select Antiarrhythmic Drugs

Drug	Major Side Effects
Quinidine	Nausea, diarrhea, abdominal cramping Cinchonism: decreased hearing, tinnitus, blurred vision, delirium Rash, thrombocytopenia, hemolytic anemia Hypotension, torsades de pointes (quinidine syncope)
Procainamide	Drug-induced lupus syndrome Nausea, vomiting Rash, fever, hypotension, psychosis, agranulocytosis Torsades de pointes
Disopyramide	Anticholinergic: dry mouth, blurred vision, constipation, urinary retention, closed angle glaucoma Hypotension, worsening heart failure
Lidocaine	CNS: dizziness, perioral numbness, paresthesias, altered consciousness, coma, seizures
Mexiletine	Nausea, vomiting CNS: dizziness, tremor, paresthesias, ataxia, confusion
Flecainide	CNS: blurred vision, headache, ataxia, tremor Congestive heart failure, ventricular proarrhythmia
Propafenone	Nausea, vomiting, constipation, metallic taste to food Dizziness, headache, exacerbation of asthma, ventricular proarrhythmia
β -Blockers	Bronchospasm, bradycardia, fatigue, depression, impotence Congestive heart failure
Calcium-channel blockers	Congestive heart failure, bradycardia, heart block, constipation
Amiodarone	Agranulocytosis, pulmonary fibrosis, hepatopathy, hyperthyroidism or hypothyroidism, corneal microdeposits, bluish discoloration of the skin, nausea, constipation, bradycardia, tremor, ataxia
Sotalol	Same as β -blockers, torsades de pointes
Dronedarone	Diarrhea, QT prolongation and torsades de pointes, death, bradycardia, congestive heart failure, hepatocellular injury, interstitial lung disease
Ibutilide	Torsades de pointes
Dofetilide	Torsades de pointes, headache, dizziness, diarrhea

CNS, Central nervous system.

disopyramide. Clinical applications include SVT, AF, atrial flutter, and VT. In the setting of atrial flutter and AF, class IA drugs are vagolytic. They may improve AV nodal conduction and should be used in conjunction with a β -blocker or calcium-channel blocker to avoid uncontrolled ventricular response rates. Quinidine is infrequently used due to its side effect profile, including diarrhea, thrombocytopenia, and QT prolongation, triggering polymorphic VT. Clinical studies highlight the proarrhythmic risk and increased mortality associated with quinidine therapy. Procainamide, available as an intravenous formulation, has an active metabolite *N*-acetylprocainamide (NAPA) and may induce a reversible lupus-like syndrome. Disopyramide, with its potent negative inotropic and antimuscarinic activity, has been used to treat vagally mediated AF.

Class IB agents rapidly dissociate from sodium channels during phase 4, providing weak sodium-channel blockade. Their therapeutic role is restricted to ventricular arrhythmias due to a lack of effect on the sinoatrial node, AV node, and atrial tissue. Lidocaine, which is available parentally, undergoes extensive first-pass hepatic inactivation. Lidocaine is more effective in relatively depolarized ventricular tissue

due to preferential affinity for inactivated sodium channels; the drug is more potent in ischemic tissue. Mexiletine, which is available orally, has slower hepatic metabolism and a longer half-life than lidocaine.

Class IC drugs are potent fast sodium-channel blockers with little effect on K^+ current. These agents have a role in the therapy of SVTs and VTs. Their use is relegated to patients without coronary disease or significant structural heart disease. The Cardiac Arrhythmia Suppression Trial proved that the use of flecainide and moricizine to suppress ventricular arrhythmias after MI increased mortality rates. These agents may convert AF to atrial flutter and slow atrial conduction sufficiently to permit 1:1 AV conduction during atrial flutter, necessitating the simultaneous use of AV nodal–blocking therapies in patients with atrial arrhythmias. Flecainide is associated with bronchospasm, leukopenia, thrombocytopenia, and neurologic side effects. Flecainide, which inhibits Ca^{2+} release from the sarcoplasmic reticulum cardiac ryanodine receptor, may be useful in the therapy for CPVT. Propafenone has β -blocking effects and can cause agranulocytosis, anemia, and thrombocytopenia.

Class II and IV Antiarrhythmic Agents

β -Adrenoceptor antagonists, the class II agents, inhibit sympathetic activation of cardiac automaticity and conduction, resulting in slowing of the heart rate, decreased AV node conduction velocity, and prolongation of the AV node refractory period. Side effects include bradycardia, hypotension, exacerbation of reactive airway disease, fatigue, worsening symptoms of peripheral vascular disease, and depression. β -Blockers have different half-lives, lipid solubilities, elimination routes, and specificities for β_1 and β_2 receptors.

Class IV agents include the nondihydropyridine calcium-channel blockers. Blockade of voltage-gated L-type calcium channels decreases AV nodal conduction velocity, increases AV nodal refractory period, slows sinus node automaticity, and decreases myocardial contractility. Calcium-channel blockers may cause hypotension, bradycardia, and heart failure. Clinical applications for these agents include rate control for atrial tachyarrhythmias, termination and suppression of SVT, and normal heart VT. In the setting of atrial arrhythmias with underlying WPW, they can potentiate accessory pathway conduction and should be avoided.

Class III Antiarrhythmic Agents

Class III antiarrhythmic agents are a heterogeneous group of drugs that block the potassium delayed rectifier currents responsible for phase 3 cardiac repolarization, prolonging the cardiac action potential duration and refractory period. These agents demonstrate reverse-use dependence, with more potent potassium-channel blockade at slower heart rates. Prolonging the action potential duration can be therapeutic or proarrhythmic (e.g., TdP). This class represents the dominant category of antiarrhythmic agents in use.

Amiodarone is an iodinated compound available orally and parentally. With oral administration, it is slowly absorbed. Because it concentrates in fat tissues, amiodarone has a large volume of distribution. This characteristic prolongs the time to reach steady-state levels and produces a long elimination half-life, approximately 35 to 100 days. Amiodarone's pharmacology is complex, with class I through IV activity, although its primary therapeutic mechanism is prolongation of the action potential duration. It is effective in treating SVTs and VTs. It is hepatically metabolized and proven safe to use in the setting of congestive heart failure. Amiodarone is commonly used to treat atrial and ventricular arrhythmias in patients with structural heart disease and renal failure. Amiodarone is the only antiarrhythmic agent to demonstrate improved survival to hospital admission after cardiac arrest. This finding led to amiodarone prioritization within the ACLS pulseless

VT/VF algorithm. Widespread chronic use of amiodarone has been limited by significant side effects necessitating drug discontinuation in up to 20% of patients. Serious adverse effects include potentially irreversible pulmonary fibrosis, optic neuropathy producing visual impairment, hyperthyroidism, and severe hepatic toxicity. Less serious adverse effects include hypothyroidism, neurologic toxicity, sun sensitivity, QT prolongation, and bradycardia.

Sotalol blocks β -adrenoreceptors and delayed rectifier K^+ channels, decreasing sinoatrial node automaticity, slowing AV conduction velocity, and prolonging repolarization. It effectively treats a large number of ventricular and supraventricular arrhythmias.

Dofetilide, a selective class III agent used primarily to treat atrial arrhythmias, blocks delayed rectifier K^+ channels to prolong action potential duration and QT intervals. The risk of TdP is about 1% among patients without structural heart disease but as high as 4.8% among patients with congestive heart failure.

Ibutilide, an intravenous class III agent, is used for the acute termination of recent-onset AF and atrial flutter. The risk of polymorphic VT with administration of ibutilide is 8.3%.

*Dronedaron*e is an orally available class III drug demonstrated to reduce the risk of first hospitalization due to cardiovascular events or death from any cause for patients in sinus rhythm with a history of paroxysmal or persistent AF. Dronedaron may not be used in the setting of permanent AF or in patients with New York Heart Association (NYHA) class IV heart failure or symptomatic heart failure with recent decompensation because the drug increases the risk of cardiovascular death in these populations. Other major side effects of dronedaron are severe hepatotoxicity, interstitial lung disease, bradycardia, and QT prolongation.

Other Antiarrhythmic Agents

The Singh–Vaughan Williams classification scheme does not describe several agents commonly used in cardiac arrhythmia management. *Adenosine* is a parenteral agent with an elimination half-life of 1 to 6 seconds. The drug binds to A1 receptors to activate K^+ channels, decreasing the action potential duration and hyperpolarizing membrane potentials in the atria, sinoatrial node, and AV node. Indirectly, adenosine blocks catecholamine-stimulated adenylate cyclase activation, decreasing cAMP and consequently decreasing Ca^{2+} influx. Used clinically for its ability to produce transient AV block, adenosine can terminate SVT when the AV node contributes to the reentrant circuit. By slowing atrial-ventricular conduction, adenosine can also establish the presence of underlying atrial tachycardia or atrial flutter when the arrhythmia mechanism is unclear.

Digoxin inhibits Na^+ , K^+ -ATPase, increasing intracellular Na^+ concentrations and stimulating the Na^+ - Ca^{2+} exchanger to increase intracellular Ca^{2+} , accounting for its positive inotropic effect. Digoxin also acts through the autonomic nervous system to enhance vagal tone, slowing sinus rates, shortening the atrial refractory period, and prolonging AV conduction. Digoxin is therefore used for rate control in patients with atrial arrhythmias. Renally excreted, digoxin has a narrow therapeutic range. Digoxin toxicity may lead to high-grade AV block, tachyarrhythmias, blurred vision, nausea, dizziness, and severe hyperkalemia.

Cardioversion and Defibrillation

Direct current cardioversion and defibrillation represent the cornerstone of acute therapy for unstable tachyarrhythmias and play an important role in the termination of medication-refractory stable tachyarrhythmias. Organized VTs and SVTs may be terminated by synchronized cardioversion—shock delivery synchronized to the QRS complex—to restore normal rhythm. Synchronization is critical to

avoid induction of VF by delivering energy during the relative refractory period of the cardiac cycle. Defibrillation entails the asynchronous delivery of electrical current to depolarize a critical mass of myocardium and terminate VF. Successful defibrillation is time dependent, with the likelihood of success declining by approximately 10% per minute from the onset of VF.

Defibrillation may be delivered internally through an implantable cardioverter-defibrillator (ICD) or externally through an automatic external defibrillator (AED). Current-generation AEDs use biphasic waveforms, achieving greater first-shock efficacy compared with older devices delivering monophasic waveforms. ICDs, implanted in patients for primary and secondary prevention of sudden cardiac death (SCD), deliver defibrillation shocks directly to the endocardium through an RV lead. With direct delivery of energy, relatively lower energy levels (<40 J) are typically effective.

Ablation

Catheter ablation plays an important role in the therapy of a broad range of arrhythmias, such as SVT, atrial arrhythmias, and VT. The ascendance of catheter ablation derives in part from the poor efficacy and side effect profiles of available antiarrhythmic drugs. Radiofrequency ablation (i.e., applying radiofrequency-range energy) and cryoablation (i.e., administering freezing temperatures, to produce localized cellular and tissue injury) are commonly used.

Focal and reentrant arrhythmias are defined and localized, permitting targeted delivery of ablation energy to eliminate the tachyarrhythmia. Ablation is associated with varied success and complication rates, depending on the mechanism and location of the arrhythmogenic focus. Cure rates for typical tricuspid-caval isthmus-dependent atrial flutter, AV nodal reentry tachycardia (AVNRT), and accessory pathway-mediated tachycardias exceed 95%, with low complication rates of about 2%. Although an important therapeutic option in the treatment of AF and VT, success rates are lower and procedural risks are higher.

For a deeper discussion on this topic, please see Chapter 56, “Approach to the Patient with Suspected Arrhythmia,” in *Goldman-Cecil Medicine*, 26th Edition. ♦

BRADYCARDIA

Bradycardia, defined as a heart rate of less than 60 beats per minute, may occur as a consequence of physiologic adaptations or pathology. Bradycardia always results from failure of sinus node function or AV conduction disturbances, or both processes. Clinically significant bradycardia or pauses may result from autonomic disturbances, drugs, chronic intrinsic conduction system disease, or acute cardiac damage as occurs with endocarditis or infarction.

Normal Conduction System: Anatomy and Physiology

Because of the normal gradient of intrinsic automaticity, heart rate usually is determined by intrinsic automaticity of the sinus node. The sinus node is a complex of cells that extends from the superior vena cava and along the upper right atrial free wall in the sulcus terminalis. Blood supply is derived from the sinus node artery, which arises from the right coronary in 66% or left coronary in 34% of patients.

Activation proceeds through the right atrium to the AV node, which is located in the low interatrial septum adjacent to the tricuspid annulus. The AV node is a complex structure with at least three preferential atrial insertions. The anterior atrial insertion has a short conduction time and usually determines the normal AV conduction time in sinus rhythm. The posterior right and left atrial insertions have long conduction times. Because they do not normally mediate

AV conduction in humans, they are functionally vestigial. However, the posterior slowly conducting insertions become important in mediating paroxysmal supraventricular tachycardia (PSVT). The AV node derives its blood supply from the AV nodal artery, which is supplied by the right coronary artery in 73% or the left coronary artery in 27% of patients.

After entry into the AV node, conduction proceeds to the His bundle through the fibrous annulus and along the membranous septum before splitting into a leftward Purkinje branch, the left bundle, which ramifies over the left ventricular endocardium, and a rightward branch, the right bundle, which similarly ramifies over the RV endocardium. The leftward branch may be damaged proximally, resulting in full left bundle branch block, or damaged more distally in its anterior or posterior divisions, resulting in fascicular hemiblock patterns.

Normal Autonomic Regulation of Heart Rate

Normal heart rate is a consequence of tonic and phasic autonomic modulation of intrinsic sinus node automaticity. The intrinsic heart rate in the absence of autonomic modulation ranges from 85 to 110 beats per minute and is somewhat faster than normal resting heart rates. That the normal heart rate is slower than the intrinsic rate is a consequence of the dominance of parasympathetic tone over adrenergic tone in the resting state.

Based on a review of Holter recordings in a normal population, the normal resting heart rate is 46 to 93 beats per minute in men and 51 to 95 beats per minute in women. It has been proposed that 50 to 90 is a clinically more accurate working definition of normal heart rate for adults than the traditional 60 to 100 beats per minute commonly used by consensus. However, heart rates well below these estimates may be seen in normal people, especially during hours of sleep. For these reasons, defining a cutoff value for pathologic bradycardia in the absence of symptoms is problematic for an otherwise healthy patient.

The maximal stress-induced heart rate (HR_{max}) is related to maximal sympathetic stimulation, accompanied by withdrawal of parasympathetic tone. This is commonly estimated as $HR_{max} = (220 - \text{age})$.

Sinus Node Dysfunction

Sick sinus syndrome, also called *sinus node dysfunction*, is a common clinical syndrome that increases in prevalence with age. The estimated prevalence is 1 case per 600 patients older than 65 years of age, and it accounts for about one half of all pacemaker implantations. Sinus node dysfunction is a consequence of two distinct processes: failure of intrinsic automaticity and failure of propagation of sinus node impulses to the surrounding atrial tissue, also referred to a *sinus node exit block*.

Sinus node dysfunction manifests clinically as one of several patterns: persistent or episodic sinus bradycardia, inability to appropriately augment rate with exercise (i.e., chronotropic incompetence), sinus pauses, or commonly a combination of these patterns. The sinus node is at the top of a cascade of automaticity and is normally backed up by a competent AV junctional escape mechanism. Severe bradycardia and associated symptoms due to sinus node dysfunction always imply sinus node dysfunction and simultaneous failure of normal subsidiary escape mechanisms. In the setting of a competent escape mechanism, even severe sinus node dysfunction may be completely asymptomatic, clinically well tolerated, and require no specific therapy.

Resting Sinus Bradycardia

Sinus bradycardia is frequently observed during routine clinical practice. Modest sinus bradycardia in the high 40s in men and 50s in women is normal and called *bradycardia* only because of the conventional choice of 60 beats per minute as the lower limit of normal rates.

Because there is no set rate at which sinus bradycardia can be labeled as pathologic, pathologic sinus node dysfunction is best defined as significant bradycardia associated with symptoms plausibly attributable to bradycardia.

Modest persistent bradycardia is often asymptomatic. When symptoms occur, they are commonly nonspecific, such as fatigue, listlessness, or dyspnea, making the attribution of symptoms to resting bradycardia difficult. Sinus bradycardia may also exacerbate congestive heart failure and limit effective use of β -blocker therapy, a cornerstone of therapy for heart failure, coronary disease, and tachyarrhythmias. When inappropriate sinus bradycardia is persistent, especially when severe, plausible symptoms are present, and alternative causes of symptoms have been excluded, pacemaker implantation is reasonable. Asymptomatic sinus bradycardia should rarely be treated with pacing unless a need for medical therapy is expected to further exacerbate bradycardia.

Chronotropic Incompetence

Cardiac output during exercise is increased by augmentation in stroke volume and an increase in heart rate. If heart rate rise with exercise is inadequate, exertional symptoms such as fatigue or dyspnea may ensue. As in the case of resting sinus bradycardia, unless severe, attribution of symptoms to chronotropic incompetence is difficult. Various criteria for this condition have been proposed that rely on the inability to achieve a set fraction of age-predicted heart rate or heart rate reserve. As for resting sinus bradycardia, the decision to implant a pacemaker for chronotropic incompetence is a matter of judgment more than criteria.

Sinus Pauses or Arrest

An abrupt failure of sinus node automaticity or failure of propagation from the sinus node to the atrium can result in a pause in atrial activity. P waves are absent, and if of adequate duration and not accompanied by a competent subsidiary escape mechanism, it can result in abrupt symptoms of lightheadedness, presyncope or true syncope. Sinus pauses of less than 3 seconds are commonly seen for normal subjects, who are rarely symptomatic. Sinus pauses exceeding 3 seconds and not occurring during sleep are often pathologic and may result in symptoms. Sinus pauses associated with simultaneous symptoms and documentation of pauses lasting 3 seconds or longer in patients with a history of symptoms plausibly related to bradycardia are indications for pacemaker therapy.

Sinoatrial Exit Block

Sinus node dysfunction is often accompanied by significant atrial fibrosis, which may lead to a block in the tissues surrounding the sinus node complex and impede propagation to the atrial tissue. Bradycardia due to sinus node dysfunction may result, not from a failure of automaticity, but from failure of propagation from the sinus node complex to the atrium. Because sinus node activity is not directly apparent from the surface ECG, the diagnosis is made indirectly by the observation of abrupt halving in the sinus P-wave rate, followed by an abrupt return to the baseline sinus rate (Fig. 9.3C and D). Although other patterns may be observed, 2:1 exit block is the most common. Therapy for sinoatrial exit block is identical to that for intermittent sinus bradycardia (discussed earlier).

Bradycardia-Tachycardia Syndrome as a Consequence of Sinus Node Dysfunction

Bradycardia-tachycardia (“brady-tachy”) syndrome refers to a clinically significant tachyarrhythmia sometimes accompanied by clinically significant bradycardia. The term may be confusing because the mechanism of tachycardia is often unrelated to the mechanism of bradycardia.

Fig. 9.3 Sinus node dysfunction. (A) Sinus bradycardia in a patient receiving metoprolol. This bradycardia results from diminished normal automaticity of the sinus node. (B) Pauses related to blocked premature atrial contractions (PACs). Blocked PACs are a common cause for apparent sinus pauses because the PAC may be early enough to be concealed by the T wave of the preceding beat (*arrows*). The pauses are not a sign of sinus node dysfunction but rather a physiologic response to an early coupled PAC. (C) The sinus pause is an abnormal finding that suggests sinus node disease. The pause is exactly two sinus cycles and may represent sinoatrial exit block. (D) Sinoatrial Wenckebach type exit block. As is the case with the RR interval preceding atrioventricular nodal Wenckebach, progressive shortening of the PP interval preceding a doubling in sinus cycle length likely represents Wenckebach exit block from the sinus node tissue to the atrium. (E) Bradycardia-tachycardia syndrome due to sinus node dysfunction. An episode of rapidly conducted atrial fibrillation or flutter terminates and is followed for a protracted period of sinus arrest before recovery of sinus rhythm and ultimate relapse of rapidly conducted atrial fibrillation. These pauses may result in syncope or near-syncope.

This syndrome most commonly manifests as intermittent pathologic atrial arrhythmias, often intermittent AF with concomitant sinus node dysfunction resulting in long pauses or symptomatic sinus bradycardia when the patient is in sinus rhythm. A typical manifestation of this syndrome is a prolonged period of asystole after termination of AF (see Fig. 9.3E) due to slow recovery of sinus node automaticity with resultant presyncope or syncope.

The combination of two seemingly independent processes is in part a consequence of the high prevalence of AF and sinus node dysfunction in the elderly and the need to use potent drugs to decrease ventricular response during AF with resultant unintended secondary sinus node dysfunction between periods of atrial arrhythmias. This type of bradycardia-tachycardia syndrome represents an important form of clinical sinus node dysfunction and is a common indication for pacemaker implantation.

Sinus node dysfunction causing bradycardia-tachycardia should be distinguished from a common, unrelated form of bradycardia-tachycardia syndrome, which is characterized by chronic rather than intermittent AF with periods of rapid and slow ventricular responses. This condition is often incorrectly referred to as *sick sinus syndrome*. However, in this syndrome, the atrium is chronically fibrillating, and the sinus node therefore has no influence on heart rate. Bradycardia or protracted pauses in the setting of chronic AF is a consequence of impaired AV conduction and is unrelated to sinus node dysfunction.

Atrioventricular Conduction Disturbances

AV conduction disturbances include disorders in which the normal physiologic AV relationship is not maintained due to pathologic delay in AV conduction or to intermittent or complete loss of AV conduction. The PR interval includes three distinct phases of AV conduction. Although the individual components of AV conduction can be readily recorded by a His bundle catheter in an electrophysiology laboratory, the salient features of AV conduction disturbances can usually be elucidated by careful interpretation of the surface ECG without resorting to invasive recording techniques.

The right atrial conduction time from the area of the sinus node where the P wave begins to the region of the AV node occupies a short first portion of the PR interval and usually lasts no more than 30 milliseconds. Because the atrial conduction time is short and does not change much over time in a given patient, it can conveniently be ignored when assessing AV conduction. The second portion of the PR interval is the propagation time through the AV node, which is normally 50 to 120 milliseconds. The last component of the PR interval is the time for propagation through the His bundle and bundle branches, which is typically 30 to 55 milliseconds. Although this last portion, constituting His-Purkinje conduction, is short, it is the major prognostic component of AV conduction and therefore clinically important. Because the last portion of the PR interval is the time from the onset

Fig. 9.4 Heart block. (A) First-degree atrioventricular (AV) block is associated with 1:1 conduction but a prolonged PR interval more than 200 milliseconds. (B) Mobitz type I (Wenckebach) second-degree AV block. Notice the progressive PR prolongation preceding the blocked P wave (arrows) followed by recovery of conduction with a shorter PR interval before repetition of the same pattern. (C) Mobitz type II second-degree AV block. Notice that the PR interval does not prolong in the beat preceding the blocked P wave (arrows). (D) A 2:1 second-degree AV block. Notice that every other P wave fails to conduct. Because there are never two consecutively conducted P waves to assess for the presence or absence of progressive prolongation, this type of block is neither Mobitz I nor Mobitz II. (E) Complete heart block with a junctional escape rhythm. Notice that the atrial rate is faster than the ventricular rate and that there is AV dissociation. The narrow QRS escape rhythm implies a level of block high in the conduction system near the AV node.

of His bundle to the time of ventricular activation, it is commonly referred to as the HV interval. Although the HV interval cannot be measured directly from the surface ECG, a block in the His-Purkinje system can be inferred from the characteristic features that can be gleaned from review of the surface ECG.

First-Degree Atrioventricular Block

First-degree AV block is defined as a PR interval exceeding 0.2 seconds (200 milliseconds) in the setting of otherwise preserved AV conduction (Fig. 9.4A). First-degree block implies a conduction delay in one of the components of AV conduction, usually at the level of the AV node or His-Purkinje system (i.e., infranodal conduction system). First-degree AV block is usually asymptomatic, but it is a sign of AV conduction system disease and may be a diagnostic clue to the mechanism of intermittent electrocardiographically undocumented symptoms in a patient with unexplained syncope.

Second-Degree Atrioventricular Block

Second-degree AV block is defined as intermittent failure of AV conduction with interspersed periods of intact AV conduction. Second-degree AV block, like sinus bradycardia and pauses, may be seen normally during hours of sleep as well as in athletes with high parasympathetic tone. Alone, it is not an indication of AV conduction system disease.

Second-degree block may be asymptomatic, may be associated with mild symptoms such as palpitations, or if resulting in protracted

pauses or persistent bradycardia, may result in hemodynamic symptoms, including lightheadedness, syncope, and fatigue. Second-degree AV block at the level of the AV node is usually indolent and gradually progressive. Because of stable junctional escape mechanisms associated with progression to complete heart block at the level of the AV node, second-degree AV block at this level tends to have a benign prognosis and, in the absence of symptoms, can be followed safely without intervention.

Second-degree block in the infranodal conduction system, which is composed of the His bundle and bundle branches, can be malignant with a tendency to progress abruptly and unpredictably to higher degrees of AV block accompanied by unstable or absent subsidiary escape mechanisms. After a patient becomes symptomatic, the infranodal block may progress to complete heart block and, in some cases, to sudden death. Despite its malignant nature, SCD is rarely attributable to complete heart block, suggesting that most patients have symptoms permitting intervention before progression to sudden death.

Because of the profound difference in natural history of second-degree AV block at the AV node and that at an infranodal level, the major clinical task in evaluating patients with second-degree AV block is to establish the probable level of the block. The surface ECG and pattern of block are quite useful.

Mobitz type I second-degree atrioventricular block. Also referred to a Wenckebach block, *Mobitz type I second-degree AV block* is a progressive prolongation in the PR interval before development of AV

block, usually for one cycle followed by recovery of conduction with a return to the baseline PR interval (see Fig. 9.4B). Because the degree of prolongation of the PR interval is less with each successive beat before the block, the RR intervals can paradoxically shorten in the final beats before the block.

Mobitz I AV block typically is associated with block at the level of the AV node. However, this pattern is rarely seen with advanced infranodal disease in the His bundle and bundle branches. Because Mobitz type I AV block usually occurs at the level of the AV node, infranodal conduction is commonly normal and associated with a narrow conducted QRS complex. In ambiguous cases, other clues may be helpful. Because AV node function is improved with exercise, Mobitz I block tends to normalize with activity and return at rest. Second-degree block at the level of the AV node is improved with atropine and exacerbated by carotid sinus massage. If associated with periods of complete heart block, a block at the level of the AV node is associated with a junctional escape with a QRS morphology similar to that in conducted sinus rhythm. In contrast, the observation of a wide complex escape that is different from the conducted QRS points to infranodal causes of block in the His-Purkinje system. The block may be malignant (discussed later) and require expeditious use of ventricular pacing to prevent catastrophic bradycardia.

Mobitz type II second-degree atrioventricular block. *Mobitz type II second-degree AV block* is intermittent failure of AV conduction during stable atrial rates without antecedent PR prolongation and followed by recovery of AV conduction (see Fig. 9.4C). Mobitz II AV block is believed to always be a sign of block in the infranodal tissues, including the His bundle and bundle branches. Whereas infranodal block may rarely display Mobitz I (Wenckebach) periodicity, AV block at the level of the AV node does not result in true Mobitz II AV block periodicity.

The finding of Mobitz II AV block is always reason for concern. Although it may result from block in the His bundle or subsidiary bundle branches, block within the His bundle accompanied by a narrow QRS complex is uncommon. In practice, Mobitz II AV block is usually preceded by the development of fixed bundle branch block. It has been believed that such bundle branch block patterns implied disease of the bundle branches themselves as they ramify within the ventricles. However, in many cases of left bundle branch block, the disease process may actually be within the His bundle affecting fibers that will ultimately extend to the left bundle branch. Regardless of the exact anatomic level of clinical bundle branch block, it remains a good clinical rule that most patients exhibiting Mobitz II AV block will also exhibit a full bundle branch block pattern during periods of conduction between episodes of second-degree AV block.

In ambiguous cases, other clues may be helpful. Because infranodal function improves relatively little with exercise, infranodal block tends to worsen with the increasing heart rates associated with exercise or stress. Atropine is not helpful for infranodal block, and because it may accelerate sinus rates, it may cause a patient to progress to higher degrees of AV block with a consequent decrease in the conducted ventricular rate. Exogenous catecholamines such as isoproterenol infusion may be helpful acutely but should not be relied on. Because of its malignant potential, hemodynamically significant Mobitz II AV block should be addressed with early temporary or permanent pacing.

2:1 and High-Grade Atrioventricular Blocks

2:1 AV block is a failure of conduction of every other P wave (see Fig. 9.4D). This pattern is most commonly seen with an infranodal block in the His bundle or bundle branches. However, 2:1 AV block may also be observed in advanced AV nodal disease. It can be distinguished from the more common infranodal form of 2:1 block by the typical Mobitz

I periodicity accompanied by a usually narrow QRS complex at other times in the same patient. Because two consecutive conducted P waves are not available to assess the Mobitz pattern, a 2:1 AV block is neither truly Mobitz I nor Mobitz II, although it is common in clinical practice to describe 2:1 block as Mobitz II.

High-grade AV block is second-degree AV block with conduction failure of two or more consecutive P waves. High-grade AV block is neither Mobitz I nor Mobitz II. Although Mobitz periodicity cannot be assigned, like other forms of second-degree AV blocks, the level of block must be established to assess prognosis and guide therapy. In this case, the ancillary clues described for Mobitz blocks remain useful.

Third-Degree Atrioventricular Block

Third-degree AV block or equivalently complete heart block is a complete failure of AV conduction. In the setting of underlying sinus rhythm, this is an atrial rate faster than the ventricular rate associated with AV dissociation (see Fig. 9.4E). However, when the underlying rhythm is AF, the definition of complete heart block cannot rely on the demonstration of AV dissociation. Because conducted AF always results in an *irregular* ventricular response, the finding of a *regular and slow* ventricular response during AF implies an associated complete heart block.

As is the case for second-degree AV block, the level of the third-degree block determines the clinical behavior and prognosis of complete heart block. Complete heart block at the level of the AV node is associated with a generally stable junctional escape with rates between 40 and 50 beats per minute and usually with a narrow QRS complex. If the patient had a bundle branch block before the development of complete heart block, a block at the level of the AV node is associated with a wide QRS escape, identical to the conducted QRS before the development of a block.

Complete heart block at an infranodal level is associated with a wide and slow ventricular escape rhythm, which often is slower than 40 beats per minute with a QRS different from the antecedent conducted morphology. Unfortunately, infranodal escape rhythms may be absent entirely, leading to asystole and loss of consciousness. When infranodal complete heart block is suspected, regardless of tolerance of the ventricular escape rhythm, prompt institution of temporary or permanent ventricular pacing is appropriate.

TACHYCARDIAS

Overview and Classification

Tachyarrhythmias are categorized as supraventricular and ventricular arrhythmias. SVT relies mechanistically on the atrium, the AV node, or both. During SVT, normal depolarization of the ventricles by the His-Purkinje system typically produces a narrow complex tachycardia. SVT can manifest as a wide-complex tachycardia in the setting of aberrancy with left bundle branch block or right bundle branch block conduction, or antegrade conduction down an accessory pathway, producing an abnormal sequence of ventricular activation. Ventricular tachyarrhythmias do not depend on the atrium or AV node; they originate in the ventricles, generating a wide-complex tachycardia.

Supraventricular Tachycardias

SVTs can be categorized as paroxysmal supraventricular tachycardia (PSVT), focal atrial tachycardia, atrial flutter, and AF. This classification scheme, which addresses the underlying arrhythmic mechanism, clinical presentation, and prognosis, guides evaluation and therapy.

PSVT typically manifests in young patients without structural heart disease. The PSVT syndrome is characterized by recurrent tachypalpitations with abrupt onset and offset. Focal atrial tachycardia is more

often observed in patients with underlying atrial enlargement and valvular heart disease. AF and atrial flutter are associated with advancing age, hypertension, structural heart disease, diabetes, obstructive sleep apnea, and pulmonary disease. Unlike PSVT, AF carries an increased risk of stroke, heart failure, and death.

Paroxysmal Supraventricular Tachycardia

The incidence of PSVT is 35 cases per 100,000 person-years, with a prevalence of 2.25 per 1000 person-years. Patients report recurrent tachypalpitations. Associated symptoms may include shortness of breath, lightheadedness, chest pain, and syncope. Anginal chest pain and ischemic ST-segment depression are common and related to increased myocardial oxygen demand coupled with the loss of normal diastolic coronary perfusion time. These findings do not necessarily indicate underlying coronary artery disease and typically resolve with tachycardia termination.

PSVT typically occurs independent of structural heart disease and may manifest at any point from infancy to advanced age. PSVT relies on reentry, which is localized in the AV node in approximately 60% of cases and uses a concealed or manifest accessory pathway in 40%. Unless a delta wave indicative of WPW is identified, the underlying mechanism of PSVT may not be apparent on initial clinical presentation.

An ECG obtained during PSVT can provide useful clues to establish the diagnosis and guide management. The AV relationship should be assessed during tachycardia. By ascertaining the relationship of the P wave to the preceding QRS complex, it is possible to classify PSVT as a *short RP tachycardia* or a *long RP tachycardia*. Short RP tachycardias demonstrate a short RP pattern with P waves embedded within or occurring closely after the preceding QRS complex. Short RP tachycardias occur with reentrant SVT when the retrograde VA conduction time is shorter than the antegrade AV conduction time. This pattern is observed in the two most common forms of PSVT: typical AV nodal reentry tachycardia and reciprocating AV tachycardia related to an accessory pathway.

Long RP tachycardias are characterized by an RP interval that is longer than the next PR interval during tachycardia. This pattern occurs when the retrograde VA conduction time in reentrant arrhythmias is long due to a slowly conducting retrograde pathway during tachycardia. Atypical AV node reentry, in which retrograde conduction occurs over the slow AV nodal pathway, is the most common example of a long RP reentrant tachycardia.

Atrioventricular nodal reentry tachycardia. AVNRT is the most common form of PSVT. The arrhythmic mechanism depends on two distinct pathways in the AV node: a slowly conducting pathway with a short effective refractory period (i.e., slow pathway) and a rapidly conducting pathway with a longer refractory period (i.e., fast pathway). The fast pathway is located anteriorly near the bundle of His, and the slow pathway posteriorly near the coronary sinus ostium. Although dual pathways are a common feature of the AV node, patients with clinical tachycardia have more robust slow pathway conduction.

Tachycardia is most commonly triggered by a premature atrial contraction that blocks in the fast pathway due to its prolonged refractory period and conducts slowly antegrade down the slow pathway, producing a long PR interval on the ECG. On reaching the distal common pathway where the fast and slow AV nodal inputs meet, if the fast pathway is no longer refractory, the impulse may penetrate the fast pathway in a retrograde direction and rapidly activate the atrium, producing a short RP interval and reinitiating reentry down the slow pathway and up the fast pathway. In typical slow-fast AVNRT, the RP interval is so short that the P wave is often buried in the preceding QRS complex (Fig. 9.5A).

Atypical fast-slow AVNRT may occur with antegrade conduction over the fast pathway and retrograde conduction over the slow pathway. This form of AVNRT is uncommon and produces a long RP pattern on the ECG with characteristically deeply inverted retrograde P waves in leads II, III, and aVF.

Vagal maneuvers cause temporary AV nodal blockade and may terminate sustained AVNRT. Alternatively, intravenous adenosine is a highly effective acute therapy. The need for chronic or definitive therapy is determined by symptoms, arrhythmia frequency, and patient preference. Catheter ablation of the slow pathway at the posterior AV node is highly successful, eliminating AVNRT with a greater than 95% success rate and a low risk of complications. Drug therapy with β -blockers and calcium-channel blockers directed at the AV node may be helpful for chronic suppression. Occasionally, class IC and III antiarrhythmics may be required. AVNRT should be easily distinguished from automatic junctional tachycardia, with a narrow complex and rapid, irregular rhythm typically demonstrating AV dissociation (see Fig. 9.5B).

Reciprocating atrioventricular tachycardia and preexcitation syndromes. Congenital anomalous extranodal AV muscle fibers or accessory pathways may arise as a consequence of incomplete development of the AV annulus. These pathways are usually observed in patients with otherwise anatomically normal hearts, although right-sided accessory pathways are infrequently associated with Ebstein's anomaly and left-sided accessory pathways with hypertrophic cardiomyopathy.

Accessory pathways, or bypass tracts, may conduct antegrade, retrograde, or bidirectionally. They typically fail to demonstrate decremental conduction or the slowed conduction with increasingly frequent stimulation that characterizes the AV node. Accessory pathways capable of antegrade conduction produce early activation of the ventricle in sinus rhythm because conduction over the accessory pathway surpasses conduction over the AV node. The relatively rapid AV conduction produces a shortened PR interval, and eccentric ventricular activation over the pathway slurs the QRS onset, resulting in a delta wave (see Fig. 9.5C). If the accessory pathway is capable only of retrograde conduction, the baseline ECG in sinus rhythm does not show evidence of an accessory pathway, and the extranodal AV connection is called *concealed*.

Short PR intervals during sinus rhythm are also observed in patients with Lown-Ganong-Levine syndrome. These patients have a normal-appearing QRS complex without a delta wave because ventricular activation occurs through the His-Purkinje system (see Fig. 9.5D).

Whether accessory pathways are concealed or manifest, the most common associated arrhythmia is *orthodromic AV reentrant tachycardia* (AVRT). Tachycardia is mediated by antegrade conduction down the AV node to the ventricle and subsequent retrograde conduction up the accessory pathway to activate the atrium, then antegrade again down the AV node. Because the ventricles are activated during tachycardia exclusively over the AV node, the resulting tachycardia is typically a narrow complex unless aberrancy occurs (see Fig. 9.5E). A short RP pattern is observed on the ECG, although the RP is slightly longer than commonly observed in a typical AVNRT. Because the atria and ventricles constitute portions of the reentrant circuit, tachycardia depends on 1:1 AV conduction.

Less frequently, *antidromic AV reentrant tachycardia* is seen in patients with accessory pathways capable of antegrade conduction. The accessory pathway provides the antegrade limb of the reentrant circuit, and the AV node serves as the retrograde pathway, resulting in a wide QRS tachycardia due to complete preexcitation of the ventricles, or activation of the ventricles entirely over the accessory pathway.

Special considerations for patients with supraventricular tachycardia and delta waves in sinus rhythm. Asymptomatic patients may have delta waves on the ECG, which is called a *WPW pattern*. Prevalence

Fig. 9.5 Atrioventricular (AV) nodal (junctional) rhythm disturbances. (A) Supraventricular tachycardia. The lack of visible P waves during tachycardia suggests that they are concealed within the QRS complex, a pattern indicative of underlying AV nodal reentrant tachycardia. (B) Automatic junctional tachycardia. Notice the AV dissociation during tachycardia. The P waves (*arrows*) are dissociated from the QRS complexes. (C) Sinus rhythm with a short PR interval due to the presence of delta waves in a patient with Wolff-Parkinson-White (WPW) syndrome. The slurred QRS upstroke of the delta wave results from early activation of the ventricle by the extranodal bypass tract, followed by fusion with rapid conduction down the normal conduction system and resulting in narrowing of the terminal QRS. (D) Sinus rhythm with a short PR interval but no delta waves. Despite the short PR, the P wave is normally vectored, excluding a junctional rhythm that appears similar but with an inverted P wave. A short PR interval in sinus rhythm without delta waves is caused by an abnormally rapid AV nodal conduction and is described as a Lown-Ganong-Levine pattern. (E) Supraventricular tachycardia. Unlike tracing A, there is a clear P wave (*arrow*) inscribed immediately after each QRS in the ST segment. This pattern is seen most commonly with orthodromic AV reciprocating tachycardia in a patient with WPW syndrome. The early P wave in WPW is caused by retrograde conduction up the accessory pathway after ventricular activation during tachycardia. (F) Preexcited atrial fibrillation (AF) in a patient with WPW syndrome. Notice the rapid and irregular ventricular response with widening of the QRS due to preexcitation. This pattern results from rapid conduction of the AF down the accessory pathway, bypassing the normal conduction system. As in this arrhythmia, occasional conduction down the AV node may occur during ongoing tachycardia, resulting in periods with a narrow QRS complex.

of the WPW pattern in the general population is approximately 1 case per 1000 people. Accessory pathways may be poorly conducting and less likely to promote tachycardia, accounting for the absence of symptoms. These patients have a favorable prognosis, particularly if spontaneous and abrupt cessation of ECG preexcitation (delta wave) occurs with exercise or during ambulatory monitoring. In many cases, no specific therapy is required for asymptomatic patients.

Asymptomatic young patients participating in high-risk activities with WPW pattern may be subjected to invasive electrophysiologic testing for risk stratification. Patients with delta waves demonstrating clinical SVT or suggestive arrhythmic symptoms are said to have WPW syndrome, and invasive electrophysiologic testing is ordinarily recommended in these patients. Invasive testing helps to stratify the risk of sudden cardiac death.

Curative ablation is highly effective, with a success rate of 95%, and poses a low risk of procedural complications. Chronic therapy with

antiarrhythmic drugs that prolong the accessory pathway refractory period (i.e., class IA, IC, or III agents) may be effective, but the potential for adverse drug effects has made accessory pathway ablation the treatment of choice for symptomatic and high-risk patients.

The use of agents that slow AV nodal conduction in patients with WPW syndrome warrants special mention. Digoxin, β -blockers, and calcium-channel blockers should not be used in patients with WPW because they slow conduction through the AV node, resulting in preferential excitation of the ventricles over the accessory pathway. In the setting of AF or atrial flutter, this may cause rapid ventricular rates and hemodynamic instability.

Wolff-Parkinson-White syndrome and atrial fibrillation. WPW syndrome is associated with a 0.25% per year risk of sudden cardiac death (SCD), which is related to the development of AF with rapid antegrade conduction over the accessory pathway producing VF. This risk is greatest for patients demonstrating very short preexcited RR

Fig. 9.6 Atrial arrhythmias. (A) Runs of focal atrial tachycardia with variable atrioventricular (AV) block. The tachycardia occurs in salvos with interspersed periods of sinus rhythm. The P waves (*arrows*) during tachycardia appear uniform although their cycle length varies, resulting in variable patterns of AV conduction and an irregular ventricular rate. (B) Multifocal atrial tachycardia. Notice the incessant atrial premature beats (*arrows*) with at least three distinct morphologies. Because of the irregularly irregular response, this arrhythmia can be easily misdiagnosed as atrial fibrillation (which lacks discrete P waves) if the tracing is not carefully reviewed. (C) Atrial flutter with rapid, variable conduction. Notice the continuous sawtooth atrial activity. Although commonly manifesting with stable 2:1 block and a regular response, the block varies in this patient, progressing through periods of 2:1 and 3:1 ratios and resulting in an irregular ventricular response. (D) Atrial fibrillation with a rapid ventricular response. Notice the wavering baseline without distinct P waves and an irregularly irregular response.

intervals during AF. For some WPW patients, SCD may be the initial presentation. Successful catheter ablation of the accessory pathway eliminates this possibility.

Patients with WPW and rapidly conducted AF have the characteristic electrocardiographic findings of a rapid, irregularly irregular, wide QRS rhythm with various degrees of QRS widening or preexcitation from beat to beat (see Fig. 9.5F). During AF in the setting of underlying WPW, activation of the ventricle over the AV node produces concealed retrograde activation of the accessory pathway, prolonging the refractory period of the pathway and moderating the rate of antegrade accessory pathway conduction.

Treating patients with AV nodal–blocking therapy decreases concealed retrograde activation of the pathway, facilitating antegrade accessory pathway conduction and potentiating hemodynamic instability. Appropriate acute therapy includes drugs that prolong the accessory pathway refractory period, such as intravenous procainamide, ibutilide, or amiodarone. In the event of hemodynamic instability, electrical cardioversion is preferred.

Role of catheter ablation in Wolff-Parkinson-White syndrome.

Catheter ablation is highly effective for treating WPW, with success rates of approximately 95% and recurrence rates of only 5%. Procedural complications are uncommon, with major complications occurring in 2% to 4% of cases and deaths related to ablation occurring in 0.1%.

Although antiarrhythmic drug therapy may control symptoms, the expense and risks of pharmacologic therapy along with the safety and efficacy of ablation have made radiofrequency ablation the first-line therapy for symptomatic WPW. Because older patients with

asymptomatic WPW patterns have a favorable prognosis, they should not routinely be subjected to ablation.

Atrial Arrhythmias

Overview and Classification

Atrial arrhythmias depend entirely on the atria but are mechanistically independent of AV conduction. As a consequence, intra-atrial arrhythmias persist despite the development of spontaneous or pharmacologically induced AV block. Tachycardias originating in the atria may be organized and repetitive, resulting from automaticity or intra-atrial reentry, or may be chaotic and disorganized, as is the case in AF. Therapy is directed at moderating the ventricular response during episodes of tachycardia or suppressing the underlying atrial arrhythmia.

Focal arrhythmias originate from a point source in one of the atria, and circumferential spread encompasses the remainder of the atrium. These arrhythmias display distinct P waves separated by a clear isoelectric segment. Focal arrhythmias commonly have an automatic mechanism, but in some cases, they may result from micro-reentry involving an anatomically small portion of the atrium (e.g., around a single pulmonary vein), followed by radial spread to the rest of the atrium. Although most commonly a single abnormal focus may be active, in the setting of severe physiologic stress, multiple foci may be active simultaneously, leading to a chaotic electrocardiographic appearance with multiple distinct P waves, referred to as *multifocal atrial tachycardia* (MAT) (Fig. 9.6B). Automatic arrhythmias tend to be episodic and nonsustained, sometimes recurring incessantly. Cycle length often varies within a run, between runs, and with changes in autonomic tone.

Macro-reentrant atrial arrhythmias are a consequence of stable reentrant circuits, which encompass large portions of the atria. All such circuits require a central obstacle and a region of slowed atrial conduction related to atrial dilation or fibrosis. The most common of these arrhythmias is *typical atrial flutter*, which is mediated by right atrial reentry around normal anatomic obstacles. In addition to typical flutter, reentry may occur around acquired obstacles, most commonly scars resulting from prior cardiac surgery or ablation involving the atria. Reentrant arrhythmias tend to manifest clinically as paroxysmal sustained or persistent arrhythmias. Although they may be self-terminating and episodic, individual episodes tend to be protracted.

The final mechanism of atrial arrhythmia is AF. This arrhythmia involves components of focal automatic mechanisms and reentry. The major advances made in the understanding and management of this common arrhythmia are reviewed in the following sections.

Focal Atrial Tachycardia

Focal atrial tachycardia also is referred to as ectopic atrial tachycardia and automatic atrial tachycardia. These terms describe a characteristic clinical pattern that usually manifests as runs of unifocal PACs lasting for seconds or minutes, usually followed by spontaneous termination and subsequent spontaneous reinitiation of additional salvos of tachycardia (see Fig. 9.6A). This arrhythmia less commonly manifests as a paroxysmal sustained tachycardia. When mapped in the electrophysiologic laboratory, these arrhythmias have a focal origin, and although they are sometimes triggered by rapid pacing, suggesting triggered activity, they appear to be automatic rather than a reentrant mechanism.

The electrocardiographic features are characteristic and usually permit accurate diagnosis. Because the arrhythmia is focal and automatic, the morphology of the first PAC of the run is identical to the subsequent PACs. Cycle length tends to vary between and within runs, and tachycardia is unaffected by intermittent AV block, which may occur during the runs. The same focus often fires erratically between runs, resulting in frequent atrial ectopy that is morphologically similar to the P wave observed during the runs.

The arrhythmia appears to be caused by intracellular calcium overload and resultant triggered activity related to delayed afterdepolarizations, making it responsive to calcium-channel blockers and β -blockers. The paroxysmal sustained form of this arrhythmia is also adenosine responsive, giving the false impression of dependence on AV conduction. The use of digoxin may exacerbate triggered causes of atrial tachycardia. Class IC agents, such as flecainide and propafenone, may be useful in patients without structural heart disease or coronary artery disease. Amiodarone can also be used in these patients for rhythm control. The arrhythmia is readily amenable to catheter ablation if ectopy occurs frequently enough to permit mapping.

Typical Atrial Flutter

Atrial flutter is a persistent atrial arrhythmia with an atrial rate of at least 250 beats per minute (see Fig. 9.6C). Because the normal AV node cannot conduct 1:1 at these rates, this arrhythmia characteristically manifests with 2:1 conduction and a ventricular response of about 140 to 150 beats per minute. During 2:1 conduction, the difficulty in perceiving flutter waves may lead to diagnostic confusion. Typical atrial flutter is the most common form of this arrhythmia, and it is mediated by macro-reentry restricted to the right atrium. The central obstacles in this circuit consist of normal anatomic structures, accounting for its stereotyped pattern.

Typical atrial flutter is mediated by counterclockwise reentry around the tricuspid valve as viewed from the ventricle. The valve prevents anterior collapse of the circuit, and posteriorly a long ridge in

the atrial wall (i.e., crista terminalis) forms a functional line of block, preventing the circuit from collapsing posteriorly. Because the normal obstacles already exist, flutter development results from the abnormally slowed conduction related to atrial enlargement, fibrosis, or edema, which sometimes is combined with shortened atrial refractory periods due to catecholamine stress. Typical counterclockwise atrial flutter demonstrates a deeply negative F wave in leads II, III, and aVF; a sharply positive F wave in V_1 ; and a negative F wave in V_6 .

A less common reversed form of this arrhythmia is caused by clockwise reentry around the tricuspid valve. It demonstrates an ECG exactly opposite to the counterclockwise form, with a strongly positive F wave in leads II, III, and aVF; a sharply negative F wave in V_1 ; and a positive F wave in V_6 . In both cases, the F waves are often difficult to perceive because of 2:1 conduction. If the unusual F-wave vector is not recognized, the ECG may be misinterpreted as sinus tachycardia. Clues to identification of atrial flutter are persistent, unexplained heart rates of about 150 beats per minute with a variation of only a few beats per minute over time and the finding of a negative P wave in the inferior leads, which is expected to be positive in sinus rhythm.

The most fruitful method of diagnosis is the provocation of transient AV block with carotid sinus massage or adenosine infusion. This transiently exposes the underlying flutter waves but does not terminate the arrhythmia.

Although acute therapy involves rate control or cardioversion if drugs are poorly tolerated, long-term rate control for this arrhythmia is difficult. Drug doses that result in acceptable block at rest often fail to control exercise rates, and doses that result in exercise rate control often provoke bradycardia at rest. Early restoration of sinus rhythm is preferred for this arrhythmia.

Atrial flutter is a common transient arrhythmia in acute care hospital settings. The right atrial wall is thin, and pericarditis resulting from cardiac or thoracic surgery results in atrial edema and inflammation that may permit adequate slowing and promote transient atrial flutter. Acute pulmonary decompensation may result in right heart failure and may promote transient atrial flutter. In all of these settings, endogenous or pharmacologic catecholamine stimulation exacerbates the arrhythmia. Transient therapy for up to a month is appropriate in these settings.

When atrial flutter occurs in the absence of an acute precipitant, long-term therapy is required. Given the difficulty of achieving rate control in atrial flutter and the need for antiarrhythmic agents with associated potential morbidity to maintain sinus rhythm, catheter ablation has become the primary means of treating this arrhythmia. Antiarrhythmic therapy for atrial flutter is similar to that for AF (discussed later). Antiarrhythmic drug therapy should be reserved for temporary treatment of likely transient flutter or for patients who are not suitable candidates for invasive management. Catheter ablation of typical atrial flutter is a low-risk procedure with a long-term success rate exceeding 90% in experienced centers.

Atypical Atrial Flutter and Macro-Reentrant Atrial Tachycardia

In addition to the typical atrial flutter circulating around normal anatomic obstacles, atrial disease with associated fibrosis or, more commonly, atrial scars created at the time of prior catheter or surgical ablation or cardiac surgery for valvular or congenital heart disease may create alternative substrates for intra-atrial reentry. Common to these arrhythmias is a significant region of scar with a channel of surviving myocardium bridging the scar or between the scar and a normal anatomic obstacle. Within the channel, conduction is slow and electrocardiographically silent, resulting in an isoelectric PP interval. Because the circuit is different from that of typical atrial flutter, the P-wave morphology is atypical.

When the rate is 250 beats per minute or greater, the arrhythmia is arbitrarily classified as atypical atrial flutter, and when the rate is less than 250 beats per minute, it is arbitrarily classified as atrial tachycardia. Like typical atrial flutter, these arrhythmias are paroxysmal sustained or persistent arrhythmias, and when manifesting with 2:1 conduction, they may be misdiagnosed as sinus tachycardia if the abnormal P-wave vector and fixed heart rate over time are not recognized. Therapy and prognosis are otherwise similar to those for typical atrial flutter.

Atrial Fibrillation

Overview and Classification

AF is a chaotic atrial rhythm related to continuous and variable activation of the atria. There are no distinct P waves or periods of atrial quiescence. It is characterized electrocardiographically by a wavering baseline associated with an irregular ventricular response (see Fig. 9.6D).

AF is the most common clinically significant arrhythmia. It affects 2.2 million people in the United States. Its prevalence is between 0.4% and 1% in the general population, and it increases with age, reaching 8% in those older than 80 years. Patients with AF have a higher risk of stroke, heart failure, and mortality. However, the role of AF as an independent determinant of mortality is uncertain because it commonly coexists with other important conditions. Patients with lone AF do not have an increased mortality rate, and carefully designed trials exploring the benefit of maintenance of sinus rhythm over rate control show, in most populations, no survival benefit for sinus rhythm. One exception may be in patients with systolic heart failure in addition to AF where ablation of AF may have a survival advantage. The recently completed CASTLE-AF (Catheter Ablation vs. Standard Conventional Treatment in Patients with LV Dysfunction and AF) showed a significant reduction in mortality with catheter ablation of AF in this select population. AF is often classified by its clinical presentation and pattern. When AF is first detected, it is called *new onset*, and its ultimate pattern is initially undetermined. When AF relapses during follow-up, it is called *recurrent* and classified by its clinical pattern. If AF terminates spontaneously, it is called *paroxysmal* AF. Although episodes lasting up to 7 days are defined as paroxysmal, most episodes of paroxysmal AF terminate within the first 24 hours and many terminate within minutes or hours of onset. When AF lasts longer than 7 days, it is designated as *persistent*. AF that persists for a long interval, typically more than a year, without return of an interim period of sinus rhythm (spontaneously or as a result of medical intervention such as cardioversion) is termed long-standing persistent AF. Finally, when a clinical decision is made to no longer try to maintain sinus rhythm, the term *permanent* AF is used.

Mechanisms of Atrial Fibrillation

Because of its chaotic nature, it has been difficult to study AF, and its mechanisms remain incompletely understood. The initiation of spontaneous AF is a consequence of rapid electrical firing from preferential focal sites of origin. The most common site of focal origin is from left atrial muscle sleeves extending along the outer surface of the pulmonary veins. When firing does not originate from a pulmonary vein, it is commonly from the left atrial tissue immediately adjacent to one of the veins or occasionally from one of the other thoracic veins such as the ostium of the superior vena cava or the ostium of the coronary sinus. Atrial rates recorded in and around the pulmonary veins are significantly higher than at other atrial sites, suggesting that activity in the region of the veins is important in perpetuating AF after initiation.

These insights have produced highly effective techniques for the cure of AF. Ablation techniques designed to isolate these trigger sites from the atrium have success rates of 70% to 80% for the cure of

paroxysmal AF and somewhat lower rates for the cure of persistent AF. Ablation restricted to the region of the pulmonary veins and adjacent left atrium is curative in most patients with AF, implying that most cases of AF are arrhythmias entirely contained within and maintained by the left atrium and connecting veins. In the same way that typical atrial flutter is the characteristic arrhythmia of the right atrium, AF is the characteristic arrhythmia of the left atrium.

Anticoagulation and Atrial Fibrillation

During AF (and to some extent, atrial flutter), the atria have incomplete and ineffective contractions. Blood stasis occurs and may result in the formation of intracardiac thrombus, which may lead to thromboembolism and stroke. The overall risk of stroke in patients with AF is 5% per year. Certain risk factors may adjust this risk, including age, gender, rheumatic heart disease, prior stroke, left ventricular dysfunction, vascular disease, hypertrophic cardiomyopathy, left atrial enlargement, hypertension, and diabetes.

Scoring systems have been developed to estimate a patient's AF-related stroke risk based on his or her constellation of risk factors. Formerly, the most used system was the CHADS₂ score (cardiac failure, hypertension, age \geq 75 years, diabetes mellitus, and prior stroke). This system has been well validated in assessing the stroke risk of patients with AF. It assigns a single point for age of 75 years or older, diabetes, history of heart failure, and hypertension. It assigns two points for a history of stroke or transient ischemic attack. A score of 0 correlates with a relatively low risk of stroke at 1.9% per year, a score of 1 has a stroke risk of 2.8% per year, a score of 2 has a risk of 4.0% per year, and a score of 3 or higher has a stroke risk of more than 5.9% per year.

The CHADS₂ underwent further refinement to increase the granularity of stroke risk stratification with the creation of the CHA₂DS₂-VASc (vascular disease, age, and sex) scoring system, currently the primary score for thromboembolic risk stratification. In this system, congestive heart failure, hypertension, diabetes mellitus, vascular disease, age between 65 and 74 years, and female gender are assigned 1 point, and age of 75 years or older and prior stroke are assigned 2 points. A CHA₂DS₂-VASc score of 0 was associated with a 0% stroke rate, a score of 1 with a 0.6% per year risk, a score of 2 with a 1.6% risk, and a score of 3 with a risk of 3.9%. This system may be most useful for identifying truly low-risk patients.

After a patient's individualized stroke risk is determined, it can be balanced against the risk of anticoagulation to determine what would be appropriate for stroke prevention. A useful tool for estimating bleeding risk due to oral anticoagulation is the HAS-BLED (hypertension, abnormal renal/liver function, stroke, bleeding history or predisposition, labile international normalized ratio, elderly, drugs/alcohol) score. Patients with a HAS-BLED score of 0 had a risk of 0.59 severe bleeds per 100 patient-years, those with a score of 1 had a risk of 1.51, those with a score of 2 had a risk of 3.20, and those with a score of 3 had a risk of 19.51.

In patients with an acceptable bleeding risk, and with a CHA₂DS₂-VASc score of 2 or greater in men or 3 or greater in women, the 2019 AHA guidelines recommend oral anticoagulation to help prevent embolic stroke. Recommended agents include warfarin, dabigatran, rivaroxaban, apixaban or edoxaban. For patients with low CHA₂DS₂-VASc scores, aspirin is no longer recommended. Oral anticoagulants might be reasonable for intermediate CHA₂DS₂-VASc scores (1 in men and 2 for women), but this has less evidence.

Warfarin is the longest-studied antithrombotic used for reducing the rate of AF-related stroke and reduces the risk by 50%. Warfarin can be difficult to administer; the level of blood-thinning effect must be constantly monitored with international normalized ratio (INR) blood testing. An INR less than 2.0 is associated with higher rates of ischemic

stroke; a level greater than 3.0 is associated with increased intracranial bleeding. On average, a therapeutic INR (between 2.0 and 3.0) is maintained in only two thirds of cases, and there are many drug and dietary interactions with warfarin.

Several newer oral anticoagulants (NOACs) have effectiveness and bleeding risk rates similar to warfarin, but they do not require drug level monitoring. They include dabigatran, rivaroxaban, apixaban, and edoxaban. These drugs have been studied in large patient groups and found to be noninferior to warfarin, and some may be superior in certain aspects. NOACs are preferred in eligible patients over warfarin except in cases of moderate-to-severe mitral stenosis or the presence of a mechanical heart valve.

Percutaneous occlusion of the left atrial appendage with the Watchman device has been compared to Coumadin in patients with nonvalvular atrial fibrillation and found generally to offer similar protection against stroke. Oral anticoagulation remains the preferred therapy for stroke prevention in most patients; however, in those who are poor candidates for long-term anticoagulation (because of the propensity for bleeding or poor drug tolerance or adherence), the Watchman device provides an alternative.

The highest risk of stroke related to AF occurs at time of conversion to sinus rhythm achieved spontaneously or by chemical or electrical cardioversion. If thrombus has formed within the left atrium or left atrial appendage, it may not leave the atria during AF due to ineffective atrial mechanics. However, after sinus rhythm is restored, the improved atrial function may eject the thrombus and cause embolic stroke or other systemic embolic sequelae. Even with restoration of electrical atrial systole, the recovery of normal atrial mechanics may be delayed several days to weeks (i.e., atrial stunning). To reduce the risk of pericardioversion stroke, it is important to reduce the risk of preexisting thrombus and to prevent formation in the time period immediately after cardioversion.

The risk of preexisting thrombus can be reduced by 3 weeks of oral anticoagulation or Doppler transesophageal echocardiography (TEE) before cardioversion. These steps are recommended for any patient who has been in AF for an unknown period or has been documented to be in AF more than 48 hours. Although thrombi have been identified in patients with AF for shorter periods, current clinical practice presumes that most thrombus formation requires at least 48 hours. Thrombus related to AF occurs most commonly in the left atrial appendage, which cannot be well visualized by transthoracic echocardiography; TEE is often recommended before cardioversion for optimal imaging of the left atrial appendage. After cardioversion, at least 4 weeks of oral anticoagulation is recommended for everyone, with the exception of low CHA₂DS₂-VASc score patients (0 in men or 1 in women) who had AF less than 48 hours prior to the cardioversion, in whom postconversion anticoagulation may be omitted.

Acute Management of Atrial Fibrillation: Rate Control

The acute management of AF centers on the control of the ventricular response, timely restoration of sinus rhythm, and identification of potentially reversible factors that might have precipitated the arrhythmia. AF with rapid ventricular response results in acute deterioration in stroke volume and cardiac output and an increase in myocardial oxygen demand with the potential for coronary ischemia. Patients who are symptomatic must be controlled promptly. When pursuing rate control for acute AF of recent onset, the fastest way to achieve rate control is the restoration of sinus rhythm. If rate control in ongoing rapidly conducted AF proves difficult or is not well tolerated, cardioversion should be undertaken early.

For the acute control of rapidly conducted AF, intravenous administration of a β -blocker (i.e., esmolol, metoprolol, or propranolol)

or a nondihydropyridine calcium-channel blocker (i.e., diltiazem or verapamil) is preferred. In the setting of decompensated heart failure, the use of a calcium-channel blocker may exacerbate heart failure and should be avoided. In this setting, digoxin is a useful agent for resting rate control. Digoxin is also a useful second-line drug in addition to a calcium-channel or β -blocker for resting rate control. If this therapy is ineffective or not tolerated, intravenous amiodarone is a useful rate control agent, especially in the setting of congestive heart failure, and it may facilitate restoration of sinus rhythm.

Long-term targets for rate control of permanent AF have been a matter of debate. The Rate Control Efficacy in Permanent Atrial Fibrillation II (RACE II) study showed no advantage to strict rate control. Targeting a resting rate of less than 80 beats per minute showed no advantage over a target of less than 110 and was much harder to achieve. For long-term management, the results suggest that achieving a resting heart rate of less than 110 beats per minute may be sufficient and safe.

Acute Management of Atrial Fibrillation: Restoration of Sinus Rhythm

When sinus rhythm is restored in the first 48 hours of acute AF, the thromboembolic risk is low, and anticoagulation is not required. New-onset AF should be managed with a plan to restore sinus rhythm during this period if possible. At least one half of new-onset AF episodes terminate spontaneously in the first 24 to 48 hours.

Pharmacologic conversion of atrial fibrillation. Pharmacologic conversion of AF can be undertaken when restoration of sinus rhythm is not urgent. Several antiarrhythmic drugs have been effective in increasing the rate of early conversion of AF. Pharmacologic conversion usually is more successful with AF of recent onset than with chronic AF.

Oral agents with efficacy in the early conversion of AF include flecainide, propafenone, and dofetilide. Oral amiodarone and sotalol have been associated with a 27% and 24% conversion rate, respectively, occurring after 28 days of therapy. However, due to low early conversion rates, these oral drugs are not recommended for conversion. Intravenous agents with efficacy for early conversion include ibutilide and amiodarone. Ibutilide is limited by a relatively high 4% rate of drug-induced QT prolongation and TdP VT. This risk is even higher in the setting of LV dysfunction, electrolyte disturbances, or heart failure. Ibutilide should be reserved for the pharmacologic conversion of stable patients with a baseline normal QT interval. In contrast, intravenous amiodarone is well tolerated by unstable patients and is the preferred pharmacologic agent for conversion in the critically ill.

Electrical cardioversion of atrial fibrillation. Electrical cardioversion should be performed urgently in the case of severe compromise related to acute AF, including angina, heart failure, hypotension, and shock. Cardioversion should also be attempted at least once electively in most cases of new-onset AF regardless of tolerance. When performing electrical cardioversion, an anterior-posterior patch or paddle position is more effective than the conventional anterior-to-lateral patch or paddle position used for ventricular defibrillation. Although low-output discharges may be effective in some patients, a strategy of starting at higher outputs decreases the number of shocks required and the average cumulative energy delivered. An initial shock energy of 200 J is recommended. After a failed initial shock, full output should be used for the next attempt.

Long-Term Maintenance of Sinus Rhythm

Antiarrhythmic therapy. Despite the association of AF with an increase in stroke-related and all-cause mortality, no study has established a benefit for pharmacologic maintenance of sinus rhythm in terms of stroke risk or survival. This may be because AF is

merely a marker and not a mechanism of mortality. It may also be a consequence of the relative inefficacy of pharmacologic therapy in the maintenance of sinus rhythm and the difficulty of establishing whether patients thought to be in sinus rhythm are consistently in sinus rhythm at follow-up.

The largest and best designed trial addressing this issue was the Atrial Fibrillation Follow-up Investigation of Rhythm Management (AFFIRM) trial. The study included 4060 patients randomly assigned to rhythm control with antiarrhythmic drugs, most commonly amiodarone, or to rate control without attempts to maintain sinus rhythm. AFFIRM demonstrated no advantage in stroke or mortality rates using a strategy of sinus rhythm maintenance compared with rate control. Either strategy can be offered to patients with an expectation of similar outcomes with regard to hard end points. The decision to pursue sinus rhythm usually is determined by the management of symptoms that may be better addressed by maintaining sinus rhythm in selected patients.

In the absence of antiarrhythmic drugs, more than 80% of patients relapse during the first year after cardioversion of AF. Antiarrhythmic drugs remain the primary strategy for maintaining sinus rhythm after cardioversion and for preventing symptomatic episodes in patients with paroxysmal AF. However, antiarrhythmic therapy has many limitations, and alternative ablative therapies may over time overtake antiarrhythmic therapy in the management of AF.

All antiarrhythmic drugs have the potential for proarrhythmia, the unintended precipitation of a new arrhythmic problem caused by the drug. Adverse rhythm effects of drugs may include sinus node dysfunction, heart block, promotion of drug-slowed atrial flutter permitting rapid 1:1 conduction, and promotion of potentially lethal ventricular arrhythmias. Class I drugs such as flecainide, propafenone, and disopyramide may result in significant direct myocardial depression and consequent exacerbation of heart failure. The array of potential adverse effects of antiarrhythmic drugs is beyond the scope of this chapter, but certain essential concepts are important to recognize.

Class I drugs such as flecainide and propafenone, which work by slowing conduction, have a high risk of ventricular proarrhythmia and potential for sudden death in the setting of heart failure, LV dysfunction, and coronary artery disease. Use of these drugs is restricted to patients with preserved cardiac function and no evidence of obstructive coronary artery disease. However, in this selected group of patients with normal hearts, these drugs are exceedingly safe, well tolerated, and often effective.

Class III drugs, which prolong repolarization and refractoriness, include sotalol, dofetilide, dronedarone, and amiodarone. They are safe for patients with coronary artery disease, and in the case of dofetilide and amiodarone, they are safe for those with congestive heart failure. However, sotalol and dofetilide may provoke TdP, even in patients with normal cardiac function, and they must be used with caution. Amiodarone has greater long-term efficacy than other drugs and a lower risk of proarrhythmia, but long-term somatic toxicity consisting of thyroid dysfunction, pulmonary, and occasional hepatotoxicity limits the use of this drug in older patients or those with limited expected longevity or an inability to safely tolerate alternative agents due to advanced cardiac disease or proarrhythmia. Amiodarone is highly effective for the short-term, acute management of arrhythmias in critically ill patients when the potential risk of long-term toxicity is not an issue.

Dronedarone was derived by modification of the amiodarone molecule. Like amiodarone, the drug has a low risk of proarrhythmia and TdP VT. Unlike amiodarone, the drug does not cause thyroid toxicity. In common use, hepatotoxicity is also uncommon with dronedarone. However, rare cases of hepatic failure have been associated

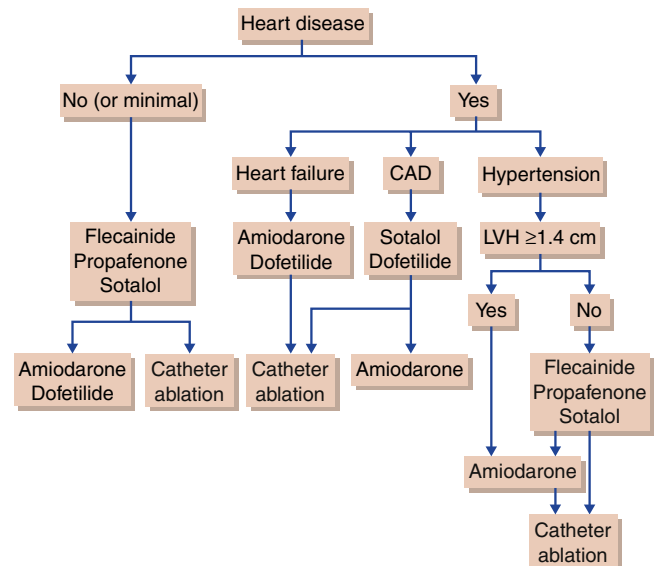

Fig. 9.7 A strategy for the selection of therapy to maintain sinus rhythm in patients with recurrent atrial fibrillation. Patients are stratified by the presence or absence of structural heart disease, and drugs expected to have the greatest efficacy and lowest therapeutic risk in each group are selected. Catheter ablation becomes a therapeutic option after failure of at least one antiarrhythmic drug. The class IC drugs flecainide and propafenone are not advised for patients with heart failure or coronary artery disease (CAD). Amiodarone is an acceptable first-line drug for those with heart failure and severe left ventricular hypertrophy. Because of its potential for somatic toxicity, amiodarone is otherwise reserved as a second-line agent that is used as an alternative to catheter ablation.

with dronedarone use. Dronedarone has increased mortality rates for patients with recently decompensated heart failure and when used as a simple rate control agent in patients with permanent AF. It is contraindicated in these settings.

In addition to being useful agents for the prevention of AF, sotalol, dronedarone, and amiodarone provide substantial rate control during relapses of AF. However, rate control with other antiarrhythmic agents may not be adequate to prevent rapid conduction with relapse, and class I drugs such as flecainide may accelerate response at the time of relapse. Antiarrhythmic drugs other than sotalol, dronedarone, or amiodarone should therefore be combined with a rate control agent such as a β -blocker or nondihydropyridine calcium-channel blocker during long-term therapy. Fig. 9.7 is a proposed strategy for antiarrhythmic drug selection for the long-term maintenance of sinus rhythm in patients with AF.

Surgical ablation of atrial fibrillation. The surgical treatment of AF was pioneered by Cox with the development of the atrial maze procedure. The procedure was predicated on the concept that AF was maintained by multiple interacting wave fronts of activity. By surgically dividing the atria into narrow channels, most with connection back to the sinus node, it was thought that AF could be abolished while preserving physiologic activation and contraction of the atrium. The circuitous path left for atrial activation and the multiple barriers created in the atrium intended to prevent AF gave rise to the term *maze procedure* to describe the technique. The initial procedure was thought to be highly successful but was associated with significant surgical risks and problems with sinus node dysfunction. Because of the surgical complexity of making and then closing multiple incisions in the atria and the complications associated with the procedure, the initial cut-and-sew maze procedure has fallen out of clinical use.

Although the original maze procedure is no longer used, many techniques have been developed to simplify the operation by substituting linear thermal ablation (by heating or cooling tissue) to create lines of conduction block in the atria without the need for extensive atrial dissection and reconstruction. Surgical ablation is commonly applied in patients with a history of AF who are undergoing concomitant heart operations for other indications such as valvular or coronary disease. Less frequently, surgical ablation has been applied as a stand-alone procedure for the sole management of AF. In that setting, various minimally invasive techniques have been developed. However, the techniques used vary widely from one center to another and long-term reporting of outcomes is inconsistent. In a large series that included 282 patients undergoing an open bi-atrial ablation procedure, 78% were in sinus rhythm without antiarrhythmic therapy at the 1-year follow-up evaluation.

Another important potential benefit of surgical ablation for AF is that it provides an opportunity to eliminate the left atrial appendage as a potential site of thrombus formation and source of thromboembolism. This can be accomplished by complete amputation of the appendage with oversewing of the appendage or clamping off the opening to the appendage with special devices designed for this purpose. This may be especially important in patients with absolute or relative contraindications to anticoagulation.

Catheter ablation of atrial fibrillation. Catheter ablation has become a common procedure for the management of AF after failure of initial attempts at medical therapy. Initial attempts to cure AF using catheter techniques were based on attempts in the early 1990s to emulate the linear lesion set of the Cox maze procedure with multiple endocardial lesions. High complication rates and limited efficacy led to abandonment of this approach.

In 1998, Haissaguerre reported the important role of rapid activity originating in the musculature of the pulmonary veins in initiation of paroxysmal AF. This led to the development of procedures designed to target the pulmonary veins and eventuated in the technique of electrical pulmonary vein isolation (PVI), which is currently the primary ablative approach to treatment of paroxysmal AF by catheter techniques. This technique has had acceptably high success rates ($\approx 70\%$) at multiple centers for the treatment of paroxysmal AF without antiarrhythmic therapy.

Despite the high success rate of catheter PVI ablation for the treatment of paroxysmal AF, this technique has not proved reliably effective in the management of more persistent forms of AF, especially long-standing persistent AF. This likely reflects the importance of factors other than pulmonary vein activity in the initiation and maintenance of persistent AF that are not addressed by PVI ablation. Multiple ablative techniques are currently used in an attempt to increase the success rates for patients with persistent AF. They have included addition of linear lesions to block reentrant wave fronts, ablation of regions of unusually rapid atrial activity during ongoing AF, and interruption of stable rotors of atrial activity identified during multisite mapping of AF. Although these techniques have improved success rates in limited series, it is uncertain which, if any, of these methods represents the optimal approach to the ablation of long-standing persistent AF.

In summary, catheter ablation is the preferred secondary strategy for treatment of symptomatic AF after initial attempts at medical therapy have failed. Simple pulmonary vein isolation has a high success rate for the management of patients with paroxysmal AF. Success rates for all ablative techniques are lower for persistent AF, especially for long-term AF. As in the case of surgical ablation, multiple techniques are used at various centers, and the different strategies for follow-up and definitions of response have made it difficult to ascertain the relative efficacy of the various approaches in common use.

Catheter ablation of the atrioventricular node. Although less commonly used today than in the past, the older technique of catheter ablation of the AV node resulting in complete heart block followed by placement of a ventricular pacemaker to maintain physiologic heart rates remains an option for patients when rate control cannot be achieved medically. This technique continues to have an important role in the management of patients who are too infirm to safely undergo AF ablation or in patients for whom ablative techniques have failed to control the arrhythmia.

For a deeper discussion on this topic, please see Chapter 58, “Supraventricular Cardiac Arrhythmias,” in *Goldman-Cecil Medicine*, 26th Edition. ❖

SYNCOPE

Syncope is a sudden loss of consciousness that is transient. Syncope has cardiac causes (e.g., low cerebral blood pressure) and noncardiac causes. Common causes and categories of syncope are outlined in [Table 9.4](#). Cerebrovascular disease or stroke uncommonly manifests as syncope unless a large cerebral territory is involved. Syncope is a common reason for emergency room or hospital admission.

The diagnostic approach to a patient with syncope is given in [Fig. 9.8](#). Most causes can be identified by the medical history and physical examination alone. Conditions surrounding the syncopal episode often suggest a cause. For example, vasovagal episodes often occur during stress, pain, straining, coughing, or urination. Exercise-induced syncope may indicate obstructive coronary disease, channelopathies such as long QT or CPVT, obstructive cardiomyopathy, aortic stenosis, or arrhythmia. A history of palpitations or syncope with no warning may be related to cardiac arrhythmias. Very long episodes of syncope (>5 minutes) suggest noncardiac causes. A recent change in medications or dizziness with position changes suggests orthostatic hypotension. Witnessed limb movements or posturing is not specific for neurologic causes and can result from any type of cerebral hypoperfusion, even from cardiac causes.

Beyond the history, physical examination, and routine ECG, further testing has little diagnostic utility. Holter or loop recorders may be useful. Implantable loop recorders may have utility in cases of recurrent, infrequent syncope. Electrophysiologic testing may be useful in some patients with other abnormalities suggesting an arrhythmic cause.

Despite thorough evaluations, more than 30% of patients with syncope have no identifiable cause. Cardiac causes of syncope have the highest morbidity and mortality rates. Because patients with unknown causes of syncope have long-term outcomes similar to those with noncardiac syncope, the major goal of an evaluation is to identify cardiac causes of syncope.

VENTRICULAR ARRHYTHMIAS AND SUDDEN CARDIAC DEATH

Ventricular ectopy is defined as cardiac beats that originate from within the right or left ventricular muscle or conduction system. Premature ventricular contractions (PVCs) can occur singly or as ventricular couplets or triplets. VT is four or more consecutive beats that originate from the ventricle at a rate of at least 100 beats per minute. VT is classified as *sustained* if it lasts longer than 30 seconds or requires termination due to hemodynamic instability; otherwise, it is classified as *nonsustained* VT (NSVT).

Ventricular ectopy also may be classified based on maintenance of a similar electrocardiographic morphology. The beats of monomorphic VT (MMVT) appear to be identical and usually originate from

TABLE 9.4 Causes of Syncope

Cause	Features
Peripheral Vascular or Circulatory	
Vasovagal syncope (neurally mediated)	Prodrome of pallor, yawning, nausea, diaphoresis; precipitated by stress or pain; occurs when patient is upright, aborted by recumbency; fall in blood pressure with or without a decrease in heart rate
Micturition syncope	Syncope with urination (probably vagal)
Post-tussive syncope	Syncope after paroxysm of coughing
Hypersensitive carotid sinus syndrome	Vasodepressor and/or cardioinhibitory responses with light carotid sinus massage
Drugs	Orthostasis; occurs with antihypertensive drugs, tricyclic antidepressants, phenothiazines
Volume depletion	Orthostasis; occurs with hemorrhage, excessive vomiting or diarrhea, Addison's disease
Autonomic dysfunction	Orthostasis; occurs in diabetes, alcoholism, Parkinson's disease, deconditioning after a prolonged illness
Central Nervous System	
Cerebrovascular	Transient ischemic attacks and strokes are unusual causes of syncope; associated neurologic abnormalities are usually identified
Seizures	Warning aura sometimes present, jerking of extremities, tongue biting, urinary incontinence, postictal confusion
Metabolic	
Hypoglycemia	Confusion, tachycardia, jitteriness before syncope; patient may be taking insulin
Cardiac	
Obstructive	Syncope is often exertional; physical findings consistent with aortic stenosis, hypertrophic obstructive cardiomyopathy, cardiac tamponade, atrial myxoma, prosthetic valve malfunction, Eisenmenger's syndrome, tetralogy of Fallot, primary pulmonary hypertension, pulmonic stenosis, massive pulmonary embolism
Arrhythmias	Syncope may be sudden and occurs in any position; episodes of dizziness or palpitations; may be history of heart disease; bradyarrhythmias or tachyarrhythmias may be responsible—check for hypersensitive carotid sinus

the same area of the heart. *Ventricular flutter* is a term that may be used to describe MMVT with rates of more than 300 beats per minute. Polymorphic VT (PMVT) has a more variable appearance on the ECG than MMVT. TdP is a special form of PMVT that has a repetitive, undulating periodicity and usually implies a long-QT triggered mechanism. VF is the most chaotic form of ventricular ectopy. It is associated with no meaningful cardiac output and usually leads to death unless rapidly treated. The other forms of VT may eventually degrade into VF.

Determining whether a patient has a rhythm of ventricular origin usually is done by 12-lead surface ECG. Ventricular ectopy typically has a wide QRS morphology (Fig. 9.9). Not all wide QRS morphologies are ventricular in origin, and there are criteria for determining whether a wide-complex tachycardia is supraventricular or ventricular. SVT may appear as a wide-complex tachycardia if it conducts to the ventricle with aberrancy (e.g., bundle branch block) or through an accessory pathway (e.g., WPW syndrome). Features that may help distinguish between SVT and VT include AV dissociation with capture beats and fusion beats and the QRS morphology and duration (Table 9.5). The Brugada algorithm is commonly used for determining the site of origin of wide-complex tachycardia. The tachycardia has a ventricular origin in more than 90% of patients with a history of ischemic heart disease.

VT may occur by the same mechanisms as other tachycardias, such as reentry, enhanced automaticity, or triggered activity. VT often occurs as a reentrant tachycardia around an area of prior MI scar in the left ventricle. VT in the chronic phase of ischemic heart disease is mediated by reentry through channels or sheets of surviving myocardium, especially in the partially spared border zone of a region of scar resulting from a prior MI. In these channels, conduction is abnormally slow due to poor coupling between sparse surviving myocytes. Susceptibility to sustained VT increases with worsening left ventricular dysfunction, likely due to the greater extent of ventricular scar.

VT can occur in the absence of ischemic heart disease in the form of idiopathic VT, nonischemic cardiomyopathies, hypertrophic cardiomyopathies, arrhythmogenic RV dysplasia, bundle branch reentry, cardiac ion channel disorders, or electrolyte disturbances. The right ventricular outflow tract (RVOT) is the most common origin of idiopathic VT, which is likely caused by triggered activity. This form of VT (or PVCs) is usually sensitive to catecholamines and may terminate with adenosine (i.e., adenosine-sensitive VT). Another common form of idiopathic VT originates from the left ventricular conduction system (i.e., fascicular VT) and may be verapamil sensitive. Idiopathic VTs are common targets for successful catheter ablation.

Nonsustained VT usually does not require specific therapy unless the patient is symptomatic. The Cardiac Arrhythmia Suppression Trial treated PVCs and NSVT after the acute phase of MI with class I antiarrhythmic drugs, and the trial demonstrated increased mortality rates when the arrhythmias were treated. If VT is attributed to reversible causes such as electrolyte disturbances or acute ischemia, the underlying mechanism should be treated. VT not due to reversible causes may be treated with β -blockers, antiarrhythmic drug therapy (e.g., amiodarone), or catheter ablation. If urgent treatment is required due to hemodynamic instability, direct current cardioversion is performed. It should be synchronized to the QRS complex if a regular morphology exists; otherwise, it should be nonsynchronized. Performing direct current cardioversion during the refractory period (T wave) of MMVT may degrade the rhythm to VF. An ICD often is used in patients who survive VT or VF to quickly treat recurrent episodes. Endocardial and epicardial catheter ablation has become an effective treatment for VT.

Prevention of Sudden Cardiac Death

SCD is defined as death within 1 hour of the onset of symptoms. It may result from a variety of cardiac or noncardiac conditions (Table 9.6). SCD is one of the most common causes of death, with 400,000 events occurring annually in the United States. The most common cause of SCD is VT

Fig. 9.9 Ventricular arrhythmias. (A) Monomorphic ventricular tachycardia (VT). Notice the wide QRS with a stable appearance with each beat. Detecting P waves during VT is difficult due to the overlying ventricular activity, but it is visible at several points on this tracing, some of which are marked by arrows. The AV dissociation is diagnostic of VT and excludes supraventricular tachycardia. (B) An initially organized agonal (preterminal) rhythm (arrows) degenerates into coarse ventricular fibrillation. Notice the irregular baseline and the absence of organized QRS complexes. During ventricular fibrillation, there is no forward cardiac output, and cardiac arrest immediately ensues.

or VF. Cardiac conditions that increase the risk of SCD include LQTS, hypertrophic cardiomyopathy, Brugada syndrome, arrhythmogenic RV dysplasia, and nonischemic or ischemic cardiomyopathy. The most common cardiac condition that may lead to SCD is acute or distant MI.

The successful treatment of SCD due to VF usually requires rapid access to cardioversion; if treatment is delayed by more than 5 to 10 minutes, permanent brain injury is common. AEDs can reduce the

TABLE 9.5 Differentiation of Ventricular Tachycardia From Supraventricular Tachycardia With Aberrancy

Helpful Features	Implications
Positive QRS concordance	Diagnostic of VT
AV dissociation, capture beats, or fusion beats	Diagnostic of VT
Atypical RBBB (monophasic R, QR, RS, or triphasic QRS in V_1 ; R:S ratio <1, QS or QR, monophasic R in V_6)	Suggests VT
Atypical LBBB (R >30 min or R to S [nadir or notch] >60 min in V_1 or V_2 ; R:S ratio <1, QS or QR in V_6)	Suggests VT
Shift of axis from baseline	Suggests VT
History of CAD	Suggests VT
QRS during tachycardia identical to QRS during sinus rhythm	Suggests SVT
Termination with adenosine	Suggests SVT

time to defibrillation and improve survival when placed in public areas, although they have been less effective when installed in private residences, even for patients at risk for SCD.

ICDs used in the treatment of SCD have improved mortality rates. Patients who are at high risk for SCD are often offered an ICD to enable rapid defibrillation before the onset of anoxic brain injury. If a patient survives the first episode of SCD due to documented or presumed VT

TABLE 9.6 Causes of Sudden Cardiac Death**Noncardiac Causes**

 Complications of infective endocarditis
 Hypertrophic cardiomyopathy (arrhythmia or obstruction)
 Myocardial ischemia
 Atherosclerosis
 Prinzmetal angina
 Kawasaki arteritis

or VF from nonreversible or unknown causes, he or she is offered an ICD. ICDs are extremely successful in the detection and treatment of VT or VF. They do not always prevent loss of consciousness because it takes 15 to 20 seconds to treat the arrhythmia, and low cardiac output may cause syncope before restoration of normal rhythm, especially if several cardioversions are required.

The earliest ICD trials examined their use in the secondary prevention of SCD (i.e., treating patients who had already survived an episode of cardiac arrest). The largest study was the Antiarrhythmics Versus Implantable Defibrillators (AVID) trial, which randomized patients with a history of poorly tolerated sustained VT or cardiac arrest to empirical amiodarone or ICD implantation. In this trial and several others, ICD therapy was associated with a lower risk of arrhythmic and all-cause death compared with antiarrhythmic therapy.

Several trials have examined the use of ICDs for the primary prevention of SCDs (i.e., treating patients who are at risk for SCD). The first was the Multicenter Automatic Defibrillator Implantation Trial (MADIT), which enrolled patients with a prior MI and an ejection fraction of 35% or less who had frequent ventricular ectopy and inducible VT at electrophysiologic testing. The study demonstrated a substantial mortality reduction with ICD therapy. MADIT-II enrolled patients with a prior MI and an ejection fraction of 30% or less in the chronic phase, without requiring invasive testing. A significant mortality benefit was associated with ICD therapy.

The Sudden Cardiac Death in Heart Failure trial enrolled a broader population consisting of patients with ischemic and nonischemic cardiomyopathy, symptomatic heart failure, and an ejection fraction of 35% or less. A survival benefit was found for patients treated with an ICD compared with conventional therapy or empirical amiodarone therapy. The degree of benefit was similar for patients with ischemic or nonischemic cardiomyopathy, suggesting that primary prevention with ICDs for patients with prior MI or nonischemic cardiomyopathy and heart failure was appropriate.

TABLE 9.7 Predictors of Sudden Cardiac Death After Myocardial Infarction

Decreased left ventricular ejection fraction
 Residual ischemia
 Delayed enhancement on cardiac MRI
 Late potentials on signal-averaged electrocardiography
 Decreased heart rate variability
 Prolonged QT on ECG
 Induction of sustained MMVT with programmed electrical stimulation
 Complex ventricular ectopy (e.g., NSVT) on ambulatory monitoring

ECG, Electrocardiogram; MMVT, monomorphic ventricular tachycardia; MRI, magnetic resonance imaging; NSVT, nonsustained ventricular tachycardia.

The risk of SCD after MI is highest in the few months after the index event. However, ICDs have not been effective when implanted immediately after MI or revascularization procedures. The reason for this is unclear; it may reflect the large percentage of patients who have improved cardiac function early on, which decreases the risk of SCD and therefore the benefit of an ICD. Alternatively, the mechanism for SCD in the early period after an MI or revascularization procedure may be recurrent ischemia rather than reentrant tachycardia and therefore less amenable to ICD therapy. The Defibrillator in Acute Myocardial Infarction Trial (DINAMIT) randomized 675 patients with low ejection fractions immediately after MI to ICD or medical therapy; no difference in mortality rates was seen. The current recommendations are to avoid primary prevention with ICDs within 40 days of an MI or 3 months of revascularization.

A significant challenge in modern medicine is identifying patients who have an elevated risk of SCD to allow effective use of primary prevention interventions such as ICDs. Some known predictors of SCD after MI are shown in Table 9.7, but many are not specific or sensitive enough for practical use. Reduced ejection fraction has been the most successful noninvasive measure that can predict increased risk of SCD. An electrophysiologic study is a minimally invasive catheter procedure that with electrical stimulation can help to identify patients who are prone to VT. Electrophysiologic studies are most sensitive in patients with prior MI, but they may be less useful in other cardiac conditions. Cardiac magnetic resonance imaging (MRI), which can directly image cardiac function and cardiac scar or fibrosis, is showing great promise as a more sensitive and specific, noninvasive risk predictor of SCD.

Ventricular Tachycardia and Ventricular Fibrillation Without Evident Heart Disease

Ventricular arrhythmias occurring in the absence of structural heart disease usually carry a benign prognosis but can be associated with SCD in patients with genetic arrhythmic syndromes predisposing to life-threatening polymorphic VT. Genetic screening for these syndromes is important to identify at-risk family members.

Idiopathic Ventricular Tachycardia

Idiopathic VT most commonly originates from the outflow tracts, with approximately 80% localized to the RVOT and the remainder originating in the left ventricular outflow tract (LVOT), the aortic sinuses of Valsalva, and the region of the aortomitral continuity. Idiopathic RVOT VT manifests with the characteristic electrocardiographic findings of left bundle branch block and inferior axis VT QRS morphology. Triggered activity is the mechanism underlying outflow tract tachycardias. This calcium-dependent mechanism explains why an outflow tract VT often terminates with adenosine, β -blockers, and calcium-channel blockers.

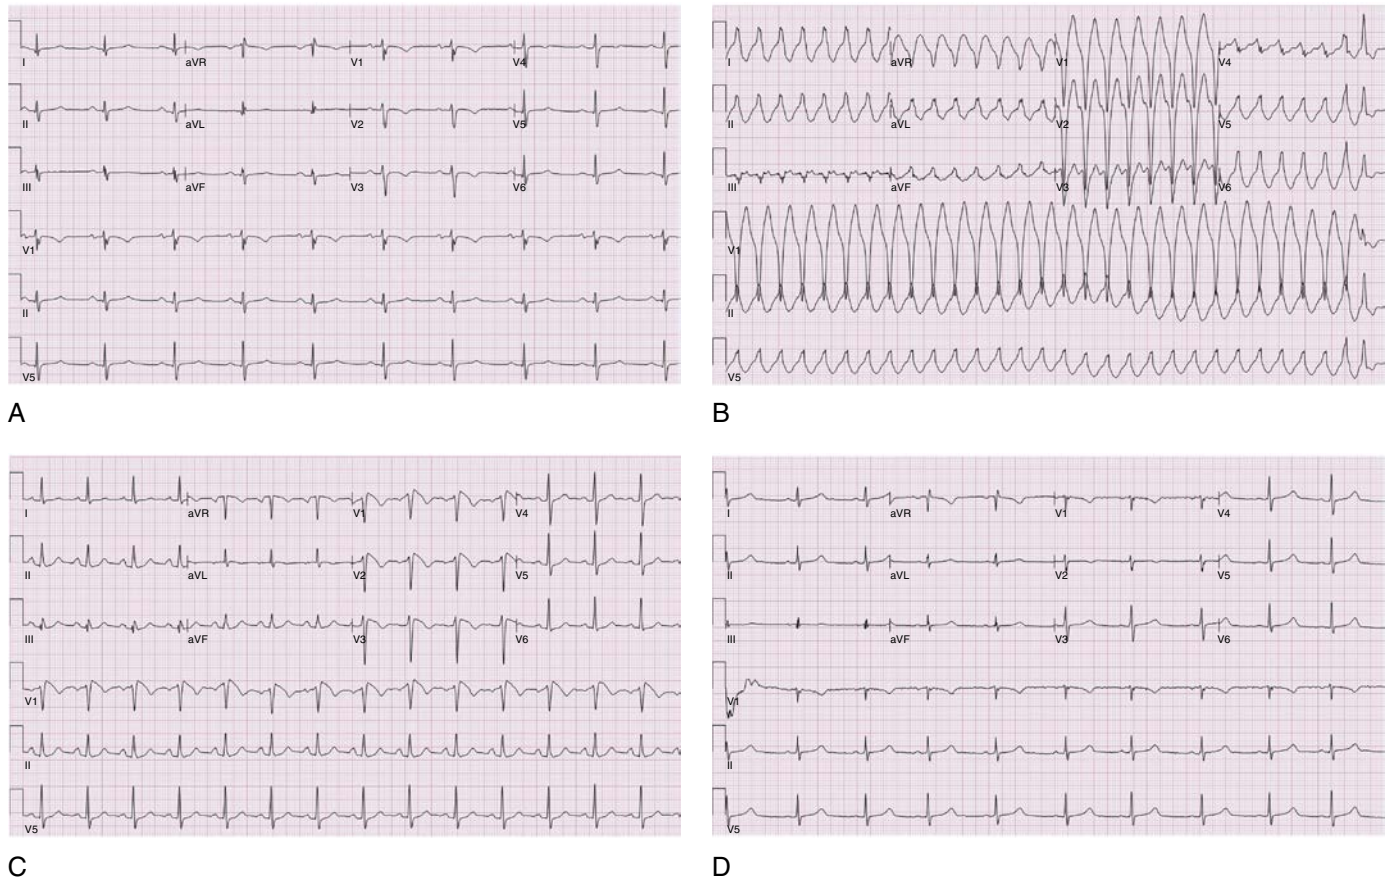

Fig. 9.10 Characteristic electrocardiograms associated with genetic disorders predisposing to SCD. (A) ARVC ECG demonstrating inverted T waves V_1 - V_3 during sinus rhythm. (B) Monomorphic ventricular tachycardia with left bundle branch block morphology characteristic of ARVC. (C) Type I Brugada ECG pattern with coving ST elevation and T inversion in V_1 - V_2 . (D) ECG from patient with hereditary LQTS, with mutation *KCNQ1*.

Patients in their third or fourth decade typically have palpitations, shortness of breath, and lightheadedness at presentation. Reports of cardiac arrest are rare, and treatment is directed at controlling symptoms. β -Blockers and calcium-channel blockers are often used initially, although some patients require catheter ablation or antiarrhythmic drug therapy. A subset of asymptomatic patients may develop tachycardia-mediated cardiomyopathy due to frequent ventricular ectopy. The PVC burden posing the greatest risk for producing left ventricular dysfunction is likely more than 10,000 PVCs daily. Fortunately, PVC suppression with catheter ablation usually improves ventricular function.

Arrhythmogenic Right Ventricular Cardiomyopathy or Dysplasia

Arrhythmogenic right ventricular cardiomyopathy (ARVC) is an inherited cardiomyopathy with typically autosomal dominant transmission. It is associated with mutations affecting desmosomes, which are molecular complexes of cell adhesion proteins that bind cardiac myocytes. Although morphologic changes in the RV free wall predominate, biventricular or primary left ventricular variants occur. Due to myocyte death, large portions of the right ventricle are replaced with adipose tissue, leading to wall motion abnormalities, cardiac dysfunction, and aneurysm formation. Structural changes spread from the epicardium to the endocardium. RV imaging classically demonstrates RV enlargement with focal wall motion abnormalities and RV hypokinesis. The RV free wall is not well imaged by routine cardiac echocardiography, and MRI has become the gold standard for the diagnosis of ARVC.

ARVC patients develop ventricular arrhythmias with associated symptoms, including palpitations, lightheadedness, syncope, and SCD. Given the typical RV origin of arrhythmias in ARVC, the ventricular arrhythmias have a left bundle branch morphology (Fig. 9.10B). The surface ECG during sinus rhythm may demonstrate inverted T waves in the V_1 to V_3 leads or epsilon waves, which are low-amplitude deflections at the end of the QRS complex in the right precordial leads resulting from slowed RV conduction (Fig. 9.10A).

Distinguishing ARVC from idiopathic RVOT VT is essential because of the different prognostic and therapeutic implications of the two diagnoses. The diagnosis of ARVC is established by the ARVC Task Force Criteria. Risk factors for SCD of ARVC patients include prior aborted episodes of SCD, syncope, young age, LV dysfunction, and markedly diminished RV function.

Patients with documented ARVC typically receive ICDs. Adjunctive therapy with antiarrhythmic drugs or ablation, particularly strategies incorporating combined epicardial and endocardial ablation, may be useful in treating symptomatic VT.

Congenital Long QT Syndrome

Congenital LQTS is a genetic disorder characterized by abnormal cardiac repolarization producing QT prolongation on the ECG (corrected QT [QTc] >440 milliseconds in men and >460 milliseconds in women) (Fig. 9.10D). It is a leading cause of SCD in the young.

Mutations in 16 genes that participate in cardiac repolarization have been identified in patients with LQTS. Mutations of *KCNQ1* (encodes

the α -subunit of the I_{Ks} potassium channel) produce LQT1; mutations of *KCNH2* (encodes the α -subunit of the I_{Kr} potassium channel) produce LQT2; and mutations of *SCN5A* (encodes the α -subunit of the cardiac sodium channel) cause LQT3. Together, they account for 75% of cases of congenital LQTS.

Decreased outward potassium currents or increased inward sodium currents prolong action potential duration, predisposing to early afterdepolarizations and TdP, a specific type of polymorphic VT. Symptoms typically begin during adolescence and include syncope, seizures, and SCD. The arrhythmia triggers in LQTS are gene specific. Patients with LQT1 are at risk during high adrenergic states, such as exercise; arrhythmias in LQT2 are triggered by sudden noises such as alarms; and LQT3 patients are more likely to experience arrhythmias during sleep. The autosomal dominant Romano-Ward variant has a prevalence of 1 case in 2000 live births.

Chronic treatment is directed at prevention of SCD. Initial therapy includes avoidance of QT-prolonging agents and initiation of β -blockers in symptomatic patients and asymptomatic patients with significant QT prolongation. ICDs are recommended after resuscitation from a cardiac arrest and for recurrent syncope despite β -blockade. The acute treatment of TdP is different from that of other forms of VT because many antiarrhythmic agents prolong the QT interval and should therefore be avoided.

Brugada Syndrome

The Brugada syndrome is a genetic disorder predisposing to polymorphic VT and SCD. The ECG characteristically displays coving ST elevation in the right precordial leads, V_1 to V_3 , and a right bundle branch block pattern (Fig. 9.10C). These electrocardiographic abnormalities may be dynamic, and they are characteristically exacerbated by fever and therapy that blocks sodium channels.

The syndrome is linked to mutations in *SCN5A*, which encodes the cardiac sodium channel. Mutations result in a reduction in the sodium current. The mode of transmission is autosomal dominant. Patients typically have syncope or cardiac arrest, often occurring during sleep.

Although quinidine, by virtue of its ability to block transient outward potassium current (I_{to}), may have a therapeutic role, there are no established medical therapies to prevent VT in Brugada syndrome. Intravenous β -adrenergic stimulation with isoproterenol or a similar agent, by virtue of its ability to augment the sodium current, is potentially useful in the acute management of recurrent VT or VF in Brugada syndrome. Paradoxically, because of a protective effect of catecholamine stimulation, β -blockers are potentially harmful in patients with Brugada syndrome and should be avoided.

ICDs represent the only proven therapy for prevention of cardiac arrest. ICD therapy is recommended for secondary prevention of SCD. For high-risk patients with a spontaneous Brugada electrocardiographic pattern and syncope, primary prevention with an ICD is indicated.

Catecholaminergic Polymorphic Ventricular Tachycardia

CPVT is a genetic disorder that alters myocardial calcium handling, resulting in exercise-induced polymorphic or bidirectional VT. Exercise-triggered syncope or SCD during childhood is the common presenting symptom. About 50% to 60% of patients have an inherited or sporadic autosomal dominant mutation affecting the cardiac ryanodine receptor gene (*RYR2*), producing abnormal calcium-induced calcium release from the sarcoplasmic reticulum and intracellular calcium overload.

β -Blockers along with exercise restriction represent the primary therapy, although arrhythmia breakthrough is common. ICD therapy may be used for secondary prevention, although ICD shocks can produce

catecholamine surges that may exacerbate the underlying arrhythmia. Left cardiac sympathetic denervation is useful in selected cases.

Acquired Long QT Syndrome

Environmental factors may prolong cardiac repolarization and produce QTc prolongation, leading to the development of early afterdepolarizations and TdP. Patients with acquired LQTS may have background genetics predisposing them to develop excessive QTc prolongation and polymorphic VT in response to electrolyte abnormalities (i.e., hypokalemia, hypomagnesemia, and hypocalcemia), bradycardia, and the use of QT-prolonging medications. Most QTc-prolonging drugs block the rapid component of the delayed rectifier potassium channel (I_{Kr}) encoded by the *KCNE2* gene. Drugs known to prolong the QTc interval are updated on an Internet registry. Therapy for acquired LQTS requires reversal of inciting physiologic factors and discontinuation of offending medications.

Genetic Testing for Channelopathies

Commercial laboratories offer genetic testing for congenital LQTS, Brugada syndrome, and CPVT. The yields of genetic testing vary from 25% for Brugada syndrome up to 80% for congenital LQTS. The limited sensitivity of current assays and the common finding of genetic variants of unknown significance represent ongoing challenges. Despite these considerations, cascade screening or screening of family members for a disease-causing mutation once characterized in a proband has been effectively used to identify mutation carriers.

Mutation-positive family members may benefit from prophylactic therapy. Reassurance for mutation-negative individuals is also valuable. Before ordering genetic testing, patients should be thoroughly informed of the risks, benefits, and limitations of testing. Genetic counselors ideally play an important advisory role.

For a deeper discussion on this topic, please see Chapter 59, "Ventricular Arrhythmias," in *Goldman-Cecil Medicine*, 26th Edition. ♦

SUMMARY

Cardiac arrhythmias are caused by disorders of action potential formation or propagation and are broadly categorized as abnormally slow rhythms (i.e., bradycardias) or abnormally rapid rhythms (i.e., tachycardias). The cardiac cellular action potential is composed of five phases determined by the activity of multiple ion channels, including the rapid sodium channel, several potassium channels, and a calcium current. Disruptions of these currents may lead to abnormal automaticity and triggered activity, which may mediate pathologic tachyarrhythmias. Reentry is the dominant mechanism of clinically significant tachyarrhythmias and requires a functional or fixed obstacle to propagation, an area of slowed conduction, and differential refractoriness for initiation and perpetuation of the arrhythmia.

Antiarrhythmic drugs are commonly divided into four broad groups using the Singh-Vaughan Williams classification. Despite its clinical utility, many antiarrhythmic drugs have multiple effects and do not fit neatly into this framework. Some, such as adenosine and digoxin, fall completely outside of it. Class I drugs slow membrane conduction by blockade of the sodium channel. Class II drugs, or β -blockers, function by blockade of the cardiac β -receptor. Class III drugs prolong repolarization and the QT interval. Class IV drugs block the slow calcium channel and are primarily active in slow-response myocytes such as the sinus and AV node.

All bradycardia is a consequence of impairment of sinus node function or AV conduction, or both. Sinus and AV nodal function is strongly influenced by autonomic tone. Parasympathetic tone dominates at rest, and significant bradycardia and second-degree

AV block may be observed in normal patients due to increased parasympathetic tone, especially during sleep or athletic training. Clinical sinus node dysfunction manifests as one of several syndromes, including sinus bradycardia, chronotropic incompetence, exit block, and bradycardia-tachycardia syndrome due to sinus pauses and bradycardia when concomitant atrial arrhythmias terminate to sinus rhythm.

AV conduction disturbances may occur at the AV nodal level or infranodal level. A block at the level of the AV node tends to be indolent, characterized by gradual progression and competent subsidiary escapes that usually protect the patient from catastrophic bradycardia. This permits asymptomatic patients to be followed clinically for the development of symptoms before intervention. In contrast, second- or third-degree infranodal block at the His bundle, or more commonly at the level of the bundle branches, is potentially malignant and is often not accompanied by stable escape mechanisms. If not managed appropriately, it can cause sudden death. Clues to an infranodal level of block are Mobitz II periodicity, associated bundle branch block, worsening heart block with tachycardia or exercise, and a wide QRS escape rhythm different from the conducted QRS in the setting of a high-degree or third-degree AV block.

Tachycardias are broadly categorized as SVTs, which depend on the atrium and AV conduction system, and ventricular arrhythmias, which depend on the ventricular myocardium. Supraventricular arrhythmias are further categorized as PSVTs, which depend on AV nodal conduction, and intra-atrial arrhythmias, which depend only on atrial tissue and not on AV conduction. The PSVTs include AVNRT and AV reciprocating tachycardia related to WPW syndrome. Intra-atrial arrhythmias include organized atrial arrhythmias, such as focal atrial tachycardia, atrial flutter, macro-reentrant atrial tachycardia, and AF, a common disorganized atrial arrhythmia. Recurrent atrial flutter and AF carry a risk of thromboembolism and, based on risk stratification, should be treated with antithrombotic therapy when appropriate. Catheter ablation has an important role in the management of all supraventricular arrhythmias but remains a second-line strategy for AF, for which success rates are lower and complication rates are higher than for other supraventricular arrhythmias.

Ventricular arrhythmias include isolated ventricular premature beats; short, nonsustained runs of tachycardia; and sustained

ventricular arrhythmias. Sustained VT lasts more than 30 seconds or requires intervention before then. It is classified as monomorphic if beats all share a single electrocardiographic morphology, polymorphic if the electrocardiographic morphology is variable, TdP when the morphology is variable and the arrhythmia is associated with pathologic QT prolongation, and VF when the surface ECG continuously varies without distinct QRS complexes. VT is poorly tolerated and is the major cause of cardiac arrest. Although commonly seen in the setting of ischemic heart disease, idiopathic VT may be seen in the absence of structural heart disease.

Antiarrhythmic drugs have not been effective in reducing the risk of SCD after MI. In contrast, ICDs have been shown to improve mortality rates for patients with impaired LV function after an MI and patients with heart failure and impaired LV function with or without coronary disease.

In addition to advanced structural heart disease as a cause for VT, several syndromes may result in VT in the absence of evident structural heart disease. They include the syndrome of idiopathic VT, ARVC, arrhythmogenic RV dysplasia, congenital LQTS, Brugada syndrome, and CPVT. Several of these conditions are familial, and genetic testing and family screening have important roles in their management.

Pericardial and Myocardial Disease

Jennifer L. Strande

PERICARDIAL DISEASE

The pericardium is a thin, fibrous sac that envelops the heart and consists of two layers: visceral and parietal. The space between these two layers contains a small amount of fluid (15 to 50 mL), which is a plasma ultrafiltrate. The pericardium has mechanical, immunologic, and anatomic barrier functions.

Due to a paucity of randomized trial data and absence of practice guideline statements, the recommendations for assessment and treatment of pericardial disorders in this chapter are largely based on expert opinion and professional consensus.

Acute Pericarditis

Definition and Epidemiology

Acute pericarditis or inflammation of the pericardium has several causes. The exact incidence of acute pericarditis is unknown because a subclinical course is common.

Pathology

About 85% of cases are from idiopathic or viral causes. Less commonly, infection (other than viral), uremia, trauma, metabolic disorders, autoimmune disorders, and neoplastic involvement can also cause pericarditis. Causes of acute pericarditis are listed in [Table 10.1](#).

Clinical Presentation

The classic manifestation of acute pericarditis is severe and sharp chest pain, which is often aggravated by a supine position, inspiration, and cough and relieved by sitting up and leaning forward. The pain is usually substernal and left precordial, and may radiate to the neck, shoulder, and scapular ridge, mimicking that of myocardial ischemia. Chest discomfort may be mild or absent in patients with connective tissue disorders, uremia, or neoplastic involvement. Patients may also have symptoms of low-grade fever, malaise, dyspnea, and less frequently, hiccups (i.e., phrenic nerve irritation).

In the absence of significant pericardial effusion, results of the inspection and palpation of the precordium are normal. A high-pitched, rasping pericardial friction rub is heard on cardiac auscultation in most patients with acute pericarditis. It may have three components corresponding to atrial contraction, ventricular systole, and early diastole, and it is best appreciated at end expiration with the patient leaning forward. It can be intermittent, and serial auscultation is recommended.

Diagnosis

The electrocardiographic (ECG) changes of acute pericarditis typically evolve over days to weeks. The early stage findings are characterized by diffuse ST segment elevation (i.e., concave upward) with upright T waves and PR depression. PR depression occasionally precedes the

ST segment elevation. Resolution of the ST elevations is followed by diffuse T wave inversion. These ECG changes are not always seen and serial tracings should be obtained.

The laboratory findings of acute idiopathic pericarditis are not specific and consist of mild elevation of the white blood cell count, sedimentation rate, and C-reactive protein level. If indicated, specific testing for tuberculosis, human immunodeficiency virus (HIV), thyroid disease, or autoimmune disorders is recommended. However, routine performance of viral serologic testing has limited utility. Elevation of serum cardiac biomarkers (e.g., creatine kinase, troponin) reflects involvement of the adjacent myocardium. In uncomplicated acute pericarditis, the chest radiograph and echocardiographic findings are normal. Although not essential for the diagnosis of pericarditis, echocardiography is the diagnostic imaging modality of choice for the detection and determination of the hemodynamic significance of a pericardial effusion.

Treatment

Patients with uncomplicated idiopathic or viral pericarditis can be managed as outpatients. For patients with fever, large pericardial effusions, or elevated levels of cardiac biomarkers and for those with possible secondary causes or immunocompromised status, hospitalization for further investigation and treatment should be considered. Treatment consisting of high-dose nonsteroidal anti-inflammatory drugs (NSAIDs) is usually effective. Colchicine with NSAIDs or as monotherapy provides prompt resolution of symptoms and decreases the recurrence rate. The use of glucocorticoids results in rapid symptomatic improvement. However, glucocorticoids are associated with higher rates of symptomatic recurrence.

Prognosis

Most patients with idiopathic or viral pericarditis have an uneventful clinical course with complete recovery. Possible complications include recurrent pericarditis, cardiac tamponade, and constrictive pericarditis.

Pericardial Effusion and Cardiac Tamponade

Definition and Epidemiology

Pericardial effusion, an abnormal collection of fluid in the pericardial space, is a relatively common and incidental echocardiographic finding that is encountered in approximately 10% of studies. Cardiac tamponade occurs when fluid accumulation results in increased intrapericardial pressure, leading to cardiac compression, impaired ventricular filling, and reduced cardiac output. Accumulation of pericardial fluid can be caused by virtually any type of acute pericarditis. Pericardial effusions due to bacterial pericarditis (including tuberculosis), neoplastic involvement, uremic pericarditis, and trauma have a high incidence of progression to tamponade.

TABLE 10.1 Causes of Pericarditis

Idiopathic
Infectious
Viral (echovirus, coxsackievirus, adenovirus, cytomegalovirus, hepatitis B virus, Epstein-Barr virus, human immunodeficiency virus)
Bacterial (<i>Staphylococcus</i> , <i>Streptococcus</i> , and <i>Mycoplasma</i> species; <i>Borrelia burgdorferi</i> , <i>Haemophilus influenzae</i> , <i>Neisseria meningitidis</i>)
Mycobacterial (<i>Mycobacterium tuberculosis</i> , <i>Mycobacterium avium-intracellulare</i>)
Fungal (<i>Histoplasma</i> and <i>Coccidioides</i> species)
Protozoal
Immune or inflammatory
Connective tissue disease (systemic lupus erythematosus, rheumatoid arthritis, scleroderma)
Arteritis (polyarteritis nodosa, temporal arteritis)
Late after myocardial infarction (Dressler syndrome), late postcardiotomy or thoracotomy
Drug induced
Procainamide, hydralazine, isoniazid, cyclosporine
Trauma or damage to adjacent structures
Penetrating trauma
Acute myocardial infarction, cardiac surgery, coronary angioplasty, implantable defibrillators, pacemakers
Pneumonia
Neoplastic disease
Primary: mesothelioma, fibrosarcoma, lipoma
Secondary (metastatic or direct extension): breast, lung, thyroid carcinoma, lymphoma, leukemia, melanoma
Radiation induced
Miscellaneous
Uremia
Hypothyroidism
Gout

Pathology

The hemodynamic consequences of a pericardial effusion depend on the rate of accumulation. The normal pericardium has relatively limited reserve volume. The mechanical properties of the parietal pericardium are such that when stretched, it becomes rapidly inelastic and resistant to further expansion. As a result, rapidly accumulating effusions may result in significant hemodynamic compromise with only 100 to 200 mL of fluid. Conversely, when the accumulation of fluid is slow, the pericardium undergoes adaptive changes and can accommodate large (>1500 mL) effusions without the development of tamponade.

Clinical Presentation

The clinical manifestations of a pericardial effusion depend on the size and rate of fluid accumulation and may range from dyspnea, chest discomfort, and orthopnea to circulatory collapse, pulseless electrical activity, and death. Compression of adjacent structures such as the phrenic nerve and the recurrent laryngeal nerve can result in cough or hiccups and hoarseness, respectively. Compression of the esophagus may cause dysphasia.

A normal cardiac examination is not uncommon in patients with small effusions. With larger effusions, the apical impulse can be decreased or absent, and the cardiac sound may be muffled. In patients with acute pericarditis, disappearance of the pericardial friction rub may indicate development of an effusion. Compression of the left lung base can result in dullness to percussion, egophony, and bronchial breath sounds under the left scapula (i.e., Ewart sign).

Patients with tamponade usually appear to be in distress with tachypnea and tachycardia. The classic physical findings include hypotension, jugular venous distention with an absent *y* descent, and muffled or absent heart sounds. Pulsus paradoxus, a characteristic physical finding, is defined as a greater than 10 mm Hg of inspiratory decline of the systolic blood pressure. This results from the inspiratory decrease of the left ventricular stroke volume and systemic blood pressure. Under normal conditions, the intrathoracic pressure decreases during inspiration, resulting in enhanced right ventricular filling and enlargement. In cases of cardiac tamponade, the total heart volume is fixed, and the right ventricular expansion displaces the interventricular septum toward the left ventricle, with consequent reduction of the left ventricular stroke volume and systemic hypotension. Pulsus paradoxus is not pathognomonic of cardiac tamponade and can be detected in severe chronic obstructive airway disease, pulmonary embolism, bronchial asthma, constrictive pericarditis, and hypovolemic shock.

Diagnosis

The ECG findings of moderate to large pericardial effusions include low-voltage QRS complexes and occasionally electrical (QRS) alternans caused by the heart's swinging motion within the fluid-filled pericardium. The chest radiograph demonstrates an enlarged cardiac silhouette. Transthoracic echocardiography, the imaging modality of choice, provides information regarding the size, location (circumferential vs. loculated), and most importantly, the hemodynamic consequences of the pericardial effusion suggesting tamponade.

The two-dimensional findings of tamponade include right atrial and right ventricular collapse, distention of the inferior vena cava, and evidence of increased ventricular interdependence (Fig. 10.1). Doppler quantification of the mitral and tricuspid inflow velocity respiratory variation is more sensitive than two-dimensional echocardiography for determining the hemodynamic significance of pericardial effusions. Right heart catheterization demonstrates decreased cardiac output, elevated right atrial pressure with diminished or absent *y* descent, and equalization of the cardiac filling pressures (i.e., right atrial, pulmonary wedge, and diastolic pulmonary artery pressures).

Computed tomography (CT) and magnetic resonance imaging (MRI) can accurately identify pericardial effusions and may be used along with echocardiography to assess for loculated effusions, pericardial thickening, and extracardiac structures. A diagnostic pericardiocentesis should be performed for evaluating for bacterial, tuberculous, or malignant causes.

Treatment

Routine drainage of pericardial effusions is unnecessary in the absence of hemodynamic compromise. Cardiac tamponade is a life-threatening emergency requiring urgent drainage of the pericardial effusion. Fluid resuscitation should be initiated to increase preload and filling of the cardiac chambers. Inotropic and vasopressor support has limited utility. Surgical drainage is appropriate and therapeutic for loculated, purulent, and tuberculous effusions and for tissue biopsy.

Fluid should be analyzed for pH, cell count, glucose, protein, cholesterol, triglycerides, and acid-fast bacilli by Gram stain, culture, cytology, and laboratory tests. For patients with chronic, recurring effusions, the surgical creation of a pleuropericardial window provides a long-term solution.

Prognosis

The underlying cause of the pericardial effusion and the availability of effective treatment determine the prognosis.

Fig. 10.1 Parasternal long axis echocardiographic views of the right ventricle in systole and diastole show right ventricular diastolic collapse (*arrow*) in a patient with a large, circumferential pericardial effusion. LV, Left ventricle; PE, pericardial effusion; RV, right ventricle.

Constrictive Pericarditis

Definition and Epidemiology

Pericardial constriction is caused by pericardial inflammation and is a condition characterized by a rigid, scarred pericardium that limits diastolic filling of the ventricles, resulting in increased intracardiac pressures. The most common causes are infection, prior cardiac surgery, trauma, and irradiation. Less common causes include connective tissue disorders, uremia, and neoplastic involvement of the pericardium. In developing countries, tuberculous pericarditis is a more common cause of pericardial constriction. Often a specific cause cannot be determined.

Pathology

Constriction is the end result of pericardial inflammation with scarring, fibrosis, calcification, and adhesion of the parietal and visceral layers of the pericardium. Although pericardial thickening is a usual pathologic finding, its absence does not exclude constriction.

Clinical Presentation

In the early stages, symptoms consist of dyspnea, fatigue, decreased exercise tolerance, and lower extremity edema. As the disease progresses, early signs and symptoms may be accompanied by ascites, anasarca, cachexia, and muscle wasting.

Physical examination reveals jugular venous distention with prominent *x* and *y* descents and an increase (or failure to decrease) of central venous pressure with inspiration (i.e., Kussmaul sign). The arterial blood pressure is usually normal, and pulsus paradoxus is absent in most patients. Ascites and hepatomegaly can be prominent with advanced disease. On cardiovascular examination, the apical impulse may be decreased, and the cardiac sounds muffled. An early diastolic sound (i.e., pericardial knock) corresponding to the abrupt cessation of early ventricular diastolic filling is pathognomonic of pericardial constriction, but it is not always detected.

Diagnosis

The diagnosis of pericardial constriction may be challenging and frequently requires the use of multiple imaging modalities. The electrocardiogram may display low QRS voltage, left atrial enlargement, and nonspecific T-wave changes. Atrial fibrillation occurs in one third of cases. The chest radiograph may reveal pleural effusions and pericardial calcification, which are best appreciated in the lateral projection.

Transthoracic echocardiography shows dilation of the inferior vena cava, abnormal interventricular septal motion, and pericardial thickening. Doppler echocardiography demonstrates abnormal respirophasic variations of the pulmonary and hepatic venous flow and mitral valve inflow. CT and MRI can accurately measure pericardial thickness.

Fig. 10.2 Pressure recordings from a patient with constrictive pericarditis. Simultaneous right ventricular and left ventricular pressure tracings show equalization of diastolic pressure and dip-and-plateau morphology. LV, Left ventricle; RV, right ventricle.

Cardiac catheterization is essential in the diagnosis of pericardial constriction and differentiation from restrictive cardiomyopathy (RCM). The right atrial pressure tracing shows prominent *x* and *y* descents with equalization of the end-diastolic atrial and ventricular pressures. The ventricular pressure tracings show a rapid early diastolic filling of the ventricles, with abrupt cessation in middle and end diastole due to the finite volume of the rigid pericardium (i.e., dip-and-plateau morphology or the square root sign) (Fig. 10.2). Enhanced ventricular interdependence demonstrated by simultaneous measurement of right and left ventricular pressures during respiration is a more specific finding of pericardial constriction.

Treatment

Medical therapy with sodium restriction and diuretics is of limited efficacy and is only appropriate in patients who are not surgical candidates due to comorbidities. Pericardiectomy is the only definitive treatment for constrictive pericarditis.

Prognosis

Pericardiectomy is associated with substantial operative risk that depends on the extent of cardiac involvement and existence of comorbid conditions. Successful pericardial resection leads to resolution of the symptoms of constriction over a period of weeks to months. For patients who are not surgical candidates, the prognosis is poor.

Effusive Constrictive Pericarditis

Effusive constrictive pericarditis is characterized by a pericardial effusion and a noncompliant or fibrotic parietal and visceral pericardium. Although it may result from any type of pericardial inflammation, it is usually seen after cardiac surgery or radiation injury. It likely represents a transition stage between acute pericarditis with effusion and pericardial constriction. It shares the clinical and hemodynamic features of both conditions.

Typically, drainage of the effusion does not result in resolution of symptoms, and the central venous and right atrial pressures remain elevated. In the early stage of the disease, patients may respond to prolonged treatment with NSAIDs. However, visceral and parietal pericardiectomy is often required. For a deeper discussion of this topic, please see Chapter 68, “Pericardial Diseases,” in *Goldman-Cecil Medicine*, 26th Edition.

DISEASES OF THE MYOCARDIUM

Myocarditis

Definition and Epidemiology

Myocarditis is an inflammation of the myocardium caused by a variety of toxins, medications, and viruses. Viral myocarditis, which accounts for about 20% of cases of dilated cardiomyopathy (DCM), is commonly caused by the enteroviruses, specifically Coxsackie group B serotypes and, less commonly, adenoviruses, parvovirus B19, hepatitis C virus, cytomegalovirus, and HIV.

Other causes include bacterial infections such as diphtheria, brucellosis, clostridial infections, legionnaires disease, and meningococcal, streptococcal, and *Mycoplasma pneumoniae* infections. Q fever, Rocky Mountain spotted fever, spirochetal infections (e.g., leptospirosis, Lyme disease), fungal infections, and parasitic infections (e.g., *Trypanosoma cruzi* [Chagas' disease]) are also known causes of myocarditis.

Pathology

The pathogenesis of viral myocarditis is thought to begin with direct viral invasion of the myocardium and subsequent immunologic activation. Normal cellular and antibody-mediated immune responses lead to viral clearing and myocardial healing. However, a few patients go on to develop DCM and heart failure due to an abnormal immune response that furthers myocardial damage. The exact mechanisms are unknown, but they involve cytokines, autoantibodies, and possibly other processes associated with persistent, low-level viral replication in myocytes, leading to myocyte atrophy, myocyte apoptosis, and adverse remodeling of the ventricles. In nonviral infections, the damage is attributed to the bacterial toxins or abnormal immune responses, and in parasitic infections, it is largely immune mediated.

Multiple chemicals and drugs can lead to myocardial inflammation by direct effect or as part of a hypersensitivity reaction. Some of the common causes include cocaine, chemotherapeutics (e.g., daunorubicin, doxorubicin), and antibiotics.

Giant cell myocarditis is a rare disorder of uncertain origin, but it can be rapidly fatal. It is usually associated with ventricular arrhythmias and progressive, severe heart failure. Multinucleated giant cells seen on myocardial biopsy are pathognomonic.

Clinical Presentation

The clinical manifestations range from asymptomatic ECG abnormalities to cardiogenic shock. Patients report heart failure symptoms, including exercise intolerance, shortness of breath, fluid retention, and persistent fatigue. In the setting of viral myocarditis, they often report a viral prodrome, including fever, myalgia, fatigue, respiratory symptoms, or gastroenteritis that precedes the heart failure symptoms.

Patients are often tachycardic and hypotensive. They may have an elevated jugular venous pressure, S₃ gallop, crackles, and peripheral edema. Myocarditis can masquerade as an acute coronary syndrome.

Diagnosis

Testing is performed to determine a possible infectious cause. Rising viral titers are often seen in cases of viral myocarditis. Serum cardiac enzymes (e.g., troponin, creatine kinase) are measured when myocarditis is suspected. Sinus tachycardia and nonspecific ST- and T-wave abnormalities are common ECG findings. When the pericardium is also involved by the inflammatory process, diffuse ST-segment elevations typical for acute pericarditis are also seen. Ventricular ectopy is common, and atrioventricular conduction defects are seen in myocarditis associated with Lyme disease.

Echocardiography is recommended in the initial diagnostic evaluation to identify ventricular remodeling, including increasing chamber size and ventricular systolic dysfunction. Cardiac MRI is a promising technique to detect myocardial inflammation and injury based on small, observational clinical studies.

Transvenous endomyocardial biopsy should be performed only when there is rapid deterioration of the clinical condition. Histopathologic abnormalities such as infiltrating white cells (i.e., macrophages, lymphocytes, and eosinophils), evidence of myocardial damage, and interstitial fibrosis help to establish acute myocarditis, but the determination is subject to significant intraobserver and interobserver variability. Often the biopsy does not provide a conclusive diagnosis. The endomyocardial biopsy is helpful in diagnosing giant cell myocarditis (i.e., multinucleated giant cells are seen) or hypersensitivity myocarditis (i.e., eosinophilic infiltrate is seen). Polymerase chain reaction testing can detect specific viral genomes in the myocardium.

Treatment

Supportive care is the mainstay of treatment. A few patients with fulminant or acute myocarditis require an intensive level of hemodynamic support and aggressive pharmacologic intervention similar to that for patients with advanced heart failure.

After initial hemodynamic stabilization, treatment should follow current American College of Cardiology and American Heart Association (ACC/AHA) recommendations for the management of left ventricular systolic dysfunction. Treatment includes β -adrenergic blockers, angiotensin-converting enzyme inhibitors, aldosterone receptor blockers, and diuretics.

No evidence-based guided therapy for viral myocarditis has been established. Clinical trials of various forms of antiviral or immunosuppressive therapy (e.g., prednisone, cyclosporine, azathioprine, intravenous immunoglobulin, interferon immunoadsorption) have not resulted in conclusive evidence of benefit. Treatment of nonviral myocarditis is aimed at eradication of the specific infectious agent. For Chagas' disease, treatment with antiprotozoal therapy, if initiated early in the course of infection, may be beneficial.

Hypersensitivity myocarditis and myocarditis associated with toxins respond to withdrawal of the offending agent. Immunosuppressive therapy has been effective in giant cell myocarditis.

Prognosis

The diverse clinical presentations and causes of myocarditis have limited the understanding of its natural history. It is thought that one third of the patients fully recover, one third of the patients have some sequelae in the form of left ventricular systolic dysfunction but are stable on medical therapy, and one third of patients progress to advanced heart failure. Patients who progress to chronic DCM have 5-year survival rates of less than 50%.

TABLE 10.2 Cardiomyopathies

Disorder	Description and Cause
Dilated cardiomyopathy	Dilation and impaired systolic function of the left or both ventricles
Familial (genetic)	Known or unknown genetic mutations
Nonfamilial	Viral myocarditis, nonviral infective myocarditis, idiopathic (immune) myocarditis Toxins (drugs, alcohol) Pregnancy (peripartum cardiomyopathy) Nutritional (thiamine deficiency [beriberi], vitamin C deficiency [scurvy], selenium deficiency) Endocrine (diabetes mellitus, hyperthyroidism, hypothyroidism, hyperparathyroidism, pheochromocytoma, acromegaly) Autoimmune (rheumatoid arthritis, systemic lupus erythematosus, dermatomyositis) Tachycardia induced
Hypertrophic cardiomyopathy	Left and/or right ventricular hypertrophy, often asymmetrical (usually more prominent hypertrophy of the interventricular septum)
Familial (genetic)	Mutations of sarcomeric proteins (several hundred described) Metabolic storage diseases of the myocyte
Restrictive cardiomyopathy	Restrictive filling of the ventricles; ventricles are usually small, atria are markedly enlarged
Familial (genetic)	Mutations of sarcomeric proteins Familial amyloidosis (transthyretin, apolipoprotein) Hemochromatosis Desminopathy, pseudoxanthoma elasticum, glycogen storage diseases Unknown genetic mutations
Nonfamilial	Amyloidosis, sarcoidosis, carcinoid, scleroderma Endomyocardial fibrosis (hypereosinophilic syndrome, idiopathic, chromosomal defect, drugs) Radiation, metastatic cancer, anthracycline toxicity
Arrhythmogenic right ventricular	Progressive fibrofatty replacement of the right and, to a lesser degree, left ventricular cardiomyopathy
Familial	Unknown gene mutation Mutations of intercalated disk protein, cardiac ryanodine receptor, transforming growth factor- β 3
Unclassified Cardiomyopathies	
Takotsubo (stress-induced) cardiomyopathy	Transient dilation and dysfunction of the distal parts of the left ventricle (apical ballooning) in the setting of a stressful situation; usually resolves within weeks
Left ventricular noncompaction	Characterized by prominent left ventricular trabeculae and deep intertrabecular recesses; familial in most cases, caused by arrest in the normal embryogenesis of the heart; apex and periapical regions of the left ventricle most affected; some patients remain asymptomatic, but others develop left ventricular dilation and systolic dysfunction
Cardiomyopathies associated with muscular dystrophies and neuromuscular disorders	Duchenne-Becker muscular dystrophy, Emery-Dreifuss muscular dystrophy, myotonic dystrophy, Friedreich's ataxia, neurofibromatosis, tuberous sclerosis
Ion channelopathies	Disorders caused by mutations in genes encoding ionic channel proteins; not considered cardiomyopathies because they are not associated with typical structural changes of the heart but rather manifest with electrical dysfunction; some classifications include these disorders as cardiomyopathies: long QT syndrome, short QT syndrome, Brugada syndrome, catecholaminergic polymorphic ventricular tachycardia

Cardiomyopathies

Cardiomyopathies are a heterogeneous group of diseases in which the major structural abnormality is limited to the myocardium. The four main cardiomyopathic groups are dilated, hypertrophic, restrictive, and arrhythmogenic right ventricular cardiomyopathy. Atrophic cardiomyopathy is a newer recognized group. Familial (genetic) and nonfamilial (acquired) forms of the diseases have been described.

Dilated Cardiomyopathy

Definition and epidemiology. Cardiac enlargement and systolic dysfunction in DCM result from a wide spectrum of genetic, inflammatory, toxic, and metabolic causes (Table 10.2), although most cases are idiopathic. Abnormal loading conditions such as hypertension, valvular disease, or coronary artery disease can lead to similar structural and functional changes; these conditions are not considered to be part of the DCM group and are discussed elsewhere.

Most cases are thought to result from acute viral myocarditis, a process described earlier. Exposures to cardiac toxins such as chemotherapeutic

agents, alcohol, cocaine, and radiation, along with deficiency of nutrients such as thiamine (causes beriberi), vitamin C (causes scurvy), carnitine, selenium, phosphate, and calcium, can cause DCM. Peripartum cardiomyopathy is a rare cause of DCM that can develop during the last month of pregnancy and up to 6 months after delivery. The pathogenesis of this peripartum cardiomyopathy is not completely understood, and it is a diagnosis of exclusion. Risk factors include older maternal age, being African American, and having multiple pregnancies. Prolonged periods of supraventricular or ventricular tachycardia can lead to idiopathic DCM (i.e., tachycardia-induced cardiomyopathy). The structural and functional changes usually reverse after the rapid heart rhythm is controlled.

Familial forms of DCM may be responsible for 20% to 30% of cases. Specific mutations involve genes that encode proteins of the sarcomere, cytoskeleton, nuclear membrane, and mitochondria; many mutations remain unknown. The mode of inheritance is typically autosomal dominant, but it can be an X-linked or mitochondrial pattern.

Pathology. Marked enlargement of all four cardiac chambers is typical of DCM, although the disease sometimes is limited to the left

or right chambers. The dilation is out of proportion to the ventricular thickness. Histology reveals evidence of myocyte degeneration with irregular hypertrophy and atrophy of myofibers with often extensive interstitial and perivascular fibrosis.

Clinical presentation. DCM usually manifests with symptoms of heart failure such as fatigue, weakness, dyspnea, and edema. In some patients, the presenting episode is related to arrhythmia or an embolic event. On physical examination, signs of decreased cardiac output are often found, including cool extremities, narrow pulse pressure, and tachycardia. The cardiac examination reveals a laterally displaced apex. An S_3 gallop is common, along with murmurs of mitral and tricuspid regurgitation. Pulmonary edema manifests as auscultatory crackles over the lung fields, and breath sounds may be diminished if there are pleural effusions. In some patients, the clinical features of right ventricular heart failure may predominate, with jugular venous distention, hepatomegaly, ascites, and peripheral edema.

Diagnosis. Standard diagnostic procedures include a chest radiograph, an electrocardiogram, serum markers, and echocardiography. The radiograph shows cardiomegaly, pulmonary venous congestion, and pleural effusions. The electrocardiogram may reveal enlargement of the heart chambers along with other nonspecific ST- and T-wave abnormalities. Serum B-type natriuretic peptide (BNP) levels are elevated.

Echocardiography provides a comprehensive evaluation of ventricular size and function and valvular function, and it can show a ventricular thrombus. Similar information can be obtained with MRI.

A complete work-up should rule out ischemic, valvular, and hypertensive heart disease as the cause of myocardial dysfunction, and it should include evaluation for potentially reversible causes of DCM (e.g., alcohol, nutritional deficiencies). Myocardial biopsy may be considered if the cause of DCM is in question. In patients with a strong family history, a referral for genetic testing should be considered.

Treatment. Potential reversible causes of DCM should be addressed (e.g., alcohol cessation, correction of nutritional deficiencies, removal of cardiotoxic agents). Treatment should follow current ACC/AHA recommendations for the management of left ventricular systolic dysfunction and include β -adrenergic blockers, angiotensin-converting enzyme inhibitors, aldosterone receptor blockers, and diuretics.

Patients with idiopathic DCM who have persistent, moderate to severe symptoms of heart failure and a QRS duration longer than 120 milliseconds may benefit from cardiac resynchronization therapy with a biventricular pacemaker. Survival of patients with a left ventricular ejection fraction less than 35% despite maximal medical management is improved with the use of implantable cardioverter-defibrillators (ICDs). Patients with limiting heart failure symptoms despite use of the previously described therapies may be considered for heart transplantation or support with a left ventricular assist device.

Prognosis. The prognosis of patients with DCM depends on the response to medical therapy. Some patients have a significant improvement in symptoms and cardiac function, but in others, the disease is progressive and associated with a high mortality rate.

Hypertrophic Cardiomyopathy

Definition and epidemiology. Hypertrophic cardiomyopathy (HCM) is a disease state characterized by left ventricular hypertrophy with nondilated ventricular chambers in the absence of an apparent cause for hypertrophy (e.g., hypertensive disease, aortic stenosis). This is a relatively common genetic disease (1 case in 500 people in the general population) with autosomal dominant inheritance, although spontaneous mutations have been described. More than 1400 mutations identified among at least eight genes encoding proteins of the cardiac sarcomere have been described, with mutations of the β -myosin heavy chain being the most common.

Pathology. The main pathophysiologic abnormalities seen in HCM are left ventricular outflow obstruction, diastolic dysfunction, mitral regurgitation, and arrhythmias. Obstruction of left ventricular outflow occurs in roughly one half of the patients. During systole, the hypertrophied septum bulges into the left ventricular outflow tract, creating a gradient between the lower part of the left ventricular cavity and the left ventricular outflow. This causes high-velocity turbulent flow through the narrowed path, which results in a suction force (i.e., Venturi effect) that pulls the anterior leaflet of the mitral valve into the outflow tract. This worsens the obstruction and causes mitral regurgitation. Diastolic dysfunction from impaired relaxation properties of the abnormal myocardium causes marked elevation of left ventricular filling and pulmonary venous pressures, pulmonary congestion, and limitation in cardiac output. Patients with HCM are also predisposed to supraventricular and ventricular arrhythmias.

Clinical presentation. HCM is a heterogeneous cardiac disease with a diverse course and clinical manifestations. Most patients probably do not suffer sequelae from this disease during their lifetimes. When the disease does result in complications, there are three relatively discrete but not mutually exclusive clinical manifestations: sudden cardiac death due to unpredictable ventricular tachyarrhythmia, most commonly in young asymptomatic patients (<35 years of age); heart failure characterized by exertional dyspnea (with or without chest pain) that may progress despite preserved systolic function and sinus rhythm; and atrial fibrillation that associates with various degrees of heart failure.

Heart failure symptoms result from the dynamic obstruction to left ventricular outflow and diastolic dysfunction. The most frequent symptom is dyspnea on exertion, followed by ischemic chest pain due to the increased oxygen demand by the hypertrophied ventricle and elevated wall tension that reduces blood flow to the subendocardium. Abnormalities of the structure of small myocardial arteries in HCM can contribute to myocardial ischemia. Presyncope or syncope can result from outflow tract obstruction and an inability to increase cardiac output during exertion or from arrhythmias that can be triggered by exertion. In some, sudden death caused by ventricular arrhythmia is the initial manifestation of the disease.

Physical examination findings include pulsus bisferiens, a brisk initial upstroke in pulse followed by a midsystolic dip corresponding to the development of left ventricular outflow tract obstruction, followed by another rise in late systole. Cardiac examination may reveal a forceful and sustained apical impulse, an audible S_4 gallop, and a harsh crescendo-decrescendo systolic murmur best heard along the left sternal border with radiation to the base of the heart.

Patients may also have an apical holosystolic murmur of mitral regurgitation. The intensity of the murmur of HCM varies with changing degrees of obstruction. This can be observed with physiologic or pharmacologic maneuvers that change preload (i.e., left ventricular filling) or contractility. The intensity of the murmur increases with a Valsalva maneuver, with assuming a standing position, and after administration of nitroglycerin or inotropic drugs. The intensity of the murmur decreases with squatting, volume loading, and administration of β -blockers.

Diagnosis. Clinical diagnosis is made most commonly with echocardiography and increasingly with cardiac MRI. The diagnosis is based on a maximal left ventricular wall thickness of 15 mm or more; a wall thickness of 13 to 14 mm is considered borderline. The diagnosis can be made in the setting of other compelling information (e.g., family history of HCM). Genetic testing is available to confirm the diagnosis and to screen family members.

Treatment. The ACC/AHA hypertrophic cardiomyopathy guideline recommends tailored therapy based on the individual patient. For

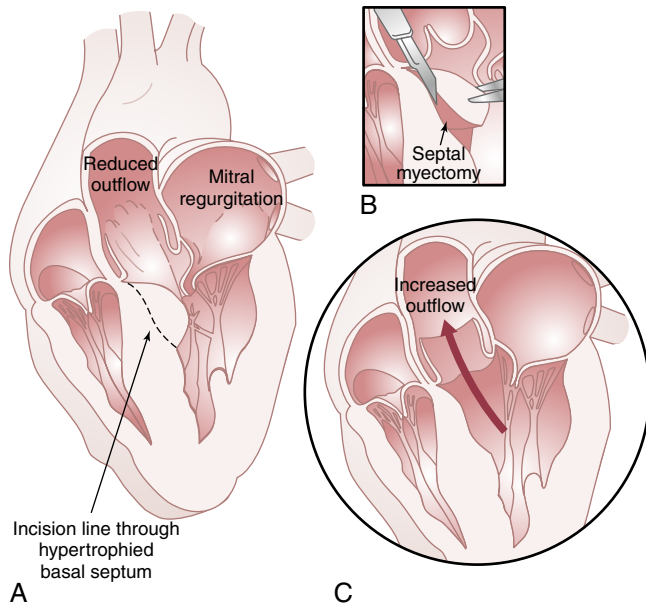

Fig. 10.3 (A to C) Schematic diagrams of a septal myectomy. (From Nishimura RA, Holmes DR Jr: Clinical practice: hypertrophic obstructive cardiomyopathy, *N Engl J Med* 350:1320-1327, 2004.)

asymptomatic patients, the usefulness of β -blockade and verapamil may be considered. For patients symptomatic with dyspnea or angina, β -blockers and verapamil are recommended. If patients remain symptomatic, it is reasonable to add disopyramide to a β -blocker or verapamil.

Nonpharmacologic therapies should be considered in patients with considerable symptoms despite medical management. Septal reduction therapy is recommended only for patients with severe drug-refractory symptoms and left ventricular outflow tract obstruction (Fig. 10.3). Use of ICD therapy for prevention of sudden death is guided by the perceived risk for ventricular arrhythmias in individual patients. Some of the characteristics that have been associated with this risk are prior cardiac arrest or sustained ventricular tachycardia; great (>30 mm) ventricular wall thickness; syncope, especially if exertional or recurrent; and a first-degree relative with sudden cardiac death. Certain genotypes appear to convey an increased risk of sudden cardiac death. Patients with HCM should be excluded from most competitive sports and should avoid strenuous exercise.

Prognosis. The clinical course of HCM varies. Sudden cardiac death is the leading cause of mortality. Heart failure symptoms may gradually progress and patients who are unresponsive to conventional therapy may require heart transplantation.

Restrictive Cardiomyopathies

Definition and epidemiology. RCM is an uncommon form of cardiomyopathy characterized by impaired ventricular filling of nondilated ventricles. RCM can be genetic or acquired. Causes include infiltrative disorders (e.g., amyloidosis, sarcoidosis, Gaucher's disease, Hurler's syndrome, fatty infiltration), storage diseases (e.g., hemochromatosis, Fabry's disease, glycogen storage disease), other disorders (e.g., hyper eosinophilic syndrome, carcinoid heart disease), drugs (e.g., serotonin, methysergide, ergotamine), and cancer treatment (e.g., irradiation, chemotherapy).

Pathology. In the purest form of the disease, the atria are disproportionately dilated compared with the normal ventricular size, and the left ventricle has normal or near-normal systolic function

in the absence of hypertrophy. Histology is normally nondistinctive and can reveal normal findings or nonspecific degenerative changes, including myocyte hypertrophy, disarray, and degrees of interstitial fibrosis.

Clinical presentation. Patients often have symptoms and signs of pulmonary and systemic congestion. The most common symptoms include dyspnea, palpitations, fatigue, weakness, and exercise intolerance due to poor cardiac output. As central venous pressure continues to increase in advanced cases, there may be hepatosplenomegaly, ascites, and anasarca. The chest radiograph shows atrial enlargement, pulmonary venous congestion, and pleural effusions.

Diagnosis. The diagnosis of RCM should be considered for patients with predominantly right ventricular heart failure without evidence of cardiomegaly or systolic dysfunction. The correct diagnosis often is not made until months or years after symptom onset. Constrictive pericarditis can mimic RCM and establishing the correct diagnosis can be challenging. Distinctive features of the two disorders are described in Table 10.3.

Treatment. Treatment of RCM focuses on alleviating the symptoms of heart failure. Diuretics are used for decongestion, but intravascular depletion may compromise ventricular filling and lead to reduced cardiac output and hypotension. Supraventricular tachyarrhythmias are poorly tolerated. In patients with conduction system disease such as advanced atrioventricular block, a permanent pacemaker may be indicated. Specific therapies for underlying disorders include chemotherapy in amyloidosis, phlebotomy and iron chelation therapy in hemochromatosis, and steroids in sarcoidosis and endomyocardial fibrosis.

Prognosis. The course of RCM depends on the pathology, and treatment is often unsatisfactory. In the adult population, the prognosis usually is poor, with progressive deterioration and death due to low-output heart failure.

Arrhythmogenic Right Ventricular Cardiomyopathy

Definition and epidemiology. Arrhythmogenic right ventricular cardiomyopathy (ARVC) is an autosomal dominant disease characterized by specific myocardial pathology. The estimated prevalence of ARVC is about 1 case in 2000 to 5000 people, and it has a male predominance.

Pathology. The myocardium of the right ventricular free wall is progressively replaced by fibrous and adipose tissue. Right ventricular function is abnormal, with regional akinesis or dyskinesis or global right ventricular dilation and dysfunction.

Clinical presentation. The disease typically manifests in young adults as palpitations, dizziness or syncope, or sudden cardiac death. Symptoms of right ventricular failure are rare, despite evidence of right ventricular dysfunction on imaging studies.

Diagnosis. The clinical diagnosis of ARVC is suggested by integration of the information from the clinical presentation (e.g., arrhythmias), electrocardiogram, family history, and imaging studies. When available, histologic examination of the right ventricle confirms the diagnosis. The resting electrocardiogram may be normal, but common abnormalities include incomplete or complete right bundle branch block, the so-called epsilon waves that follow the QRS complex, and inverted T waves in the precordial leads. Right ventricular dilation and systolic dysfunction can be seen with echocardiography and MRI. The latter modality can also show myocardial fat.

Treatment. Treatment consists of ICD therapy to prevent sudden cardiac death, but the indications for implantation are not well defined. Antiarrhythmics and radiofrequency ablation of ventricular tachycardia are used in patients with frequent arrhythmias, but they have not been shown to reduce the risk of sudden cardiac death.

TABLE 10.3 Differentiation of Restrictive Cardiomyopathy From Constrictive Pericarditis

Type of Evaluation	Restrictive Cardiomyopathy	Constrictive Pericarditis
Physical examination	Kussmaul sign present Apical impulse may be prominent Regurgitant murmurs are common	Kussmaul sign may be present Apical impulse usually not palpable Pericardial knock may be present
Electrocardiography	Low QRS voltage (especially in amyloidosis) Pseudoinfarction pattern Bundle branch blocks AV conduction disturbances Atrial fibrillation	Low QRS voltage Repolarization abnormalities
Chest radiography		Calcification of the pericardium may be present
Echocardiography	Marked enlargement of the atria Increased wall thickness (especially in amyloidosis)	Atria usually of normal size Normal wall thickness Pericardial thickening may be seen
Doppler echocardiography	Restrictive mitral inflow (dominant E wave with short deceleration time) No significant variation (<10%) of transvalvular velocities with respiration Reversal of forward flow in hepatic veins during inspiration	Restrictive mitral inflow (dominant E wave with short deceleration time) Increased velocity of RV filling and decreased velocity of LV filling with inspiration; opposite with expiration; variation in velocity exceeds 15% Reversal of forward flow in hepatic veins during expiration
Cardiac catheterization	Prominent atrial x and y descents (w sign) Dip-and-plateau appearance of ventricular diastolic pressure Diastolic pressures increased but not equalized; LV diastolic pressure higher than RV diastolic pressure	Prominent atrial x and y descents (w sign) Dip-and-plateau appearance of ventricular diastolic pressure Increase and equalization of diastolic pressures Discordance of RV and LV peak systolic pressures (with inspiration, RV systolic pressure increases and LV systolic pressure decreases)
Endomyocardial biopsy	May reveal specific cause of restrictive cardiomyopathy	No specific findings on endomyocardial biopsy Pericardial biopsy may reveal abnormality
Computed tomography, magnetic resonance imaging		Pericardial thickening

AV, Atrioventricular; LV, left ventricular; RV, right ventricular.

Patients with a probable or definite diagnosis of ARVC should be excluded from competitive sports.

Prognosis. The prognosis for these patients remains uncertain.

Unclassified Cardiomyopathies

Some cardiomyopathies that do not fit the current categories are described in Table 10.2.

CARDIAC DISEASE IN PREGNANCY

Pregnancy is associated with dramatic changes in the cardiovascular system that may result in significant hemodynamic stress to the patient with underlying heart disease. During a normal pregnancy, plasma volume increases an average of 50%, beginning in the first trimester and peaking between the 20th and 24th weeks of gestation. This change is accompanied by increases in stroke volume, heart rate, and, accordingly, cardiac output. In addition, a concomitant fall in systemic vascular resistance and mean arterial pressure occurs because of the effects of gestational hormones on the vasculature and the creation of a low-resistance circulation in the pregnant uterus and placenta. During labor, uterine contractions result in a transient increase of up to 500 mL of blood in the central circulation, resulting in further increases in stroke volume and cardiac output. After delivery, intravascular volume and cardiac output increase further as compression of the inferior vena cava by the gravid uterus is relieved and extravascular fluid is mobilized. The American Heart Association guidelines for the prevention of cardiovascular disease in women identified pregnancy complications as risk factors for cardiovascular disease in women. Hypertensive disorders of pregnancy and gestational diabetes mellitus are independently associated with increased 10-year cardiovascular risk.

Most women with cardiovascular disease can complete a pregnancy and delivery with proper follow-up. While cardiac disease may sometimes be manifested for the first time in pregnancy, the symptoms and signs that may mimic cardiac disease often accompany the usual hemodynamic changes of pregnancy, including fatigue, reduced exercise tolerance, lower-extremity edema, distention of the neck veins, S₃ gallop, and new systolic murmurs. Differentiating symptoms produced by cardiac disease from those attributable to a normal pregnancy can be difficult. Under such circumstances, echocardiography can be a safe and helpful noninvasive test to assess cardiac structure and function in the pregnant patient.

Certain cardiac conditions, including pulmonary hypertension, cardiomyopathy, valvular heart disease and connective tissue disorders including Marfan syndrome with a dilated aortic root, are associated with a high risk for cardiovascular complications and maternal death and require special consideration and counseling. The risk for cardiac complications during pregnancy depends on the maternal conditions as summarized in [Table 11.1](#).

Specific Cardiac Conditions

Valvular Heart Disease

Due to the declining incidence of rheumatic heart disease in Western countries, valvular heart disease is infrequent in North America but remains prevalent in developing countries. Bicuspid aortic stenosis and mitral stenosis are the most common valvular diseases encountered during pregnancy. When aortic stenosis complicates pregnancy, it is

usually secondary to a congenital bicuspid aortic valve whereas mitral stenosis is the most common rheumatic valvular disease encountered during pregnancy. These valvular conditions tend to worsen during pregnancy due to the increased cardiac output and tachycardia. Congestive heart failure may develop as the pregnancy progresses and may be worsened by the onset of atrial fibrillation. Careful echocardiographic assessment is recommended, and the cornerstone of therapy for the symptomatic patient is β -blockade. In patients with symptoms refractory to medical therapy aortic balloon valvuloplasty for aortic stenosis or mitral balloon valvotomy for mitral stenosis can be considered. Mitral and aortic regurgitation are usually well tolerated in pregnancy provided the regurgitation is no more than moderate in severity, the woman is symptom-free before pregnancy, and the left ventricular function is normal.

Prosthetic valves. When selecting a prosthetic valve for women of childbearing age, careful consideration has to be made with regards to the type of valve. Mechanical valves have greater longevity but routinely involve the use of warfarin, which is associated with a higher chance of fetal loss, placental hemorrhage, and prosthetic valve thrombosis. Tissue valves are less thrombogenic but tend to degenerate after an average of 10 years, necessitating a re-operation, which carries certain operative risks including mortality.

There is no universal consensus on the management of a pregnancy when the mother has a mechanical valve prosthesis. Prepregnancy counseling should include a detailed discussion of the risks to the patient. During pregnancy, increased platelet adhesiveness, increased concentration of clotting factors, and decreased fibrinolysis increase the risk of maternal valve thrombosis and thromboembolism. Unfractionated heparin, used subcutaneously or intravenously, is begun in the first trimester, as soon as pregnancy is diagnosed, to minimize fetal exposure to the teratogenic effects of warfarin. It is usually continued until week 13 or 14 of pregnancy, when fetal embryogenesis is complete, after which warfarin is resumed. Continuing heparin throughout pregnancy has been shown to increase valve thrombosis risk to 33%. Low-molecular-weight heparin is an alternative to unfractionated heparin but its use remains controversial with no large prospective studies or evidence base to support its use and therapeutic monitoring.

Marfan Syndrome

Pregnant women with Marfan syndrome are at increased risk for aortic dissection and rupture, especially during the third trimester and the first postpartum month. Pregnancy is contraindicated in women with an aortic root diameter greater than 40 mm. Periodic echocardiographic surveillance every 6 to 8 weeks is recommended to monitor the mother's aortic root size and treatment with β -adrenergic blockers is recommended. Vaginal delivery is safe in patients with Marfan syndrome with an aortic diameter less than 40 mm. To

TABLE 11.1 Specific Maternal Cardiac Conditions and Risk for Cardiac Complications During Pregnancy

Low Risk	Intermediate Risk	High Risk
Small left-to-right shunts	Large left-to-right shunt	New York Heart Association class III or IV symptoms
Repaired lesions without residual dysfunction	Unrepaired or palliated cyanotic congenital heart disease	Severe pulmonary hypertension
Mitral valve prolapse without regurgitation	Mechanical prosthetic valves	Marfan syndrome with aortic root dilation or major valvular disease
Bicuspid aortic valve without stenosis	Mitral or aortic valve stenosis	Severe aortic stenosis
Mild to moderate pulmonic stenosis	Severe pulmonic stenosis	History of peripartum cardiomyopathy with residual ventricular dysfunction
Valvular regurgitation with normal ventricular systolic function	Moderate to severe ventricular dysfunction	
	Unrepaired coarctation of the aorta	
	History of peripartum cardiomyopathy without residual ventricular dysfunction	

minimize pain and hemodynamic changes, epidural anesthesia and β -blockers or vasodilators should be used and forceps or vacuum use is recommended to shorten the second stage of labor. In patients with aortic diameter 40 mm or greater, delivery via elective C-section should be performed in a tertiary care center with cardiothoracic surgical expertise.

Congenital Heart Disease

Congenital heart disease is the predominant maternal cardiac disease in Western societies, and all patients with a history of congenital heart disease, whether or not they have had repair, should receive a detailed evaluation and appropriate counseling before conception. Patients with uncomplicated atrial or ventricular septal defects usually tolerate pregnancy without complications unless they have concomitant pulmonary hypertension or atrial fibrillation. In patients with pulmonary hypertension, pregnancy is contraindicated. The added volume load of pregnancy may potentially precipitate left ventricular failure in patients with large intracardiac shunts.

In women with coarctation of the aorta, symptoms may first present during pregnancy, typically as systemic hypertension. Therapeutic options such as antihypertensive therapy, percutaneous stenting of the coarctation, and surgical intervention are available and most women will have a successful pregnancy with proper care.

Women with uncorrected tetralogy of Fallot should undergo palliative or definitive repair before conception to improve maternal and fetal outcomes. Women with residual obstruction of the right ventricular outflow tract are at risk of worsening cyanosis and risk to both mother and fetus during pregnancy.

Heart Disease Arising During Pregnancy

Hypertension

Hypertension is the most common medical problem in pregnancy. It is defined as absolute blood pressure values greater than 140 mm Hg systolic or 90 mm Hg diastolic. The major forms of hypertension that may develop during pregnancy are essential or primary hypertension, gestational hypertension, preeclampsia superimposed on essential hypertension, and preeclampsia. Essential hypertension is defined as hypertension, without a secondary cause, present before pregnancy or that is diagnosed before week 20 of gestation. Gestational hypertension is new hypertension without proteinuria that occurs after the 20th week of gestation and resolves within 2 weeks after delivery.

The mainstay of treatment of hypertension in pregnancy is antihypertensive medications, which are usually effective in treating

essential hypertension but not effective in preventing preeclampsia. Agents that have been safely used in pregnancy include hydralazine, α -methyldopa, clonidine, β -blockers, and labetalol. Diuretics should be used with caution because of the increased risk for placental hypoperfusion. When preeclampsia develops, typically characterized by hypertension and proteinuria, bedrest, salt restriction, and close monitoring are initiated and magnesium sulfate can be administered to prevent eclamptic seizures and prolong pregnancy to facilitate fetal maturity. Blood pressure usually normalizes rapidly with delivery.

Peripartum Cardiomyopathy

Peripartum cardiomyopathy (PCM) is a form of dilated cardiomyopathy that may begin during the last trimester of pregnancy or within 5 months of delivery in a previously healthy woman. The true incidence of the disease is unknown, but estimates conclude that 1 in every 2500 to 4000 pregnancies is affected in the United States. Although the cause of PCM is unknown, myocardial injury is thought to be immunologically mediated with inflammation playing a key role as evidenced by elevated serum markers of inflammation in many patients. Known risk factors include multiparity, black race, older maternal age and preeclampsia. Women usually exhibit symptoms and signs of congestive heart failure and cardiac imaging, usually with a transthoracic echocardiogram, establishes the diagnosis.

Management is similar to that for congestive heart failure (see Chapter 5) and usually includes the use of hydralazine, β -blockers, digoxin, and diuretics for symptom management and preload reduction. Diuretics may potentially reduce placental blood flow and must be used with caution. Angiotensin-converting enzyme inhibitors have been associated with increased fetal wastage in pregnant animals and aldosterone antagonists may have antiandrogenic effects on the fetus; therefore both classes of drugs should be avoided. Nitrates and inotropes may be necessary in severe cases and early fetal delivery may be necessary. Mechanical circulatory support may be necessary and cardiac transplantation may be considered in those cases refractory to mechanical circulatory support.

The outcome with PCM is variable. Left ventricular function normalizes in approximately 23% to 54% of women and death or progressive heart failure occurs in one third of affected women. The recurrence rate with subsequent pregnancies is 30%. In patients with full recovery of left ventricular function, mortality is negligible in subsequent pregnancies; however, women with a left ventricular ejection fraction less than 25% at diagnosis or persistent left ventricular dysfunction should be counseled against a subsequent pregnancy.

Fig. 11.1 Postpartum anterior wall myocardial infarction from spontaneous coronary dissection of the left anterior descending and diagonal arteries demonstrated by (A) left coronary angiography showing diffusely narrowed coronary lumen (proximal left anterior descending artery indicated by the arrow), and (B) intravascular ultrasound confirming hematoma in the medial-adventitial layer of the vessel. The imaging catheter is central in the lumen. *Black arrows* indicate the vessel media and the *white arrow* the hematoma. The intima of the vessel is thin and normal.

Spontaneous Coronary Artery Dissection

Spontaneous coronary artery dissection (SCAD) is defined as a separation of the arterial wall and subsequent coronary artery obstruction caused by the formation of an intramural hematoma that is not associated with atherosclerosis, trauma or iatrogenic injury (Fig. 11.1). While SCAD is the most common cause of pregnancy-associated myocardial infarction, pregnancy-associated SCAD represents a relatively small proportion of SCAD cases. The prevalence is 1.81 SCAD events per 100,000 pregnancies during pregnancy or in the postpartum period. SCAD has been reported as early as 5 weeks' gestation and up to a year or more postpartum, particularly in lactating women.

The cause of pregnancy-associated SCAD is not fully understood; however, hormonal changes of pregnancy are thought to alter the architecture of the arterial wall, weakening the wall and making it prone to rupture, intramural hematoma, and the subsequent development of clinical symptoms. Risk factors for pregnancy-associated SCAD include black race, chronic hypertension, lipid abnormalities, chronic depression, migraines, advanced maternal age, multiparity, and treatment for infertility.

Women with pregnancy-associated SCAD have poorer prognosis than women with SCAD not related to pregnancy. They have larger infarcts, more proximal artery dissections, and lower mean left ventricular ejection fraction immediately and at follow-up. Maternal complications of pregnancy-associated SCAD include cardiogenic shock, ventricular fibrillation, and mechanical circulatory support. In-hospital mortality has been reported to be as high as 4%.

CARDIAC TUMORS

Cardiac tumors are broadly divided into primary and secondary tumors. Primary cardiac tumors, defined as benign or malignant neoplasms that arise from any tissue of the heart, are extremely rare, with an autopsy incidence of 0.001% to 0.03%. Secondary, or metastatic, cardiac tumors are 30 times more common than primary tumors, with an autopsy incidence of 1.7% to 14%.

It is not uncommon for patients with cardiac tumors to initially have no symptoms or physical findings, but rather present with abnormalities on imaging. Alternatively, patients may present with a constellation of nonspecific symptoms or findings on physical examination.

The initial evaluation is typically imaging such as a two-dimensional transthoracic echocardiogram or magnetic resonance imaging (MRI). Once a mass is identified and described, additional imaging may be undertaken

Fig. 11.2 Atrial myxoma vascularization identified on cardiac catheterization. Selective right coronary angiography demonstrates that the vascular supply to the tumor originates from atrial branches. The vascularized tumor is indicated by the arrow.

such as three-dimensional echocardiography with contrast, transesophageal echocardiography for anatomic information, MRI with gadolinium, coronary angiography to define coronary anatomy, position emission tomography (PET) for staging, and/or computed tomography (CT) to delineate other intrathoracic structures. When assessing a cardiac mass, the clinical context is critical to the diagnosis. The differential diagnosis of a cardiac mass is broad and includes tumors, thrombi, infection, and artifact.

Benign Primary Cardiac Tumors

Most primary cardiac tumors are benign, and myxoma is the most common primary tumor of the heart (Fig. 11.2). Most myxomas are

TABLE 11.2 Cardiac Trauma Categorized by Mechanism of Injury

Penetrating	Nonpenetrating (Blunt)
Stab wounds (e.g., knives, swords, ice picks)	Motor vehicle accident
Gunshot wounds (e.g., handguns, nail guns)	Vehicular-pedestrian accident
Shotgun wounds	Falls from height
Blast fragments	Crush (e.g., industrial accidents)
	Blast (e.g., explosives)

found in the left atrium. Less commonly, they may be found in the right atrium, right ventricle, and left ventricle in decreasing frequencies. While most myxomas occur sporadically, a familial pattern of myxomas can occur in an autosomal dominant manner. In a particular syndrome called the Carney complex, patients may present with cardiac myxomas, cutaneous myxomas, breast fibroadenomas, hyperpigmented nevi, hyperactive adrenal or testicular glands, and pituitary tumors. The Carney complex occurs in young individuals and should be considered in myxomas in atypical locations in the heart. Surgical removal is the only definitive treatment of cardiac myxomas. Myxomas tend to recur with rates varying from 5% to 14%; therefore, it is imperative that lifelong follow-up continue after surgical removal.

Less common benign tumors include rhabdomyomas, fibromas, lipomas, and papillary fibroelastomas. Rhabdomyomas are the most common cardiac tumors found in children and are usually located in the ventricle. They are often associated with a family history of tuberous sclerosis. Surgery can often be avoided unless the patient develops clinical evidence of arrhythmias and heart failure. Fibromas are composed of fibroblasts or collagen and typically occur in childhood. They are most often located on the interventricular septum and patients may present with chest pain, pericardial effusion, heart failure, arrhythmias, and sudden death. While both occur in the ventricle, the distinguishing feature of fibromas, in contrast to rhabdomyomas, is the presence of calcification. Lipomas are rare and occur most frequently in the left ventricle and the right atrium, although they can be found anywhere in the heart and the pericardium. They are frequently asymptomatic but can grow large enough to cause obstructive symptoms. Papillary fibroelastomas are pedunculate tumors with filiform attachments that typically arise from the aortic or mitral valve. They carry an elevated risk of embolic phenomena and, when situated on the aortic valve, can cause coronary ostial occlusion. Complete surgical resection is recommended because of the risk of systemic embolism. Recurrence rates are low and long-term anticoagulation is not recommended unless the patient has other indications.

Malignant Primary Cardiac Tumors

Malignant primary cardiac tumors commonly cause symptoms via three mechanisms: obstruction, embolization, and arrhythmia. Obstructive tumors can present with syncope, chest pain, dyspnea or heart failure. Pericardial invasion and tamponade are rarely the first manifestation of the disease. Primary cardiac sarcoma is the most common malignant primary cardiac tumor. Once diagnosed, treatment for cardiac sarcomas is primarily surgical with complete resection as the goal followed by adjacent chemotherapy. Cardiac sarcomas carry a very poor overall prognosis.

Secondary Cardiac Tumors

Cardiac metastases are common and can be found in up to 14% of patients dying with a known malignancy. Cardiac metastases can occur either by direct extension, by way of the bloodstream or lymphatics, or by

intracavitary diffusion through the inferior vena cava (IVC). Metastases to the pericardium are most common, followed by epicardium, myocardium, and endocardium. Primary thoracic cancers, including breast and lung cancer, tend to invade the pericardium directly whereas abdominal and pelvic tumors reach the right atrium usually through the IVC. Renal cell carcinoma is the most common tumor to exhibit this tendency. In men and women, lung cancer is the most frequent cause of cardiac metastasis. In men, this is followed by esophageal cancer and lymphoma whereas in women it is followed by lymphoma and breast cancer.

The prognosis of metastatic cardiac tumors is poor, with 1-year mortality being 50%. Treatment therefore is primarily palliative and may include radiation therapy, chemotherapy, and surgical resection, if possible. Malignant pericardial effusion is typically managed with pericardiocentesis and may need a pericardiectomy to reduce subsequent reaccumulation of pericardial fluid.

TRAUMATIC HEART DISEASE

Traumatic heart disease can be categorized based on the mechanism of injury (Table 11.2).

Nonpenetrating Cardiac Trauma

Nonpenetrating or blunt cardiac trauma accounts for about 10% of all traumatic heart disease. Nonpenetrating cardiac trauma can manifest as a spectrum of pathology including septal rupture, free wall rupture, coronary artery thrombosis or dissection, rupture of the cordae tendinae or papillary muscle, pericarditis or cardiac tamponade, and arrhythmias. Commotio cordis is a type of nonpenetrating cardiac trauma that occurs more often in child athletes as a result of a projectile such as a ball striking the chest, resulting in ventricular fibrillation and sudden cardiac death.

Nonpenetrating cardiac trauma can present with clinically significant or clinically insignificant injury. Conduction disturbances are common and a screening 12-lead electrocardiogram (ECG) can be useful for initial evaluation. Sinus tachycardia is the most common ECG abnormality. Other possible findings on ECG include T-wave and ST-segment changes, bradycardia, first- and second-degree atrioventricular block, right bundle branch block, third-degree heart block, atrial fibrillation, premature ventricular complexes, ventricular tachycardia, and ventricular fibrillation. Elevated cardiac enzymes are not specific for blunt cardiac trauma and may be related to severity of non-cardiac injury or underlying coronary disease. In one study, only 485 of patients with elevated troponin were clinically found to have significant blunt cardiac trauma. A negative troponin, however, had a negative predictive value of 93%. The major use of transthoracic echocardiography in the evaluation of nonpenetrating cardiac trauma is for the assessment of pericardial effusion, the presence of which is concerning for chamber rupture. Transesophageal echocardiography is a more sensitive test for the evaluation of more subtle features of blunt cardiac injury.

Most patients who present with suspected blunt cardiac injury can be managed with observation and monitoring. Patients in cardiogenic shock in whom structural injury is confirmed should be promptly referred to cardiothoracic surgery for surgical repair.

Penetrating Cardiac Trauma

Penetrating cardiac injury is the most common cause of significant cardiac injury, most often by firearms and knives. Due to their anterior location on the chest wall, the right and left ventricles are at the greatest risk for injury. Most penetrating cardiac injuries involve the myocardium, sparing additional structures, and are managed effectively with surgical intervention and rarely requiring reoperation for a residual defect.

Penetrating injury to the epigastrium and precordium should raise suspicion for penetrating cardiac injury. The clinical presentation

IABP, Intraaortic balloon pump; LA, left atrium; LV, left ventricle; LVEDP, left ventricular end-diastolic pressure; MAP, mean arterial pressure; PCWP, pulmonary capillary wedge pressure; RA, right atrium; V-A ECMO, veno-arterial extracorporeal membrane oxygenation.

could be varied from normal vital signs to circulatory collapse. This is because after a weapon injuring the myocardium and pericardium is withdrawn, blood filling the pericardium may not be able to escape. As pericardial fluid accumulates, ventricular filling is impaired and stroke volume decreases. In response to a decrease in stroke volume, there is a catecholamine surge resulting in tachycardia and increased right-sided filling pressures. As little as 60 mL to 100 mL of blood in the pericardial sac can result in clinical pericardial tamponade where the limits of distensibility are reached and there is bowing of the interventricular septum, further compromising left ventricular function, reducing cardiac output, and resulting in irreversible shock. The classic findings of Beck triad (muffled heart sounds, hypotension and distended neck veins) is rarely seen. Pulsus paradoxus (a fall in systolic blood pressure of 20 mm Hg or more during inspiration) and Kussmaul sign (increase in jugular venous distention on inspiration) may be present but not reliably predictive of pericardial tamponade. Narrowing of the pulse pressure, however, is a reproducible sign of tamponade. In the case of penetrating cardiac injury, definitive treatment involves surgical intervention.

PERCUTANEOUS MECHANICAL CIRCULATORY SUPPORT

Mechanical circulatory support (MCS) is a term that refers to mechanical pumps designed to assist or replace the function of the left ventricle, right ventricle or both ventricles of the heart. There are several MCS systems available including the intra-aortic balloon pump (IABP), extracorporeal membrane oxygenation (ECMO) or extracorporeal life support (ECLS), ventricular assist devices (VADs), and total artificial hearts (TAHs). Further details on the disease process and management of chronic heart failure are covered in [Chapter 5](#). The following discussion will focus on temporary or percutaneous MCS as indicated in patients with cardiogenic shock refractory to medical therapy when the objective is rapid augmentation of cardiac output, reduction of ventricular filling pressures, and life support. Longer-term support, with VADs, TAHs, and cardiac transplantation are covered elsewhere. A comparison of the key features of the available percutaneous assist devices is summarized in [Table 11.3](#).

Percutaneous Left Ventricular Assist Devices

Intra-Aortic Balloon Pump

The IABP remains the most commonly used form of circulatory support. A polyethylene helium-filled balloon is placed percutaneously through the femoral artery into the thoracic aorta, just distal to the left subclavian artery. Timing of balloon inflation and deflation is based on

the ECG or the arterial waveform of the patient. The balloon inflates with the onset of diastole and deflates at the onset of left ventricular systole. Balloon inflation during diastole increases diastolic blood pressure, referred to as diastolic augmentation, allowing for maximal delivery of oxygenated blood to the coronary arteries. Deflation during systole decreases the afterload and myocardial oxygen consumption while modestly enhancing cardiac output. The IABP reduces myocardial oxygen demand but provides only modest ventricular unloading. Patients must have some left ventricular function and electrical stability for an IABP to be most effective because the device only results in an increase in cardiac output of 0.5 to 1.0 liter per minute.

The major contraindication for IABP is greater than mild aortic valve regurgitation because the diastolic inflation of the balloon may worsen the degree of regurgitation. Severe peripheral arterial disease or aortic disease increases the risk of vascular complication such as thromboembolism and lower extremity and visceral ischemia. Potential major complications include balloon leak, severe bleeding (e.g., retroperitoneal), thromboembolic events, major limb or visceral ischemia, vascular trauma, thrombocytopenia from platelet deposition in the IABP membrane, and infection.

Impella

The Impella (Abiomed, Danvers, Mass.) is a nonpulsatile axial flow Archimedes-screw pump that propels blood from the left ventricle into the proximal ascending aorta. Depending on the version used, these devices can deliver up to 5.0 L/min of maximal flow. Designed to be placed via the femoral artery, delivery can either be percutaneous (Impella 2.5 and CP) or via a surgical cutdown (Impella 5.0). At the tip of the catheter there is a flexible pigtail loop that stabilizes the device in the left ventricle. The main body of the device contains the pump inlet and outlet areas, motor housing, and pump pressure monitor. Unlike the IABP, the Impella does not require ECG or arterial pressure timing and therefore provides stability despite transient arrhythmias.

The hemodynamic effects of the Impella are to unload the left ventricle and increase forward flow, reducing myocardial oxygen consumption, improving mean arterial pressure, and reducing pulmonary capillary wedge pressure. Compared to the IABP, the Impella delivers a significant increase in cardiac output. Adequate right ventricular function is necessary to maintain left ventricular preload and hemodynamic support. In cases where there is significant biventricular failure or unstable ventricular arrhythmias, a concomitant right ventricular assist device may be necessary.

Contraindications to the use of the Impella are the presence of a mechanical aortic valve, left ventricular thrombus, severe aortic stenosis, moderate to severe aortic insufficiency, severe peripheral arterial disease, and the inability to tolerate systemic anticoagulation. Possible complications of Impella use include limb ischemia, vascular complications, hemolysis due to mechanical erythrocyte shearing, and bleeding requiring blood transfusion.

TandemHeart

The TandemHeart (TandemLife, Pittsburgh, Penn.) is a percutaneous centrifugal pump that provides up to 4 L/min of mechanical circulatory support via a continuous-flow centrifugal pump. The TandemHeart is inserted through the femoral vein and advanced across the interatrial septum into the left atrium. Oxygenated blood is then withdrawn from the left atrium via a 21-Fr inflow cannula and reinjected into the lower abdominal aorta or iliac arteries via a 15-Fr to 17-Fr outflow cannula. The need for transseptal puncture is a limitation to the widespread use of this device. The potential complications of the TandemHeart include the need for blood transfusion, sepsis/systemic inflammatory response syndrome, bleeding around the cannula, gastrointestinal bleeding, coagulopathy, stroke, left atrial perforation, and device-related limb ischemia.

Right Ventricular Support

Acute right ventricular (RV) failure may occur in a number of clinical settings such as acute myocardial infarction, fulminant myocarditis, acute pulmonary embolism, pulmonary hypertension, postcardiotomy shock, postcardiac transplantation, and following LVAD implantation. The mainstay of therapy for RV failure is inotropic and pulmonary vasodilator support and volume status optimization. Vasopressors are often used to maintain coronary perfusion pressure and inhaled nitric oxide can be used to reduce RV afterload. When these measures are insufficient to augment RV systolic function, mechanical circulatory support may be required to unload the RV, ensure adequate LV preload, and optimize tissue perfusion.

There are both surgical and percutaneous options for RV mechanical circulatory support. The surgical right ventricular assist device (RVAD) was associated with worse outcomes when compared to patients with RV failure who did not need an RVAD. Unfavorable outcome data and the need for repeat sternotomy for both insertion and removal of the device has limited clinical utilization. There are two percutaneous devices currently available for RV support: (1) Impella RP (Abiomed, Danvers, Mass.), an axial catheter-based pump and (2) the Protek Duo (Cardiac Assist Inc., Pittsburgh, Penn.), a catheter with an extracorporeal centrifugal pump. The Impella RP provides RV unloading with up to 4 L/min of continuous flow from the inlet in the inferior vena cava through a cannula to the outlet in the pulmonary artery. The pump is inserted via a 23-Fr sheath in the femoral vein into the atrium and across the tricuspid and pulmonic valves into the main pulmonary artery. The Protek Duo is a dual-lumen cannula that is inserted percutaneously via the internal jugular vein. The inflow lumen is positioned in the right atrium and the outflow lumen is positioned in the main pulmonary artery. The extracorporeal pump allows flows up to 5 L/min and an oxygenator can also be introduced into the circuit to allow for oxygenation support.

Extracorporeal Membrane Oxygenation

ECMO provides cardiopulmonary support in patients whose heart and/or lungs no longer provide adequate physiologic support. ECMO can be either veno-venous (V-V ECMO) for isolated pulmonary failure only or veno-arterial (V-A ECMO) for pulmonary and cardiac failure. Cannulas are placed in the right side of the heart, from the vena cava,

to drain blood into the ECMO circuit for oxygenation. Blood can then either be returned to the right side of the heart in V-V ECMO or to the arterial system (proximal or distal aorta) in V-A ECMO. The bypass circuit in ECMO is composed of a centrifugal, nonpulsatile pump for blood propulsion, and a membrane oxygenator for gas exchange. V-A ECMO requires anticoagulation while V-V ECMO does not. Complications relate to bleeding, thromboembolism, and mechanical complications such as hemolysis and arterial insufficiency.

V-V ECMO offers gas exchange and is useful for conditions resulting in severe impairment of gas exchange such as ARDS or pulmonary embolism. V-V ECMO does not provide hemodynamic support. Alternatively, V-A ECMO provides additional hemodynamic support with flows sometimes exceeding 6 L/min depending on the cannula French size and length and properties of the pump. V-A ECMO alone, however, does not reduce ventricular wall stress and the use of a concomitant MCS such as IABP or percutaneous VAD is usually needed to vent or unload the left ventricle.

NONCARDIAC SURGERY IN THE PATIENT WITH CARDIOVASCULAR DISEASE

Noncardiac surgery in patients with known cardiovascular disease may be associated with an increased risk for death or cardiac complications such as MI, congestive heart failure, and arrhythmias. To determine an individual patient's risk for a procedure, the consulting physician must have knowledge of the type and severity of the patient's cardiac disease, the comorbid risk factors, and the type and urgency of surgery. In general, the preoperative evaluation and management are the same as in the nonoperative setting; for patients who are at risk, additional noninvasive and invasive testing may be performed if the results would affect treatment or outcome.

Estimation of a patient's perioperative risk can be determined by a careful clinical evaluation, including a history, physical examination, ECG, and type of surgery. Risk models can then be applied to guide the clinician with regards to additional testing and treatment. The most widely used risk model was developed in a study of 4315 patients 50 years or older undergoing major noncardiac procedures in a tertiary care teaching hospital and has been validated over the past 15 years. The index includes six independent predictors of complications in a revised cardiac risk index (RCRI): high-risk type of surgery, history of cerebrovascular disease, preoperative treatment with insulin, history of ischemic heart disease, history of congestive heart failure, and preoperative serum creatinine concentration greater than 2.0 mg/dL. The evaluating clinician can risk stratify the patients into low, intermediate, or high cardiovascular risk on the basis of having zero, one to two, or three or more risk factors, respectively. Another risk model was developed from the American College of Surgeons 2007 National Surgical Quality Improvement Program database (NSQIP), which identified five predictors of perioperative myocardial infarction or cardiac arrest: type of surgery, dependent functional status, abnormal creatinine level, American Society of Anesthesiologists class, and increasing age.

Once the clinical evaluation is complete and the type of surgery is known, the need for additional testing and treatment can be determined. Very high-risk patients are defined as those with recent myocardial infarction (within 60 days), unstable angina, decompensated heart failure, and hemodynamically important valvular disease. These patients are at very high risk of preoperative myocardial infarction, heart failure, fatal arrhythmia, and cardiac death. All such patients should be optimally treated and referred to a cardiologist for evaluation.

If emergency surgery is contemplated, little in the way of cardiac assessment can be performed, and recommendations may be directed at perioperative medical management and surveillance. If surgery is not urgent, additional evaluation is based on the clinical assessments of the risk and type of surgery.

Disease-Specific Approaches

Ischemic Heart Disease

About 70% of MIs occur within the first 6 days after an operation, with the peak incidence between 24 and 72 hours. Multiple stresses associated with surgery such as volume shifts, anemia, and infection can increase the heart rate and blood pressure perioperatively and can provoke myocardial ischemia. Identification of known or symptomatic stable coronary artery disease or risk factors for coronary artery disease can guide further evaluation or changes in perioperative management.

Patients with stable angina represent a continuum from mild to severe. In mild cases, patients manifest angina only after strenuous exercise and do not have signs of left ventricular dysfunction. These patients can be stabilized with optimal medical therapy with aspirin, β -adrenergic blocking agents and statins. On the severe end of the continuum, patients with angina on mild exertion are at high risk for development of perioperative major cardiovascular events and warrant consideration of additional cardiovascular testing.

Coronary angiography and revascularization should be reserved for individuals in whom this treatment would otherwise result in significant improvement in symptoms or long-term survival. Current data do not support a clear benefit of preoperative coronary revascularization.

The preoperative management of patients with a history of recent coronary artery revascularization on antiplatelet therapy is challenging as clinicians balance the cardiac risks of discontinuing therapy with the bleeding risks of continuing antiplatelet agents. Several large observational studies have shown an increased risk of adverse cardiovascular events in patients undergoing noncardiac surgery, particularly within 6 weeks of receiving a coronary stent. While the risk extends to 12 months, it stabilizes without significant decrease in risk from 6 to 12 months. The American College of Cardiology (ACC) and American Heart Association (AHA) guidelines recommend the following algorithm for patients with a coronary stent. If surgery is elective and can be safely delayed, the optimal timing is 12 months after PCI. For those in whom surgery cannot be delayed and are within 30 days of bare metal or 6 months of a drug-eluting stent, dual-antiplatelet therapy with aspirin and P2Y₁₂ inhibitor should be continued. If the risk of bleeding is prohibitive, the P2Y₁₂ inhibitor is temporarily interrupted (for 5 to 7 days) and aspirin is continued throughout the perioperative period because typically aspirin provides benefits that outweigh the bleeding risk. Possible exceptions to this include intracranial procedures, transurethral prostatectomy, intraocular procedures, and operations with extremely high bleeding risk. In clinical practice, the decision is made with a multidisciplinary team approach considering a number of factors such as the risk of stent thrombosis if DAPT needs to be interrupted, the consequences of delaying the surgical procedure, the increased intra- and periprocedural bleeding risks, and possible consequences of such bleeding if DAPT is continued.

Heart Failure

Studies have shown that heart failure is associated with increased perioperative cardiac morbidity after noncardiac surgery. During the postoperative period, congestive heart failure most commonly occurs in the first 24 to 48 hours, when fluid administered during surgery is mobilized from the extravascular space. However, heart failure may also result from myocardial ischemia and new arrhythmias. Initial management includes identification and treatment of the underlying cause. In addition, intravenous diuretics usually provide rapid relief of pulmonary congestion. If heart failure is complicated by hypotension or poor urine output, insertion of a pulmonary artery catheter may be helpful to guide additional therapy.

Valvular Heart Disease

In regard to valvular heart disease the greatest risk for complications after noncardiac surgery is in those with aortic or mitral stenosis. Patients with symptomatic, severe aortic or mitral stenosis should be evaluated for valve replacement before high-risk noncardiac surgery. In patients with mild to moderate aortic or mitral stenosis, careful attention to volume status and heart rate control are necessary to optimize left ventricular filling and avoid pulmonary congestion. In patients with valve disease or prosthetic heart valves, prophylactic antibiotics are recommended if appropriate. Lifelong anticoagulation with an oral vitamin K antagonist (VKA) is recommended for all patients with mechanical prosthetic heart valves. In addition to the thrombogenic nature of the intravascular prosthetic material, mechanical valves create abnormal flow conditions and areas of high-shear stress, both of which can result in platelet activation leading to valve thrombosis and embolic events. The preoperative management of patients with mechanical heart valves in whom interruption of anticoagulation therapy is needed for diagnostic or surgical procedures should account for the type of procedure, risk factors, and type, location, and number of heart valve prostheses. The ACC/AHA guidelines recommend continuation of VKA anticoagulation with a therapeutic INR in patients undergoing minor procedures (such as dental extractions or cataract removal) where uncontrolled bleeding risk is low. The guidelines recommend bridging anticoagulation with either intravenous unfractionated heparin or subcutaneous low-molecular-weight heparin during the time interval when INR is subtherapeutic in patients who are undergoing invasive or surgical procedures with (1) mechanical aortic valves and any thromboembolic risk factor, (2) older-generation mechanical aortic valves, or (3) mechanical mitral valves.

Arrhythmias and Conduction Defects

Patients with symptomatic, high-grade conduction disturbances, such as third-degree atrioventricular (AV) block, have an increased perioperative risk for cardiac complications and should have a temporary pacemaker inserted before surgery. Patients with first-degree AV block, Mobitz type I AV block, or bifascicular block (right bundle branch block and left anterior fascicular block) do not require prophylactic pacemaker insertion.

Atrial arrhythmias such as atrial fibrillation are common after surgery and usually are not associated with significant complications if the ventricular rate is well controlled. Mounting evidence suggests that new-onset postoperative atrial fibrillation following noncardiac surgery carries a similar risk of thromboembolism as in patients with nonvalvular atrial fibrillation. Therefore, the long-term management of these patients should be similar with regards to anticoagulation.

Ventricular premature beats and nonsustained ventricular tachycardia are also common after noncardiac surgery and do not require specific therapy unless they are associated with myocardial ischemia or heart failure. In most instances, treatment of the underlying cause (e.g., hypoxia, metabolic abnormalities, ischemia, volume overload) results in significant improvement or resolution of the rhythm disturbance without specific antiarrhythmic therapy.

Vascular Diseases and Hypertension

Thomas Sperry, Wanpen Vongpatanasin

INTRODUCTION

Diseases of the systemic and pulmonary vasculature are among the most common clinical problems encountered in internal medicine. Yet these important diseases are not often given the emphasis they deserve; they fall between the cracks of traditional medical subspecialties. Early clinical recognition is important because effective therapy often can prevent or at least delay needless suffering and death. This chapter reviews the causes, clinical manifestations, diagnostic evaluations, and therapeutic approaches to the major forms of systemic and pulmonary vascular diseases, as well as arterial hypertension.

SYSTEMIC VASCULAR DISEASE

Peripheral Arterial Disease

Peripheral arterial disease (PAD) refers to atherosclerotic vascular disease of mainly the lower extremities. The prevalence increases with age, ranging from 2% to 6% for adults under the age of 60 years to 20% to 30% for those over age 70. As with coronary atherosclerosis, the major reversible risk factors are cigarette smoking, diabetes mellitus, hyperlipidemia, and hypertension. The diagnosis of PAD may at times be elusive, as only 30% to 50% of patients with PAD become symptomatic. PAD may present with symptoms of intermittent claudication, critical limb ischemia, or acute limb ischemia. Roughly 10% to 15% of patients present with the classic syndrome of intermittent claudication, which refers to ischemic muscle pain or weakness brought on by exertion and promptly relieved by rest. A larger proportion of PAD patients (50%) have more atypical leg symptoms different from classic claudication, which either may not limit an individual from walking or may not resolve within 10 minutes of rest. Claudication is also associated with a significant 10-year risk of morbidity and mortality. Approximately 10% to 20% of patients will develop worsening claudication or critical limb ischemia, 5% will require amputation, 10% to 20% will require revascularization, and up to 30% will die of a cardiovascular event (e.g., heart attack, stroke) as a result of concomitant coronary and/or cerebrovascular atherosclerosis. To minimize progression of PAD and avoid complications, risk factor modification is absolutely essential. This includes tight control of blood pressure (BP), plasma lipids, and blood glucose. Complete cessation of tobacco use is a must.

The diagnosis of PAD begins with a careful history and physical examination and is confirmed with noninvasive laboratory testing. Ischemic pain occurs in the leg muscles supplied by arterial segments that are distal to the site of stenosis. Calf claudication is the hallmark of femoral-popliteal disease, whereas discomfort in the thigh, hip, or buttock associated with impotence indicates aortoiliac disease (Leriche syndrome). Depending on the severity of the stenosis, the pain is experienced at a predictable walking distance and is promptly relieved by

rest. Claudication must be differentiated from the pseudoclaudication of lumbar degenerative spinal canal stenosis. In the latter condition, walking can also aggravate leg pain, but it is not relieved simply by the cessation of exercise. Rather, assuming positions that minimize lumbar extension such as stooping forward or sitting alleviates the pain. The characteristic physical findings of PAD are absent or diminished pulses distal to the stenosis, bruits over the diseased artery, hair loss, thin shiny skin, and muscle atrophy. Severe ischemia causes pallor, cyanosis, decreased skin temperature, ulceration, and gangrene.

Noninvasive techniques are quite good in the diagnosis of PAD. The *ankle-brachial index* (ABI) is the ratio of the highest systolic BP measured from either the dorsalis pedis or posterior tibialis artery to the highest systolic BP obtained from the brachial artery of either arm using a Doppler stethoscope. The normal ABI range is 1.0 to 1.4. An ABI of 0.9 or less indicates PAD. This simple noninvasive test has a sensitivity and specificity of 68% to 84% and 84% to 99%, respectively, when compared to vascular imaging. In the occasional patient with a high likelihood of PAD but with borderline (between 0.9-1.0) or normal ABI, ABI obtained during exercise treadmill testing may prove useful in the diagnosis. In some patients with diabetes mellitus or renal failure, the media of the affected leg vessels become so heavily calcified that they resist compression except during very high levels of cuff inflation. The result is a falsely elevated ankle BP and an artificially normal or supernormal ABI of greater than 1.4 (Table 12.1). Measurement of toe BP to obtain toe-brachial index in that situation is recommended to verify presence of PAD. Patients with a toe-brachial index of less than or equal to 0.70 are considered to have hemodynamically significant PAD.

Duplex ultrasonography is an important adjunct to the ABI, with a similar sensitivity and specificity. This test is particularly useful to diagnose PAD in patients with noncompressible vessels from medial wall calcification. The Doppler velocity waveform remains abnormal, despite a spuriously normal or elevated ABI. Magnetic resonance (MR) angiography and computed tomographic (CT) angiography also

TABLE 12.1 Interpretation of Ankle-Brachial Index

Ankle-Brachial Index	Interpretation
1.00-1.40	Normal
0.90-0.99	Borderline
0.70-0.89	Mild PAD
0.40-0.69	Moderate PAD
<0.40	Severe PAD
>1.40	Noncompressible vessels

PAD, Peripheral arterial disease.

permit excellent visualization of vascular stenosis and identification of runoff vessels. With these noninvasive imaging modalities, spatial resolution is comparable with that of traditional invasive angiography, which now is reserved for patients undergoing revascularization.

The medical management of PAD includes lifestyle and risk factor modification, as well as antiplatelet therapy. Smoking cessation reduces the risk of limb loss, myocardial infarction, and death. Lipid-lowering therapy with high-intensity statin therapy should be initiated and intensified to reduce the rate of vascular events regardless of cholesterol levels. In addition, PAD patients with LDL-C greater than 70 mg/dL despite maximally tolerated statin therapy should be considered for additional lipid-lowering therapy such as ezetimibe. Those with persistently elevated LDL-C despite statin and ezetimibe may then be considered for PCSK9 inhibition. Antihypertensive medication should be initiated and intensified until BP is less than 130/80 mm Hg. Choice of antihypertensive regimen should be based on corresponding comorbidities, but there is some evidence to support the use of ACE inhibitors or angiotensin-receptor blockers. β -Adrenergic blockers do not reduce walking capacity or worsen intermittent claudication in patients with PAD. Aspirin reduces the risk of myocardial infarction, death, and stroke. However, clopidogrel is an effective alternative treatment and is more effective than aspirin in reducing cardiovascular events. Newer antiplatelet agents, such as ticagrelor, have not been proven to be more effective than clopidogrel in reducing cardiovascular events or limb ischemia in patients with symptomatic PAD. More recently, the combination of low-dose factor Xa inhibitor rivaroxaban (2.5 mg twice daily) and low-dose aspirin (≤ 100 mg) was shown to reduce the risk of cardiovascular events and limb amputation in PAD patients when compared to low-dose aspirin alone. While the overall bleeding risk is increased with the combination therapy, fatal bleeding is not. Therefore, this combination should be considered in PAD patients with high cardiovascular risk but low bleeding risk. Each patient also needs an exercise prescription as exercise training improves walking capacity and quality of life. This exercise training should be conducted in a medical facility or clinic at a minimal frequency of three times weekly for 12 weeks, preferably for 30 to 45 minutes per session. Cilostazol, a phosphodiesterase-3 inhibitor, is effective in improving claudication

symptoms but is not effective in preventing cardiovascular events. Side effects of cilostazol include headache, diarrhea, dizziness, and palpitation. However, cilostazol must be avoided in patients with congestive heart failure because its use in such patients may increase mortality. Pentoxifylline should not be used in PAD as it is no more effective than placebo for intermittent claudication.

Revascularization (percutaneous or surgical) is indicated for patients with severe claudication that is resistant to medical therapy, limb-threatening ischemia, or ischemia-induced impotence (Fig. 12.1). A variety of devices are now available for aortoiliac, femoropopliteal, and infrapopliteal percutaneous interventions, including drug-coated balloons, cutting balloons, laser atherectomy, self-expanding stents, and drug-coated stents. However, efficacy of these newer devices has not been directly compared to each other or to surgical revascularization. In general, surgical revascularization is more suitable for longer areas of stenosis and remains the best option for some patients. The decision between surgery versus endovascular intervention also depends on a patient's life expectancy and other comorbid conditions. Overall, the selection of surgery versus percutaneous intervention as the initial mode of revascularization in patients with limb-threatening ischemia is complex and should be a decision made amongst an interdisciplinary team of physicians.

Acute limb ischemia (ALI) is a vascular emergency. Sudden occlusion of a peripheral artery is caused by either arterial embolism or thrombosis in situ. Arterial emboli usually originate in the cardiac chambers in the setting of preexisting cardiac disease such as myocardial infarction (e.g., left ventricular mural thrombus), congestive heart failure, or atrial arrhythmias (e.g., left atrial thrombus in a patient with atrial fibrillation). Thrombosis in situ usually occurs in arteries with a preexisting severe stenosis in the setting of long-standing PAD with or without previous vascular surgery. Patients with arterial embolism usually experience sudden onset of symptoms without a history of claudication, whereas those with thrombosis in situ typically have a history of claudication that has previously been stable and then suddenly assumes a crescendo pattern over a period of days. In either case, the physical examination reveals a cold, cyanotic (bluish) extremity with absent pulses distal to the site of arterial occlusion and diminished

Fig. 12.1 Angiogram of the distal abdominal aorta and iliac arteries demonstrates an occluded left common iliac artery with extensive collateral circulation from the contralateral internal iliac artery (*left*), which resolved after successful stent implantation (*right*). (Courtesy of Bart Domatch, MD, Radiology Department, University of Texas Southwestern Medical Center, Dallas, Texas.)

motor and/or sensory function. A handheld Doppler device is used to assess signals at different arterial segments and confirms the diagnosis of acute vascular occlusion. Anticoagulation should be initiated immediately with intravenous heparin titrated to maintain the activated partial thromboplastin time equal to 2.0 to 2.5 times control. Catheter-directed infusion of thrombolytic therapy offers a similar success rate in salvaging the limbs as surgical revascularization (thromboembolectomy or bypass surgery). However, survival rate is higher with catheter-based therapy, likely related to the multiple comorbidities of patients with ALI. Patients with irreversible tissue necrosis, regardless of the cause, should be treated with emergent amputation rather than revascularization to reduce the risk of kidney failure (myoglobinuria), sepsis, and multiorgan failure.

Aortic Aneurysm

An aortic aneurysm is commonly defined as a dilation of all three layers of the vessel to more than 50% of the expected normal diameter. The two main types are thoracic aortic aneurysms (TAA), which occur above the diaphragm, and abdominal aortic aneurysms (AAA), which occur below the diaphragm. Abdominal aortic aneurysm is a common vascular disease in older adults, affecting 4% to 8% of men and 0.5% to 1.5% of women over the age of 65 years. Thoracic aortic aneurysm is much less prevalent (0.4% to 0.5%). Besides age, the major risk factors for abdominal aortic aneurysms are cigarette smoking, hypertension, and a family history of aortic aneurysms. Atherosclerosis is responsible for most cases of abdominal aortic aneurysm, while other causes such as genetic (Marfan syndrome, Ehlers-Danlos syndrome, Loeys-Dietz, Turner syndrome, or bicuspid aortic valve), vasculitis with connective tissue disease (Takayasu's arteritis, giant-cell arteritis), chronic infection (syphilitic aortitis), and trauma may cause thoracic or abdominal aortic aneurysms. Abdominal aortic aneurysms gradually grow in size over time at an average rate of 1 to 4 mm per year. The risk of rupture is low until the diameter reaches 5 cm, and then it increases exponentially. The risk of aortic rupture is 1% per year for aneurysms between 3.5 and 4.9 cm in diameter and 5% per year for aneurysms larger than 5 cm.

Most cases of aortic aneurysms are asymptomatic and detected incidentally during routine screening or imaging for other indications. However, some patients with AAA may develop vascular complications such as aneurysm expansion with compression of adjacent structures. Occasionally, mural thrombi form within the aneurysm and embolize, causing acute occlusion of distal arterial segments. Patients with iliac aneurysm may develop hydronephrosis or recurrent urinary tract infection from ureteral compression. Others develop neurologic symptoms from compression of sciatic or femoral nerves. The classic physical finding is a pulsatile nontender mass below the umbilicus (distal to the origin of the renal arteries). In thin patients, normal aortic pulsations are often palpable but above the umbilicus. Hypotension and acute abdominal pain should prompt consideration of aneurysm rupture, which requires emergent operative repair. Duplex ultrasonography is an accurate and reliable diagnostic tool for abdominal aortic and iliac aneurysms. Routine screening for AAA with ultrasonography is recommended for all men between the ages of 65 and 75 years who have ever smoked or men above the age of 60 with family history of AAA among first-degree relatives. Such screening has a proven mortality benefit. CT and MR angiography allow visualization of the thoracic and abdominal aorta, as well as the iliac arteries and its branches (Fig. 12.2).

Medical treatment for aortic aneurysm includes smoking cessation, tight BP control to less than 130/80 mm Hg, and intensive statin therapy. Although transforming growth factor- β has been implicated in the pathogenesis of aortic aneurysm in Marfan syndrome, which is mediated by angiotensin-II receptor activation, losartan was not shown to be more effective than beta adrenergic receptor blockade in reducing the

rate of aortic root enlargement. β -Adrenergic blockade has not proven beneficial in patients with abdominal aortic aneurysm from other causes. Similarly, a randomized clinical trial failed to demonstrate superiority of angiotensin-converting enzyme inhibitors (ACEI) over calcium-channel blockers in preventing AAA expansion. However, small sample size and inclusion of patients with well-controlled hypertension may have limited the investigators' ability to detect a difference. Patients who develop symptoms from thoracic aneurysms of any size should undergo repair. For asymptomatic patients, presence of large aneurysms (diameter 5.5 cm or above) or rapid aneurysm expansion regardless of the size are also indications for aneurysm repair (Table 12.2). Open surgical repair remains the treatment of choice for thoracic aneurysms involving the aortic root, ascending aorta, or aortic arch. However, thoracic endovascular aortic repair (TEVAR) has now emerged as the procedure of choice for descending thoracic aneurysm given lower early morbidity and mortality compared to open surgical repair in several observational studies. Elective abdominal aortic aneurysm repair carries a perioperative mortality rate of 2% to 6%.

Fig. 12.2 CT angiogram of the distal abdominal aorta shows abdominal aortic aneurysm with the largest diameter of 6.2 cm and severe stenosis at the origin of the right common iliac artery. (Courtesy of Bart Domatch, MD, Radiology Department, University of Texas Southwestern Medical Center, Dallas, Texas.)

TABLE 12.2 Indications for Surgical Treatment of Arterial Aneurysms

Symptoms from expansion of aneurysm or compression of adjacent structure
Rupture of aneurysm
Rapid aortic aneurysm expansion of ≥ 1 cm per year
Asymptomatic with large size
Thoracic aneurysm (ascending or descending aneurysm) with diameter >5.5 cm in adults
For genetic cause of thoracic aneurysm (such as Marfan, Loeys-Dietz, Ehlers-Danlos, Turner syndrome, or bicuspid aortic valve), a lower diameter or aortic size may be considered (generally of at least 5 cm or >4.5 cm in the presence of family history of aortic dissection)
Abdominal aorta >5.5 cm
Iliac aneurysm >3 cm

Furthermore, a large randomized study failed to demonstrate any benefit of surgery in patients with aneurysms 4.0 to 5.4 cm in diameter. For these reasons, patients with small aortic aneurysms (4.0 to 5.4 cm in diameter) should be treated medically with close monitoring of aneurysm size with periodic imaging studies every 6 to 12 months (see Table 12.2).

Percutaneous endovascular aneurysm repair (EVAR) is an alternative method to open surgical repair for treatment of abdominal aortic aneurysm. EVAR offers lower perioperative death than surgical repair with equivalent long-term survival. However, EVAR should be reserved for patients with favorable anatomy who are able to return for follow-up visits and repeated imaging studies of the aneurysm sites to ensure that the stent graft is free from endovascular leaks or displacement.

Aortic Dissection

In aortic dissection, the intimal layer is torn from the aortic wall leading to the formation of a false lumen in parallel with the true lumen. Risk factors include hypertension, cocaine use, trauma, hereditary connective tissue disease (e.g., Marfan syndrome, Ehlers-Danlos syndrome), vasculitis (e.g., Takayasu's arteritis, giant-cell arteritis), Behçet's disease, bicuspid aortic valve, and aortic coarctation. Aortic dissection can be classified as types A and B (Stanford system). Type A dissection involves the ascending aorta, whereas type B dissection involves the distal aorta. The DeBakey system subdivides aortic dissection into three subtypes—types I, II, and III. Type I dissection involves the entire aorta, whereas type II involves only the ascending aorta and type III involves only the descending aorta. Aortic dissection involving the ascending aorta carries a high mortality rate of 1% to 2% per hour during the first 24 to 48 hours. Patients usually develop acute onset of severe chest or back pain. Abdominal pain, syncope, and stroke are common. Retrograde propagation of the dissection can cause pericardial tamponade or coronary artery dissection with acute myocardial infarction. Dissection involving the aortic valve causes acute severe aortic insufficiency with acute pulmonary edema. The dissection plane may propagate in an antegrade direction to compromise flow in the carotid and subclavian arteries, producing a stroke or acute upper limb ischemia. Patients with distal (type B) aortic dissection exhibit acute onset of back pain or chest pain often accompanied by lower extremity ischemia and ischemic neuropathy.

The physical findings include pulse deficits, neurologic deficits, or a diastolic murmur of aortic regurgitation. However, acute aortic regurgitation into an unprepared ventricle produces only a short, soft diastolic murmur that is often missed. The widened pulse pressure and associated physical findings of chronic aortic regurgitation are absent, and the clinical picture is that of an acutely ill patient with tachypnea, tachycardia, and a narrow pulse pressure. Hypotension, jugular venous distention, and pulsus paradoxus should prompt the diagnosis of pericardial tamponade. Transesophageal echocardiography, MR angiography, or CT angiography confirm the diagnosis by demonstrating an intimal flap that separates the true lumen from the false lumen (Fig. 12.3). Type A aortic dissection is uniformly fatal without emergent surgical repair. With surgery, mortality is reduced to 10% at 24 hours and 20% at 30 days. Patients with type B aortic dissection should be treated medically because 1-year survival is higher with medical therapy than it is with surgery (75% versus 50%). However, surgery is indicated if type B dissection compromises blood flow to the legs, kidneys, or other viscera. Tight control of BP is essential because aortic aneurysm was found to develop in 30% to 50% of patients with type B aortic dissection when studied over 4 years.

Fig. 12.3 CT angiogram of the aorta shows type B aortic dissection. The intimal flap (*arrow*) separates the true lumen (*T*) from the false lumen (*F*) and compromises blood flow to the right kidney causing renal atrophy and cortical thinning. (Courtesy of Bart Domatch, MD, Radiology Department, University of Texas Southwestern Medical Center, Dallas, Texas.)

Penetrating Aortic Ulcers and Intramural Hematoma

Penetrating aortic ulcers and intramural hematomas exhibit chest pain that is indistinguishable from that of aortic dissection. In contrast to aortic dissection, however, the pathologic condition is localized. No identifiable intimal flap and thus no branch vessel occlusion are produced. Disruption of the internal elastic lamina produces aortic ulcers that erode into the medial wall and protrude into the surrounding structures. Rupture of the vasa vasorum causes formation of localized hematoma underneath the adventitia with resultant asymmetric thickening of the aortic wall. Patients with either condition typically are older than those with aortic dissection, have a larger aortic size, and have a higher prevalence of abdominal aortic aneurysm. Aortic rupture is the major complication of both penetrating ulcers and intramural hematomas, particularly with those aneurysms located in the ascending aorta. The diagnosis is made with invasive angiography, CT angiography, or MR angiography (Fig. 12.4). Surgical intervention should be considered for ulcers and hematomas of the ascending aorta, deeply penetrating ulcers, or severely bulging hematomas, irrespective of their location. Ulcers and hematomas of the descending aorta may be managed successfully with β -adrenergic blockade and tight control of BP.

Other Arterial Diseases

Buerger's disease, or thromboangiitis obliterans is a nonatherosclerotic disease of the arteries, veins, and nerves of the arms and legs affecting mostly young men before the age of 45 years. The mechanism is unknown, but all patients have a history of heavy tobacco addiction. The presenting symptom is claudication of the feet, legs, hands, or arms. Multiple-limb involvement and superficial thrombophlebitis are common. The C-reactive protein and Westergren sedimentation rate typically are normal, and a search for serologic markers for connective tissue disease (e.g., antinuclear antibody or rheumatoid factor, anti-phospholipid antibody) is negative. The diagnosis is based on the typical clinical presentation. If the presentation is atypical, then biopsy is needed to make the diagnosis. The histologic hallmark is inflammatory intramural thrombi within the arteries and veins with sparing of internal elastic lamina and other arterial wall structures. The most effective

Fig. 12.4 CT angiogram of the descending thoracic aorta shows a large penetrating aortic ulcer above the diaphragm (arrow). (Courtesy of Bart Domatch, MD, Radiology Department, University of Texas Southwestern Medical Center, Dallas, Texas.)

treatment for Buerger's disease is complete tobacco abstinence. The prostacyclin analog iloprost constitutes adjunctive therapy to reduce limb ischemia and improve wound healing.

Raynaud's phenomenon is a vasospastic disease of the small arteries of mainly the fingers and toes. Primary (idiopathic) Raynaud's phenomenon occurs in the absence of underlying disorders. Secondary Raynaud's phenomenon occurs in association with connective tissue diseases (e.g., scleroderma, polymyositis, rheumatoid arthritis, systemic lupus erythematosus), as well as with repeated mild physical trauma (e.g., use of jackhammers), certain drugs (e.g., antineoplastic chemotherapeutic agents, interferon, monoamine-reuptake inhibitors such as tricyclic antidepressants, serotonin agonists), and Buerger's disease. Patients usually complain of recurrent episodes of digital ischemia, with a characteristic white-blue-red color sequence. Pallor is followed by cyanosis if ischemia is prolonged and then by erythema (reactive hyperemia) when the episode resolves. Episodes are precipitated by cold temperature or emotional stress. Physical examination can be entirely normal between attacks with normal radial, ulnar, and pedal pulses. Some patients may have digital ulcers or thickening of fat pad (sclerodactyly). Patients should be instructed to avoid cold temperatures and dress warmly. Calcium-channel blockers (CCBs) reduce the frequency and severity of vasospastic episodes.

Giant-cell arteritis is an immune-mediated vasculitis predominantly involving medium-sized and large arteries such as the subclavian artery, axillary artery, and aorta of the older adult with a strong male predominance. Approximately 40% of patients with giant-cell arteritis also have polymyalgia rheumatica, a syndrome characterized by severe stiffness and pain originating in the muscles of the shoulders and pelvic girdle. Patients may exhibit headache from temporal arteritis, jaw claudication from ischemia of the masseter muscles, or visual loss from involvement of the ophthalmic artery. Chest pain suggests the coexistence of aortic aneurysm or dissection. Physical findings include low-grade fever, scalp tenderness in the temporal area, pale and edematous fundi, or a diastolic murmur of aortic regurgitation. BP difference of more than 15 mm Hg between arms suggests subclavian artery stenosis. Laboratory findings include significantly elevated C-reactive protein and Westergren sedimentation rate plus anemia. The diagnosis is confirmed by histologic examination of the arterial tissue (frequently from temporal artery biopsy), showing infiltration

of lymphocytes and macrophages (i.e., giant cells) in all layers of the vascular wall. High-dose corticosteroids are highly effective and should be initiated immediately when the diagnosis is suspected to prevent potentially permanent blindness. To minimize complications from long-term corticosteroid administration, the steroid dose should be tapered to find the lowest dose needed to suppress symptoms, which often wane. Every attempt should be made to discontinue corticosteroids over time, and treatment with methotrexate or the interleukin-6 receptor antagonist tocilizumab may be used as steroid sparing agents.

Takayasu's arteritis is an idiopathic granulomatous vasculitis of the aorta, its main branches, and the pulmonary artery. This condition is particularly common in young women of Asian descent, but it also occurs in non-Asian women and men. The inflammatory process in the vascular wall can lead to stenosis and/or aneurysm formation. Hypertension, as a result of renal artery stenosis or aortic coarctation, is the most common manifestation and is present in as many as 80% of affected individuals. Because the vascular involvement is so widespread, patients may have symptoms and signs of coronary ischemia, congestive heart failure, stroke, vertebrobasilar insufficiency, or intermittent claudication. Physical findings include bruits over the subclavian arteries or aorta, as well as diminished brachial pulses and thus a low brachial artery BP. The diagnosis is based primarily on this clinical presentation. First-line treatment is with corticosteroids. Other immunosuppressive agents such as methotrexate or cyclophosphamide are often added to prevent disease progression and relapse, and newer biologics such as anti-TNF inhibitors (infliximab, etanercept) provide a viable alternative. Immunosuppressive therapy does not cause regression of preexisting vascular stenoses or aneurysms. For this reason, percutaneous or surgical revascularization is usually required.

Arteriovenous (AV) fistulas are abnormal vascular communications that shunt blood flow from the arterial system directly into the venous system, bypassing the capillary beds that normally ensure optimal tissue perfusion and nutrient exchange. AV fistulas may be congenital, as in AV malformation (AVM), or acquired. The main causes of acquired AV fistula are penetrating trauma (e.g., gunshot, knife wound) and surgically created shunts for hemodialysis access. Patients may exhibit a pulsatile mass, symptoms related to compression of an adjacent organ, or bleeding from spontaneous rupture of an AVM. Systolic and diastolic bruits or thrills may be detectable over the fistula or AVM. An AVM in skeletal muscle may lead to bone malformation or a pathologic fracture, whereas AVM in the brain may result in neurologic deficits or seizures. High-output heart failure is another complication from a large AVM or fistula. MR angiography, CT angiography, or conventional angiography confirms the diagnosis. Depending on the size and location of the AVM, treatment options include surgical resection, transcatheter embolization, or pulse laser irradiation. Patients with acquired AV fistulas from trauma usually need surgical closure.

PULMONARY VASCULAR DISEASE

Pulmonary hypertension is characterized by elevated mean pulmonary artery pressure (PAP) of greater than 20 mm Hg at rest. The many causes of pulmonary hypertension are summarized in [Table 12.3](#).

Patients with pulmonary hypertension not only have an elevated pulmonary arterial pressure but also a low cardiac output, causing symptoms of exertional dyspnea, fatigue, and syncope. Pulmonary capillary wedge pressure is usually normal (≤ 15 mm Hg) except in patients with pulmonary hypertension due to impaired left ventricular systolic or diastolic function or left-sided valvular heart disease.

TABLE 12.3 Classification of Pulmonary Hypertension**Category 1: Pulmonary Arterial Hypertension (PAH)**

Primary pulmonary hypertension (PPH) or idiopathic pulmonary hypertension (IPAH):

- Sporadic
- Familial

PPH associated with:

- Connective tissue disease
- Congenital heart disease
- Portal hypertension
- Human immunodeficiency viral infection
- Drugs and toxins: Anorexigens, cocaine, methamphetamine

Category 2: Pulmonary Venous Hypertension

- Left ventricular heart failure
- Left ventricular valvular heart disease

Category 3: Pulmonary Hypertension Associated With Chronic Respiratory Disease or Hypoxemia

- Chronic obstructive pulmonary disease
- Obstructive sleep apnea

Category 4: Pulmonary Hypertension Associated With Chronic Venous Thromboembolism

- Left ventricular valvular heart disease

Category 5: Pulmonary Hypertension Due to Miscellaneous Disorders Directly Affecting the Pulmonary Vasculature

- Sarcoidosis, histiocytosis X, compression of pulmonary vessels (adenopathy, tumor, fibrosing mediastinitis)

Pulmonary Arterial Hypertension

Pulmonary arterial hypertension (PAH) is caused by a combination of pulmonary vasoconstriction, endothelial cell and/or smooth muscle proliferation, intimal fibrosis, and thrombosis in the pulmonary capillaries and arterioles. PAH is either idiopathic (primary pulmonary hypertension [PPH]) or secondary to connective tissue disease, congenital heart disease, portal hypertension, or human immunodeficiency viral (HIV) infection, as well as anorexigenic drugs or toxins. Connective tissue diseases, particularly scleroderma, are the most common secondary causes of PAH.

Patients with mild PAH can be asymptomatic, but patients with more advanced disease complain of exertional dyspnea, chest pain, syncope, or presyncope. Orthopnea is an uncommon symptom associated with PAH and more commonly identified in patients with pulmonary hypertension from left-sided heart disease. Physical findings include a left parasternal lift, loud pulmonary component of the second heart sound, murmur of tricuspid or pulmonic regurgitation, hepatomegaly, peripheral edema, or ascites. Associated ECG abnormalities indicate right ventricular hypertrophy, right atrial enlargement, or right axis deviation. Echocardiography provides important information about the severity of the pulmonary hypertension (i.e., estimated pulmonary artery pressure, right ventricular dimensions and function) and its potential causes (e.g., left ventricular failure, valvular lesions, congenital heart disease with left-to-right shunts). Pulmonary function tests, ventilation-perfusion (\dot{V}/\dot{Q}) lung scans, polysomnography or overnight oximetry, autoantibody tests, HIV serology, and liver-function tests also should be performed to determine other potential causes. Right ventricular catheterization should be performed in all patients

with suspected PAH. Under basal conditions in the catheterization laboratory, an elevated mean pulmonary artery pressure exceeding 20 mm Hg, a pulmonary capillary wedge pressure below 15 mm Hg, and a pulmonary vascular resistance exceeding 3 units confirm the diagnosis. Acute vasodilator drug challenge should be performed during right ventricular catheterization to guide appropriate treatment.

Without treatment, the prognosis of PAH is poor with a median survival of less than 3 years. Patients with high-risk features for clinical deterioration or death, including poor functional capacity, history of syncope, or right ventricular failure, should be treated with intravenous epoprostenol (a prostacyclin analog) because of its proven efficacy to improve exercise capacity and overall survival. Other prostacyclin analogs such as beraprost, treprostinil, and iloprost or prostacyclin-receptor agonists such as selexipag are also effective in reducing pulmonary artery pressure and improving exercise capacity. Other classes of medications approved for treatment of PAH include drugs that target the endothelin pathway and nitric oxide (NO) pathway. Currently available endothelin-receptor antagonists (ERAs) include bosentan, ambrisentan, macitentan. Drugs in the NO pathway include soluble guanyl cyclase stimulators (riociguat), and phosphodiesterase (PDE)5 inhibitors (sildenafil, tadalafil). Combination therapy of two to three drugs from different classes improves exercise capacity when compared to monotherapy and should be considered in patients with severe disease or those who fail to improve with monotherapy. Oral calcium-channel blockers (CCBs) are indicated only for the small subset of patients with mild-to-moderate symptoms who demonstrate significant reduction in pulmonary pressure with acute CCB challenge (decrease in mean PAP of at least 10 mm Hg to an absolute level of less than 40 mm Hg without a decrease in cardiac output). Supplemental home oxygen is indicated for all patients with hypoxemia. Travel to high elevations exacerbates hypoxia, and relocation to sea level improves symptoms. Oral anticoagulation should be considered for patients with PAH, particularly in those with a chronic indwelling central venous catheter for intravenous epoprostenol. Iron status should be monitored regularly to avoid iron deficiency anemia to prevent further deterioration in functional capacity. Diuretics should be prescribed for patients with peripheral edema or hepatic congestion. Lung transplantation is recommended only for patients in whom severe symptoms occur despite intensive medical therapy.

VENOUS THROMBOEMBOLIC DISEASE

Venous thromboembolism (VTE) encompasses both deep vein thrombosis (DVT) and pulmonary embolism (PE). Among the adult United States population, the overall combined annual incidence is as high as 2 new cases per 1000 persons. The incidence of VTE is higher in men than it is in women and higher in African Americans and white individuals than it is in Asians and Hispanics. Over 150 years ago, Dr. Rudolf Virchow recognized three predisposing factors: (1) endothelial damage, (2) venous stasis, and (3) hypercoagulation (Virchow's triad). Endothelial damage is common with surgery or trauma, venous stasis is common with prolonged bedrest or immobilization (leg cast), and hypercoagulation is more prevalent with cancer, oral estrogen use, and pregnancy. Trousseau syndrome consists of migratory thrombophlebitis with noninfectious vegetations on the heart valves (marantic endocarditis) typically in the setting of mucin-secreting adenocarcinoma. Dr. Trousseau, a pathologist, diagnosed his own pancreatic carcinoma on the basis of the association that now bears his name. Hypercoagulable states include hereditary diseases such as deficiencies in antithrombin III, protein C, or protein S; mutation in factor V gene (factor V Leiden) or factor II gene (prothrombin G20210A); as well as

hyperhomocysteinemia. However, a thorough search for identifiable risk factors will come up negative in 25% to 50% of patients with VTE.

Deep Vein Thrombosis

Most DVT starts in the calf veins. Without treatment, 15% to 30% of these clots propagate to the proximal calf veins. The risk of a subsequent PE is much higher with proximal DVT than with clots confined to the distal calf vessels (40% to 50% versus 5% to 10%, respectively). Involvement of the upper extremities is much less common, but subclavian and/or axillary vein thrombosis also can lead to PE in as many as 30% of affected individuals. The same risk factors that cause lower extremity DVT also cause upper extremity DVT. In addition, other specific causes of upper extremity DVT include traumatic damage of the vessel intima from heavy exertion such as rowing, wrestling, or weight lifting (Paget-Schroetter syndrome), from extrinsic compression at the level of thoracic inlet (thoracic outlet obstruction), or from insertion of central venous catheters or pacemakers. Pain and/or swelling are the major complaints from patients with DVT; however, a large number of patients with DVT are asymptomatic, particularly if the DVT is restricted to the calf. Patients with upper-extremity DVT can develop the superior vena caval syndrome of facial swelling, blurred vision, and dyspnea. Thoracic outlet obstruction can compress the brachial plexus leading to unilateral arm pain associated with hand weakness. Physical examination frequently reveals tenderness, erythema, warmth, and swelling below the site of thrombosis. Pain with dorsiflexion of the foot (Homan's sign) may be present, but the low sensitivity and the low specificity limit its usefulness in the diagnosis of lower extremity DVT. A palpable tender cord, dilated superficial veins, and low-grade fever occur in some patients. Upper extremity DVT can cause brachial plexus tenderness in the supraclavicular fossa and atrophic hand muscles. For patients with probable thoracic outlet obstruction, several provocative tests should be performed. Adson test is positive if the radial pulses weaken during inspiration and during extension of the arm of the affected side while rotating the head to the same side. Wright test is positive if the radial pulses become weaker and painful symptoms are reproduced while abducting the shoulder of the affected side with the humerus externally rotated.

The laboratory diagnosis of DVT includes measurement of D-dimers, which are fibrin degradation products. D-dimer elevation is a highly sensitive indicator of DVT that can be performed rapidly in the emergency department. In a patient with low to intermediate probability, a negative D-dimer test effectively excludes the diagnosis of DVT. However, the test is not specific and can be elevated in many other conditions frequently encountered in hospitalized patients (e.g., inflammation, recent surgery, malignancy). Duplex ultrasonography can be used to demonstrate the presence of a blood clot and/or noncompressibility of the affected veins proximal to the site of occlusion. Duplex ultrasonography has greater sensitivity in detecting proximal DVT (90% to 100%) than distal DVT (40% to 90%) of the lower extremities. With upper extremity DVT, acoustic shadowing of the clavicle may obscure detection of thrombosis in subclavian vein segments. MR angiography is particularly helpful in making the diagnosis of upper extremity DVT and pelvic vein thrombosis. Contrast venography is the conventional gold standard test, but it is invasive and technically difficult in patients with edematous extremities. Therefore, invasive venography should be reserved for patients in whom the clinical suggestion is high, despite negative or inconclusive results from noninvasive imaging.

Patients with DVT should be treated initially with subcutaneous low-molecular-weight heparin (LMWH), or subcutaneous selective factor Xa inhibitor fondaparinux to prevent thrombus propagation and to maintain the patency of venous collaterals. Oral administration of

factor Xa inhibitors, rivaroxaban or apixaban, may also be used in the initial monotherapy without pretreatment with heparin. In contrast, other direct anticoagulants such as dabigatran and edoxaban should be started only after an initial parenteral heparin or fondaparinux therapy for 3 to 5 days. Intravenous unfractionated heparin (UFH) should be given to only selected patients with DVT, such as those with severe renal failure (creatinine clearance of <30 mL/minute) in whom LMWH and fondaparinux are contraindicated or those with hemodynamic instability who may require thrombolytic therapy or invasive intervention. Intravenous UFH should be given as a bolus, followed by continuous infusion to maintain an activated partial thromboplastin time of at least 1.5 times the control value. LMWH and fondaparinux has a longer half-life than UFH and can be given once or twice daily with similar efficacy. Oral anticoagulation should be initiated after the acute phase. In general, direct anticoagulants (DOACs) including dabigatran, rivaroxaban, apixaban, and edoxaban are preferred over warfarin because of lower risk of intracranial hemorrhage without compromising anti-thrombotic efficacy. If warfarin is chosen, it should be initiated without delay with an overlap period with LMWH, UFH, or fondaparinux therapy and titrated until the international normalized ratio (INR) reaches a value between 2 and 3. DOACs, however, have rapid onset of action and should be started at the discontinuation of UFH, LMWH, or fondaparinux without overlap period to avoid bleeding complication. After the acute phase, oral anticoagulants should be continued for 3 months in most patients. Lifelong anticoagulation should be considered in patients with unprovoked proximal DVT (either first episode or recurrent event) as well as patients with cancer-associated DVT with low to moderate bleeding risk. Furthermore, avoidance of frequent clinic visits to monitor INR during the initial period of warfarin titration is another major advantage of DOACs. When DVT is confined to the calf, the risk of PE is lower than proximal DVT. Therefore, anticoagulants should be started only in patients with severe symptoms or those with high-risk features for clot expansion, such as elevated D-dimer, large thrombus with greater than 5 cm in length, multiple vein involvement, history of thromboembolic events or active cancer, unprovoked DVT, or inpatient status. Oral anticoagulants should be continued for 3 months in most patients. In the absence of severe symptoms or risk factors for clot extension, patients with isolated distal DVT should be treated conservatively without anticoagulation with close monitoring via serial imaging of the deep veins for 2 weeks.

When upper extremity DVT occurs in the subclavian veins or axillary veins in patients who are severely symptomatic but otherwise healthy with low risk of bleeding, catheter-directed thrombolysis should be considered as it carries lower risk of bleeding than systemic thrombolytic therapy. The purpose of thrombolysis is to prevent or minimize the post-thrombotic syndrome, which includes chronic arm pain, swelling, hyperpigmentation, and ulceration from residual venous obstruction. In asymptomatic patients with occlusion in the more distal location, anticoagulation is preferred. If anticoagulation is stopped prematurely for any reason, aspirin should be considered in the absence of contraindication as it has been shown to reduce recurrent venous thromboembolism by 20% to 40% without increased risk of bleeding.

Catheter-based direct thrombolysis is effective in restoring venous patency and reducing post-thrombotic syndrome of venous congestion but increases risk of bleeding. Therefore, it should be considered for patients with iliofemoral DVT of recent onset who have low risk of bleeding. Vena cava filters are effective in reducing the incidence of PE, but they increase the risk of recurrent DVT. Consequently, IVC filters should be removed after 3 months. In patients treated with anticoagulation, addition of an IVC filter to anticoagulation offers no additional benefit in reducing recurrent venous thromboembolism compared

to anticoagulation alone. Therefore, it should be considered only in patients in whom anticoagulation is contraindicated.

Pulmonary Embolism

PE occurs when a thrombus dislodges from the deep veins of the upper or lower extremities. Pulmonary vascular resistance and pulmonary arterial pressure increase from two mechanisms: (1) anatomic reduction in cross-sectional area of the pulmonary vascular bed and (2) functional hypoxia-induced pulmonary vasoconstriction. The pressure overload on the right ventricle can lead to dilation, hypokinesis, and tricuspid regurgitation. When severe, elevated right ventricular end-diastolic pressure can compress the right coronary artery, causing subendocardial ischemia. In acute PE, areas of lung tissue are ventilated but underperfused. This \dot{V}/\dot{Q} mismatch and the resultant redistribution of pulmonary blood flow from the obstructed pulmonary artery to other lung regions with lower \dot{V}/\dot{Q} ratios cause arterial hypoxemia. In patients with a patent foramen ovale, hypoxemia worsens when the sudden elevation in right atrial pressure causes right-to-left shunting across the foramen.

The classic symptoms of acute PE are the sudden onset of dyspnea and pleuritic chest pain. Additional symptoms include anginal chest pain from right ventricular ischemia, hemoptysis from pulmonary infarction, and syncope or presyncope from massive PE with acute right ventricular failure (cor pulmonale). The most common physical findings are tachypnea and tachycardia. Additional physical findings include a right ventricular lift, inspiratory crackles, a loud pulmonary component of the second sound, expiratory wheezing, and a pleural rub. Symptoms and signs of proximal DVT are present in 10% to 20% of patients. Arterial blood gas analysis often reveals hypoxemia, respiratory alkalosis, and a high alveolar-to-arterial oxygen tension gradient. However, normal arterial blood gases values do not exclude the diagnosis. The most common finding with ECG analysis is sinus tachycardia. Atrial fibrillation, premature atrial contraction, and supraventricular tachycardia are less common. Other ECG changes suggest acute right ventricular strain. These include the S1-Q3-T3 pattern, a new right bundle branch block or right-axis deviation, and P-wave pulmonale. However, these findings are present in only 30% of patients with even massive PE. Common but nonspecific abnormalities with chest radiographic studies include atelectasis, pleural effusion, and pulmonary infiltrates. Less common but more specific radiographic findings include Hampton's hump (i.e., wedge-shaped infiltrate in the peripheral lung field), which is indicative of pulmonary infarction and Westermark's sign (decreased vascularity). The plasma D-dimer test is elevated in most patients with PE as a result of activation of the endogenous fibrinolytic system, which is not sufficient to dissolve the clot. Commercially available D-dimer assays have a high sensitivity and negative predictive value but low specificity, particularly with increasing age. Therefore, it is important to use age-adjusted cut-off values ($\text{age} \times 10 \mu\text{g/L}$) in patients older than 50 years old to improve specificity without compromising sensitivity of detection to above 97%. A normal age-adjusted D-dimer test effectively excludes the diagnosis of PE in patients in whom the clinical suggestion is low or intermediate. However, it should not be used to screen patients with high index of suspicion because of low negative predictive value. Elevated levels of cardiac troponin I and troponin T and other markers of myocardial injury can be found in patients with PE and are indicative of right ventricular dysfunction and a poor prognosis. Similarly, elevated natriuretic peptides, including B-type natriuretic peptide (BNP) and N-terminal pro-BNP have been shown to be predictive of adverse outcomes.

CT angiography is the imaging modality of choice in patients with suspected PE and high clinical probability because of its excellent visualization of the pulmonary artery (Fig. 12.5). The resolution of 1 mm

Fig. 12.5 Spiral chest CT angiogram shows a large thrombus in the right main pulmonary artery (arrow). (Courtesy of Michael Landay, MD, Department of Radiology, University of Texas Southwestern Medical Center, Dallas, Texas.)

or less rivals that of conventional invasive angiography. The speed of the newer generation of scanners allows acquisition of all images within a single breath-hold, avoiding respiratory motion artifacts. The overall negative predictive value of multidetector CT angiography exceeds 99%. A negative CT excludes the diagnosis of PE and eliminates the need for further diagnostic testing. The CT scan also permits detection of other pathologic conditions involving the lung parenchyma, pleura, and mediastinal structures. Such pathologic findings may mimic PE and constitute alternative causes of chest pain and dyspnea. The requirement for intravenous injection of iodinated contrast material restricts applicability to those without a history of kidney disease or an allergic reaction to contrast dye. In such patients, \dot{V}/\dot{Q} scan is a more suitable imaging modality. A completely normal \dot{V}/\dot{Q} scan effectively excludes the diagnosis without further testing. However, less than 10% of \dot{V}/\dot{Q} scans are interpreted as definitively normal. In patients in whom a moderate or high level of clinical probability of PE exists, a high-probability \dot{V}/\dot{Q} scan has a diagnostic accuracy of 90% to 100%; however, a low or intermediate probability scan is no more helpful than a coin flip. Fig. 12.6 presents an algorithm for the work-up of PE based on current evidence. Echocardiography may directly detect thrombi in the right atrium, right ventricle, or pulmonary artery or indirectly demonstrate right ventricular dysfunction, signifying presence of hemodynamically significant emboli. Therefore, it is helpful in diagnosis of PE in patients with hypotension or shock. Invasive pulmonary angiography should be reserved for patients in whom noninvasive testing is inconclusive.

Once diagnosis of PE is made, clinical risk assessment should be made to guide treatment approach. Patients with low risk based on stable hemodynamic parameters without history of cardiovascular disease or excessive bleeding risk for anticoagulation treatment may be suitable for outpatient treatment or a brief inpatient observation. Similar to the treatment of DVT described previously, oral direct anticoagulants with or without initial parenteral therapy are preferred over warfarin because of lower risk of intracranial bleeding and increased ease of use associated with DOACs. PE patients with moderate to high risk features for cardiovascular decompensation (Table 12.4) should be admitted and monitored closely (PESI class III-V, or simplified PESI of at least 1). Aggressive parenteral therapy is preferred when patients have one or more features of high clinical risk. Thrombolytic therapy with recombinant tissue plasminogen activator (rt-PA) is indicated for patients with hypotension or shock. In patients with right

ventricular enlargement or dysfunction alone without hypotension (known as submassive PE), thrombolytic therapy reduces the risk of hemodynamic decompensation at the cost of increased risk of major hemorrhage and stroke. Thus, anticoagulation alone is preferred in most cases of submassive PE. After initial treatment with heparins or fondaparinux in high-risk patients, DOACs should be administered in a similar manner to treatment of DVT. If warfarin therapy is chosen instead of DOACs, parenteral anticoagulation should be administered until a therapeutic INR of 2 to 3 is reached. Surgical or percutaneous

removal of emboli should be considered in patients with massive PE who have contraindications for thrombolytic therapy.

The time necessary to continue anticoagulation after an acute PE or DVT episode depends on the presence or absence of reversible risk factors for recurrent VTE. Patients with a history of trauma or surgery generally have a low rate of recurrent VTE; therefore, warfarin can be discontinued after 3 months of administration. Patients with cancer and VTE should be treated initially with subcutaneous fixed-dose LMWH for 3 to 6 months because of its greater efficacy than warfarin in preventing recurrent thromboembolism in this setting. Preliminary studies indicated that DOACs are as effective as LMWH in preventing thromboembolic events though the bleeding risk is higher with DOACs. After this initial period, treatment with LMWH or DOACs should be continued indefinitely unless the cancer is cured. Patients with unprovoked PE with low risk of bleeding should be treated with oral anticoagulation for more than 3 months while those with high bleeding risk should be on treatment for at least 3 months. Beyond 3 months, aspirin is an alternative to long-term warfarin and should be considered for patients who have contraindication for anticoagulation or high bleeding risk.

Venous Thromboembolism Prophylaxis

Patients who are at high risk for VTE should receive pharmacologic prophylaxis. Subcutaneous LMWH is generally preferred over subcutaneous UFH because of a modest reduction in venous thromboembolism in high-risk patients. UFH is usually reserved for patients with creatinine clearance less than 30 mL/min. Patients at high risk include those who are hospitalized with acute medical illness—particularly congestive heart failure, acute respiratory illness, acute inflammatory diseases—those who are expected to be immobilized for 3 days or longer, or patients with previous VTE. Major surgery, either elective or emergent, is an important indication for VTE prophylaxis. Subcutaneous LMWH has a marginal advantage over UFH in preventing symptomatic DVT in patients undergoing general surgery, gynecologic surgery, or neurosurgery in some but not all studies. However, LMWH is more effective

than UFH and adjusted dose warfarin (INR between 2-3) and is preferred for prevention of DVT in orthopedic surgery such as hip surgery or total knee replacement because of superior efficacy (level of evidence A). DOACs, such as dabigatran, rivaroxaban, and apixaban, have similar efficacy and safety when compared with LMWH in preventing VTE after knee surgery without increasing perioperative bleeding. Efficacy of DOACs in preventing VTE after hip surgery relative to LMWH has not been directly tested in the randomized trials. DVT prophylaxis should be continued for 10 to 14 days after knee surgery and 35 days after hip surgery. Patients undergoing major cancer surgery should receive continued prophylaxis after discharge up to 28 days. Mechanical prophylaxis with intermittent pneumatic compression has not been shown to confer additional benefit in preventing VTE in medical, surgical, and trauma ICU patients when used in combination with pharmacologic thromboprophylaxis versus pharmacologic thromboprophylaxis alone. However, it should be considered in patients with high risk of bleeding in whom anticoagulation is contraindicated.

ARTERIAL HYPERTENSION

Arterial hypertension is the leading cause of death in the world, affecting 103 million adults in the United States and 1.4 billion people worldwide. It is the most common cause for an outpatient visit to a physician and the most easily recognized treatable risk factor for stroke, myocardial infarction, heart failure, peripheral vascular disease, aortic dissection, atrial fibrillation, and end-stage kidney disease. Despite this knowledge and unequivocal scientific proof that treating hypertension with medication dramatically reduces its attendant morbidity and mortality, hypertension remains untreated or undertreated in the majority of affected individuals in all countries, including those with the most advanced systems of medical care. The 2017 American Heart Association/American College of Cardiology guideline has introduced the new threshold for diagnosis and treatment of hypertension to less than 130/80 mm Hg while most other countries in the world have continued the old thresholds of less than 140/90 mm Hg in their guidelines. Fewer than one in two Americans with hypertension have their blood pressure treated and controlled to below the new 130/80 mm Hg guideline. Globally, hypertension control rates among treated individuals have plateaued at the range below 70% since the mid-2000s (Fig 12.7). Thus, hypertension remains one of the world's great public health problems. The asymptomatic nature of the condition impedes early detection, which requires regular BP measurement. Because most cases of hypertension cannot be cured, BP control requires lifelong treatment with prescription medications, which can be costly. Effective hypertension management requires continuity of care by a regular and knowledgeable medical provider, as well as sustained active participation by an educated patient. This section reviews the most important principles in the early detection and effective treatment of hypertension.

Initial Evaluation for Hypertension

The initial evaluation for hypertension needs to accomplish three goals: (1) staging of BP, (2) assessing the patient's overall cardiovascular risk, and (3) detecting clues of secondary hypertension. The initial clinical data needed to accomplish these goals are obtained through a thorough history and physical examination, routine blood tests, a spot (preferably first morning) urine specimen, and a resting 12-lead ECG. Home BP monitoring is indicated in most patients to confirm the diagnosis of hypertension and to exclude white coat syndrome. In most cases, home BP or 24-hour ambulatory BP monitoring provides helpful additional data about the time-integral burden of BP on the cardiovascular system.

Goal 1: Accurate Assessment of Blood Pressure

Across populations, the risks of heart disease and stroke increase continuously and logarithmically with increasing levels of systolic and diastolic BPs at or above 115/75 mm Hg (Fig. 12.8). Thus, the dichotomous separation of *normal* from *high* BP is artificial. BP is currently staged as normal, elevated, or hypertension based on the average of two or more readings taken on at least two separate occasions. When a patient's average systolic and diastolic pressures fall into different stages, the higher stage applies (Table 12.5). *Elevated BP* is designated as BP in the 120 to 129 mm Hg systolic in the presence of diastolic BP below 80 mm Hg. Individuals with elevated BP are at higher risk for progression into hypertension and cardiovascular events.

BP normally varies dramatically throughout a 24-hour period. To minimize variability in readings, BP should be measured at least twice after 5 minutes of rest with the patient seated, the back supported, and the arm bare and at heart level. The most common mistake in measuring BP is using a standard-issue cuff that is too small for a large arm, producing spuriously elevated readings. Most overweight adults will require a large adult cuff. Tobacco and caffeine should be avoided for at least 30 minutes. To avoid underestimation of systolic pressure in older adults who may have an *auscultatory gap* as a result of arteriosclerosis, radial artery palpation should be performed to estimate systolic pressure; then the cuff should be inflated to a value 20 mm Hg higher than the level that obliterates the radial pulse and deflated at a rate of 3 to 5 mm Hg per second. BP should be measured in both arms and after 5 minutes of standing, the latter to exclude a significant postural fall in BP, particularly in older persons and in those with diabetes or other conditions (e.g., Parkinson's disease) that predispose the patient to autonomic insufficiency.

However, out-of-office readings either with home or ambulatory BP monitoring are required to accurately assess a person's typical BP. Because of the anxiety of going to the physician, BPs often are higher in the physician's office than when measured at home or during normal daily life outside the home. Self-monitoring of BP outside of the physician's office actively engages a patient in his or her own health care and provides a better estimate of a person's usual BP for medical decision making. BP should be measured in early morning and evening times. Three BP readings should be obtained during each measurement, separated by at least 1 minute. Because the first BP tends to be the highest, average BP should be used to assess home BP. Many electronic home monitors are available, but only a handful of models have been rigorously validated against mercury sphygmomanometry and can be recommended.

Ambulatory monitoring provides automated measurements of BP over a 24- or 48-hour period while patients are engaged in their usual activities, including sleep (Fig. 12.9). The *normal limits of 24-hour ambulatory BP*, which are corresponding to office BP of 130/80 mm Hg, are a mean daytime BP of less than 130/80 mm Hg, mean nighttime BP of 110/65 mm Hg, and a mean 24-hour BP of less than 125/75 mm Hg. To avoid undertreating hypertension, these lower treatment thresholds must be used when incorporating ambulatory monitoring in medical decision making. With self-monitoring of BP at home, an average value of less than 130/80 mm Hg should be considered the upper limit of normal.

Up to one third of patients with elevated office BPs have normal home or ambulatory BPs. If the 24-hour BP profile is completely normal and no target organ damage has occurred despite consistently elevated office readings, then the patient has *office only*, or *white coat*, hypertension, presumably the result of a transient adrenergic response to the measurement of BP in the physician's office (see Fig. 12.9). In other patients, office readings underestimate ambulatory BP,

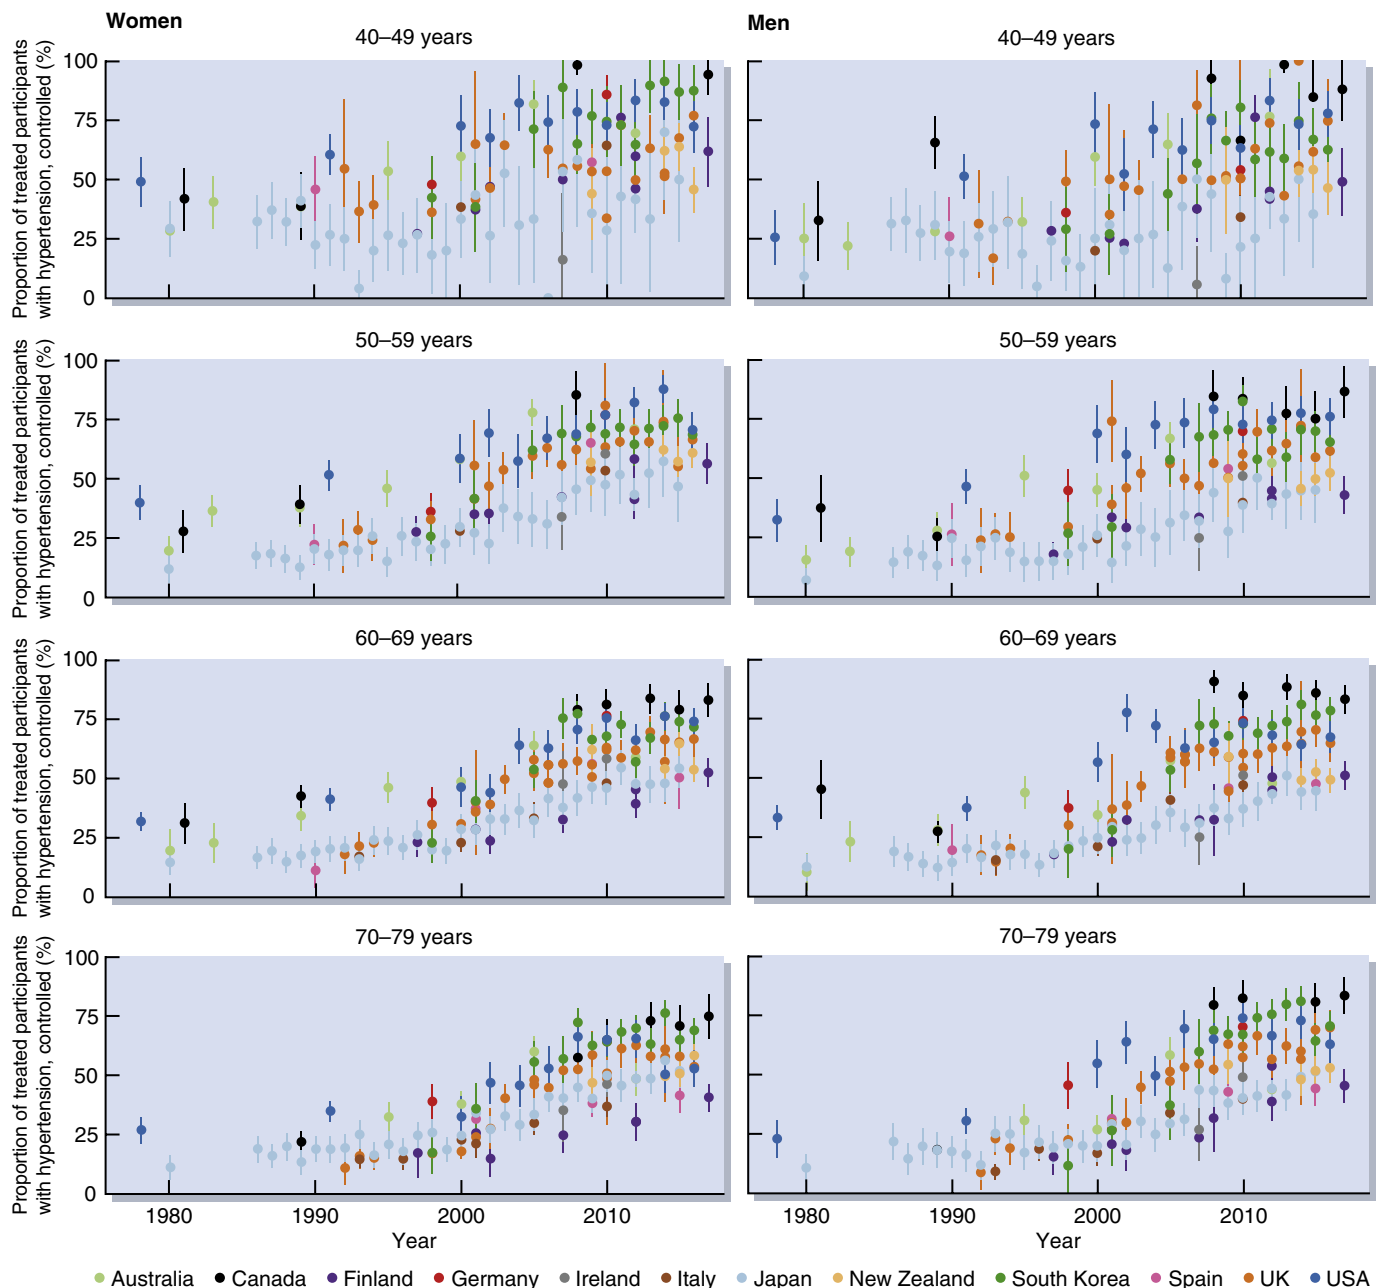

Fig. 12.7 Trends in hypertension control rates in 12 high-income countries. (NCD Risk Factor Collaboration [NCD-RisC], Lancet July 2019;10199:639-651.)

presumably because of sympathetic overactivity in daily life owing to job or home stress, tobacco use, or other adrenergic stimulation that dissipates when coming to the office (Fig. 12.10). Such documentation prevents underdiagnosing and undertreating this *masked hypertension*, which is also associated with high cardiovascular risks and identified in 10% of hypertensive patients in general, up to 40% of those with diabetes, and 70% of African American patients with hypertensive kidney disease.

Goal 2: Cardiovascular Risk Stratification

The great majority of patients with BPs in the prehypertensive or hypertensive range will have one or more additional modifiable risk factors for atherosclerosis (e.g., hypercholesterolemia, cigarette smoking, diabetes). The Pooled Cohort Equations (PCEs) is now recommended to estimate the 10-year risk of ASCVD

(atherosclerotic cardiovascular disease) among patients without history of cardiovascular disease in hypertensive patients. Patients with 10-year ASCVD risk of 10% or higher with BP of at least 130/80 mm Hg should be started on antihypertensive drug treatment without delay. In addition to ASCVD risk, presence of target organ involvement, such as left ventricular hypertrophy or proteinuria, which are not captured by PCEs but should be considered as a high-risk feature.

Goal 3: Identification of Secondary (Identifiable) Causes of Hypertension

A thorough search for secondary causes is not cost-effective in most patients with hypertension, but it becomes critically important in two circumstances: (1) when a compelling cause is found on the initial evaluation, or (2) when the hypertensive process is so severe that

Fig. 12.8 Age-specific relevance of usual blood pressure to vascular mortality. Increased risk of myocardial infarction and stroke was observed with increasing levels of systolic BP beginning at the level of 115 mm Hg. (From Lewington S, et al. Age-specific relevance of usual blood pressure to vascular mortality: A meta-analysis of individual data for one million adults in 61 prospective studies. *The Lancet* 2002;360:1903-1913.)

TABLE 12.5 Staging of Office Blood Pressure*

Blood Pressure Category	Systolic Blood Pressure (mm Hg)	Diastolic Blood Pressure (mm Hg)
Normal	<120	and <80
Elevated	120-129	and <80
Stage 1 hypertension	130-139	or 80-89
Stage 2 hypertension	≥140	or ≥90

*Calculation of seated blood pressure is based on the mean of two or more readings on at least two separate occasions.

From Whelton PK, Carey RM, Aronow WS, et al. 2017 ACC/AHA/AAPA/ABC/ACPM/AGS/APhA/ASH/ASPC/NMA/PCNA guideline for the prevention, detection, evaluation, and management of high blood pressure in adults: a report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines. *Circulation* 2018. 138(17):e426-e483.

it either is refractory to intensive multiple-drug therapy or requires hospitalization. **Table 12.6** summarizes the major causes of secondary hypertension that should be suggested on the basis of a good history, physical, and routine laboratory tests.

Renal Parenchymal Hypertension

Chronic kidney disease is the most common cause of secondary hypertension. Hypertension is present in more than 85% of patients with chronic kidney disease and is a major factor causing their increased cardiovascular morbidity and mortality. The mechanisms causing the hypertension include an expanded plasma volume and peripheral vasoconstriction, with the latter caused by both activation of vasoconstrictor pathways (renin-angiotensin and sympathetic nervous systems) and inhibition of vasodilator pathways (nitric oxide). Renal insufficiency should be considered when microalbuminuria of more than 30 mg/gram of creatinine is present or when the estimated glomerular filtration rate (eGFR) is below 60 mL/min/1.73 m².

Renovascular Hypertension

Unilateral or bilateral renal artery stenosis is present in less than 2% of patients with hypertension in a general medical practice but up to 30% in patients with medically refractory hypertension. The main causes of renal artery stenosis are atherosclerosis (85% of patients), typically in older adults with other clinical manifestations of systemic atherosclerosis and fibromuscular dysplasia (15% of patients), typically in women between the ages of 15 and 50 years. Unilateral renal artery stenosis leads to underperfusion of the juxtaglomerular cells, thereby producing renin-dependent hypertension even though the contralateral kidney is able to maintain normal blood volume. In contrast, bilateral renal artery stenosis (or unilateral stenosis with a solitary kidney) constitutes a potentially reversible cause of progressive renal failure and volume-dependent hypertension. The following clinical clues increase the suggestion of renovascular hypertension: any hospitalization for urgent or emergent hypertension; recurrent *flash* pulmonary edema; recent worsening of long-standing, previously well-controlled hypertension; severe hypertension in a young adult or in an adult after 50 years of age; precipitously and progressively worsening of renal function in response to angiotensin-converting enzyme (ACE) inhibition or angiotensin II-receptor blockade (ARB); unilateral small kidney by any radiographic study; extensive peripheral arteriosclerosis; or a flank bruit. The diagnosis is confirmed by noninvasive testing with MR or spiral computed tomographic (CT) angiography (**Fig. 12.11**). Renal artery angioplasty often cures fibromuscular dysplasia. Atherosclerotic renal artery stenosis should be treated with intensive medical management of atherosclerotic risk factors (hypertension, lipids, smoking cessation). Revascularization should be considered for the following indications: (1) medically refractory hypertension, (2) progressive renal failure on medical therapy, and (3) bilateral renal artery stenosis or stenosis of a solitary functioning kidney.

Primary Aldosteronism

The most common causes of primary aldosteronism are (1) a unilateral aldosterone-producing adenoma and (2) bilateral adrenal hyperplasia. Because aldosterone is the principal ligand for the mineralocorticoid

Fig. 12.9 Twenty-four hour ambulatory blood pressure (BP) monitor tracings in two different patients. (A) Optimal blood pressure (BP) in a healthy 37-year-old woman. The normal variability in BP, the nocturnal dip in BP during sleep, and the sharp increase in BP on awakening are noted. (B) Pronounced white coat effect in an 80-year-old woman referred for evaluation of medically refractory hypertension. Documentation of the white coat effect prevented overtreatment of the patient's isolated systolic hypertension.

Fig. 12.10 Twenty-four hour ambulatory blood pressure (BP) monitor tracing shows both masked hypertension and nocturnal hypertension in a 55-year-old man with stage 3 chronic kidney disease. Treatment with three different antihypertensive medications in this patient produced an office BP of 125/75 mm Hg, which seems to be at goal. However, progressive hypertensive heart disease and deterioration of renal function suggested masked hypertension. Ambulatory monitoring revealed that the patient's treated BP was much higher out of the office, documenting both masked hypertension (ambulatory BP of 175/95 mm Hg) and sustained nocturnal hypertension (BP of 175/90 mm Hg). Additional medication was added. (Courtesy of Ronald G. Victor, MD, Hypertension Division, Department of Internal Medicine, University of Texas Southwestern Medical Center, Dallas, Texas.)

receptor in the distal nephron, excessive aldosterone production causes excessive renal Na^+ - K^+ exchange, often resulting in hypokalemia. The diagnosis should always be suggested when hypertension is accompanied by either unprovoked hypokalemia (serum K^+ less than 3.5 mmol/L in the absence of diuretic therapy) or a tendency to develop excessive hypokalemia during diuretic therapy (serum K^+ less than 3.0

mmol/L). However, more than one third of patients do not have hypokalemia on initial presentation, and the diagnosis should be considered in any patient with refractory hypertension. The diagnosis is confirmed by the demonstration of nonsuppressible hyperaldosteronism during salt loading, followed by adrenal vein sampling to distinguish between a unilateral adenoma and bilateral hyperplasia. Laparoscopic adrenalectomy is the treatment of choice for unilateral aldosterone-producing adenoma, whereas pharmacologic mineralocorticoid-receptor blockade with eplerenone is the treatment for bilateral adrenal hyperplasia.

Mendelian Forms of Hypertension

Nine very rare forms of severe early-onset hypertension are inherited as Mendelian traits. In each case, the hypertension is mineralocorticoid-induced and involves excessive activation of the epithelial sodium channel (*ENaC*), the final common pathway for reabsorption of sodium from the distal nephron. The resultant salt-dependent hypertension can be caused by both gain-of-function mutations of *ENaC* (Liddle's syndrome) or the mineralocorticoid receptor (i.e., a rare form of pregnancy-induced hypertension) and by increased production or decreased clearance of mineralocorticoids. These include aldosterone (glucocorticoid-remediable aldosteronism), deoxycorticosterone (17-hydroxylase deficiency), and cortisol (syndrome of apparent mineralocorticoid excess). Mutations in the potassium channel subunit *KCNJ5* and chloride channel *CLCN2* have been linked to familial aldosteronism by increasing aldosterone release and/or increasing proliferation of zona glomerulosa cells.

Pheochromocytoma and Paraganglioma

Pheochromocytomas are rare catecholamine-producing tumors of the adrenal chromaffin cells. Paragangliomas are even rarer extra-adrenal catecholamine-producing or nonfunctional tumors of sympathetic and parasympathetic ganglia. The diagnosis should be suggested when hypertension is accompanied by paroxysms of headaches, palpitations, pallor, or diaphoresis. However, the most common presentation of pheochromocytoma is an adrenal incidentaloma, an incidental adrenal mass discovered unexpectedly on abdominal imaging for another indication. In some patients,

TABLE 12.6 Guide to Evaluation of Secondary Hypertension

Probable Diagnosis	Clinical Clues	Diagnostic Testing
Renal parenchymal hypertension	Estimated GFR <60 mL/min/1.73 m ² Urine albumin:creatinine >30 mg/g	Renal ultrasound
Renovascular disease	New elevation in serum creatinine, significant elevation in serum creatinine with initiation of ACEI or ARBs, refractory hypertension, flash pulmonary edema, abdominal bruit Coarctation of the aorta pulses, arm BP >leg BP, chest bruits, rib notching on chest radiograph	MR or CT angiography, invasive angiogram Arm pulses >leg chest MR or CT, aortogram
Primary aldosteronism	Hypokalemia, refractory hypertension	Plasma renin and aldosterone, 24-hr urine potassium, 24-hr urine aldosterone and potassium after salt loading, adrenal CT scan, adrenal vein sampling
Cushing's syndrome	Truncal obesity, wide and blanching	24-hr urine cortisol, purple striae, muscle weakness, dexamethasone suppression test, adrenal CT scan
Pheochromocytoma	Spells of paroxysmal hypertension, palpitations, perspiration, pallor Pain in the head Diabetes	Plasma and 24-hr urine metanephrines and catecholamines, adrenal CT scan
Obstructive sleep apnea	Loud snoring, daytime somnolence, obesity, large neck	Sleep study

ACEI, Angiotensin-converting enzyme inhibitor; ARBs, angiotensin-receptor blockers; BP, blood pressure; CT, computed tomography; GFR, glomerular filtration rate; MR, magnetic resonance.

Fig. 12.11 Computed tomography (CT) angiogram with three-dimensional reconstruction. (A) Classic *string-of-beads* lesion of fibromuscular dysplasia. pheochromocytoma is misdiagnosed as panic disorder. A family history of early-onset hypertension may suggest pheochromocytoma as part of the multiple endocrine neoplasia syndromes or familial paraganglioma. If the diagnosis is missed, then outpouring of catecholamines from the tumor can cause an unsuspected hypertensive crisis during unrelated radiologic or surgical procedures; the perioperative mortality exceeds 80% in such patients.

Laboratory confirmation of pheochromocytoma is made by demonstrating elevated levels of plasma or urinary metanephrines; these are methylated derivatives of norepinephrine and epinephrine that are made in the adrenal medulla and continually leak out into

the plasma even between blood pressure spikes. Pheochromocytomas are typically large adrenal tumors that can usually be localized by CT or MR imaging, although nuclear scanning with specific isotopes that localize to chromaffin tissue is occasionally needed to identify smaller tumors and paragangliomas.

Treatment of these tumors is surgical resection. Patients must receive adequate preoperative management with α -blockade followed by β -blockade and volume expansion to prevent the hemodynamic swings that can occur during surgical manipulation of the tumor. For unresectable tumors, chronic therapy with the α -adrenergic blocker phenoxybenzamine is usually effective.

TABLE 12.7 Oral Antihypertensive Agents

Drug	Dose Range, Total mg/day (Doses Per Day)	Drug	Dose Range, Total mg/day (Doses Per Day)
Diuretics		Diuretics	
Thiazide Diuretics		Thiazide Diuretics	
Hydrochlorothiazide (HCTZ)	6.25-50 (1)	Ramipril	2.5-20 (1)
Chlorthalidone	12.5-25 (1)	Trandolapril	1-8 (1)
Indapamide	1.25-5 (1)	Angiotensin-Receptor Blockers	
Metolazone	2.5-5 (1)	Azilsartan	40-80 mg (1)
Loop Diuretics		Candesartan	8-32 (1)
Furosemide	20-160 (2)	Eprosartan	400-800 (1-2)
Torsemide	2.5-20 (1-2)	Irbesartan	150-300 (1)
Bumetanide	0.5-2 (2)	Losartan	25-100 (2)
Ethacrynic acid	25-100 (2)	Olmesartan	5-40 (1)
Potassium-Sparing		Telmisartan	20-80 (1)
Amiloride	5-20 (1)	Valsartan	80-320 (1-2)
Triamterene	25-100 (1)	Direct Renin Inhibitor	
Spiroglactone	12.5-400 (1-2)	Aliskiren	75-300 (1)
Eplerenone	25-100 (1-2)	α-Blockers	
β-Blockers		Doxazosin	1-16 (1)
Acebutolol	200-800 (2)	Prazosin	1-40 (2-3)
Atenolol	25-100 (1)	Terazosin	1-20 (1)
Betaxolol	5-20 (1)	Phenoxybenzamine	20-120 (2) for pheochromocytoma
Bisoprolol	2.5-20 (1)	Central Sympatholytics	
Carteolol	2.5-10 (1)	Clonidine	0.2-1.2 (2-3)
Metoprolol	50-450 (2)	Clonidine patch	0.1-0.6 (weekly)
Metoprolol XL	50-200 (1-2)	Guanabenz	2-32 (2)
Nadolol	20-320 (1)	Guanfacine	1-3 (1) (q hs)
Nebivolol	5-40 (1)	Methyldopa	250-1000 (2)
Penbutolol	10-80 (1)	Reserpine	0.05-0.25 (1)
Pindolol	10-60 (2)	Direct Vasodilators	
Propranolol	40-180 (2)	Hydralazine	10-200 (2)
Propranolol LA	60-180 (1-2)	Minoxidil	2.5-100 (1)
Timolol	20-60 (2)	Fixed-Dose Combinations	
β/α-Blockers		Aliskiren/HCTZ	75-300/12.5-25 (1)
Labetalol	200-2400 (2)	Amiloride/HCTZ	5/50 (1)
Carvedilol	6.25-50 (2)	Amlodipine/benazepril	2.5-5/10-20 (1)
Calcium-Channel Blockers		Amlodipine/valsartan	5-10/160-320 (1)
Dihydropyridines		Amlodipine/olmesartan	5-10/20-40 (1)
Amlodipine	2.5-10 (1)	Atenolol/chlorthalidone	50-100/25 (1)
Felodipine	2.5-20 (1-2)	Azilsartan/chlorthalidone	40-80/12.5-25 (1)
Isradipine CR	2.5-20 (2)	Benazepril/HCTZ	5-20/6.25-25 (1)
Nicardipine SR	30-120 (2)	Bisoprolol/HCTZ	2.5-10/6.25 (1)
Nifedipine XL	30-120 (1)	Candesartan/HCTZ	16-32/12.5-25 (1)
Nisoldipine	10-40 (12)	Enalapril/HCTZ	5-10/25 (1-2)
Nondihydropyridines		Eprosartan/HCTZ	600/12.5-25 (1)
Diltiazem CD	120-540 (1)	Fosinopril/HCTZ	10-20/12.5 (1)
Verapamil HS	120-480 (1)	Irbesartan/HCTZ	15-30/12.5-25 (1)
Angiotensin-Converting Enzyme Inhibitors		Losartan/HCTZ	50-100/12.5-25 (1)
Benazepril	10-80 (12)	Olmesartan/amlodipine	20-40/5-10 (1)
Captopril	25-150 (2)	Olmesartan/HCTZ	20-40/12.5-25 (1)
Enalapril	2.5-40 (2)	Olmesartan/amlodipine/HCTZ	20-40/5-10/12.5-25 (1)
Fosinopril	10-80 (1-2)	Spiroglactone/HCTZ	25/25 (1/2-1)
Lisinopril	5-80 (1-2)	Telmisartan/HCTZ	40-80/12.5-25 (1)
Moexipril	7.5-30 (1)	Trandolapril/verapamil	2-4/180-240 (1)
Perindopril	4-16 (1)	Triamterene/HCTZ	37.5/25 (1/2-1)
Quinapril	5-80 (1-2)	Valsartan/HCTZ	80-160/12.5-25 (1)
		Valsartan/amlodipine/HCTZ	80-160/5-10/12.5-25 (1)

Pheochromocytoma is a great masquerader and the large differential diagnosis includes causes of neurogenic hypertension such as sympathomimetic agents (cocaine, methamphetamine), baroreflex failure, and obstructive sleep apnea. A history of surgery and radiation therapy for head-and-neck tumors suggests the possibility of baroreceptor damage. Loud snoring, obesity, and somnolence suggest obstructive sleep apnea. Weight loss, continuous positive airway pressure, and corrective surgery improve BP control in some patients with sleep apnea.

Other causes of secondary hypertension include nonsteroidal anti-inflammatory drugs (NSAIDs), hypothyroidism, hyperthyroidism, coarctation of the aorta, and immunosuppressive drugs, especially cyclosporine and tacrolimus.

TREATMENT OF HYPERTENSION

Prescription medication is the cornerstone of treating hypertension. Lifestyle modification should be used as an adjunct but not as an alternative to life-saving BP medication. Most dietary sodium (Na^+) comes from processed foods, and daily salt consumption should be reduced to less than 4 grams, which is equivalent to 1500 mg or 65 mmol of Na^+ . The **Dietary Approach to Stop Hypertension** (DASH diet), which is rich in fresh fruits and vegetables (for high potassium content) and low-fat dairy products, has been shown to lower BP in feeding trials. Other lifestyle modifications that can lower BP include weight loss in overweight patients with hypertension, regular aerobic exercise, smoking cessation, and moderation in alcohol intake.

The list of antihypertensive drugs marketed for the treatment of hypertension in the United States is shown in [Table 12.7](#). Major contraindications and side effects of these drugs are summarized in [Table 12.8](#).

Patients With Uncomplicated Hypertension

The three first-line drug classes for uncomplicated hypertension are: (1) CCB, (2) ACEI or ARB, and (3) thiazide diuretic. The 2017 ACC/AHA high blood pressure guideline, recommended any one of these three drug classes as initial therapy for most patients with hypertension. It also recommended initiating therapy with two first-line drugs of different classes, either as separate agents or in a fixed-dose combination for individuals with BP more than 20/10 mm Hg above their target goal. β -Blockers are not recommended as first-line therapy unless patients have other compelling indications (such as heart failure or ischemic heart disease) because it is inferior to three first-line drug classes in preventing target organ damage and cardiovascular events. In contrast, the European Society of Hypertension endorses β -blocker as the first-line agent, arguing that the most effective drugs are those that the patient will tolerate and take. Long-term patient adherence is best with an ARB, intermediate with an ACEI or CCB, and worst with a thiazide. Initiation of single pill combination therapy is encouraged as it allows BP control to reach target goal faster and improves long-term adherence. The European Society of Hypertension advocates a treatment strategy that is based on the patient's age and ethnicity. It recommends upfront combination therapy of RAS blocker (either an ACE inhibitor or an ARB) with a CCB or diuretic except in frail older adults with mild hypertension, in whom a monotherapy is recommended.

A growing body of evidence from clinical trials emphasizes the overriding importance of lowering BP with combinations of drugs rather than belaboring the choice of a single, best agent to begin therapy. Primary hypertension is multifactorial, and typically several medications (at least two or more) with different mechanisms of action (see [Table 12.7](#)) are required simultaneously to reach BP goal. In most

patients with hypertension, low-dose combination drug therapy is the only way to control BP adequately and to minimize side effects. With many classes of antihypertensive medication, the dose-response relationship for BP is rather flat. Most of the BP lowering occurs at the lower end of the dose range. However, many of the side effects are steeply dose-dependent, becoming problematic mainly at the high end of the clinical dose range. Thus, low-dose combinations achieve therapeutic synergy and minimize side effects. Fixed-dose combinations reduce pill burden and cost.

One highly effective well-tolerated combination is a CCB plus an ACEI or ARB. A large benefit of combination therapy with an ACEI plus a dihydropyridine CCB over the combination of an ACEI plus a thiazide diuretic is reducing cardiovascular events in high-risk patients. In contrast, the combination of ARB plus an ACEI or direct renin inhibitor ("dual renin-angiotensin system blockade") should be avoided because it results in deterioration of renal function and increases risk of hypotension without added cardiovascular benefit.

Kaiser-Permanente of Northern California, a large managed care organization, has increased the control of hypertension among its membership over the past decade from 44% to an astounding 80% by: increasing access with walk-in BP checks by medical assistants, registry rounds to identify and contact patients with elevated office BP, and institution of a system-wide simple medication treatment protocol that features once-daily combination therapy.

Along with antihypertensive medication, statin therapy should be strongly considered as an integral part of most antihypertensive regimens in patients with 10-year ASCVD risk of at least 7.5%.

Hypertension in African Americans

Hypertension disproportionately affects African Americans. The explanation is unknown, but the dominant importance of environmental factors is indicated by geographic variation in hypertension prevalence among African-origin and European-origin populations. Hypertension is rare among Africans living in Africa and is more prevalent in several European countries than it is in the United States. As monotherapy for hypertension, an ACEI (or ARB) generally yields a smaller decrease in BP in black African patients than it does in non-black patients and thus affords less protection against stroke. However, when an ACEI or ARB is used in combination with a CCB or a diuretic, antihypertensive efficacy is amplified and ethnic differences disappear. In addition, combination of CCB with an ACEI (or ARB) or a diuretic is superior to combination of ACEI and diuretics in lowering BP in this population. Nevertheless, an ACEI-based treatment should be considered in African American patients with hypertensive nephrosclerosis as it slows the deterioration in renal function.

Hypertensive Nephrosclerosis

Hypertension is the second most common cause of chronic kidney disease, accounting for over 25% of cases. Hypertensive nephrosclerosis is the result of persistently uncontrolled hypertension, causing chronic glomerular ischemia. Typically, proteinuria is mild (<0.5 g/24 hr). Nondiabetic chronic kidney disease is a compelling indication for ACEI-based or ARB-based antihypertensive therapy. ACEIs cause greater dilation of the efferent renal arterioles, thereby minimizing intraglomerular hypertension. In contrast, arterial vasodilators such as dihydropyridine CCBs, when used without an ACEI or ARB, preferentially dilate the afferent arteriole and impair renal autoregulation. Glomerular hypertension can result if systemic BP is not sufficiently lowered. The ACEI should be withdrawn only if the rise in serum creatinine exceeds 30% of the baseline value or the serum K increases to greater than 5.6 mmol/L.

TABLE 12.8 Major Contraindications and Side Effects of Antihypertensive Drugs

Drug Class	Major Contraindications	Side Effects
Diuretics		
Thiazides	Gout	Insulin resistance, new onset type 2 diabetes (especially in combination with β -blockers) Hypokalemia, hyponatremia Hypertriglyceridemia Hyperuricemia, precipitation of gout Erectile dysfunction (more than other drug classes) Potentiate nondepolarizing muscle relaxants Photosensitive dermatitis
Loop diuretics	Hepatic coma	Interstitial nephritis Hypokalemia Potentiate succinylcholine Potentiate aminoglycoside ototoxicity
Potassium-sparing diuretics	Serum K >5.5 mEq/L	Fatal hyperkalemia if used with salt substitutes, ACE inhibitors, ARBs, high-potassium foods, NSAIDs
β -Blockers	GFR <30 mg/mL/1.73 m ² Heart block Asthma Depression Cocaine and/or methamphetamine abuse	Insulin resistance, new onset type 2 diabetes (especially in combination with thiazides) Heart block, acute decompensated CHF Bronchospasm Depression, nightmares, fatigue Cold extremities, claudication (β 2 effect) Stevens-Johnson syndrome Agranulocytosis
ACEIs	Pregnancy Bilateral renal artery stenosis Hyperkalemia	Cough Hyperkalemia Angioedema Leukopenia Fetal toxicity Cholestatic jaundice (rare fulminant hepatic necrosis if the drug is not discontinued)
ARBs	Pregnancy Bilateral renal artery stenosis Hyperkalemia	Hyperkalemia Angioedema (very rare) Fetal toxicity
Direct Renin Inhibitors	Pregnancy Bilateral renal artery stenosis Hyperkalemia	Hyperkalemia Diarrhea
Dihydropyridine CCBs	As monotherapy in chronic kidney disease with proteinuria	Fetal toxicity Headaches Flushing Ankle edema CHF Gingival hyperplasia Esophageal reflux
Nondihydropyridine CCBs	Heart block Systolic heart failure	Bradycardia, AV block (especially with verapamil) Constipation (often severe with verapamil) Worsening of systolic function, CHF Gingival edema and/or hypertrophy Increase cyclosporine blood levels Esophageal reflux
α -Blockers	Monotherapy for hypertension Orthostatic hypotension Systolic heart failure Left ventricular dysfunction	Orthostatic hypotension Drug tolerance (in the absence of diuretic therapy) Ankle edema CHF First-dose effect (acute hypotension) Potentiate hypotension with PDE5 inhibitors (e.g., sildenafil)
Central sympatholytics	Orthostatic hypotension	Depression, dry mouth, lethargy Erectile dysfunction (dose dependent)

Continued

TABLE 12.8 Major Contraindications and Side Effects of Antihypertensive Drugs—cont'd

Drug Class	Major Contraindications	Side Effects
Direct vasodilators	Orthostatic hypotension	Rebound hypertension with clonidine withdrawal Coombs positive hemolytic anemia and elevated LFTs with α -methyldopa Reflex tachycardia Fluid retention Hirsutism, pericardial effusion with minoxidil Lupus with hydralazine

ACE, Angiotensin-converting enzyme; ARBs, angiotensin-receptor blockers; AV, arteriovenous; CCBs, calcium channel blockers; CHF, congestive heart failure; GFR, glomerular filtration rate; LFTs, liver function tests; MI, myocardial infarction; NSAIDs, nonsteroidal anti-inflammatory drugs; PDE5, phosphodiesterase type 5.

Hypertensive Patients With Diabetes

Compared with its 25% prevalence in the general adult population, hypertension is present in 75% of patients with diabetes and is a major factor contributing to excessive risk of myocardial infarction, stroke, heart failure, microvascular complications, and diabetic nephropathy progressing to end-stage renal disease. The Action to Control Cardiovascular Risk in Diabetes blood pressure trial (ACCORD BP) failed to show benefit of lowering systolic BP below 120 mm Hg in patients with type 2 diabetes mellitus in terms of reducing overall mortality or cardiovascular mortality. However, the risk of stroke was reduced by 60% in these patients. ACCORD trial also tested intensive versus standard glycemic targets (glycated hemoglobin <6% versus 7.0% to 7.9%). A more recent analysis has demonstrated benefit of intensive BP lowering in lowering cardiovascular events in diabetic patients in the standard glycemia arm but not in the intensive glycemic arm. Increased hypoglycemic events associated with intensive glycemic control may negate potential cardiovascular benefit of intensive BP lowering in this population. The Systolic Blood Pressure Intervention Trial (SPRINT), which was conducted in nondiabetic patients and has similar study design to the ACCORD trial, showed benefit of intensive BP lowering in patients with prediabetes. Consequently, the 2017 ACC/AHA guideline endorses a BP target of less than 130/80 mm Hg for diabetic patients. The 2019 American Diabetes Association endorses lower targets only in diabetic patients with 10-year ASCVD risk of greater than 15%. In general, an ACEI or ARB plus a CCB is an excellent combination to treat hypertension in patients with diabetes. Thiazide diuretics and standard β -blockers exacerbate glucose intolerance, whereas the vasodilating β -blockers such as carvedilol and nebivolol have neutral or possibly beneficial effects.

Hypertensive Patients With Coronary Artery Disease

To lower myocardial oxygen demands in patients with coronary disease, the antihypertensive regimen should reduce BP without causing reflex tachycardia. For this reason, a β -blocker is often prescribed in conjunction with a dihydropyridine CCB such as amlodipine. β -Blockers are indicated for patients with hypertension who have sustained a myocardial infarction and for most heart failure patients with reduced ejection fraction (HFrEF). In contrast, diuretics are recommended as the first therapy in heart failure patients with preserved ejection fraction (HFpEF) with evidence of volume overload. After euolemia is achieved, ACEIs, ARBs, or spironolactone may be considered in patients with persistently elevated BP. In patients with stable coronary artery disease, a cardioprotective effect of ACE inhibition has also been demonstrated in patients with moderate cardiovascular risk profiles but not in those with lower risk profiles.

Isolated Systolic Hypertension in Older Adults

In developed countries, systolic pressure rises progressively with age; if individuals live long enough, then almost all (>90%) develop hypertension. Diastolic pressure rises until the age of 50 years and decreases thereafter, producing a progressive rise in pulse pressure (i.e., systolic pressure minus diastolic pressure) (Fig. 12.12).

Different hemodynamic faults underlie hypertension in younger and older persons. Patients who develop hypertension before 50 years of age typically have *combined systolic and diastolic hypertension*: systolic pressure greater than 140 mm Hg and diastolic pressure greater than 90 mm Hg. The main hemodynamic fault is vasoconstriction at the level of the resistance arterioles. In contrast, the majority of patients who develop hypertension after 50 years of age have *isolated systolic hypertension*: systolic pressure greater than 140 mm Hg but diastolic pressure less than 90 mm Hg (often less than 80 mm Hg). In isolated systolic hypertension, the primary hemodynamic fault is decreased distensibility of the aorta and other large conduit arteries (see Fig. 12.12). Collagen replaces elastin in the elastic lamina of the aorta, an age-dependent process that is accelerated by atherosclerosis and hypertension. The cardiovascular risk associated with isolated systolic hypertension is related to pulsatility, the repetitive pounding of the blood vessels with each cardiac cycle and a more rapid return of the arterial pulse wave from the periphery, both begetting more systolic hypertension. In the United States and Europe, the majority of uncontrolled hypertension occurs in older patients with isolated systolic hypertension. A BP of 160/60 mm Hg (pulse pressure of 100 mm Hg) carries twice the risk of fatal coronary heart disease as 140/110 mm Hg (pulse pressure of 30 mm Hg) (Fig. 12.13).

In older persons with isolated systolic hypertension, lowering systolic pressure from higher than 160 to lower than 150 mm Hg reduces the risks of stroke, myocardial infarction, and overall cardiovascular mortality; it also reduces heart failure admissions and slows the progression of dementia. Trial data do not yet exist in older persons to determine whether the treatment of isolated elevations in systolic pressure below 140 mm Hg is beneficial; however, in the absence of such data, treatment may be warranted to prevent progression of systolic hypertension if patients can tolerate treatment without side effects such as orthostatic hypotension.

The combination of a low-dose thiazide diuretic with a dihydropyridine CCB or with an ACEI reduces the risk of CV events in older patients with isolated systolic hypertension. According to the 2017 ACC/AHA high BP guideline, chlorthalidone is the preferred thiazide diuretic given its long half-life and more consistent reduction in cardiovascular events in clinical trials than other thiazide diuretics. To prevent orthostatic hypotension, medication should be titrated to standing BP and one low-dose medication should be started at a time.

Fig. 12.12 Age-dependent changes in systolic and diastolic blood pressure (BP) in the United States (*left panel*). Schematic diagram explains the relation between aortic compliance and pulse pressure (*right panel*). (*Left panel*, From Burt V, Whelton P, Rocella EJ, et al: Prevalence of hypertension in the U.S. adult population: Results from the Third National Health and Nutrition Examination Survey, 1988–1991. *Hypertension* 25:305-313, 1995. *Right panel*, Courtesy of Dr. Stanley Franklin University of California at Irvine. (Neaton JD, Wentworth D: Serum cholesterol, blood pressure, cigarette smoking, and death from coronary heart disease: Overall findings and differences by age for 316,099 white men. *Arch Intern Med* 152:56-64, 1992.)

Blood Pressure Lowering for Secondary Prevention of Stroke

Most neurologists do not recommend BP reduction during an acute stroke unless BP is extremely elevated (see section Acute Severe Hypertension). After the acute phase, BP should be lowered with a thiazide diuretic, adding an ACEI or additional drugs as needed to achieve BP lower than 140/90 mm Hg; whether BP should be lowered

further remains unsettled. Lower BP target of less than 130/80 mm Hg for patients may be reasonable for patients with transient ischemic attack or lacuna infarct to prevent intracranial hemorrhage.

Blood Pressure Lowering for Prevention of Cognitive Impairment

Increasing number of studies have shown that high BP and other cardiovascular risk factors such as hyperlipidemia predisposes not only to increased cardiovascular damage but also brain injury and cognitive impairment in older adults, which is independent of stroke (i.e., what is good for the heart is good for the brain). The recent SPRINT MIND clinical trial showed that intensive lowering of systolic BP to below 120 mm Hg in adults with high cardiovascular risk but without history of stroke prevents development of cognitive impairment. There was no significant reduction in new cases of dementia but the trial was limited by short duration of follow-up. Additional studies are needed to clarify optimal BP target to prevent cognitive dysfunction in hypertensive adults.

Hypertensive Disorders of Women

Oral contraceptives cause a small increase in BP in most women but rarely cause a large increase into the hypertensive range. If hypertension develops, oral contraceptive therapy should be discontinued in favor of other methods of contraception. Oral estrogen replacement therapy seems to cause a small increase in BP. In contrast, transdermal estrogen (which bypasses first-pass hepatic metabolism) seems to avoid this side effect.

Hypertension, the most common nonobstetric complication of pregnancy, is present in 10% of all pregnancies. Of these women, one third are caused by chronic hypertension and two thirds are due to preeclampsia, which is defined as an increase in BP to 140/90 mm Hg or greater after the twentieth week of gestation accompanied by proteinuria (>300 mg/24 hr) and pathologic edema. This is sometimes accompanied by seizures (eclampsia) and the multisystem HELLP syndrome of hemolysis (H), elevated liver enzymes (EL), and low

platelets (LP). Although the cause remains an enigma, preeclampsia is the most common cause of maternal mortality and perinatal mortality. Nifedipine and α -methyl dopa are considered to be first-line drug therapy for preeclampsia and chronic hypertension in pregnancy. Labetalol is also effective in lowering BP but may result in intrauterine growth restriction.

Resistant Hypertension

Defined as persistence of usual BP above 140/90 mm Hg despite treatment with full doses of three or more different classes of medications in rational combination and including a diuretic, *resistant hypertension* is the most common reason for referral to a hypertension specialist. In practice, the majority of these patients have pseudoresistant hypertension due to: (1) *white coat aggravation*, a white coat reaction superimposed on chronic hypertension that is well-controlled with medication outside the physician's office; (2) an inadequate medical regimen; (3) nonadherence to medication, which is present in 30% to 60% of patients using direct measurement of drug levels in the plasma or urine; and (4) ingestion of pressor substances. Common shortcomings of the medical regimen include under-treatment of hypertension with monotherapy and clonidine, a potent central sympatholytic that causes rebound hypertension between doses particularly with PRN dosing. Several common causes of pseudoresistant hypertension are related to the patient's behavior: medication nonadherence, recidivism with lifestyle modification (e.g., obesity, a high-salt diet, excessive alcohol intake), or habitual use of pressor substances such as sympathomimetics (e.g., tobacco, cocaine, methamphetamine, phenylephrine-containing cold or herbal remedies) or NSAIDs, with the latter causing renal sodium retention. Once these behavioral factors have been excluded, the search should begin for secondary hypertension.

The most common forms of secondary hypertension include obstructive sleep apnea, chronic kidney disease, and primary aldosteronism. Either a loop diuretic such as furosemide or a potent thiazide-type diuretic such as chlorthalidone may be required to control hypertension in patients with resistant hypertension and chronic kidney disease. The treatment of primary aldosteronism was discussed earlier. After excluding pseudoresistant hypertension and secondary hypertension, some patients have severe drug-resistant primary hypertension. Fourth- and fifth-line therapy includes a vasodilating β -blocker and spironolactone (even in the absence of primary aldosteronism). Percutaneous catheter-based renal denervation is proposed as a novel interventional approach to treat drug-resistant hypertension. Although the initial results raised enormous enthusiasm, subsequent randomized controlled trials have been disappointing as the magnitude of reduction in BP is modest (less than 10 mm Hg) when compared to the sham control arm. A number of studies that use other neuromodulation techniques, such as baroreflex activation, to reduce overall sympathetic tone beyond renal sympathetic activity alone, are being conducted to determine BP outcome in this population.

Acute Severe Hypertension

Of all the patients in the emergency department, 25% have an elevated BP. *Hypertensive emergencies* are acute, often severe elevations in BP that are accompanied by acute or rapidly progressive target organ dysfunction such as myocardial or cerebral ischemia or infarction, pulmonary edema, or renal failure. *Hypertensive urgencies* are severe elevations in BP without severe symptoms and without evidence of acute or progressive target organ dysfunction. Thus, the key distinction and approach to the patient depends on the state of the patient and the assessment of target organ damage, not simply the absolute level of BP. The full-blown clinical picture of a hypertensive emergency is a critically ill patient with a BP greater than 220/140 mm Hg,

headaches, confusion, blurred vision, nausea and vomiting, seizures, heart failure, oliguria, and grade III or IV hypertensive retinopathy (Fig. 12.14). Hypertensive emergencies require immediate admission in an intensive care unit (ICU) for intravenous therapy and continuous BP monitoring, whereas hypertensive urgencies can often be managed with oral medications and appropriate outpatient follow-up in 24 to 72 hours. The most common hypertensive cardiac emergencies include hypertension associated with acute aortic dissection, coronary artery bypass graft surgery, acute myocardial infarction, and unstable angina. Other hypertensive emergencies include those accompanying eclampsia, head trauma, severe body burns, postoperative bleeding from vascular suture lines, and epistaxis that cannot be controlled with anterior and posterior nasal packing. Neurologic hypertensive emergencies, which include acute ischemic stroke, hemorrhagic stroke, subarachnoid hemorrhage, and hypertensive encephalopathy, can be difficult to distinguish from one another. Hypertensive encephalopathy is characterized by severe hypertensive retinopathy (i.e., retinal hemorrhages and exudates, with or without papilledema) and a posterior leukoencephalopathy affecting mainly the white matter of the parieto-occipital regions as seen on cerebral MR imaging or CT scanning. A new focal neurologic deficit suggesting a stroke-in-evolution demands a much more conservative approach to correcting the elevated BP.

Fig. 12.14 Hypertensive retinopathy is traditionally divided into four grades. (A) Grade 1 shows very early and minor changes in a young patient; increased tortuosity of a retinal vessel and increased reflectiveness (silver wiring) of a retinal artery are seen at the 1-o'clock position in this view. Otherwise, the fundus is completely normal. (B) Grade 2 also shows increased tortuosity and silver wiring (*arrowheads*). In addition, *nipping* of the venules at arteriovenous (AV) crossings is visualized (*arrow*). (C) Grade 3 shows the same changes as grade 2 plus flame-shaped retinal hemorrhages and soft *cotton-wool* exudates. (D) In grade 4, swelling of the optic disc (papilledema) is observed, retinal edema is present, and hard exudates may collect around the fovea, producing a typical *macular star*. (From Forbes CD, Jackson WF: *Color atlas and text of clinical medicine*, 3rd ed. London, Mosby, 2003, with permission.)

In most other hypertensive emergencies, the goal of parenteral therapy is to achieve a controlled and gradual lowering of BP. The rapidity of BP reduction is highly dependent on clinical presentation. Patients with acute aortic dissection require rapid reduction to the 120/80 mm Hg range almost immediately to reduce shear stress and prevent further intimal tear in the aortic wall, which could be life-threatening. On the other hand, patients with acute ischemic stroke who are not candidates for intravenous thrombolysis or endovascular treatment should not be treated with antihypertensive agents unless BP is 220/120 mm Hg or higher. Following initial therapy, a more conservative BP reduction goal to no more than 15% during the first 24 hours after onset of stroke is recommended. In those who are candidates for thrombolysis, however, BP should be less than 185/110 mm Hg before administration of intravenous tissue plasminogen activator and should be maintained below 180/105 mm Hg for at least the first 24 hours after initiating drug therapy. The widely cited goal of BP lowering by 10% in the first hour and by an additional 15% over the next 3 to 12 hours is limited to patients who present with hypertensive encephalopathy or other presentations. Unnecessarily rapid correction of the elevated BP to completely normal values places the patient at high risk for worsening cerebral, cardiac, and renal ischemia. In chronic hypertension, cerebral autoregulation is reset to higher-than-normal BPs. This compensatory adjustment prevents tissue overperfusion (i.e., increased intracranial pressure) at very high BPs, but it also predisposes the patient to tissue underperfusion (i.e., cerebral ischemia) when an elevated BP is lowered too quickly.

Parenteral agents for the treatment of hypertensive emergency are summarized in Table 12.9. Sodium nitroprusside, a nitric oxide donor, is the most popular agent because it can be titrated rapidly

to control BP. Intravenous nitroglycerin, another nitric oxide donor, is indicated mainly for hypertension in the setting of acute coronary syndrome or decompensated heart failure. Nicardipine is a parenteral dihydropyridine CCB that is particularly useful in the postoperative cardiac patient and patients with renal failure to avoid the thiocyanate toxicity with nitroprusside. Clevidipine is another intravenous CCB with shorter half-life than nicardipine of only 1 minute. Fenoldopam is a selective dopamine-1-receptor agonist that causes both systemic and renal vasodilation, as well as increased glomerular filtration, natriuresis, and diuresis. Intravenous labetalol is an effective treatment of a hypertensive crisis particularly in the setting of myocardial ischemia with preserved ventricular function.

Most patients in the emergency department with hypertensive urgencies are either nonadherent with their medical regimen or are being treated with an inadequate regimen. To expedite the necessary changes in medications, outpatient follow-up should be arranged within 72 hours. To manage the patient during the short-interim period, effective oral medication includes labetalol, clonidine, or captopril, which is a short-acting ACEI.

BPs greater than 160/110 mm Hg are a common incidental finding among patients in emergency departments and other acute care settings for urgent medical or surgical care of symptoms that are unrelated to BP (e.g., musculoskeletal pain, orthopedic injury). In these settings, the elevated BP is more often the first indication of chronic hypertension than a simple physiologic stress reaction, providing an important opportunity to initiate primary care referral for formal evaluation and treatment of chronic hypertension. Home and ambulatory BP monitoring are indicated to determine whether the patient's BP normalizes completely once the acute illness has resolved.

TABLE 12.9 Parenteral Agents for Management of Hypertensive Emergencies

Agent	Dose	Onset of Action	Precautions
Parenteral Vasodilators			
Sodium nitroprusside	0.25-10 mcg/kg/min IV infusion	Immediate	Thiocyanate toxicity with prolonged use
Nitroglycerin	5-100 mcg/min IV infusion	2-5 min	Headache, tachycardia, tolerance
Nicardipine	5-15 mg/hr IV infusion	1-5 min	Protracted hypotension after prolonged use
Clevidipine	1-21 mg/hr IV infusion	2-4 min	Tachycardia
Fenoldopam mesylate	0.01-0.3 mcg/kg/min IV infusion	1-5 min	Headache, tachycardia, increased intraocular pressure
Hydralazine	5-10 mg as IV bolus or 10-40 mg IM; repeat every 4-6 hrs	10 min IV 20 min IM	Unpredictable and excessive falls in tachycardia; angina exacerbation; blood pressure
Enalaprilat	0.625-1.25 mg every 6 hr IV bolus	15-60 min	Unpredictable and excessive falls in blood pressure; acute renal failure in patients with stenosis bilateral renal artery
Parenteral Adrenergic Inhibitors			
Labetalol	20-80 mg as slow IV injection every 10 min, or 0.5-2.0 mg/min IV as infusion	5-10 min	Bronchospasm, heart block, orthostatic hypotension
Metoprolol	5 mg IV every 10 min for three doses	5-10 min	Bronchospasm, heart block, heart failure, exacerbation of cocaine-induced myocardial ischemia
Esmolol	500 mcg/kg IV over 3 min; then 25-100 mg/kg/min as IV infusion	1-5 min	Bronchospasm, heart block, heart failure
Phentolamine	5-10 mg IV bolus every 5-15 min	1-2 min	Tachycardia, orthostatic hypotension

IM, Intramuscular; IV, intravenous.

PROGNOSIS

One of the most important prognostic factors in hypertension is ECG or echocardiographic LVH, with the latter already present in as many as 25% of patients with newly diagnosed hypertension. LVH predisposes the patient to heart failure, atrial fibrillation, and sudden cardiac death.

Because of their relatively short duration (typically <5 years), randomized controlled trials underestimate the lifetime protection against premature disability and death afforded by several decades of antihypertensive therapy in clinical practice. In the Framingham Heart Study, treating hypertension for 20 years in middle-aged adults reduced total cardiovascular mortality by 60%, which is considerably greater than the results of most randomized trials despite the less intense treatment guidelines when therapy was initiated in the 1950s through the 1970s.

PROSPECTS FOR THE FUTURE

- Further delineation of genetic causes of hypertension and application of this research to the treatment and prevention of hypertension, including development of pharmacologic and non-pharmacologic therapy that target the various signaling pathways in hypertension
- Determination of antihypertensive drug classes that are most effective in preventing dementia and cognitive decline
- Evaluation of the comparative efficacy and safety of DOACs against LMWH in preventing VTE in patients with active malignancy
- Further assessment of safety and efficacy of combination of direct anticoagulants and antiplatelet therapy in patients with atrial fibrillation, venous thromboembolism, and vascular disease

Lung in Health and Disease

Sharon Rounds, Debasree Banerjee, Eric J. Gartman

INTRODUCTION

The lung is part of the respiratory system and consists of conducting airways, blood vessels, and gas exchange units with alveolar gas spaces and capillaries (Fig. 13.1). The neural control of the respiratory system includes the brain cortex and medulla, the spinal cord, and peripheral nerves that innervate the skeletal muscles of respiration, airways, and vessels. The airways of the respiratory system include the upper airway—the nose, pharynx, and larynx—where inspired air is humidified and particulate matter is filtered. The intrathoracic airways continue down the trachea to the carina where the mainstem bronchi branch defining the right- and left-sided airways. Bronchi continue to branch into smaller airways (bronchioles) that eventually take on gas exchange capacity and end in alveolar sacs. Both pulmonary arteries and veins and lymphatics follow the branching patterns of the airways. The lung also has systemic circulation via the bronchial arteries. The bony structure of the chest wall protects the heart, lungs, and liver, and the lungs are maintained in an inflated state by mechanical coupling of the chest wall with the lungs. The skeletal muscles of respiration include the

diaphragm and the accessory muscles; the latter are important when disease causes diaphragm fatigue.

The lung is a complex organ with an extensive array of airways and vessels arranged to efficiently transfer the gases necessary for sustaining life. The organ has an immense capacity for gas exchange and can accommodate increased demand during exercise in healthy individuals. In lung disease, however, as exchange becomes compromised, the host's activities and function become increasingly compromised. The most dramatic consequence of acute and chronic abnormalities in lung function is systemic hypoxemia, which causes tissue hypoxia in multiple other organs.

In addition to gas exchange, the lungs have other functions, such as defense against inhaled infectious agents and environmental toxins. The entire cardiac output passes through the pulmonary circulation, which serves as a filter for blood-borne clots and infections. Additionally, the massive surface area of endothelial cells lining the pulmonary circulation has metabolic functions, such as conversion of angiotensin I to angiotensin II.

Lung disorders are common and range from well-known conditions such as asthma and chronic obstructive pulmonary disease (COPD) to rarely encountered disorders such as lymphangioleiomyomatosis. The chapters in Section III discuss the diagnosis, evaluation, and management of pulmonary disorders that develop in direct response to lung injury and those that develop indirectly through injuries to other organs. Section III also addresses critical illness such as acute lung injury, which is frequently managed by pulmonary or critical care specialists.

This chapter reviews the structural-functional relationships of the lung during development, the epidemiology of pulmonary disease, and the classification of pulmonary disorders.

LUNG DEVELOPMENT

The lung begins to develop during the first trimester of pregnancy through complex and overlapping processes that transform the embryonic lung bud into a functioning organ with an extensive airway network, two complete circulatory systems, and millions of alveoli responsible for the transfer of gases to and from the body. Lung development occurs in five consecutive stages: embryonic, pseudoglandular, canalicular or vascular, saccular, and alveolar postnatal (Table 13.1).

During the embryonic stage (between 21 days and 7 weeks' gestation), the rudimentary lung emerges from the foregut as a single epithelial bud surrounded by mesenchymal tissue. This stage is followed by the pseudoglandular stage (between 5 and 17 weeks' gestation), during which repeated extensive branching forms rudimentary airways, a process called *branching morphogenesis* (Fig. 13.2). Coinciding with airway formation, new bronchial arteries arise from the aorta.

Fig. 13.1 The respiratory system includes neural structures that control breathing, the chest wall and skeletal muscles of breathing, the upper airway, and lung parenchyma.

TABLE 13.1 Stages of Lung Development

Stage	Period	Comments
Embryonic	3-7 wk	Embryonic lung bud emerges from the foregut.
Pseudoglandular	5-17 wk	Airway tree is formed through a process of extensive branching accompanied by growth.
Canalicular	17-24 wk	Angiogenesis and vasculogenesis form the developing vascular network.
Saccular	24-38 wk	Alveoli begin to form through thinning of the mesenchyme, apposition of vascular structures with the air spaces, and maturation.
Alveolar (postnatal)	36 wk-2 yr	Further alveoli development and maturation occurs.

Fig. 13.2 Lung branching morphogenesis occurs during the pseudoglandular stage of lung development. It is the process by which the embryonic lung develops the primitive airway system through extensive branching.

The canalicular stage (between 17 and 24 weeks' gestation) is characterized by the formation of the acinus, differentiation of the acinar epithelium, and development of the distal pulmonary circulation. Through the processes of angiogenesis and vasculogenesis, capillary networks derived from endothelial cell precursors are formed, extend from and around the distal air spaces, and connect with the developing pulmonary arteries and veins. By the end of this stage, the thickness of the alveolar capillary membrane is similar to that in the adult.

During the saccular or prenatal alveolar stage (between 24 and 38 weeks' gestation), vascularized crests emerging from the parenchyma divide the terminal airway structures called *sacculi*. Thinning of the interstitium continues, bringing capillaries from adjacent alveolar structures into close apposition and producing a double capillary network. Near birth, capillaries from opposing networks fuse to form a single network, and capillary volume increases with continuing lung growth and expansion.

During the alveolar postnatal stage (between 36 weeks' gestation and 2 years of age), alveolar development continues, and maturation occurs. The lung continues to grow through the first few years of childhood with the creation of more alveoli through septation of the air sacs. By age 2 years, the lung contains double arterial supplies and venous drainage systems, a complex airway system designed to generate progressive decreases in resistance to airflow as the air travels distally, and a vast alveolar network that efficiently transfers gases to and from the blood.

The processes that drive lung development are tightly controlled, but mishaps occur. Congenital lung disorders include cystic adenomatoid malformation of the lung, lung hypoplasia or agenesis, bullous changes in the lung parenchyma, and abnormalities in the vasculature, including aberrant connections between systemic vessels and lung compartments (e.g., lung sequestration) and congenital absence of one or both pulmonary arteries. In children without congenital

abnormalities, lung disorders are uncommon, except for those caused by infection and accidents.

Congenital lung disorders are rare compared with the number of infants born annually with abnormal lung function as a result of prematurity. In premature infants, the type II pneumocytes of the lung are underdeveloped and produce insufficient quantities of surfactant, a surface-active substance produced by specific alveolar epithelial cells that helps to decrease surface tension and prevent alveolar collapse. This disorder is called neonatal *respiratory distress syndrome* (RDS). The treatment of neonatal RDS is administration of exogenous surfactant and corticosteroids to enhance lung maturation. To sustain life while allowing maturation, mechanical ventilation and oxygen supplementation are required but may promote the development of bronchopulmonary dysplasia (see [Chapter 21](#) for further discussion).

PULMONARY DISEASE

Epidemiology

Diseases of the adult respiratory system are some of the most common clinical entities confronted by physicians. According to the Centers for Disease Control and Prevention data for 2017, chronic lower respiratory diseases, influenza or pneumonia, and cancer (including lung cancer) are among the top 10 causes of death due to medical illnesses in the United States.

COPD is a leading cause of both death and disability in the United States. At a time when the age-adjusted death rate for other common disorders such as coronary artery disease and stroke is decreasing, the death rate for COPD continues to increase. More than 16 million Americans are estimated to have COPD, but the number is expected to rise because COPD takes years to develop and the incidence of cigarette smoking (the most common etiologic factor for COPD) is staggering. In 2017, more than

34.3 million Americans were daily smokers and 16 million Americans had a smoking-related illness. The true disease burden of COPD is much greater than these numbers indicate.

Other pulmonary conditions are also common. Asthma affects 8% of adults and 9.5% of children in the United States. The prevalence, hospitalization rate, and mortality rate related to asthma continue to increase. In 2016, there were 257,000 hospital visits related to pneumonia and almost 50,000 deaths. Sleep-disordered breathing affects an estimated 7 to 18 million people in the United States, and 1.8 to 4 million of them have severe sleep apnea. Interstitial lung diseases are increasingly recognized, and their true incidence appears to have been underestimated. For example, idiopathic pulmonary fibrosis, the most common of the idiopathic interstitial pneumonias, affects 85,000 to 100,000 Americans annually.

These conditions affect males and females of all ages and races. However, a disproportionate increase in the incidence, morbidity, and mortality related to lung diseases exists for minority populations. This finding is true for COPD, asthma, certain interstitial lung disorders, and other diseases. Although these differences point to genetic differences among these populations, they also indicate differences in culture, socioeconomic status, exposure to pollutants (e.g., inner-city living), and access to health care.

Classification

Lung diseases are often classified on the basis of the affected anatomic areas of the lung (e.g., interstitial lung diseases, pleural diseases, airways diseases) and the physiologic abnormalities detected by pulmonary function testing (e.g., obstructive lung diseases, restrictive lung diseases). Classification schemes based exclusively on physiologic factors are inaccurate because distinctly different disorders with different causes, consequences, and responses to therapy have similar physiologic abnormalities (e.g., restriction from pulmonary fibrosis versus restriction from neuromuscular disease) (Fig. 13.3).

Fig. 13.3 Lung diseases are caused by abnormalities in the lung structure (e.g., airways, interstitium, vasculature) or in the chest wall or by external forces (e.g., infection). Disorders affecting the lung structure cause physiologic derangements (e.g., obstruction to airflow, restricted lung volumes, pulmonary hypertension, hypoxia). These derangements are not necessarily specific to any particular lung diseases, but there is extensive overlap among them, so that different disorders can have similar physiologic abnormalities. *COPD*, Chronic obstructive pulmonary disease.

The obstructive lung diseases have in common a limitation of airflow, called an *obstructive pattern*, as determined by pulmonary function testing. Obstructive lung diseases include COPD, asthma, and bronchiectasis.

The interstitial lung diseases are less common disorders and are more difficult to categorize because they include more than 120 distinct entities, some of which are inherited, but most of which are without an obvious cause. These disorders are characterized by a restrictive physiologic condition due to decreased lung compliance and small lung volumes, which is the reason they are often referred to as *restrictive lung disorders* (e.g., idiopathic pulmonary fibrosis). However, not all interstitial lung diseases exhibit a purely restrictive pattern on pulmonary function testing. They may have airflow limitation as a result of small airway involvement (e.g., sarcoidosis, cryptogenic organizing pneumonia).

In the pulmonary vascular diseases, involvement of the pulmonary vasculature causes increased pulmonary vascular resistance. These diseases range from disorders caused by obstruction to blood flow as a result of blood clots (e.g., pulmonary embolus) to disorders characterized by tissue remodeling and obliteration of blood vessels by vascular remodeling (e.g., pulmonary arterial hypertension).

Disorders of respiratory control include conditions in which extrapulmonary abnormalities cause respiratory system dysfunction and abnormal ventilation. Included are sleep disorders such as obstructive sleep apnea and neuromuscular system disorders such as myasthenia gravis and polymyositis, in which ventilatory abnormalities result from poor excursion of the respiratory muscles.

Disorders of the pleura, chest wall, and mediastinum are classified as such because they affect these structures. Infectious agents, commonly viruses and bacteria, cause infectious diseases of the lung. Neoplastic disorders of the lung include benign (e.g., hamartomas) and malignant (e.g., lung carcinoma) tumors, which can affect the lung parenchyma or its surrounding pleura (e.g., mesothelioma).

PROSPECTUS FOR THE FUTURE

Important questions about lung development remain. What are the primary stimuli for branching morphogenesis? How does gene regulation alter lung development? How is lung airway and blood vessel development coordinated? What are the environment-gene interactions that cause abnormal lung development and subsequent lung diseases? What impact does air pollution and climate change have on our lung health?

There are important fundamental questions about the epidemiology of lung diseases. For example, it is not clear whether or how childhood asthma and adult COPD are related. The role of fine particulate matter air pollution in the pathogenesis of lung diseases is unknown, and the causes and pathogenesis of many lung diseases, such as sarcoidosis, are unclear.

General Approach to Patients With Respiratory Disorders

Michael Raymond Goggins, Brian Casserly, Eric J. Gartman

INTRODUCTION

History taking is of paramount significance in the assessment of a patient who may have pulmonary disease. Patients with respiratory disorders often complain of one or more of the following symptoms: dyspnea, fatigue, exercise intolerance, wheeze, cough, sputum production, hemoptysis, and chest pain. Aside from the establishment of a trusting doctor-patient partnership, history taking gives the physician the opportunity to ask critical questions and clarify crucial details that may point towards a specific diagnosis.

Common symptoms of respiratory disease, such as chest pain and fever, frequently occur with diseases of other organ systems (Table 14.1). For example, chest pain is a cardinal symptom of cardiovascular disease. Fever, though it is commonly observed in pneumonia, may also be attributable to a wide array of hematologic and rheumatologic conditions. A thorough assessment of the past medical history, family history, social history, and occupational history combined with a focused physical examination and an understanding of the symptomatology are the pertinent aspects of a systemic approach to patients with respiratory disease. Applying a structured process guides the investigations necessary to determine the underlying respiratory pathology.

❖ For a deeper discussion on this topic, please see Chapter 77, “Approach to the Patient with Respiratory Disease,” in *Goldman-Cecil Medicine*, 26th Edition.

CLINICAL PRESENTATION

Dyspnea (i.e., breathlessness) is perhaps the most common presentation of patients with respiratory conditions (Table 14.2). The time of onset (i.e., nocturnal), rate of onset (swift vs. gradual), exacerbating and alleviating factors (i.e., environmental triggers), frequency, and degree of functional impairment are fundamental components of the history. Determining the associated symptoms such as cough, hemoptysis, chest pain, wheeze, orthopnea, stridor, allergic rhinitis, sinusitis, and paroxysmal nocturnal dyspnea is also imperative in developing a differential diagnosis. For example, if dyspnea is of sudden onset and accompanied by chest pain then the list of differential diagnoses should include the following: pneumothorax, pulmonary embolism, myocardial infarction, and flash pulmonary edema. Conversely, long-standing dyspnea indicates that chronic conditions such as chronic obstructive pulmonary disease (COPD), interstitial lung disease, pulmonary arterial hypertension, and neuromuscular disorders are most likely.

The evolution of chronic dyspnea may be insidious, thus questions regarding variations in functional capacity over time are essential. Exertion may precipitate dyspnea or it may occur at rest. Intermittent exertional dyspnea suggests parenchymal lung disease or cardiovascular disease. Dyspnea that is seasonal or provoked by environmental exposure suggests diseases such as asthma and hypersensitivity pneumonitis.

Positional dyspnea can develop in patients with severe obstructive airway disease, diaphragmatic paralysis or neuromuscular weakness.

Orthopnea, dyspnea occurring in the supine position, may result from a reduction in vital capacity caused by abdominal contents applying pressure upon the diaphragm. Paroxysmal nocturnal dyspnea, a sudden onset of shortness of breath transpiring one to several hours after lying flat, is a commonly described symptom of decompensated congestive cardiac failure. This condition is a result of interstitial pulmonary edema secondary to increased venous return to the heart. Nocturnal dyspnea in the setting of asthma has also been frequently documented and is understood to be the consequence of decreased vital capacity in the supine position, decreased production of endogenous agents with bronchodilator functions, and increased exposure to allergens in bedclothes. Exercise-induced asthma causes dyspnea disproportionate to the level of exertion, with symptoms often being most distressing in the 15 to 30 minutes after cessation of exercise.

Wheeze, the continuous whistling noise of air passing through a narrowed tube, while often associated with asthma, may be the result of a variety of conditions. The presence of wheeze does not definitively establish asthma as the diagnosis, nor does the absence of wheeze exclude asthma as a diagnosis. Congestive heart failure, endobronchial obstruction, vocal cord abnormalities, and acute bronchitis are all causes of wheeze.

Cough is often a frustrating symptom because the underlying diagnosis may be surreptitious. The three most common sources of a chronic cough are postnasal drip, asthma, and gastroesophageal reflux disease. Cough may be mild and sporadic. However, it may also be forceful enough to provoke emesis or syncope. Cough may be dry or may generate sputum or blood (i.e., hemoptysis). The symptom may commence months after initiation of a drug (e.g., angiotensin-converting enzyme [ACE] inhibitors), resulting in a dry, hacking cough. *Bordetella pertussis* infection (i.e., whooping cough) and viral lower respiratory tract infections can produce a cough that may last longer than 3 months. Patients with asthma often have a cough, and occasionally it is their only symptom (cough-variant asthma). Nocturnal cough suggests asthma, heart failure, or gastroesophageal reflux disease.

Sputum expectoration occurring more than seldom is atypical and should be characterized with regard to volume, color, timing, frequency, diurnal variation, and presence or absence of blood. Chronic bronchitis is defined as a productive cough for more than 3 months in each of the past 3 years. Asthma patients often have a productive cough due to excess mucus production. Colored sputum may not always represent bacterial infection because the concentration of cellular debris—predominantly white cells in inflammatory processes—affects sputum color. Poorly controlled asthma and the finding of brown plugs or casts of the small bronchi in sputum may indicate allergic bronchopulmonary aspergillosis.

TABLE 14.1 Major Symptoms of Respiratory Disease

Cough
Sputum
Hemoptysis
Dyspnea (acute, progressive, or paroxysmal)
Wheeze
Chest pain
Fever
Hoarseness
Night sweats

Hemoptysis is an alarming symptom. The volume of blood may be scant or considerable enough to cause asphyxiation or exsanguination. Bronchitis is the most common cause of hemoptysis in the United States, whereas pulmonary tuberculosis is the predominant cause worldwide. Hemoptysis is frequently small in volume and self-limited or resolves with treatment of the underlying process. Massive hemoptysis, variably defined as 250 to 500 mL of blood in 24 hours, is a rare medical emergency caused by the following: lung cancer, lung cavities containing mycetomas, cavitary tuberculosis, pulmonary hemorrhage syndromes, pulmonary arteriovenous malformations, and bronchiectasis. Clinicians should distinguish hemoptysis from epistaxis and hematemesis with comprehensive upper airway examination as many patients have difficulty identifying the source of the hemorrhage.

Chest pain attributable to a respiratory cause results from pleural disease, pulmonary vascular disease, or musculoskeletal pain precipitated by coughing as no pain receptors exist in the lung parenchyma. For example, lung cancer does not cause pain until it invades the pleura, chest wall, vertebral bodies, or mediastinal structures. Disease or inflammation of the pleura causes pleuritic chest pain characterized as a sharp or stabbing pain with deep inspiration. Pulmonary emboli, infection, pneumothorax, and collagen vascular disease often cause pleuritic chest pain. Pulmonary hypertension causing right ventricular strain and demand ischemia may produce dull anterior chest pain unrelated to respiration. Additional examples of noncardiac chest pain are esophageal disease, herpetic neuralgia, musculoskeletal pain, and trauma. Thoracic pain secondary to vertebral compression or rib fractures may be seen in elderly patients or those with a history of chronic systemic steroid use.

Adequate analgesic relief, including narcotic use, in patients with chest pain and respiratory disease is essential to prevent a reduction in vital capacity due to splinting of the chest in reaction to the pain. Musculoskeletal chest pain, which is often reproducible with movement or palpation over the affected area, should only be considered as a diagnosis once other causes have been excluded.

HISTORY

The examiner should always inquire about previous respiratory illness, including pneumonia, tuberculosis, or chronic bronchitis, and chest radiograph abnormalities that have been reported to the patient. Acquired immunodeficiency syndrome (AIDS) increases the risk of developing *Pneumocystis jirovecii* pneumonia and other respiratory infections, including tuberculosis. Immunosuppression from chronic steroid use may predispose to tuberculosis and other lung infections.

Many classes of drugs can be linked to lung toxicity. Examples include pulmonary embolism due to the oral contraceptive pill, interstitial lung disease from cytotoxic agents (e.g., methotrexate, cyclophosphamide, bleomycin), bronchospasm from β -adrenergic receptor blockers or

TABLE 14.2 Causes of Dyspnea

Classification	Examples
Airways disease	Chronic obstructive pulmonary disease Asthma Laryngeal disorders Epiglottitis, bronchiolitis, and croup in children Tracheal stenosis or obstruction (foreign body or tumor) Tracheomalacia Bronchiectasis (immunodeficiency states, allergic bronchopulmonary aspergillosis, ciliary dyskinesia, cystic fibrosis)
Parenchymal lung disease	Pneumonia Interstitial lung diseases Obliterative bronchiolitis Pulmonary edema due to increased vascular permeability (acute respiratory distress syndrome) Infiltrative and metastatic malignancies
Pulmonary circulation disorders	Pulmonary thromboembolism Pulmonary arterial hypertension Pulmonary arteriovenous malformation
Chest wall and pleural disorders	Pneumothorax Pleural effusion or large-volume ascites Pleural tumor Fractured ribs, flail chest Chest wall deformities Neuromuscular diseases Bilateral diaphragmatic paresis
Cardiac disorders	Pulmonary edema due to left heart failure Myocardial infarction Pericardial effusion or constrictive pericarditis Intracardiac shunt
Hematologic disorders	Anemia Methemoglobinemia Carbon monoxide poisoning Acute chest syndrome (sickle cell disease)
Noncardiorespiratory disorders	Psychogenic diseases (hyperventilation) Midbrain lesion
Metabolic or endocrine disorders	Metabolic acidosis (diabetic ketoacidosis, sepsis, severe dehydration, inborn errors of metabolism) Hyperthyroidism Hypothyroidism Hyperammonemia Hypocalcemia (laryngospasm) Anaphylaxis Smoke inhalation Chemical agent exposures (phosgene, chlorine, cyanide) Drug overdose (salicylates)
Other causes	Biologic and chemical weapons (anthrax, tularemia, phosgene, nitrogen mustard, nerve agents, ricin) Submersion injury (near-drowning)

nonsteroidal anti-inflammatory drugs, and cough from ACE inhibitors. Physicians should be conscious that illicit substances known to cause lung disease (e.g., cocaine, heroin) may not be mentioned by the patient.

An accurate history of tobacco use and other toxic and environmental exposures is vital for patients with respiratory symptoms. Tobacco smoke is the primary environmental toxin causing lung disease. It is the physician's obligation to ask about tobacco use and attempt to motivate patients to quit smoking. The risk of smoking-related lung disease is directly correlated to individual genetic susceptibility and the total

pack-years history, while it is inversely related to the age at onset of smoking and, in the case of lung cancer, the interval since smoking cessation.

A history of exposure to other inhaled toxins, irritants, or allergens should be elicited. A thorough occupational history can uncover exposure to inorganic dust or fibers such as asbestos, silica, or coal dust. Organic dusts predispose to hypersensitivity pneumonitis and other interstitial lung diseases. Solvents and corrosive gases also induce pulmonary disease. The presence of house pets should be documented. Cats are the most allergenic for asthma while birds may cause hypersensitivity or fungal lung disease.

A travel history is pertinent in evaluating infectious causes of pulmonary disease. For example, histoplasmosis is endemic to the Ohio and Mississippi River valleys whereas coccidioidomycosis is observed in the desert Southwest. Travel to or immigration from developing countries heightens the risk of exposure to tuberculosis. A family history is crucial to establish the risk of genetic lung diseases such as cystic fibrosis and α_1 -antitrypsin deficiency and predisposition to asthma, emphysema, or lung cancer.

PHYSICAL EXAMINATION

The physical examination should be comprehensive while also focusing on areas highlighted by the history. Observation and inspection when the patient's chest is bare are the initial steps in the physical examination of the patient with pulmonary disease. The physician should begin by assessing the patient's general appearance with particular attention given to the presence or absence of respiratory distress. This observation points toward the diagnosis and identifies the level of urgency.

Body habitus is relevant because morbid obesity in a patient with exercise intolerance and somnolence suggests a diagnosis of sleep-disordered breathing, whereas dyspnea in a thin, middle-aged individual with pursed lips may indicate emphysema. Race and sex are relevant as specific cohorts have a predisposition for certain conditions. For example, sarcoidosis is frequently encountered in African Americans in the Southeast, whereas lymphangioliomyomatosis is a rare disorder that principally affects young women of childbearing age. Tachycardia and pulsus paradoxus are essential signs of severe asthma.

The physician should observe the effort required for breathing. Increased respiratory rate, accessory muscles use, pursed-lip breathing, and paradoxical abdominal movement indicate increased work of breathing. Paradoxical abdominal movement signifies diaphragm weakness and imminent respiratory failure. An inability to complete full sentences indicates severe airway obstruction or neuromuscular weakness. The potential presence of a cough should be discerned and the strength of the cough observed because it may signal respiratory muscle weakness or severe obstructive lung disease. The rib cage should expand symmetrically with inspiration. The shape of the thoracic cage should be considered. Increased anteroposterior diameter is appreciated in the setting of hyperinflation secondary to obstructive lung disease. Severe kyphoscoliosis, pectus excavatum, ankylosing spondylitis, and morbid obesity can produce restrictive ventilatory disease due to distortion and restriction of the thoracic cavity volume.

Hand examination may yield significant signs of respiratory pathology. Clubbing is often associated with respiratory disease. An uncommon association with clubbing is hypertrophic pulmonary osteoarthropathy (HPO) characterized by periosteal inflammation, swelling, and tenderness at the distal ends of long bones, the wrists, the ankles, the metacarpals and metatarsals. Rarely, HPO may occur without clubbing. The causes of HPO include pleural mesothelioma, pulmonary fibrosis, and chronic lung infections, such as lung abscess.

Finger staining (caused by tar because nicotine is colorless) is a sign of cigarette smoking. Dorsiflex of the wrists with the arms outstretched

and fingers spread may result in a flapping tremor (i.e., asterixis) seen with severe carbon dioxide retention. Wasting and weakness are signs of cachexia due to malignancy or end-stage emphysema. Peripheral lung tumor compression and infiltration of a lower trunk of the brachial plexus produces wasting of the small muscles of the hand and finger abduction weakness.

Head and neck examination is critical. The eyes are inspected for Horner syndrome (i.e., constricted pupil, partial ptosis, and loss of sweating), which may result from an apical lung tumor compressing the sympathetic nerves in the neck. The voice is evaluated for hoarseness, which may indicate recurrent laryngeal nerve palsy associated with lung carcinoma (usually left-sided) or laryngeal carcinoma. However, the most common cause is laryngitis.

The nose is evaluated for nasal polyps (associated with asthma), engorged turbinates (various allergic conditions), and a deviated septum (nasal obstruction). Sinusitis is indicated by tenderness over the sinuses on palpation.

The tongue is examined for central cyanosis. The mouth may hold evidence of an upper respiratory tract infection (e.g., erythematous pharynx, tonsillar enlargement with or without a coating of pus). A damaged tooth or gingivitis may predispose to lung abscess or pneumonia. Superior vena cava obstruction can cause facial plethora or cyanosis. Obstructive sleep apnea patients may be obese and have a receding chin, a small pharynx, and a short, thick neck.

Chest palpation is performed by first palpating the accessory muscles (i.e., scalene and sternocleidomastoid) of respiration in the neck. Hypertrophy and contraction suggest increased respiratory effort. Tracheal palpation should demonstrate the trachea residing in the midline of the neck. Deviation is suggestive of lung collapse or a mass. Neck masses should be documented.

The physician should place both hands on the lower half of the patient's posterior thorax with thumbs touching and fingers spread; the hands should be kept in place while the patient takes several deep inspirations. The physician's thumbs should separate slightly and the hands should move symmetrically apart during the patient's inspiration. Causes of asymmetry include pain, chest wall abnormalities, consolidation, and tension pneumothorax.

Fremitus is a subtle vibration appreciated best with the edge of the hand against the patient's chest wall while the patient speaks. Increased fremitus occurs in areas with underlying lung consolidation, and decreased fremitus occurs over pleural effusions. Next, the patient's chest should be percussed and the diaphragm level should be determined bilaterally. The percussion note should be compared on each side starting at the apex and moving down, including the posterior, anterior, and lateral aspects. Pleural effusions, consolidation, masses, or elevated diaphragms can produce dullness to percussion and pneumothoraces or hyperinflation can cause hyperresonance.

Lung auscultation is utilized to gauge the quality of the breathing and to detect extra sounds not heard in normal lungs. Normal breath sounds have two qualities, vesicular and bronchial. Bronchial breath sounds are heard over the central airways and are louder and coarser than vesicular breath sounds, which are heard at the lung peripheries and bases. Bronchovesicular sounds are a combination of the two and are heard over medium-sized airways. Bronchial sounds have a longer inspiratory component, whereas vesicular sounds have an elongated expiratory component and are much softer. Bronchial breath sounds and bronchovesicular breath sounds at the lung peripheries are abnormal and may be due to underlying consolidation. In the setting of consolidation, increased vocal sound transmission, called *whispered pectoriloquy*, ensues; *egophony*, in which the spoken letter *e* sounds like an *a* over the area of consolidation, is heard and sometimes likened to the bleating of a goat.

Abnormal or extrapulmonary sounds are crackles, wheezes, and rubs. Crackles can be coarse rattles or fine, velcro-like sounds. Airway mucus or the opening of large- and medium-sized airways often causes coarse crackles. In bronchiectasis, alteration of crackles occurs with coughing. Fine inspiratory crackles, caused by the opening of collapsed alveoli, are most common at the bases and are often heard in pulmonary edema or interstitial fibrosis.

Wheeze is a higher-pitched sound suggestive of large airway obstruction when heard locally. Wheeze in the setting of asthma or congestive heart failure is lower in pitch and heard diffusely over all lung fields. Localized wheezing can be heard in conditions such as pulmonary embolism, bronchial obstruction by a tumor, and foreign-body aspiration.

A pleural rub is a sound generated by inflamed pleural surfaces rubbing together, often compared to the sound of pieces of leather rubbing against each other. Rubs, which are often transient and dependent upon the amount of fluid in the pleural space, can develop post large-volume thoracentesis, along with pleuritic chest pain.

A crunching sound timed with the cardiac cycle, called *Hamman crunch* or *Hamman sign*, is heard in patients with a pneumomediastinum. The complete absence of breath sounds on one side should cause one to consider pneumothorax, hydrothorax, or hemothorax; obstruction of a main stem bronchus; or surgical or congenital absence of the lung.

EVALUATION

A differential diagnosis should be established based on a comprehensive history and a thorough physical examination. The preliminary differential diagnosis determines the battery of tests requested, recognizing that these investigations may reveal disorders not considered in the initial assessment. The objective of this extended evaluation is twofold: to affirm a diagnosis or disregard other disorders and to assess the severity of the lung derangement.

Patients with a suggested lung disorder should undergo pulmonary function testing (see [Chapter 15](#)). Spirometry evaluates airflow and helps differentiate between the obstructive pattern characteristic of COPD, asthma, and related disorders and the restrictive pattern observed in fibrotic lung disease. Spirometry also illustrates the severity of the physiologic alteration.

Lung volume measurements are effective in assessing hyperinflation or confirming a restrictive process. Calculating the diffusing capacity of the lung for carbon monoxide (DLCO) elucidates alterations in gas-exchanging capability. The recording of oxygen saturation via pulse oximetry can be utilized to further assess gas exchange.

Information regarding oxygenation and acid-base status is obtained from arterial blood gas determination. A 6-minute walk test, which evaluates oxygenation during exertion, can demonstrate that patients require supplemental oxygen. Other, more specialized tests (e.g., bronchoprovocation, cardiopulmonary stress testing, polysomnography) may be necessary, depending on the context.

Imaging studies of the chest are beneficial in evaluating pulmonary structure. The chest radiograph displays the lung parenchyma and pleura, the cardiac silhouette, mediastinal structures, and body

habitus. Examining old chest radiographic images is essential to assess for disease progression.

Computed tomography (CT) provides a more comprehensive assessment of the pulmonary and mediastinal structures and is essential in the evaluation of interstitial lung disease, lung masses, and other disorders. Together with ventilation-perfusion scanning and pulmonary angiography, CT is one of several resources used to evaluate the lung vasculature. Positron emission tomography is used to assess metabolic activity of lung masses and can indicate a diagnosis of malignancy.

Standard blood tests such as the blood counts and blood chemistry point to specific disorders or may provide information about the severity of a lung disorder (e.g., polycythemia in chronic hypoxemia, leukocytosis in lung infection). Some specialized tests should be reserved for specific diagnoses such as connective tissue disorders (e.g., rheumatoid factor, antinuclear antibodies) or hypersensitivity pneumonitis (hypersensitivity profile).

Together with the history and physical examination, these investigations are useful for narrowing a diagnosis to establish a specific management plan that can often be devised in a single visit. However, patients frequently require several follow-up visits in which the physician assesses disease progression, patient compliance, and response to treatment.

If noninvasive tests do not yield a diagnosis of the problem, more invasive tests may be necessary. Fiberoptic or rigid bronchoscopy allows direct visualization of the airways and acquisition of valuable clinical samples for examination. Transthoracic percutaneous needle aspiration or navigational bronchoscopy is useful in evaluating peripheral lung lesions. Ultimately, surgery may be required to obtain tissue through open or video-assisted thoracoscopically guided lung biopsy.

For a deeper discussion on this topic, please see [Chapter 78](#), “Imaging in Pulmonary Disease,” and [Chapter 93](#), “Interventional and Surgical Approaches to Lung Disease,” in *Goldman-Cecil Medicine*, 26th Edition.

PROSPECTUS FOR THE FUTURE

The predictive values of various facets of the history and physical examination need to be clarified. The role of quantitative CT analysis in the diagnosis and assessment of disability from lung diseases should be refined. The role of interventional pulmonary procedures must be ascertained for the diagnosis and treatment of lung diseases.

Evaluating Lung Structure and Function

Patrick Koo, F. Dennis McCool, Jigme Michael Sethi

INTRODUCTION

The satisfactory functioning of all organ systems depends on their capacity to consume oxygen and eliminate carbon dioxide. The primary function of the lung is to deliver oxygen to the pulmonary capillary blood and to excrete carbon dioxide. To accomplish this, the lung must generate a flux of air into and out of the alveoli (ventilation) while absorbing oxygen into the pulmonary blood and eliminating carbon dioxide from alveolar air (gas exchange). This is accomplished in a manner that attempts to optimize gas exchange (ventilation-perfusion matching). This remarkably efficient process allows the human to maintain optimal oxygenation and acid-base balance over a range of activities, from resting breathing to moderately strenuous activity. This chapter provides an overview of the anatomy and physiology that enable the respiratory system to perform its life-sustaining functions as well as a discussion of tests available to evaluate lung structure and function.

ANATOMY

Airway

Inspired air travels through the nose and nasopharynx, where it is warmed to body temperature, humidified, and filtered of airborne particles greater

than 10 μm in diameter. Air then enters a complex system of dichotomously branching airways that form a tree occupying the thorax. The first 15 divisions, beginning with the trachea, the mainstem bronchi, segmental and subsegmental bronchi down to the terminal bronchioles, are simply a set of conducting tubes that do not participate in gas exchange. Together, they constitute the *conducting zone* of the lung, also known as the *anatomic dead space* (about 1 mL per pound of ideal body weight, or approximately 150 mL) (Fig. 15.1). Cartilaginous rings help to maintain the patency of these large airways. In the mainstem bronchi, the rings are circumferential, whereas in the trachea, the cartilaginous rings are U-shaped, with the posterior membrane of the trachea sharing a wall with the esophagus. The branching pattern of these first 15 divisions of the airways follows the principles of fractal geometry: The reduction of airway diameter and length between each generation is similar, by a factor of 0.79, serving to densely compact the airways into the available space of the thorax (Fig. 15.2A and B). This geometry reduces bronchial path length from the trachea to the periphery and minimizes both dead space volume and resistance to convective airflow.

The remaining eight generations of airways comprise the respiratory bronchioles and alveolar ducts lined with alveolar sacs. This area of the lung is referred to as the *respiratory zone*, and the terminal respiratory unit is called the acinus. Gas exchange commences in the

Airway subdivision	Order No.	Cross-sectional area (cm^2)	Resistance ($\text{cm H}_2\text{O} \cdot \text{L}^{-1} \cdot \text{sec}$)
Larynx	0		0.5

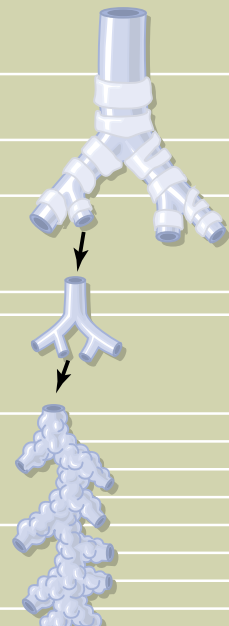

Fig. 15.1 The subdivisions of the airways and their nomenclature. (Modified from Weibel ER: Morphometry of the human lung, Berlin, 1963, Springer.)

Fig. 15.2 (A) Cast of the right lung demonstrates branching of airways. (B) The branching airways can be modeled by use of the principles of fractal geometry, which allow for efficient filling of the thoracic space.

respiratory zone but primarily occurs in the alveoli. Inspired air moves down the conducting zone primarily by bulk convective flow, whereas the movement of oxygen in the respiratory zone is by diffusion.

In total, there are an average of 23 subdivisions of the airway from the trachea to the alveolar ducts. Although it might be suspected that resistance to convective flow would be highest in the small airways because of their small diameter, the opposite is the case. The enormous number of small airways together provide a huge net cross-sectional area for airflow. For example, the cross-sectional area of the trachea is 2.5 cm^2 , compared with a total cross-sectional area of 300 cm^2 for all of the alveolar ducts combined. As a result, 80% of the resistance to airflow occurs in the first seven generations of bronchi, and the remaining “small” airways (diameters $<2 \text{ mm}$) contribute only 20% of the resistance to airflow (Fig. 15.3). As the lung expands during inspiration, the net cross-sectional area of the alveolar ducts doubles, further reducing resistance to airflow.

Alveoli

The alveoli are the grapelike clusters of air sacs that interface with the pulmonary capillaries. There are about 300 million individual alveolar sacs, or 10,000 in each of the 30,000 acini. The alveoli are thin-walled structures with a total surface area of about 130 m^2 . This is roughly half the size of a doubles tennis court. The surface of the alveoli is lined by two types of cells. The flat type I pneumocytes constitute 95% of the cells. Type II pneumocytes, which account for about 5% of the alveolar lining cells, secrete surfactant, a complex lipoprotein whose role in lowering surface tension in the alveolar space is critical to reducing the forces needed to expand the lung. Surfactant is also important in preventing alveolar collapse at low lung volumes and thereby promoting normal gas exchange. The capillaries run in the exceedingly thin septa that separate the alveoli and are therefore exposed to the air from surrounding alveoli. The epithelial lining of the alveoli, the endothelial lining of the capillaries, and the intervening fused basement membrane form the alveolar-capillary interface. Normally, this interface is less than $1 \mu\text{m}$ thick and does not significantly interfere with gas exchange.

Blood Vessels

The pulmonary artery arises from the right ventricle and branches until it terminates in a meshwork of capillaries that surround the alveoli. This creates a large surface area that facilitates gas exchange. Blood returns to the heart through pulmonary veins that course through the lungs, coalesce into four main pulmonary veins, and empty into the left atrium. The pulmonary circulation is a low-resistance circuit; pulmonary vascular resistance is about one tenth of the resistance in

Fig. 15.3 Total cross-sectional area of the airways is depicted for several generations of airways. The total cross-sectional area increases dramatically in the respiratory zone. Consequently, the velocity of gas entering the respiratory zone decreases and resistance is low.

the systemic circulation. Pulmonary vessels can easily be recruited to accommodate increases in blood flow while maintaining low pressure and resistance. Accordingly, during exercise, any increase in cardiac output can be distributed through the lung without significantly increasing pulmonary arterial pressures.

A separate vascular system, the bronchial system, also supplies the lung. The bronchial arteries originate from the aorta and, in contrast to the pulmonary arteries, are under systemic pressure. These vessels provide nutrients to lung structures proximal to the alveoli. Two thirds of the bronchial circulation drains into the pulmonary veins and then empties into the left atrium. This blood, which has low oxygen content, mixes

Fig. 15.4 Schematic diagram of the inspired volume of air that participates in gas exchange (V_A , 350 mL) and the volume of anatomic dead space (V_D , 150 mL), which together provide a tidal breath (V_T) of 500 mL.

with the freshly oxygenated blood from the pulmonary veins to lower the oxygen content of the blood that enters the systemic circulation.

PHYSIOLOGY

Ventilation

Ventilation refers to the bulk transport of air from the atmosphere to the alveolus. The product of tidal volume (V_T) and breathing frequency (f) represents the total volume of air delivered to the lung per minute (minute ventilation). However, not all air entering the lung is in contact with gas-exchanging units. The portion of V_T that fills the respiratory zone and alveoli and is available for gas exchange constitutes the alveolar volume (V_A), whereas the portion remaining in the conducting airways is the anatomic dead space volume (V_D) (Fig. 15.4). The ratio of V_D to V_T is called the *dead space ratio* (V_D/V_T). Normally, one third of a breath is dead space ($V_D/V_T = 1/3$). The amount of fresh air reaching the alveoli is $V_T - V_D$. With large breaths, the dead space becomes a smaller fraction of the total tidal volume. Therefore, for a given V_T , slow, deep breathing results in greater V_A and improved gas exchange compared with rapid, shallow breathing.

The V_D/V_T ratio can be calculated by the Bohr method, as follows:

$$V_D/V_T = (P_{aCO_2} - P_{E CO_2})/P_{aCO_2}$$

where P_{aCO_2} is the arterial partial pressure of carbon dioxide and $P_{E CO_2}$ is the partial pressure of carbon dioxide in mixed expired gas (i.e., the mixture of CO_2 -rich gas that enters the alveoli from the pulmonary capillaries and dead space gas, which is devoid of CO_2). $P_{E CO_2}$ increases during expiration, reaching a plateau at end-expiration. At end-expiration, the $P_{E CO_2}$ represents exhaled alveolar gas that has been in equilibrium with pulmonary capillary blood. In healthy individuals, the $P_{E CO_2}$ at end-expiration is equivalent to the P_{aCO_2} .

Ventilation of the dead space is wasted ventilation, because only V_A participates in gas exchange. Therefore, as the metabolic rate and carbon dioxide production increase, V_A must increase to maintain an arterial P_{CO_2} of 40 mm Hg. The relationship among these variables is described by the alveolar carbon dioxide equation:

$$P_{ACO_2} = CO_2 \text{ production}/\dot{V}_A$$

where P_{ACO_2} is the partial pressure of carbon dioxide in the alveolus and \dot{V}_A is alveolar ventilation. From this equation, one appreciates that the partial pressure of carbon dioxide in the alveolus is inversely proportional to alveolar ventilation.

The relationship described by the alveolar oxygen equation is similar:

$$P_{AO_2} = O_2 \text{ consumption}/\dot{V}_A$$

However, this relationship is more complicated because P_{AO_2} also is proportional to the fraction of inspired oxygen, the water vapor pressure, and the partial pressure of carbon dioxide in the alveolus (discussed later). The implications of the alveolar carbon dioxide and oxygen relationships are that (1) maintenance of a constant alveolar gas composition depends on a constant ratio of ventilation to metabolic rate; (2) if ventilation is too high (hyperventilation), alveolar PCO_2 will be low and alveolar PO_2 will be high; and (3) if ventilation is too low (hypoventilation), alveolar PCO_2 will be high and alveolar PO_2 will be low.

Mechanics of Breathing

Respiratory mechanics is the study of forces needed to deliver air to the lung and how these forces govern the volume and flow of gases. Mechanically, the respiratory system consists of two structures: the lungs and the chest wall. The lungs are elastic (spring-like) structures that are situated within another elastic structure, the chest wall. At end-expiration, with absent respiratory muscle activity, the inward recoil of the lung is exactly balanced by the outward recoil of the chest wall, representing the equilibrium position of the lung–chest wall unit. Normally, the recoil of the lung is always inward (favoring lung deflation), and the recoil of the chest wall is outward (favoring inflation); at high lung volumes, however, the chest wall also recoils inward (Fig. 15.5). The energy required to stretch the respiratory system beyond its equilibrium state (end-expiration during quiet breathing) is provided by the inspiratory muscles. With normal quiet breathing, gas flow out of the lung is usually accomplished by passive recoil of the respiratory system.

During a typical breath, inspiratory muscle contraction lowers the intrapleural pressure, which in turn lowers the intra-alveolar pressure. Once alveolar pressure becomes subatmospheric, air can flow from the mouth through the airways to the alveoli. At the end of inspiration, the inspiratory muscles are turned off, and the lungs and chest wall recoil passively back to their equilibrium states. This passive recoil of the respiratory system causes alveolar pressure to become positive throughout expiration until the resting position of the lung and chest wall are reestablished and alveolar pressure once again equals atmospheric pressure. During quiet breathing, pleural pressure is always subatmospheric, whereas alveolar pressure oscillates below and above zero (atmospheric) pressure (Fig. 15.6).

The major inspiratory muscle is the diaphragm. Others include the sternocleidomastoid muscles, the scalenus muscles, the parasternals, and the external intercostals. Diaphragm contraction results in expansion of the lower rib cage and compression of the intra-abdominal contents. The latter action results in expansion of the abdominal wall. The expiratory muscles consist of the internal intercostal muscles and the abdominal muscles. Expiratory flows can be enhanced by recruiting the expiratory muscles; this occurs during exercise or with cough.

To inflate the respiratory system, the inspiratory muscles must overcome two types of forces: the elastic forces imposed by the lung and the chest wall (elastic loads) and the resistive forces related to airflow (resistive loads). The elastic loads on the inspiratory muscles result from the respiratory system's tendency to resist stretch. The elastic forces are volume dependent; that is, the respiratory system becomes more difficult to stretch at volumes greater than the functional residual capacity (FRC) and more difficult to compress at volumes lower than the FRC. The elastic forces can be characterized by examining the relationship between lung volume and recoil pressure (Fig. 15.7). When either deflated or inflated, the lung and chest wall have characteristic recoil pressures. The slope of the relationship between lung volume and elastic recoil pressure of the chest wall or lung represents the

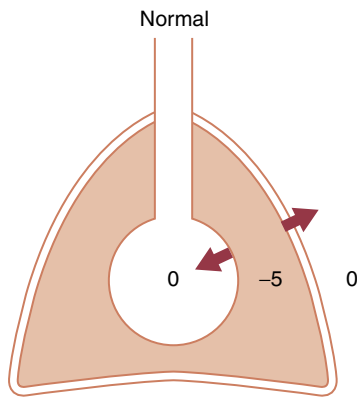

Fig. 15.5 Schematic diagram of the lung and chest wall at functional residual capacity (FRC). The arrows show that the expanding elastic force of the chest wall equals the collapsing elastic force of the lung. The intrapleural pressure is -5 at FRC because both forces are tugging on the pleural space in opposite directions.

Fig. 15.6 Volume, intrapleural pressure, and alveolar pressure during a normal breathing cycle. The letters correspond to the various phases of the cycle: A, end-expiration; B, inspiration; C, end-inspiration; and D, expiration. Alveolar pressure is biphasic, with zero crossings at times of no flow (i.e., end-expiration and end-inspiration). Intrapleural pressure remains subatmospheric throughout.

compliance of each structure. The sum of the chest wall and lung recoil pressures represents the recoil pressure of the total respiratory system.

The elastic properties of the lung are related to two factors: the elastic behavior of collagen and elastin in the lung parenchyma and the surface tension in the alveolus at the air-liquid interface. Both factors contribute equally to lung elastic recoil. A surface-active substance called *surfactant* is produced by type II alveolar cells and lines the alveoli. This substance consists primarily of phospholipids. It lowers the surface tension of the air-liquid interface, making it easier to inflate the lung. The lungs are stiff (less compliant) and difficult to inflate in diseases that are characterized by a loss of surfactant (e.g., infant respiratory distress syndrome). Diseases such as pulmonary fibrosis, which

Fig. 15.7 Volume-pressure relationship of the respiratory system and its components, the lung and chest wall. Respiratory system recoil pressure at any volume is the sum of the lung and chest wall recoil pressures. Forces creating negative pressures expand the respiratory system, whereas forces creating positive pressures collapse the respiratory system. The slope of the volume-pressure curve represents the compliance of each structure. FRC, Functional residual capacity; RV, residual volume; TLC, total lung capacity.

are characterized by excessive collagen in the lung, can make the lung stiff and difficult to inflate, whereas those such as emphysema, characterized by a loss of elastin and collagen, reduce lung recoil and increase lung compliance (Fig. 15.8). Normally, at FRC, it takes about 1 cm of water pressure (1 cm H₂O) to inflate the lungs 200 mL or to inflate the chest wall 200 mL. The lung and chest wall both need to be inflated to the same volume during inspiration, so 2 cm H₂O of pressure is required to inflate both to 200 mL. Therefore, normal respiratory system compliance is roughly 200/2 or 100 mL/cm H₂O and compliance of the lung or chest wall compliance is 200/1 or 200 mL/cm H₂O at volumes near FRC.

The second set of forces that the inspiratory muscles must overcome to inflate the lungs are flow-dependent forces; namely, tissue viscosity and airway flow resistance, the latter constituting the major component of the flow-dependent forces. Airway resistance during inspiration can be calculated by measuring inspiratory flow and the difference in pressure between the alveolus and the airway opening (ΔP_{A-a_0}).

$$\text{Resistance} = \Delta P_{A-a_0} / \dot{V}$$

The airflow velocity, the type of airflow (laminar or turbulent), and the physical attributes of the airway (radius and length) are the key determinants of airway resistance. Of the physical properties, the radius of the airways is the major factor. Resistance increases to the fourth power as the diameter decreases under conditions of laminar flow (streamline flow profile) and to the fifth power under conditions of turbulent flow (chaotic flow profile). Because airway diameter increases as lung volume increases, airway resistance decreases as lung volume increases (Fig. 15.9). Airway diameter also contributes to regional differences in airway resistance. Although the peripheral airways are narrower than the central airways, their total cross-sectional area is much greater than that of the central airways, as described earlier. Consequently, resistance to airflow of the peripheral airways is low relative to the central airways (see Fig. 15.3).

The type of airflow is another key determinant of airway resistance. Resistance is directly proportional to flow rate when flow is laminar. Resistance is much greater with turbulent flow because it is proportional to the square of the flow rate. The velocity of airflow determines,

Fig. 15.8 Compliance curves for normal individuals and for patients with emphysema or pulmonary fibrosis. The transpulmonary pressure required to achieve a given lung volume is greatest for the patient with pulmonary fibrosis (notice the horizontal dashed line at 60% of the vital capacity). This increases the work of breathing.

Fig. 15.9 As lung volume increases, the airways are dilated, and airways resistance (AWR) decreases. The reciprocal of resistance (conductance) increases as lung volume increases.

in part, whether the flow pattern is laminar or turbulent. Clinically, increased airway resistance can be seen in diseases associated with airway obstruction caused by an intrinsic mass, mucus within the airway, airway smooth muscle contraction, or extrinsic compression of the airways.

Lung elastic recoil also influences airway resistance and airflow. Decreased lung recoil increases resistance by promoting collapse of the small airways (E-Fig. 15.1). Normal resistance when breathing at FRC at low flow rates is in the range of 1 to 2 cm H₂O/L per second.

Distribution of Ventilation

The distribution of inhaled volume throughout the lung is unequal. In general, more of the inhaled volume goes to the bases of the lung than to the apex when the individual is inhaling while in an upright body position. This pattern of volume distribution leads to greater ventilation of the bases than at the apices. This inhomogeneity of ventilation results largely from regional differences in lung compliance. The alveoli at the lung apex are relatively more inflated at FRC than the alveoli at the lung base. The difference in alveolar distention from apex to base is related to pleural pressure differences from apex to base. The weight of the lung causes pleural pressure to be more negative at the apex and less negative at the base. The normal difference in pleural pressure from apex to base in an adult is about 8 cm H₂O (Fig. 15.10). Because the apical alveoli are more stretched at FRC, they are operating on a stiffer, less compliant region of their volume-pressure curve than the alveoli at the bases, making them more difficult to inflate than the basilar alveoli. Therefore, at the beginning of inspiration, more volume is directed toward the base than to the apex of the lung.

Control of Ventilation

Maintenance of adequate oxygenation and acid-base balance is accomplished through the respiratory control system. This system consists of the neurologic respiratory control centers, the respiratory effectors (muscles that provide the power to inflate the lungs), and the respiratory sensors. The respiratory center that automatically controls inspiration and expiration is located in the medulla of the brain stem. The respiratory center in the brain stem has an intrinsic rhythm generator (pacemaker) that drives breathing. The output of this center is modulated by inputs from peripheral and central chemoreceptors, from mechanoreceptors in the lungs, and from higher centers in the brain, including conscious control from the cerebral cortex. The respiratory center in the medulla is primarily responsible for determining the level of ventilation.

Carbon dioxide is the primary factor controlling ventilation. Carbon dioxide in the arterial blood diffuses across the blood-brain barrier, thereby reducing the pH of the cerebral spinal fluid and stimulating the central chemoreceptors. A change in PaCO₂ above or below normal will increase or decrease ventilation, respectively. During quiet, resting breathing, the level of PaCO₂ is thought to be the major factor controlling breathing. Only when the PaO₂ (i.e., the partial pressure of oxygen dissolved in the blood that is not bound to hemoglobin) falls substantially does ventilation respond significantly. Typically, PaO₂ needs to fall to less than 50 mm Hg before ventilation dramatically increases (Fig. 15.11). Low oxygen levels in the blood are not sensed by the respiratory center in the brain but are sensed by receptors in the carotid body. These vascular receptors are located between the internal and external branches of the carotid artery. Changes in PaO₂ are sensed by the carotid sinus nerve. Neural traffic projects to the respiratory center through the glossopharyngeal nerve, which serves to modulate ventilation. The carotid body also senses changes in PaCO₂ and pH. Nonvolatile acids (e.g., ketoacids) stimulate ventilation through their effects on the carotid body.

The outcome of this complex respiratory control system is that variables such as PaO₂, PaCO₂, and pH are held within narrow limits under most circumstances. The respiratory control center also can adjust tidal volume and frequency of breathing to minimize the energetic cost of breathing and can adapt to special circumstances such as speaking, swimming, eating, and exercise. Breathing can be stimulated by artificial manipulation of the PCO₂, PO₂, and pH. For example, ventilation is increased by rebreathing of carbon dioxide, inhalation of a concentration of low oxygen, or infusion of acid into the bloodstream.

E-Fig. 15.1 Mechanisms of airflow obstruction.

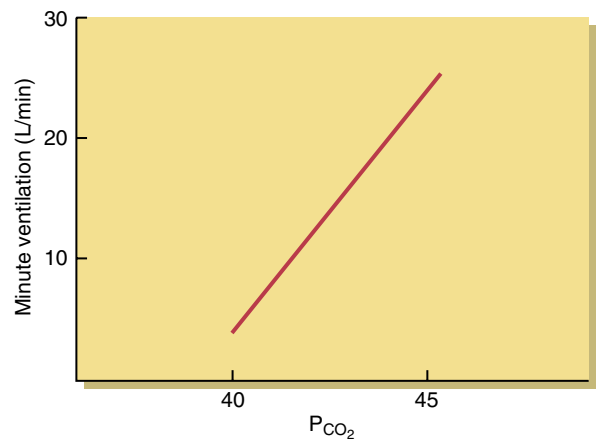

Fig. 15.10 Transpulmonary pressure and volume for lung units at the base and apex of the lung. Because pleural pressure is more negative at the apex of the lung, the alveoli in that region are stretched, placing them on a less compliant part of the volume-pressure curve. For a given change (P) in transpulmonary pressure during inspiration, the more compliant base inflates to a greater degree than the apex (V_1 and V_2 , respectively).

A

B

Fig. 15.11 (A) A rising partial pressure of carbon dioxide (P_{CO_2}) leads to a linear increase in minute ventilation. (B) The ventilatory response to hypoxemia is less sensitive and is clinically relevant only when the partial pressure of oxygen (P_{O_2}) has dropped significantly.

Perfusion

The pulmonary vascular bed differs from the systemic circulation in several respects. The pulmonary vascular bed receives the entire cardiac output of the right ventricle, whereas the cardiac output from the left ventricle is dispersed among several organ systems. Despite receiving the entire cardiac output, the pulmonary system is a low-resistance, low-pressure circuit. The normal mean systemic arterial pressure is about 100 mm Hg, whereas the normal mean pulmonary artery pressure is in the range of 15 mm Hg. The vascular bed can passively accommodate an increase in blood flow without raising arterial pressure by recruiting more vessels in the lung. During exercise, for example, there is little increase in pulmonary artery resistance despite a large increase in pulmonary blood flow. Hypoxic vasoconstriction, another feature unique to the pulmonary vascular system, regulates regional blood flow. This regulation aids in matching blood flow to ventilation by reducing flow to poorly ventilated regions of the lung.

Perfusion (\dot{Q}) refers to the blood flow through an organ (i.e., the lung). In the upright individual, there is greater perfusion of the lung bases than of the apices (Fig. 15.12). In a low-pressure system such as the pulmonary circulation, the effects of gravity on blood flow need to be taken into account. The arterial-venous pressure difference usually provides the “driving” pressure for blood flow in the systemic circulation, but this is true only for certain regions of the lung. Pulmonary blood flow also needs to be considered in the context of alveolar pressure. Venous and arterial pressures are importantly affected by gravity, whereas alveolar pressure remains constant throughout the lung, assuming the airways are open. Therefore, as one descends from the apex to the base of the lung, arterial and venous pressures increase because of gravity but alveolar pressure remains constant.

At the apex, alveolar pressure may be greater than arterial pressure. This region of the lung is referred to as *zone 1*, and, in theory, it receives no blood flow. The alveolar pressure may be greater than arterial pressure, for example, in special circumstances such as hypovolemic shock, which lowers the arterial pressure, or with very high levels of positive end-expiratory pressure (PEEP), which increases alveolar pressure.

As one descends from the apex toward the midzone of the lung, arterial and venous pressures increase, whereas alveolar pressure remains

Fig. 15.12 Zonal model of blood flow in the lung. Because of the inter-relationship of arterial (P_a) and venous (P_v) vascular pressures and alveolar (P_A) pressures, the lung base receives the most flow (see text for explanation). (From West JB, Dollery CT, Naimark A: Distribution of blood flow in isolated lung: relation to vascular and alveolar pressures, *J Appl Physiol* 19:713-724, 1964.)

constant. At some point, arterial pressure becomes greater than alveolar pressure. In this region, the driving pressure for blood flow is the arterial-alveolar pressure difference. This region is referred to as *zone 2* of the lung. Normally, zone 2 is very small because alveolar pressure is less than venous pressure in most of the lung. However, with high levels of PEEP, alveolar pressure becomes greater than venous pressure in more lung regions.

Further toward the base of the lung, the effects of gravity on arterial and venous pressures are more pronounced, venous pressure becomes greater than alveolar pressure, and the arterial-venous pressure difference provides the driving pressure for blood flow, as in the systemic circulation. This region is referred to as *zone 3* of the lung.

Normally, most of the lung is in zone 3, and most of the perfusion is to the lung base. This inequality in perfusion from apex to base is *qualitatively* similar to the inequality of ventilation from apex to base. However, blood flow increases from apex to base *more* than ventilation does, and this accounts for the small amount of ventilation-perfusion inequality that exists in the normal lung.

Gas Transfer

Oxygen and carbon dioxide are easily dissolved in plasma. Nitrogen is much less soluble and is not significantly exchanged across the alveolar-capillary interface. The driving force for the diffusion of a gas across a tissue barrier is the difference in partial pressure of the gas across the barrier. The partial pressure of oxygen in inspired room air entering the trachea is 150 mm Hg; this is derived from the equation, $PO_2 = (P_{atm} - P_{H_2O}) \times F_{IO_2}$, assuming that P_{atm} (atmospheric pressure) is 760 mm Hg, P_{H_2O} (the partial pressure of water vapor) is 47 mm Hg, and F_{IO_2} (the fraction of oxygen in inspired air) is 20.9%. In the alveolus, however, the partial pressure of oxygen is reduced to 100 mm Hg because the inspired V_T mixes with about 3 L of “oxygen-poor” air already in the lungs and is diluted by carbon dioxide moving into the alveolus from the pulmonary capillaries. The partial pressure of oxygen in the alveolus (PAO_2) is set by the balance of these processes. Increasing minute ventilation increases the amount of oxygen added to the alveolus while lowering the $PACO_2$ —the opposite result from hypoventilation. This reciprocal relationship between alveolar carbon dioxide and alveolar oxygen is described by the *alveolar gas equation*:

$$PAO_2 = [(P_{atm} - P_{H_2O}) \times F_{IO_2}] - (PACO_2 / RER)$$

where RER is the respiratory exchange ratio, usually about 0.8.

The pressure gradient that drives diffusion of oxygen from the alveolus to the capillary is the difference between the alveolar PO_2 (100 mm Hg) and the arterial PO_2 (40 mm Hg) in the capillary blood entering the alveolus. By the time the blood leaves the alveolus, the PO_2 in the capillary blood has risen to 100 mm Hg. However, because small regions of ventilation-perfusion inequality and shunt exist in the normal lung, the PO_2 in the pulmonary veins from the lungs as a whole is usually about 90 mm Hg. Therefore, the difference between the alveolar and arterial partial pressures of oxygen, known as the *A-a gradient*, is typically about 10 mm Hg in health.

The pressure gradient that drives carbon dioxide from the mixed venous blood into the alveolus is the difference in partial pressure of carbon dioxide (45 mm Hg in mixed venous blood and 40 mm Hg in the alveolus). Despite the lower driving pressure for carbon dioxide compared with oxygen, the greater solubility of carbon dioxide allows complete equilibration between the alveolus and plasma during each respiratory cycle (Fig. 15.13).

Most of the oxygen contained in the blood is bound to hemoglobin; a small fraction is dissolved and measured as the Pao_2 . The amount of oxygen dissolved is about 3 mL/L in arterial blood, whereas the

amount of oxygen bound to hemoglobin is about 197 mL/L, assuming a normal hematocrit. Each molecule of hemoglobin is capable of carrying four molecules of oxygen. The shape of the oxyhemoglobin association curve reflects the cooperative binding of oxygen to hemoglobin (Fig. 15.14). In general, the hemoglobin saturation is between 80% and 100% with Pao_2 values greater than 60 mm Hg and drops dramatically when the Pao_2 is less than 60 mm Hg. Factors that decrease the affinity of hemoglobin for oxygen include a reduction in blood pH, an increase in temperature, an increase in $PACO_2$, and an increase in the concentration of 2,3-diphosphoglyceric acid (2,3-DPG) (Fig. 15.15). These factors facilitate unloading of oxygen into tissues, which is seen as a shift of the oxyhemoglobin dissociation curve to the right. The oxygen-carrying capacity of hemoglobin is also affected by competitive inhibitors

Fig. 15.13 Changes in the partial pressures of oxygen (PO_2) and carbon dioxide (PCO_2) as blood courses from the pulmonary artery through the capillaries and into the pulmonary veins. The diffusion gradient is greater for O_2 than for CO_2 . However, equilibration of capillary and alveolar gas occurs for both molecules within the 0.75 second it takes for blood to traverse the capillaries. *Alv*, Alveolar; *Pul*, pulmonary.

Fig. 15.14 The oxyhemoglobin dissociation curve. The bulk of the oxygen (O_2) is combined with hemoglobin (Hb). Little is dissolved in plasma. PO_2 , Partial pressure of oxygen.

for binding sites, such as carbon monoxide. Carbon monoxide has an affinity for hemoglobin that is 240 times greater than that of oxygen and preferentially binds to the hemoglobin molecule. However, this does not affect the amount of oxygen dissolved in the blood. Someone with carbon monoxide poisoning may have a normal P_{aO_2} but a very low blood oxygen content because of the high amount of desaturated hemoglobin.

About 5% of carbon dioxide in the blood is dissolved in plasma, and about 10% is bound to hemoglobin. However, carbon dioxide does not exhibit cooperative binding; therefore, the shape of the carbon dioxide–hemoglobin dissociation curve is linear. Carbon dioxide binds to the protein component of the hemoglobin molecule and to the amino groups of the polypeptide chains of plasma proteins to form carbamino compounds. About 10% of carbon dioxide is transported in this fashion. Most of the carbon dioxide is transported as bicarbonate ion: As carbon dioxide diffuses from metabolically active tissue into the blood, it reacts with water to form carbonic acid. This reaction primarily occurs in the red blood cells because

it is catalyzed by the enzyme carbonic anhydrase, which resides in those cells. Carbonic acid then dissociates to bicarbonate and hydrogen ion. Although there is more carbon dioxide dissolved in blood than oxygen, it is still a small fraction of the total carbon dioxide transported by blood.

Abnormalities of Pulmonary Gas Exchange

The arterial PO_2 and PCO_2 are determined by the degree of equilibration between the alveolar gas and capillary blood, which depends on four major factors: ventilation, matching of ventilation with perfusion, shunt, and diffusion. *Hypoxemia* refers to a reduction in the oxygen content of the blood and is determined by measuring the PO_2 of arterial blood. In contrast, *hypoxia* refers to a decrease in oxygen content of an organ, for example, myocardial hypoxia. Aberrations in the four factors listed can result in hypoxemia. A fifth cause of hypoxemia is a low inspired PO_2 , which may occur at altitude.

Hypoventilation is defined as ventilation that is inadequate to keep PCO_2 from increasing above normal. Hypoxemia may occur when increased carbon dioxide in the alveoli displaces alveolar oxygen. As alveolar ventilation falls and P_{aCO_2} rises, PAO_2 will have to fall. Administration of supplemental oxygen (i.e., increasing the FIO_2) can reverse hypoventilation-induced hypoxemia. When one is breathing room air, the difference between alveolar oxygen and arterial oxygen (A-a gradient) is normally about 10 mm Hg. Typically, this difference increases when hypoxemia is present. However, if the hypoxemia is caused by hypoventilation, the A-a gradient will be within normal limits. Causes of hypoventilation are varied and range from diseases or drugs that depress the respiratory control center to disorders of the chest wall or respiratory muscles that impair respiratory pump function. Disorders associated with hypoventilation include inflammation, trauma, or hemorrhage in the brain stem; spinal cord pathology; anterior horn cell disease; peripheral neuropathies; myopathies; abnormalities of the chest wall such as kyphoscoliosis; and upper airway obstruction. Administration of a higher FIO_2 alleviates the hypoxemia but does little to improve the elevated P_{aCO_2} .

The most common cause of hypoxemia in disease states is ventilation-perfusion mismatch. In regions where the ratio of ventilation \dot{V} to perfusion \dot{Q} is low, the blood receives little oxygen from the poorly ventilated alveoli. By contrast, in regions where \dot{V}/\dot{Q} is high, the blood is well oxygenated but receives little additional oxygen despite the higher ventilation because the shape of the oxyhemoglobin dissociation curve plateaus at levels of high P_{aO_2} . As a result, lung units with high \dot{V}/\dot{Q} cannot completely correct for the low oxygen content of blood flowing past units with low \dot{V}/\dot{Q} . Thus, the oxygen uptake of the whole lung is lowered, causing hypoxemia. In the ideal lung, ventilation and perfusion would be perfectly matched (i.e., $\dot{V}/\dot{Q} = 1$). However, the \dot{V}/\dot{Q} normally ranges from 0.5 at the base to 3 at the apex, with an overall value of 0.8. If lung disease develops, ventilation-perfusion inequality may be amplified. If the \dot{V}/\dot{Q} is less than 0.8, the A-a gradient is increased and hypoxia ensues. The P_{aCO_2} is usually within the normal range but increases slightly at extremely low \dot{V}/\dot{Q} ratios (Fig. 15.16). Typically, hypoxemia in diseases that affect the airways, such as chronic obstructive pulmonary disease (COPD), is caused by ventilation-perfusion mismatch. As with hypoxemia due to hypoventilation, administration of a higher FIO_2 improves hypoxemia by improving the PAO_2 in areas of low \dot{V}/\dot{Q} .

The third cause of hypoxemia is shunt. A right-to-left shunt occurs when a portion of blood travels from the right side to the left side of the heart without the opportunity to exchange oxygen and carbon dioxide in the lung. Right-to-left shunts can be classified as anatomic or physiologic. With an anatomic shunt, a portion of the blood bypasses the lung by traversing through an anatomic canal. In all healthy individuals, there

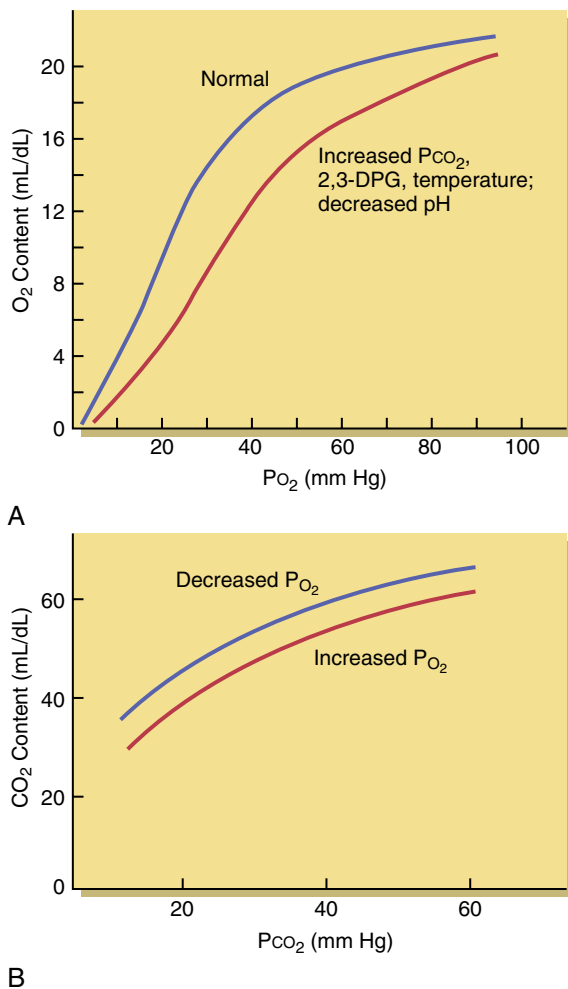

Fig. 15.15 (A) The various factors that decrease the oxygen affinity of hemoglobin are shown shifting the curve to the right. (B) The carbon dioxide dissociation curve is more linear than the oxyhemoglobin curve throughout the physiologic range. Increased partial pressure of oxygen in the arteries (P_{aO_2}) shifts the curve to the right, decreasing the carbon dioxide content for any given arterial partial pressure of carbon dioxide (P_{aCO_2}) and thereby facilitating carbon dioxide off-loading in the lungs. The shift to the left at a lower P_{aO_2} facilitates carbon dioxide on-loading at the tissues. 2,3-DPG, 2,3-Diphosphoglycerate.

Fig. 15.16 (A) The effects of increasing inequality of alveolar ventilation and perfusion (decreasing \dot{V}_A/\dot{Q}) on the arterial partial pressures of oxygen (P_{O_2}) and carbon dioxide (P_{CO_2}) when cardiac output and minute ventilation are held constant. (B) The gas tensions change when minute ventilation is allowed to increase. Increased ventilation can maintain a normal arterial P_{CO_2} but can only partially correct the hypoxemia. (Modified from Dantzker DR: Gas exchange abnormalities. In Montenegro H, editor: Chronic obstructive pulmonary disease, New York, 1984, Churchill Livingstone, pp 141-160.)

is a small fraction of blood in the bronchial circulation that passes to the pulmonary veins and empties into the left atrium, thereby reducing the P_{aO_2} of the systemic circulation. A smaller portion of the normal shunt is related to the coronary circulation draining through the thebesian veins into the left ventricle. Anatomic shunts found in disease states can be classified as intracardiac or intrapulmonary shunts. Intracardiac shunts occur when right atrial pressures are elevated and deoxygenated blood travels from the right atrium to the left atrium through an atrial septal defect or patent foramen ovale. Intrapulmonary anatomic shunts consist primarily of arteriovenous malformations or telangiectasias. With a physiologic right-to-left shunt, a portion of the pulmonary arterial blood passes through the normal vasculature but does not come into contact with alveolar air. This is an extreme example of ventilation-perfusion mismatch ($\dot{V}/\dot{Q} = 0$). Physiologic shunt can be caused by diffuse flooding of the alveoli with fluid, as seen in congestive heart failure or acute respiratory distress syndrome. Alveolar flooding with inflammatory exudates, as seen in lobar pneumonia, also causes a shunt. The fraction of blood shunted (Q_s/Q_t) can be calculated when the F_{IO_2} is 100% by the following equation:

$$Q_s/Q_t = (C_{CO_2} - C_{aO_2}) / (C_{CO_2} - C_{vO_2})$$

where Q_s is the shunted blood flow, Q_t is the total blood flow, C_{CO_2} is the end-pulmonary capillary oxygen content; C_{aO_2} is the arterial oxygen content; and C_{vO_2} is the mixed venous oxygen content (amount of oxygen attached to hemoglobin in the blood returning from the body to right side of the heart).

If the shunt is severe enough, mechanical ventilation and PEEP are required to improve arterial oxygenation. At values less than 50% of the cardiac output, a shunt has very little effect on P_{aCO_2} (Fig. 15.17). With shunting, the A-a gradient is elevated while the P_{aCO_2} is within normal range or may be low. In contrast to hypoxemia due to hypoventilation or low \dot{V}/\dot{Q} , oxygen administration does not correct hypoxemia due to shunt because the shunted blood has no exposure to oxygen in the alveoli. However, the P_{aO_2} may increase somewhat because the higher F_{IO_2} improves oxygenation of blood traveling to low \dot{V}/\dot{Q} areas that commonly coexist with shunt.

The fourth cause of hypoxemia is diffusion impairment. With normal cardiopulmonary function, the blood spends, on average, 0.75 second in the pulmonary capillaries. Typically, it takes only 0.25

Fig. 15.17 The effects of increasing shunt on the arterial partial pressures of oxygen (P_{O_2}) and carbon dioxide (P_{CO_2}). The minute ventilation has been held constant in this example. Under usual circumstances, the hypoxemia would lead to increased minute ventilation and a fall in the P_{CO_2} as the shunt increased. (From Dantzker DR: Gas exchange abnormalities. In Montenegro H, editor: Chronic obstructive pulmonary disease, New York, 1984, Churchill Livingstone, pp 141-160.)

second for the alveolar oxygen to diffuse across the thin alveolar capillary membrane and equilibrate with pulmonary arterial blood (see Fig. 15.13). However, if there is impairment to diffusion across this membrane, such as thickening of the alveolar capillary membrane by fluid, fibrous tissue, cellular debris, or inflammatory cells, it will take longer for the oxygen in the alveoli to equilibrate with pulmonary arterial blood. If the impediment to diffusion is such that it takes longer than 0.75 second for oxygen to diffuse, hypoxemia ensues, and the A-a gradient widens. Alternatively, if the time a red blood cell spends traversing the pulmonary capillary decreases to 0.25 second or less, hypoxemia may develop. Hypoxemia may be evident only during exercise in individuals with diffusion impairment because of the shortened red cell transit time. In these cases, the A-a gradient may be normal at rest but increases with exercise. With diffusion impairment, the P_{aCO_2} usually is within the normal range. As with hypoxemia due to hypoventilation or ventilation-perfusion mismatch, administration of a higher F_{IO_2} improves hypoxemia due to impaired diffusion by raising the alveolar P_{O_2} .

An additional cause of hypoxemia is low inspired oxygen. This may occur at high altitude: The F_{IO_2} is normal, but the P_{O_2} is low because the barometric pressure (P_{atm}) is low. Rarely, circumstances occur in which the F_{IO_2} is low (e.g., rebreathing air). Hypoxemia due to low inspired oxygen is associated with a normal A-a gradient and is usually accompanied by a low P_{aCO_2} . Supplemental oxygen corrects this form of hypoxemia. Finally, a low mixed venous P_{O_2} predisposes individuals to hypoxia (Fig. 15.18).

EVALUATION OF LUNG FUNCTION

Pulmonary function tests evaluate one or more major aspects of the respiratory system. Accurate measurements of lung volumes, airway function, and gas exchange require a pulmonary function laboratory. Pulmonary function tests are commonly used to aid in the diagnosis of disease and assess disease severity. In addition, they are helpful in monitoring the course of disease, assessing the risk for surgical procedures, and measuring the effects of varied environmental exposures (Table 15.1). The response to bronchodilators or other forms of treatment can also

Fig. 15.18 The effects of increasing mixed venous partial pressure of oxygen (P_{O_2}) on the arterial oxygen content under three assumed conditions: a normal lung, severe ventilation-perfusion inequality (\dot{V}/\dot{Q}), and the presence of a 40% shunt. For each situation, the patient is breathing 50% oxygen and the mixed venous P_{O_2} is altered, keeping all other variables constant. (From Dantzker DR: Gas exchange in the adult respiratory distress syndrome, Clin Chest Med 3:57-67, 1982.)

TABLE 15.1 Indications for Pulmonary Function Testing

Evaluation of signs and symptoms:
Shortness of breath
Exertional dyspnea
Chronic cough
Screening of at-risk populations
Monitoring of pulmonary drug toxicity
Follow-up after abnormal study results:
Chest radiograph
Electrocardiogram
Arterial blood gases
Hemoglobin
Preoperative assessment:
Assess severity
Follow response to therapy
Determine further treatment goals
Assess disability

be assessed with serial pulmonary function tests. Accurate interpretation of pulmonary function tests requires the appropriate reference standards. Variables that affect the predicted standards include age, height, gender, race, and hemoglobin concentration.

Spirometry, the simplest means of measuring lung function, can be performed in an office practice. A spirometer is an apparatus that measures inspiratory and expiratory volumes. Flow rates can be calculated from tracings of volume versus time. Typically, vital capacity (VC) is measured as the difference between a full inspiration to total lung capacity (TLC) and a full exhalation to residual volume (RV) (Fig. 15.19). Flow rates are measured after the patient is instructed to forcefully exhale from TLC to RV. Such a forced expiratory maneuver allows one to calculate the forced expiratory volume in 1 second (FEV_1) and the forced vital capacity (FVC) (Fig. 15.20). A value that is 80% to 120% of the predicted value is considered normal for FVC. Normally, people can exhale more

Fig. 15.19 Lung volumes and capacities. Although spirometry can measure vital capacity and its subdivisions (red circles), calculation of residual volume (RV) requires measurement of functional residual capacity (FRC) by one of the following techniques: body plethysmography, helium dilution, or nitrogen washout. ERV, Expiratory reserve volume; IC, inspiratory capacity; TLC, total lung capacity; VC, vital capacity; VT, tidal volume.

than 75% to 80% of their FVC in the first second, and the majority of the FVC can be exhaled in 3 seconds. The ratio of FEV_1/FVC is normally greater than 0.80.

Spirometry can reveal abnormalities that are classified into two patterns: obstructive and restrictive. Obstructive impairments are defined by a low FEV_1/FVC ratio. Diseases that are characterized by an obstructive pattern include asthma, chronic bronchitis, emphysema, bronchiectasis, cystic fibrosis, and some central airway lesions. The reduction in FEV_1 (expressed as % predicted FEV_1) is used to determine the severity of airflow obstruction (E-Fig. 15.2). Peak expiratory flow rate (PEFR) can be measured as the maximal expiratory flow rate obtained during spirometry or when using a handheld peak flowmeter. The lower the PEFR, the more significant the obstruction. A peak flowmeter can be used at home or in the emergency department to evaluate the presence of obstruction. Severe asthma decompensation, for example, is usually associated with PEFRs of less than 200 L/minute (normal, 500 to 600 L/minute). At home, a low PEFR can alert the patient to seek medical attention.

A restrictive pattern is characterized by loss of lung volume. With spirometry, both the FVC and the FEV_1 are reduced, so the FEV_1/FVC ratio remains normal. The restrictive pattern must be confirmed by measurements of lung volumes. Lung volumes are measured by body plethysmography or by dilution of an inert gas such as helium. Lung volumes that can be measured with these techniques include FRC, TLC, and RV (see Fig. 15.19). As described earlier, FRC is the lung volume at which the inward elastic recoil of the lung equals the outward elastic recoil of the chest wall. Changes in FRC reflect abnormalities in lung elastic recoil. Diseases associated with increased elastic recoil (e.g., pulmonary fibrosis) are associated with a reduction in FRC, whereas those with decreased recoil (e.g., emphysema) are associated with an increase in FRC. TLC is the amount of air remaining in the thorax after a maximal inspiration. It is determined by the balance of the forces generated by the respiratory muscles to expand the respiratory system and the elastic recoil of the respiratory system. Restrictive lung disease is defined as a TLC less than 80% predicted, whereas values of TLC greater than 120% predicted are consistent with hyperinflation. The lower the % predicted TLC, the more severe the restrictive impairment.

Restriction may be caused by disorders of the lung, chest wall, respiratory muscles, or pleural space. Lung diseases that cause pulmonary

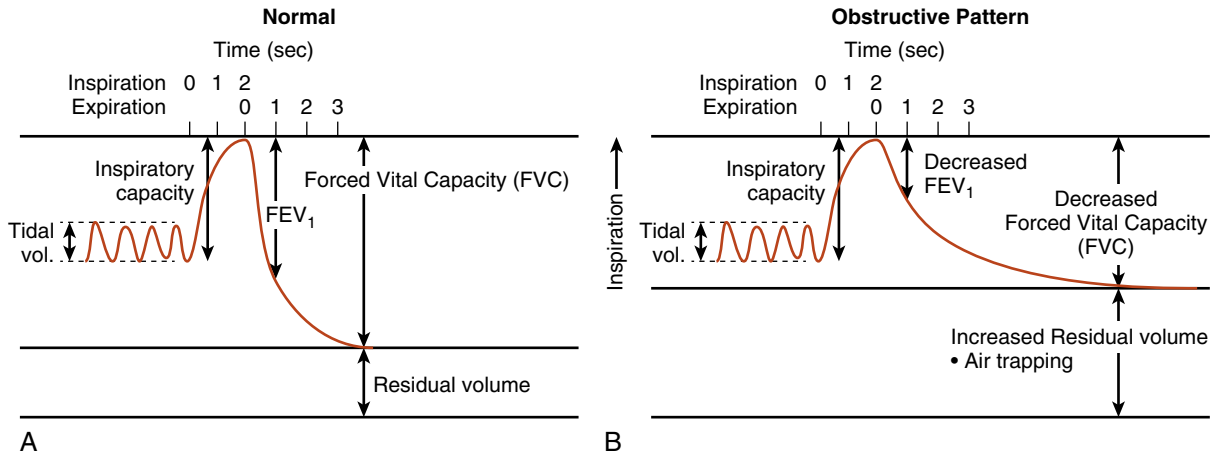

Fig. 15.20 Spirometry in a normal individual (A) and in a patient with obstructive lung disease (B). FEV₁ represents the forced expiratory volume in 1 second, and FVC represents the forced vital capacity. The FEV₁/FVC ratio is normally greater than 0.80. With obstruction, the FEV₁/FVC ratio is less than 0.70.

Flow-Volume Loop

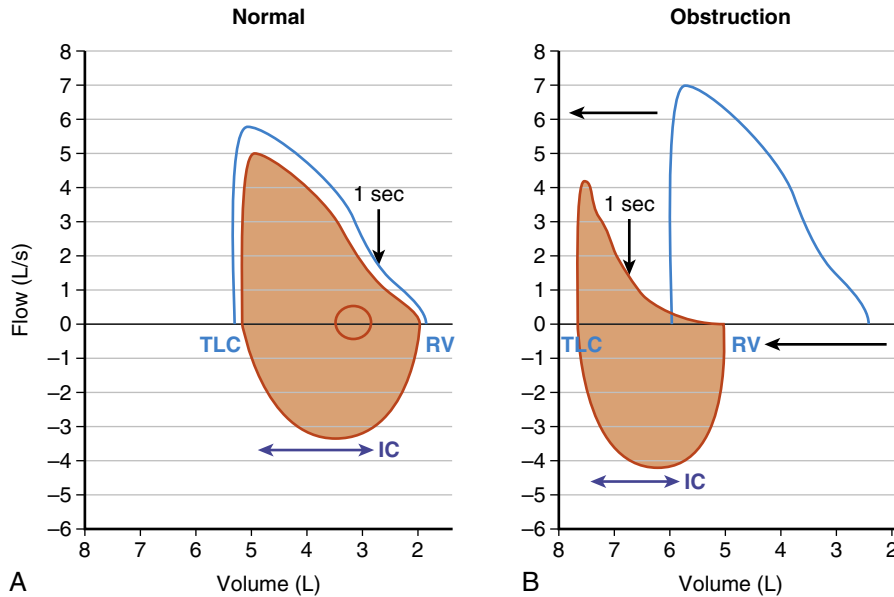

Fig. 15.21 The maximum expiratory flow and volume curve in a normal individual (A) and in an individual with obstructive lung disease (in this case, COPD) (B). Hyperinflation and air trapping (arrows) push the total lung capacity (TLC) and residual volume (RV) to the left (i.e., toward higher lung volumes). In addition, characteristic scalloping of the expiratory limb of the flow-volume curve develops. IC, Inspiratory capacity.

fibrosis cause a restrictive pattern because of the increased elastic recoil of the respiratory system. Diseases of the chest wall, such as kyphoscoliosis, obesity, or ankylosing spondylitis, can also cause restriction by reducing the elasticity of the chest wall. Weakness of the respiratory muscles causes restriction by reducing the force available to inflate the respiratory system. Myasthenia gravis, amyotrophic lateral sclerosis, diaphragm paralysis, and Guillain-Barré syndrome can be associated with weakness sufficient to cause restrictive lung disease. Finally, space-occupying lesions involving the pleural space, such as pleural effusions, pneumothorax, or pleural tumors, can cause restriction. Occasionally, RV and FRC may be elevated with no increase in TLC. This pattern is referred to as *air trapping* and can be seen with COPD or asthma.

The forced expiratory maneuver can be analyzed in terms of flow and volume by construction of a flow-volume loop (Fig. 15.21). Flow-volume loops are useful to identify obstructive and restrictive patterns. The characteristic appearance of obstructive impairment is concavity (“scooping”) of the expiratory loop, whereas with restrictive impairments, the loops have a normal shape but are reduced in size. In addition, flow-volume loops are the primary means of identifying upper airway obstruction. Upper airway obstruction is characterized by a truncated (clipped) inspiratory or expiratory loop. A fixed obstruction produces clipping of both inspiratory and expiratory loops. Variable intrathoracic upper airway obstruction exhibits clipping of the expiratory loop, whereas variable extrathoracic obstruction exhibits clipping of the inspiratory loop (Fig. 15.22).

E-Fig. 15.2 Volume-time curve in the normal lung (*left*) and in obstructive lung disease (*right*). FEV_1 , Forced expiratory volume in 1 second; FVC , forced vital capacity.

Fig. 15.22 The flow-volume loops display different patterns of upper airway obstruction. With fixed obstruction, both inspiratory and expiratory flows are reduced (clipped). With variable extrathoracic obstruction, only the inspiratory flows are clipped. With variable intrathoracic obstruction, only the expiratory flows are clipped. RV, Residual volume; TLC, total lung capacity.

Bronchoprovocation Testing

Bronchoprovocation testing is typically used to determine the presence or absence of hyperreactive airways disease. Some individuals with a clinical suspicion of asthma have normal expiratory flow rates and lung volumes. Bronchoprovocation testing in these individuals can be important to identify hyperreactive airways disease and support the diagnosis of asthma. Methacholine is a cholinergic agonist that causes bronchoconstriction. During the bronchoprovocation test, the subject inhales increasing concentrations of methacholine. Measurements of FEV₁, FVC, and specific airways conductance are obtained after the inhalation of each concentration until the maximal dose of methacholine has been administered. If the FEV₁ is reduced by 20% or more or the specific airways conductance is reduced by 40% or more, a diagnosis of hyperreactive airways disease is established. Patients with asthma demonstrate a fall in FEV₁ at considerably smaller doses than in normal individuals (Fig. 15.23).

Lung Diffusion Capacity

The diffusion of oxygen from the alveolus into the capillary can be assessed by measuring the diffusion capacity for carbon monoxide (DLCO). To calculate the diffusion capacity for oxygen, one would need to know the alveolar volume and the partial pressures of oxygen in the alveolus and in the pulmonary capillary. Because it is not practical to measure the oxygen tension of pulmonary capillary blood, carbon monoxide is used rather than oxygen to assess diffusion capacity. Carbon monoxide diffuses across the alveolar capillary membranes much as oxygen does. However, carbon monoxide has the advantage of binding completely to hemoglobin. Therefore, the partial pressure of carbon monoxide in the pulmonary venous blood is negligible. The DLCO is then measured as the rate of disappearance of carbon monoxide from the alveolus and is used as a surrogate for oxygen diffusion capacity.

The DLCO measurement provides an overall assessment of gas exchange and depends on factors such as the surface area of the lung, the physical properties of the gas, perfusion of ventilated areas, hemoglobin concentration, and the thickness of the alveolar-capillary membrane. Therefore, an abnormal value may not only signify disruption of the alveolar-capillary membrane but may also be related to a reduction in surface area of the lung (pneumonectomy), poor perfusion (pulmonary embolus), or poor ventilation of alveolar units (COPD). A low DLCO may be seen in interstitial lung diseases that alter the alveolar-capillary membrane or in diseases such as emphysema that destroy

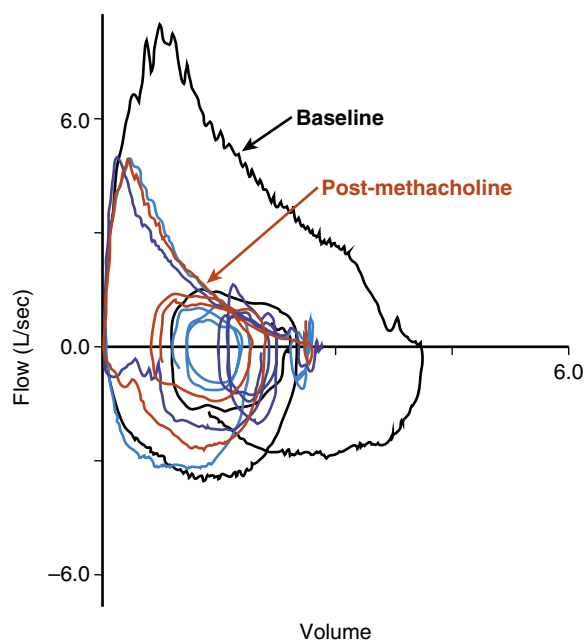

Fig. 15.23 In bronchoprovocation challenge, patients are exposed to increasing concentrations of an inhaled challenge (e.g., methacholine, histamine), followed by evaluation of the forced expiratory volume in 1 second (percentage of baseline value) or airways conductance. The FEV₁ falls by more than 20% (compared to baseline), and airways conductance by more than 40%, at lower concentrations of the challenge drug in individuals with asthma.

both alveolar septa and capillaries (E-Fig. 15.3). Anemia lowers the DLCO. Most laboratories provide a hemoglobin correction for diffusion capacity. An increased DLCO may be associated with engorgement of the pulmonary circulation by red blood cells or polycythemia.

Arterial Blood Gases

The measurement of Pao₂ and Paco₂ provides information about the adequacy of oxygenation and ventilation. This requires arterial blood sampling through arterial puncture or indwelling cannula (Table 15.2). Oxygenation also can be measured through noninvasive devices such as the pulse oximeter, which measures hemoglobin oxygen saturation, and through transcutaneous devices that measure Pao₂ and Paco₂. These devices are particularly useful for measuring oxygenation during exertion or sleep.

E-Fig. 15.3 A photomicrograph of normal and emphysematous lungs. Notice the lack of alveolar septa in the emphysematous lung.

TABLE 15.2 Normal Values for Arterial Blood Gases

Partial pressure of oxygen (P_{aO_2}): $104 - (0.27 \times \text{age})$
Partial pressure of carbon dioxide (P_{aCO_2}): 36-44
pH: 7.35-7.45
Alveolar-arterial O_2 difference = $2.5 + (0.21 \times \text{age})$

6-Minute Walk Distance

Often, alterations in oxygenation are not detected at rest but are unveiled during exertion. The 6-minute walk test is a standardized test in which the patient walks for 6 minutes while the oxygen hemoglobin saturation is measured. A decrease in saturation is abnormal and suggests impaired gas exchange capabilities, and a reduction in distance walked is a means of detecting deterioration of overall function due to lung disease. However, the 6-minute walk distance (6MWD) is primarily validated for following exercise capacity over time and in response to interventions. There is a “learning effect” that increases distance walked after the first attempt, and the minimal clinically important distance for this test is established as 30 meters. The 6MWD correlates well with peak oxygen consumption (VO_2 max) measured with maximal exercise testing.

In summary, pulmonary function tests, in conjunction with the history and physical examination, can be used to diagnose pulmonary disorders and assess severity and response to therapy, as illustrated in the flow diagram in E-Fig. 15.4.

EVALUATION OF LUNG DISEASE

Analysis of Exhaled Breath

Endogenously produced monoxides (nitric oxide and carbon monoxide) and volatile organic compounds (VOCs), collectively called the “volatolome,” can be detected in the exhaled breath and may serve as biomarkers of pulmonary inflammation or cancer. Exhaled nitric oxide is elevated in asthma, and the US Food and Drug Administration has approved the test for exhaled nitric oxide for the diagnosis and evaluation of asthma exacerbations. The VOCs can be detected by gas chromatography or mass spectroscopy but more recently electronic “noses” have been developed that use changes in electrical resistance of polymers that bind VOCs to detect unique patterns of exhaled VOCs. These provide a “fingerprint” that may identify lung cancer, various pneumoconioses, obstructive sleep apnea, active pulmonary tuberculosis, and pulmonary hypertension. Cytokines and other similar compounds in the condensate phase of exhaled breath are being investigated for possible applications in inflammatory lung diseases (e.g., cystic fibrosis, bronchiectasis). Other nonpulmonary diseases such as malabsorption syndromes and *Helicobacter pylori* infection are also detected by analysis of exhaled breath.

Chest Radiography

Generally, the evaluation of a patient with lung disease begins with routine chest radiography and then proceeds to more specialized techniques such as computed tomography (CT) or magnetic resonance imaging (MRI). Ideally, the chest radiograph consists of two different films, a posteroanterior (PA) radiograph and a lateral radiograph (E-Fig. 15.5). Many pathologic processes can be identified on a PA chest radiograph, and the lateral view adds valuable information

about areas that are not well seen on the PA projection. In particular, the retrocardiac region, the posterior bases of the lung, and the bony structure of the thorax (e.g., the vertebral column) are better visualized on the lateral radiograph. The PA chest radiograph is obtained with the patient standing with his or her back to the x-ray beam and the anterior chest wall placed against the film cassette. The chest radiograph should be obtained while the patient takes the deepest breath possible. If the patient is too weak to stand or too sick to travel to the radiology department, the chest radiograph is performed at bedside (portable chest radiograph). The cassette is placed behind the patient’s back while the patient is semi-supine in bed, and the x-ray beam travels from anterior to posterior (AP film). The quality of a portable film is not that of a standard PA film, but it still provides valuable information.

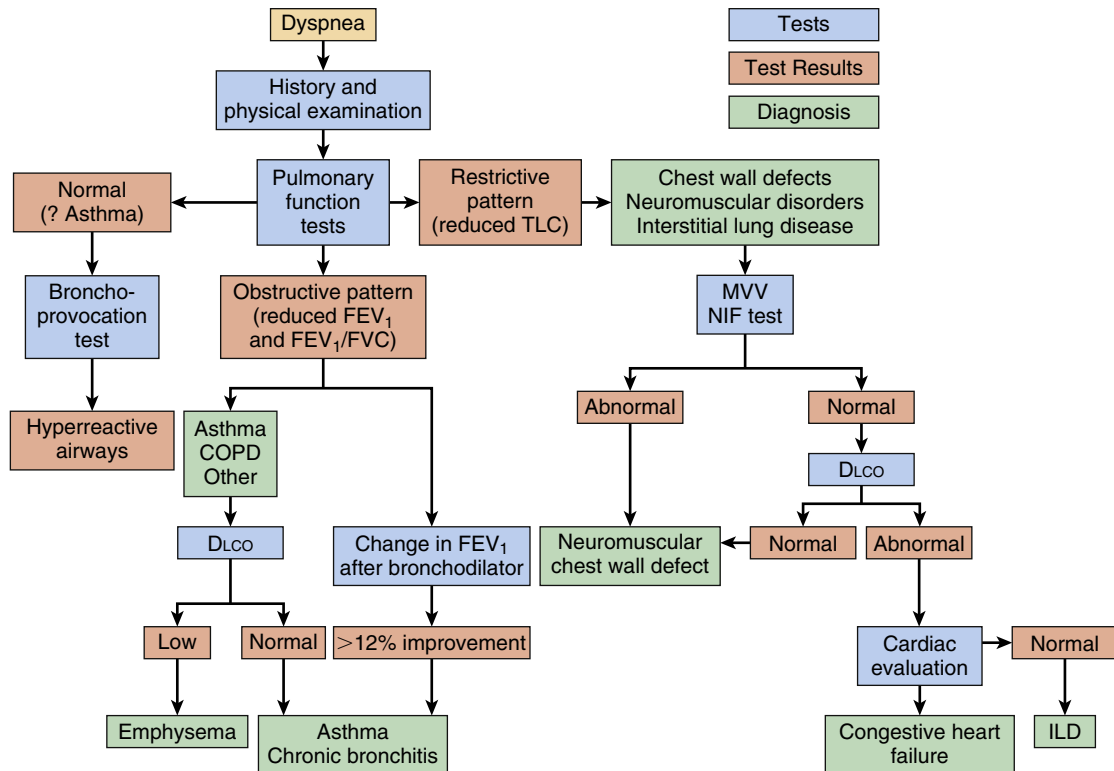

The examination of a chest radiograph should be systematic so that subtle abnormalities are not missed. It should include evaluation of the lungs and pulmonary vasculature, the bony thorax, the heart and great vessels, the diaphragm and pleura, the mediastinum, the soft tissues, and the subdiaphragmatic areas. Abnormalities that are visible on a chest radiograph include pulmonary infiltrates, nodules, interstitial markings, vascular abnormalities, masses, pleural effusions and thickening, cavitory lesions, cardiac enlargement, abnormal airway structure, and vertebral or rib fractures. In addition to the PA and lateral chest radiographs, the lateral decubitus projection is often used to identify the presence or absence of pleural effusion. The decubitus view is particularly useful in determining whether blunting of the costal phrenic sulcus is caused by freely flowing pleural fluid or related to pleural thickening. Chest radiography, in concert with a good history and physical examination, allows the clinician to diagnose chest disease in many circumstances.

Fluoroscopy

Fluoroscopic examination of the chest is useful for evaluating motion of the diaphragm. This technique is particularly helpful in diagnosing unilateral diaphragm paralysis. A paralyzed hemidiaphragm moves paradoxically when the patient is instructed to inhale or to forcefully sniff. However, fluoroscopy is limited when evaluating for bilateral diaphragm paralysis. Apparently normal descent of the diaphragm during inspiration, caused by compensatory respiratory strategies employed by the patient with bilateral diaphragm paralysis, leads to false-negative results. False-positive results are caused by paradoxical hemidiaphragm motion, which can be seen in as many as 6% of normal subjects during the sniff maneuver.

Ultrasonography

Point-of-care ultrasonography (POCUS) has improved clinical care by providing more focused and visual examinations of vital organs to aid in prompt diagnosis and management of diseases. In ultrasonography, sound waves in the frequency range of 3 to 10 MHz are reflected off internal tissues to produce images of viscera such as the liver, kidney, and heart. The air-filled lung cannot be imaged directly, but over the last decade, an understanding of various *artifacts* generated by ultrasound beams traversing normal and abnormal lung have led to increased application of ultrasound for imaging of the lung, particularly in the intensive care unit. Protocols are available to help with detecting lung consolidation, pulmonary edema, and volume responsiveness. Additionally, ultrasonography can rapidly and reliably detect a pneumothorax, pleural effusion, consolidation, and pulmonary

E-Fig. 15.4 The flow diagram shows how pulmonary function tests can be used to evaluate patients with obstructive and restrictive disorders. *COPD*, Chronic obstructive pulmonary disease; *DLco*, diffusing capacity for carbon monoxide; *FEV₁*, forced expiratory volume in 1 second; *FVC*, forced vital capacity; *ILD*, interstitial lung disease; *MVV*, maximum voluntary ventilation; *NIF*, negative inspiratory force; *TLC*, total lung capacity.

E-Fig. 15.5 Normal posteroanterior (*left*) and lateral (*right*) chest radiographs.

edema with sensitivity and specificity similar to those of a chest radiograph (Fig. 15.24).

In addition to its diagnostic capabilities, ultrasound is routinely used in real time to direct invasive procedures, such as thoracentesis, pericardiocentesis, and placement of a pleural, central venous, or arterial catheter. Other applications of pulmonary ultrasound include assessment of volume status by imaging inferior vena cava collapsibility with respiration and assessment of right ventricular function. Two-dimensional B-mode ultrasound imaging of the diaphragm can be used to visualize diaphragm function during inspiration. Failure of the diaphragm to thicken by a minimum of 35% during inspiration when visualized from the infraaxillary view is indicative of diaphragm weakness.

Ultrasonography is noninvasive, rapidly and easily applied, relatively low-cost, readily portable to the bedside, and because it does not use radiation, safe for repeated use on a patient.

Computed Tomography

CT has many applications in pulmonary medicine and provides more detailed information about lung structure than chest radiography. With the use of this technique, cross sections of the entire thorax can be obtained, usually at 2- to 5-mm intervals. CT scanning allows visualization of airways up to the seventh generation and delineation of parenchymal anatomy, texture, and density. Image contrast can be adjusted to optimize visualization of the lung parenchyma, pleura, and

Fig. 15.24 Ultrasound image of the lung depicts the diaphragm, a pleural effusion, and an infiltrate.

mediastinal structures. The use of intravenous contrast material as part of the examination permits separation of vascular from nonvascular mediastinal structures. CT scans provide tremendous anatomic resolution when compared with chest radiography, but they expose the subject to about 70 times the radiation of a routine chest radiograph.

CT of the chest helps characterize pulmonary nodules and masses, distinguish between pleural thickening and pleural fluid, estimate the size of the heart and the presence of pericardial fluid, identify patterns of involvement of interstitial lung disease, detect cavities, and identify intracavitary processes such as mycetoma. It is also used to quantify the extent and distribution of emphysema, detect and measure mediastinal adenopathy for evaluating inflammatory diseases that involve mediastinal lymph nodes (e.g., sarcoidosis) and staging of lung cancer, and identify vascular invasion by neoplasm (Fig. 15.25). Newer generations of CT scanners are able to use multiple x-ray beams to create between 4 and 256 images simultaneously at a much faster rate (<10 seconds) than with the older models, which used only a single x-ray beam and detector. CT scans using much lower radiation doses are routinely advocated on a yearly basis for the early detection of lung cancer in older, high-risk smokers.

CT angiography allows for construction of three-dimensional images of the pulmonary vascular system. This imaging technique has emerged as the procedure of choice for identifying pulmonary embolism, supplanting pulmonary ventilation-perfusion scintigraphic lung scanning. The technique is used to identify pulmonary vascular abnormalities such as aortic dissection, pulmonary venous malformations, and aortic aneurysms. Additionally, three-dimensional construction of the airway and pulmonary parenchyma using CT images and specialized software has provided a means to electromagnetically guide a biopsy catheter through a bronchoscope (electromagnetic navigation bronchoscopy) to a distal pulmonary nodule or mass for biopsy. It could also be used to place a fiducial marker at the exact location of a lung cancer to accurately focus surgical or radiotherapy treatment.

Dynamic contrast-enhanced CT with single- or multi-detector scanner has been investigated as a modality to differentiate between a malignant and benign pulmonary nodule. First, baseline images are obtained using CT without contrast enhancement. Subsequently, contrast is given over time while series of CT images are acquired. The difference time and contrast enhancement allow for evaluation of vascularity and blood flow patterns. Studies have confirmed high accuracy for differentiation.

High-resolution CT is a technique that generates thin (1-mm) anatomic slices to provide a high-contrast image of the pulmonary

Fig. 15.25 Chest radiograph (A) and chest computed tomographic (CT) scan (B) of a patient with severe bronchiectasis. The abnormally dilated airways are better appreciated on the CT scan.

parenchyma. With high-resolution CT, a special reconstruction algorithm sharpens the soft tissue interfaces to provide superior visualization of the pulmonary parenchyma. This technique is used primarily to identify interstitial lung disease and bronchiectasis. It is extremely useful for identifying interstitial lung disease that may not be apparent on a plain chest radiograph, and it has supplanted bronchography in the diagnosis of bronchiectasis.

Magnetic Resonance Imaging

MRI is a tomographic technique that uses radio waves modified by a strong magnetic field to produce an image resulting from the resonance of protons in tissue water. The chief advantage of MRI is that it does not entail the use of ionizing radiation. The ability of MRI to image pulmonary parenchyma is limited because of the low proton density in air-filled regions of the lung, which therefore cannot generate MRI images, artifacts arising from multiple air-tissue interfaces, and respiratory motion artifacts. However, vascular structures and pulmonary perfusion are well imaged by MRI, especially with the use of intravenous contrast agents such as gadolinium chelates. Therefore, MRI is very useful in the study of aortic dissection and may have a role in the evaluation of pulmonary emboli and chronic thromboembolic pulmonary hypertension. Three-directional velocity-encoded MRI allows three-dimensional, time-resolved cine reconstruction of blood flow patterns and pressures and is used in cardiac imaging. It may also have a role in the measurement of pulmonary blood flow. Infiltrative pulmonary diseases and pulmonary edema increase proton density in the lung, allowing better definition by MRI of honeycombing in pulmonary fibrosis and pulmonary edema in acute respiratory distress syndrome (ARDS). The use of inhaled hyperpolarized inert gases such as helium-3 or xenon-129 offers the ability to quantify peripheral airspace size, measure gas flow in lobar and segmental bronchi, and detect regional differences in ventilation. Ongoing studies are being completed to establish its utility. It has promising applications in the evaluation of emphysema and asthma and after lung transplantation, including assessment of bronchodilator responsiveness. In particular, MRI is very useful in delineating extension of malignant pleural mesothelioma to adjacent chest wall tissue or diaphragm, where it is much superior to CT imaging because of superior contrast resolution.

Pulmonary Angiography

Pulmonary angiography entails placement of a catheter in the pulmonary artery, followed by rapid injection of a contrast agent. In the past, this was “gold standard” for diagnosis of pulmonary thromboembolic disease. Pulmonary angiography still can be useful for detection of congenital abnormalities of the pulmonary vascular tree, but CT and MRI have largely supplanted it.

Pulmonary Ventilation-Perfusion Scanning

Ventilation-perfusion (\dot{V}/\dot{Q}) scintigraphy utilizes radiopharmaceuticals such as technetium-99m as a noninvasive means to evaluate regional blood flow and ventilation. Therefore, it has been used in the past as an alternative to pulmonary angiography to detect pulmonary embolism. With the advent of CT angiography and its improvements over the years, \dot{V}/\dot{Q} imaging is no longer favored for the initial evaluation of suspected pulmonary embolism. Additionally, alteration of regional blood flow (pulmonary vasoconstriction and shunt) due to lung diseases such as pneumonia or interstitial lung disease limits its diagnostic accuracy. The PIOPED study in 1990 investigated the diagnostic accuracy of a \dot{V}/\dot{Q} scan for the diagnosis of pulmonary embolism. The study found that a \dot{V}/\dot{Q} scan is useful when the clinical pretest probability is high but that it has poor diagnostic accuracy. Despite

its limitations, \dot{V}/\dot{Q} scan still has utility in certain clinical scenarios. These scenarios include patients who have abnormal renal function, patients who are allergic to CT contrast, and patients with suspected chronic thromboembolic pulmonary hypertension (higher sensitivity compared to CT angiography). Quantitative lung perfusion scanning is also very useful preoperatively to assess the predicted postoperative lung function remaining after planned lobectomy or pneumonectomy. Therefore, it is used by thoracic surgeons to evaluate a patient's suitability for undergoing lobectomy or pneumonectomy for curative resection of lung cancer.

Positron Emission Tomography

Positron emission tomography (PET) detects metabolically active pulmonary nodules greater than 0.8 cm in diameter. It is helpful in assessing whether a nodule is benign or malignant. However, it does not distinguish between inflammation and malignancy. Therefore, assessment of multiple pulmonary nodules by PET is limited because of false-positive findings due to active granulomatous disease, such as previous exposure to tuberculosis, sarcoidosis, or fungal infestation; or to active infection, such as bacterial or viral pneumonia, bronchiolitis, or aspiration.

Dual-modality integrated PET-CT combines morphologic and functional imaging. The combination of PET and CT is helpful for localizing solitary metastatic lymph nodes in the hila and extrapulmonary locations, allowing better staging of lung cancer. In addition, PET-CT is helpful in planning radiation therapy for patients who have lung cancer associated with atelectasis.

Bronchoscopy

Fiberoptic bronchoscopy is used for diagnostic or therapeutic indications. It is most commonly performed to directly visualize the nasopharynx, larynx, vocal cords, and proximal tracheobronchial tree for diagnostic purposes. The procedure is performed by sedating the patient and providing local anesthesia with inhaled and instilled lidocaine. The bronchial mucosa is assessed for endobronchial masses, mucosal integrity, extrinsic compression, dynamic compression, and hemorrhage. The bronchoscope is equipped with a channel for passing a variety of instruments including biopsy forceps for sampling endobronchial lesions or lung tissue (transbronchial biopsy), and fine 19- to 22-gauge needles for transbronchial aspiration biopsy from lymph nodes or lung masses. Saline also can be instilled through the channel for bronchial washings or bronchoalveolar lavage. Bronchial washings and bronchoalveolar lavage can be analyzed for cytology, culture, and special stains. A bronchial brush is used to scrape the bronchial mucosa and harvest cells for cytology. Bronchoscopes can also be adapted with a terminal ultrasound probe to provide ultrasound images of the airways and neighboring tissues. This technique, called endobronchial ultrasound (EBUS) uses high acoustic frequencies, in the range of 20 MHz, to provide high-resolution images of proximal tissue and provides accurate positional guidance for needle aspiration of mediastinal lymph nodes. It is now routinely used to detect lung cancer metastasis to mediastinal lymph nodes and for the diagnosis of granulomatous disorders of the lymph nodes. A different radial ultrasound probe inserted through the working channel of a bronchoscope can facilitate confirmation of the position of a transbronchial biopsy forceps near a lung mass during transbronchial biopsy of a lesion in the periphery of the lung parenchyma. A newer technique called transbronchial lung cryobiopsy (TBLC) uses a probe that traverses the working channel of a bronchoscope into the periphery of the lung near the chest wall. The probe is rapidly cooled to freeze the adjacent lung tissue, which adheres to the probe and is fractured off, resulting in biopsy specimens that are larger and less susceptible to the crush artifact noted on routine

forceps biopsies. This technique, though often complicated by serious hemorrhage, is in use for the diagnosis of interstitial lung disease with the hope that it will obviate the need for surgical biopsy.

Common therapeutic indications for bronchoscopy include retrieval of foreign bodies, suctioning of secretions, reexpansion of atelectatic lung by removing obstruction, detection and localization of hemoptysis, and assistance with difficult endotracheal intubations. In special centers, bronchoscopy is used to perform yttrium aluminum garnet (YAG) laser therapy, argon plasma coagulation therapy, and cryotherapy for endobronchial lesions. It is also used to guide placement of catheters for brachytherapy in lung cancer or guide placement of stents. Lasers produce a beam of light that can induce tissue vaporization, coagulation, and necrosis. Argon plasma coagulation therapy uses heat from ionized argon gas to debulk the tumor while simultaneously coagulating to stop bleeding. Cryotherapy probes induce tissue necrosis through hypothermic cellular crystallization and microthrombosis. Cryotherapy and electrocautery have been used to treat and relieve airway obstruction caused by benign tracheal bronchial tumors, polyps, and granulation tissue. The goal of endobronchial brachytherapy is to relieve airway obstruction from central tumors. This is typically used as an adjunct to conventional external-beam irradiation. Tracheobronchial stenting can be performed to manage airway compression associated with malignant tumors, tracheoesophageal fistulas, or tracheobronchomalacia. Bronchoscopy is generally a safe procedure with major complications, including significant bleeding, pneumothorax, and respiratory failure, occurring in 0.1% to 1.7% of patients.

PROSPECTUS FOR THE FUTURE

Continued refinement and evolution of techniques and methods currently used to assess pulmonary structure and function will enhance the ability to diagnose and treat individuals with lung disease. Although pulmonary function testing has been performed for decades, advances in equipment design and better standardization of methods will improve accuracy and reproducibility. Further development of noninvasive techniques used to measure changes in lung volume from body surface displacements may allow for assessment of pulmonary function in settings outside the pulmonary function laboratory. Analysis of exhaled gas for biomarkers has tremendous potential for early diagnosis of many lung diseases, especially cancer.

Great strides in assessing lung structure will evolve from advances in CT, PET, and MRI technology. CT volume-rendering techniques will provide images of the central airways, enabling “virtual bronchoscopy.” This technique will be useful to guide biopsy site selection

in conventional bronchoscopy and to allow visualization of airways distal to an endobronchial obstruction. Volumetric measurements of pulmonary nodules using CT segmentation techniques will allow more accurate calculation of nodule volume and better assessment of tumor doubling times. This, in concert with PET-CT, may provide more accurate means of determining the malignant potential of a solitary pulmonary nodule. Also, dynamic contrast-enhanced CT may help with differentiating between malignant and benign pulmonary nodules that would further improve the lung cancer screening process.

MRI may evolve into the preferred method for evaluating pulmonary emboli, mediastinal disease, and regional ventilation-perfusion matching. Velocity-encoded MRI is a promising modality for assessment of pulmonary vascular blood flow and pressures and may prove to be more accurate than current noninvasive methods. Lymph node-specific magnetic resonance contrast agents and the development of PET molecular tracers targeting tumor proteins and receptors may better differentiate enlarged lymph nodes caused by hyperplasia from those due to neoplasia. Finally, new insights into the function of the respiratory control centers in the cortex and brain stem may be attained from the use of functional MRI studies of the brain.

Obstructive Lung Diseases

Zoe G.S. Vazquez, Matthew D. Jankowich, Debasree Banerjee

INTRODUCTION

The obstructive lung diseases are a group of pulmonary disorders that result in dyspnea characterized by an obstructive pattern of expiratory airflow limitation on spirometry. These disorders include chronic obstructive pulmonary disease (COPD), asthma, cystic fibrosis (CF), bronchiectasis, and bronchiolar disorders. In some cases, these disorders overlap clinically (Fig. 16.1), sharing several features aside from the presence of expiratory airflow limitation. These features may include symptoms of wheezing and sputum production, chronic airway-centered inflammation, presence of airway structural changes resulting in remodeling of the airways, and episodic periods of temporarily worsened clinical status, known as exacerbations. However, the causes, locations, and patterns of airway inflammatory changes and remodeling, as well as the treatments, prognoses, and natural histories, are often significantly different, making clinical distinction among these disorders important.

COPD is characterized by abnormal airway inflammation and lung structure in response to an inhaled irritant (typically cigarette smoke), resulting in irreversible or incompletely reversible airflow limitation that is typically progressive over time. *Asthma* is distinguished from COPD by characteristic smooth muscle hyperreactivity and reversible airflow limitation, by its variable clinical course, and by its frequent association with atopy. These disorders are epidemic

Fig. 16.1 Classification of obstructive lung diseases. Although most patients with chronic obstructive pulmonary disease (COPD) have small airways disease, the bronchiolar disorders do not overlap with COPD. *CF*, Cystic fibrosis.

in the general population worldwide and account for a significant proportion of the morbidity and mortality associated with the obstructive lung diseases. *Bronchiectasis* is a permanent abnormal dilation of the bronchi that results in chronic cough, purulent sputum production, and hemoptysis. Bronchiectasis is caused by diverse conditions including CF, a genetic disorder resulting from mutations in the *CFTR* gene. The *bronchiolar disorders*, also called *small airways disorders*, result from inflammation and/or fibrosis of the small airways of the lung that leads to dyspnea. They may be difficult to diagnose because loss or obstruction of a majority of the small airways must occur before the appearance of expiratory airflow limitation on spirometry.

The basis for expiratory airflow obstruction varies among these disorders. The flow of air through the bronchial tree is directly proportional to the driving pressure and inversely proportional to the resistance. In obstructive lung disease, alterations in one or both of these processes may be present. Loss of lung elastic tissue, frequently present in COPD, results in decreased lung elastic recoil on expiration and therefore decreased driving pressure for expiratory airflow. By contrast, airflow limitation in asthma is primarily caused by smooth muscle contraction resulting in bronchoconstriction that increases airway resistance. Increases in airway resistance are also present in COPD and are related to small airway inflammation and fibrosis as well as small airway collapse due to decreased “tethering” of the airways in the setting of loss of surrounding lung elastic tissue. Mucus obstruction of airway lumens contributes to increased airway resistance in all the obstructive lung diseases.

Obstruction to airflow causes characteristic changes in lung volumes. The residual volume (RV) and functional residual capacity (FRC) are increased, whereas the total lung capacity (TLC) remains normal or is increased. Vital capacity, and particularly inspiratory capacity, is eventually reduced by the increase in RV. Several factors may contribute to the increase in FRC and RV in obstructive lung disease. Decreased lung elastic recoil in COPD increases the FRC because of reduced opposition to the outward force exerted by the chest wall. Loss of airway tone and decreased tethering by the surrounding lung in COPD, as well as bronchoconstriction and mucus plugging in acute asthma, allow airways to collapse at higher lung volumes and trap excessive air. Finally, under demands for increased minute ventilation (e.g., during exercise), the increased resistance to airflow may not allow the lungs to empty completely in the time available for expiration; this leads to so-called dynamic hyperinflation of the lungs as the volume of trapped air progressively increases while the inspiratory capacity is progressively limited. This phenomenon contributes to symptoms of chest tightness and dyspnea during exercise and results in exercise limitation, especially in COPD.

TABLE 16.1 Features of Obstructive Lung Disease

Disorder	Clinical Features	Laboratory Findings
Chronic obstructive pulmonary disease	Chronic progressive dyspnea Cough, sputum production Periodic exacerbations	FEV ₁ /FVC <0.70 after bronchodilator use Often reduced DLCO
Asthma	Episodic dyspnea, cough, and/or wheezing Nocturnal symptoms May have environmental trigger(s)	Variable airflow obstruction on spirometry Typically significant improvement in FEV ₁ with bronchodilator use DLCO normal or elevated Methacholine challenge shows airway hyperreactivity
Bronchiectasis	Chronic cough and purulent sputum production Hemoptysis	Chest radiograph: "tram track" shadows HRCT: dilated bronchi bigger than accompanying vessel, lack of tapering of bronchi, visible bronchi within 1-2 cm of lung border Sputum culture may grow <i>Haemophilus influenzae</i> , <i>Pseudomonas aeruginosa</i> , or atypical mycobacteria Laboratory evaluation may reveal specific etiology (e.g., decreased immunoglobulin levels in CVID)
Cystic fibrosis	Sinusitis, bronchiectasis, meconium ileus, malabsorption, infertility (in males, congenital absence of vas deferens)	Increased sweat chloride concentration, mutation in CFTR chloride channel, elevated fecal fat, abnormal nasal mucosal potential difference
Bronchiolar disorders	Progressive dyspnea Possible history of connective tissue disease, inflammatory bowel disease, lung transplantation, or hematopoietic stem cell transplantation	Fixed airflow obstruction on spirometry HRCT: mosaic attenuation pattern; centrilobular nodules; tree-in-bud opacities

CVID, Common variable immunodeficiency; DLCO, diffusing capacity for carbon monoxide; FEV₁, forced expiratory volume in 1 second; FVC, forced vital capacity; HRCT, high-resolution computed tomography.

There are two major consequences of the changes in lung volume in obstructive lung disease. First, breathing at higher lung volumes requires a higher change in pressure to achieve a smaller change in lung volume, and this requirement increases the work of breathing. Second, larger lung volumes place the inspiratory muscles at a mechanical disadvantage. The diaphragm is flattened, decreasing its ability to change intrathoracic volume, and all the inspiratory muscle fibers are shortened, decreasing the tension they are able to exert to effect changes in lung volume. The combination of a higher work of breathing and mechanical disadvantages of the respiratory muscles caused by lung hyperinflation can lead to respiratory muscle fatigue and failure in the setting of an abrupt worsening of airway obstruction, as during an acute exacerbation of COPD or asthma.

In addition to the clinical history and physical examination, spirometry is a key step in the diagnostic work-up for a patient with suspected obstructive lung disease. Although spirometry is readily available and inexpensive, it is often underutilized, and as a consequence, obstructive lung diseases are underdiagnosed. Assessment of the clinical and spirometric response to a bronchodilator is a simple and helpful step in distinguishing asthma from COPD. Measurement of the diffusing capacity of the lungs for carbon monoxide (DLCO) can also be helpful in separating asthma, which is characterized by a normal or elevated diffusing capacity, from COPD in which the diffusing capacity is often reduced by loss of surface area for gas exchange. More sophisticated testing, such as high-resolution chest computed tomography (HRCT), may be needed to help diagnose less common causes of obstructive lung disease (e.g., bronchiectasis).

The clinical features and laboratory findings associated with the various obstructive lung disorders are summarized in Table 16.1.

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Definition and Epidemiology

The Global Initiative for Chronic Obstructive Lung Disease (GOLD) currently defines COPD as a common preventable and treatable disease characterized by persistent airflow limitation that is usually progressive and associated with an enhanced chronic inflammatory response in the airways and lungs to noxious particles and gases. The presence of airflow limitation is established by spirometry: If the ratio of the forced expired volume in 1 second (FEV₁) to the forced vital capacity (FVC) is less than 0.70 after administration of a bronchodilator, airway obstruction is indicated. Although in the past COPD was defined by the presence of either *emphysema* (a pathologic enlargement of the distal air spaces) or *chronic bronchitis* (a clinical syndrome characterized by the presence of cough and sputum production for at least 3 months in each of 2 consecutive years), the current definition is based on the presence of airflow limitation and not on the presence of these entities. Both emphysema and chronic bronchitis may occur with or without the simultaneous presence of expiratory airflow limitation, and therefore these entities overlap with but are not synonymous with COPD. The current definition of COPD highlights the presence of persistent, reproducible expiratory airflow limitation and emphasizes the progressive nature of COPD and the presence of abnormal inflammation in the lungs and airways.

COPD is a common disorder in populations across the world. The Burden of Obstructive Lung Disease study, in a sample of adults from 12 countries, found that 10.1% had at least moderate airway obstruction (FEV₁/FVC <0.70 and FEV₁ <80% predicted) after administration of a bronchodilator. Prevalence rates for COPD are correlated with increasing age, lower socioeconomic status, and smoking. Although COPD is more prevalent in men than in women, the prevalence of

Fig. 16.2 Pattern of decline in forced expiratory volume in 1 second (FEV_1) with risks for morbidity and mortality from respiratory disease in a susceptible smoker compared with a normal patient and with a non-susceptible smoker. Although cessation of smoking does not replenish the lung function already lost in a susceptible smoker, it decreases the rate of further decline. (Data from Fletcher C, Peto R: The natural history of chronic airflow obstruction, *BMJ* 1:1645-1648, 1977.)

COPD in women has been increasing, and annual death rates for COPD have been steadily rising in both white and black women in the United States. COPD results in a significant economic burden in terms of health care expenditures and disability. In 2014, COPD accounted for 44.3 per 100,000 deaths in the United States. According to the World Health Organization, COPD is the fourth leading cause of death worldwide.

COPD is a complex disorder that results from a susceptibility to environmental factors brought about by a genetic predisposition. Cigarette smoking is the major environmental cause of COPD, although other factors may contribute, including outdoor air pollution, dust and fume exposure in the workplace, and indoor air pollution from use of biomass fuels for cooking and heat. Nonsmokers can and do develop COPD, highlighting the role of non-tobacco-related risk factors. A genetic predisposition is implied by the documentation of familial clusters of COPD. However, the only genetic disorder thus far definitively linked to COPD is α_1 -antitrypsin deficiency resulting from mutations in *SERPINA1*, which accounts for approximately 1% to 2% of all COPD cases. Recent studies have highlighted other areas of the genome that are also associated with COPD susceptibility.

Several longitudinal studies have defined patterns of age-related decline in lung function and have documented the concept of age-related susceptibility to COPD. These studies showed that most adult nonsmoking men exhibit a decline in FEV_1 of 35 to 40 mL/year. This rate is increased to 45 to 60 mL/year in most cigarette smokers. However, the susceptible smoker may demonstrate losses of 70 to 120 mL/year (Fig. 16.2). This information allows the physician to project the rate of decrease of lung function in patients with COPD and to assess the effects of therapeutic interventions.

Pathology

Various structural changes have been observed in the airways and lungs of individuals with COPD. The current definition of COPD emphasizes the central role of chronic inflammation in the pathogenesis of COPD and in the development of pathologic lung and airway remodeling in the setting of COPD. Structural changes observed in COPD include emphysema and abnormalities of the small and large airways. There is increasing evidence that the small airways are the major site of airflow limitation and a central focus of pathology in COPD.

Emphysema in COPD

Emphysema is defined as a permanent enlargement of the air spaces distal to the terminal bronchioles (E-Fig. 16.1). This is caused by destruction of the lung parenchyma in the absence of significant fibrosis. These changes result in an abnormal acinus with limited capabilities for gas exchange. Based on thin gross lung sections, emphysema can be classified as either centrilobular or panlobular (E-Figs. 16.2 and 16.3). In centrilobular emphysema, the proximal part of the lobule (the respiratory bronchiole) is affected; this is the most common histologic feature observed in emphysema related to smoking. Panlobular emphysema is seen in α_1 -antitrypsin deficiency.

α_1 -Antitrypsin is a serine protease inhibitor that deactivates elastase molecules released by inflammatory cells that are capable of degrading connective tissue matrices. The observations that this enzyme was associated with emphysema and that emphysema could be reproduced in experimental models by the instillation of papain (a protease) into the lungs led to the hypothesis that emphysema is caused by an imbalance between protease and antiprotease systems in the lung. This theorized imbalance would favor proteolytic destruction of lung connective tissue, resulting in emphysema (the protease-antiprotease hypothesis). Research has focused on neutrophil elastase and its role in the destruction of lung elastin. Neutrophil elastase is the main target for inactivation by α_1 -antitrypsin and has relatively unopposed effects. However, evidence for a primary role of this enzyme in cigarette smoke-induced emphysema is less clear, so the focus has broadened to include examination of the role of the matrix metalloproteinases (MMPs), produced by macrophages and other cells, in emphysema.

The inflammation induced by cigarette smoke is a trigger of the cycle of protease release and lung destruction resulting in emphysema (E-Fig. 16.4). Macrophages are activated by cigarette smoke and recruit neutrophils and other inflammatory cells to the lung, leading to the release of elastase and MMPs. The destruction of elastin and other connective tissue elements in the lungs by these proteases leads over time to the loss of elastic recoil and destruction of alveolar structures characteristic of emphysema.

Cigarette smoke contains many oxidant molecules capable of inducing oxidative stress in the lung. Oxidative stress has diverse effects, including the oxidative inactivation of antiproteases in the lung and the acetylation of specific histones in the chromatin of lung cells and macrophages, allowing the expression of various pro-inflammatory genes. Histone deacetylase activity is reduced in COPD, and this in turn may result in an inability to control the pro-inflammatory response in this condition. Pro-inflammatory gene expression promotes cytokine production and release, contributing to further inflammatory cell recruitment and activation. Systemic inflammation, triggered by ongoing pulmonary inflammation, may lead to nonpulmonary abnormalities associated with emphysema, including cachexia and skeletal muscle alterations. Finally, increased apoptosis of pneumocytes and endothelial cells has been observed in lungs with emphysema and could contribute to the loss of alveoli.

Understanding of emphysema pathogenesis has improved with the recognition that inflammation, oxidative stress, protease-antiprotease balance, and apoptosis are linked in a complex interaction induced by cigarette smoke. This improved understanding has broadened the range of potential therapies that may be effective in ameliorating the destructive process. To date, however, therapies targeted at molecular pathways involved in emphysema pathogenesis have not been successful in altering disease progression, with the possible exception of α_1 -antitrypsin replacement therapy in individuals with α_1 -antitrypsin deficiency.

α_1 -Antitrypsin, an acute phase reactant, is produced primarily in the liver, from which it travels to the lung. By its effect on elastases

in the lung, α_1 -antitrypsin prevents the uncontrolled degradation of elastin in the lung parenchyma and protects against the development of emphysema. Individuals with the ZZ genotype of α_1 -antitrypsin deficiency produce mutant forms of α_1 -antitrypsin that have a tendency to inappropriately polymerize within the hepatocyte, leading to a deficiency in secreted α_1 -antitrypsin and, in some cases, collateral damage to the liver caused by accumulation of intracellular misfolded, mutant α_1 -antitrypsin. Patients who develop emphysema at a young age (<40 years) should be evaluated for this condition whether or not they smoke, as should patients with bronchiectasis and unexplained liver disease or cirrhosis. Testing shows reduced α_1 -antitrypsin levels. Genotyping can reveal specific mutations (most commonly ZZ in severe deficiency). α_1 -Antitrypsin supplementation has been used for patients with α_1 -antitrypsin deficiency and appears to result in a decreased loss of lung density (surrogate for emphysema) by computed tomographic measurement.

Large and Small Airways Disease in COPD

Chronic bronchitis often coincides with emphysema in patients with COPD, but it may occur independently from either emphysema or COPD and is defined in clinical terms (described earlier). Cigarette smoking is the major cause, although exposure to pollutants such as dust and smoke may play a role. Pathologic findings are goblet cell hyperplasia, mucus hypersecretion and plugging, and airway inflammation and fibrosis (Fig. 16.3).

The disease mechanisms involved in the development of emphysema are also important in the pathogenesis of chronic bronchitis. However, in contrast to emphysema, chronic bronchitis is a disease of the large airways and not of the lung parenchyma. Therefore, the relationship of chronic bronchitis to airflow obstruction is less robust than for emphysema, and airflow limitation consistent with COPD in a patient with symptoms of chronic bronchitis may be more reflective of concomitant emphysema and small airways disease. Inflammation in chronic bronchitis leads to effects on the airway epithelium, including excess mucus production and impairment in mucociliary clearance.

Neurogenic stimuli are also important in the pathogenesis of airway obstruction in chronic bronchitis. The conducting airways are surrounded by smooth muscle, which contains adrenergic and

cholinergic receptors. Stimulation of β_2 -adrenergic receptors by circulating catecholamines dilates airways, whereas stimulation of airway irritant receptors constricts airways through a cholinergic mechanism by means of the vagus nerve. The irritant bronchoconstrictive pathways are normally present to protect against inhalation of noxious agents, but in pathologic states these pathways may contribute to airway hyperreactivity. A host of endogenous chemical mediators such as proteases, growth factors, and cytokines can also affect airway tone.

By definition, the predominant symptom in chronic bronchitis is sputum production. Bronchospasm may also be prominent. Recurrent bacterial airway infections are typical. As with patients with COPD, the evaluation of patients with chronic bronchitis should include pulmonary function tests and a chest radiograph in addition to standard laboratory testing.

Damage to the small airways (those less than about 2 mm in diameter) is integral to the pathogenesis of COPD. The small airways are the major site of resistance to airflow in COPD. Respiratory bronchiolitis, in which there is an accumulation of pigmented macrophages in and around the bronchioles (E-Fig. 16.5), may be an incidental finding in asymptomatic smokers without COPD. However, as COPD develops, other inflammatory cells are recruited to the small conducting airways, presumably in reaction to ongoing irritation from cigarette smoke or inhaled particles. With inflammation, the small airways in COPD can be affected by remodeling, leading to airway wall thickening and fibrosis, smooth muscle hypertrophy, and airway luminal narrowing, all of which contribute to airflow obstruction. Mucus plugs and inflammatory exudates can occlude the small airways, leading to increased resistance to airflow.

Recently, demonstration of profound decreases in small airway numbers and cross-sectional area in lungs of individuals with COPD has provided important evidence that loss of the small airways occurs with sufficient severity to result in detectable expiratory airflow limitation that characterizes COPD. Indeed, there is evidence that small airway loss may precede emphysema development in COPD.

Immune-mediated abnormalities are also seen at the level of the small airways in COPD. Lymphoid follicles may form around these airways in response to ongoing antigenic stimulation and bacterial infection, with a prominence of B cells and CD8+ T cells in more advanced COPD. These myriad changes at the small airway level contribute significantly to the physiologic abnormalities and altered local immune response in COPD.

Clinical Presentation

COPD related to chronic tobacco exposure is characterized by slowly progressive dyspnea that is first noticed during exertion but progresses over years until it is evident with minimal exertion (e.g., when dressing) or even at rest. Affected individuals complain of exercise intolerance and fatigue, and the disease eventually may lead to weight loss, depression, and anxiety as a result of increased work of breathing. Chronic cough can be present and is productive or dry, depending on the degree of mucus secretion (e.g., chronic bronchitis).

During the early stages of COPD, the physical examination may be normal. Normal examination results and the absence of symptoms often delay diagnosis. Inspection of the thorax and palpation may fail to reveal findings. As the disease progresses, the lungs may become hyperresonant to percussion, and auscultation may show diminished breath sounds with rhonchi or wheezes. The chest wall may begin to remodel, giving the patient the appearance of a “barrel chest.” During the late stages of COPD, patients show evidence of increased work of breathing with use of accessory muscles, pursed-lip breathing, and weight loss. Skeletal muscle wasting may also become evident. Despite their respiratory insufficiency, some patients are able to sustain relatively

Fig. 16.3 Pathology of chronic bronchitis: Normally, airway submucosal serous glands outnumber mucous glands and the epithelium includes ciliated cells. In chronic bronchitis, mucous glands are more prevalent than serous glands and the epithelium is abnormal. (Courtesy Dr. Charles Kuhn.)

E-Fig. 16.5 Respiratory bronchiolitis in a young smoker. (Courtesy Dr. Charles Kuhn.)

normal oxygen levels in blood until very late in the disease, leading to the classic clinical presentation of the “pink puffer.” Other patients tend to retain carbon dioxide and diminish their work of breathing, resulting in chronic respiratory acidosis and, in extreme cases, polycythemia and cyanosis; this is the prototypical “blue bloater” phenotype. There is also an overlap of COPD with other respiratory disorders, such as obstructive sleep apnea, that may contribute to carbon dioxide retention.

Although COPD results in chronic, progressive dyspnea, periodic acute exacerbations are also characteristic. A rapid worsening of pulmonary function and an increased burden of respiratory symptoms such as dyspnea, cough, and sputum production characterize COPD exacerbations. Acute exacerbations are associated with various triggers, most importantly viral or bacterial respiratory infections, air pollution or other environmental factors, pulmonary embolism, and cardiac failure. Exacerbations are more common with increasing severity of COPD, with increasing age, and during the winter months. Exacerbations vary widely in severity. Severe exacerbations may lead to hospitalization, acute respiratory failure, and death. After an exacerbation, it may take weeks for the patient to return to a baseline level of function. Patients with frequent exacerbations of COPD experience an accelerated rate of decline in FEV₁. Patients who have experienced a COPD exacerbation are more likely to experience future exacerbations, suggesting that exacerbation is an important event in the natural history of COPD. On occasion, an exacerbation of COPD leading to acute respiratory failure is the first event leading to the diagnosis of COPD in an individual patient.

COPD is associated with a number of comorbid conditions, such as atherosclerotic heart disease, lung cancer, osteoporosis, and depression. These comorbidities may be related to smoking, to the chronic systemic inflammation present in patients with COPD, to the impaired quality of life resulting from COPD, or to treatments (e.g., corticosteroids) administered during the course of COPD. Monitoring for and appropriate management of these coexisting disorders is an important part of the ongoing assessment of patients with COPD.

As COPD progresses, the lung volumes increase (hyperinflation) and the diaphragms flatten, rendering inspiratory excursions inefficient. Tidal volume decreases and respiratory rate increases in an effort to decrease the work of breathing. In advanced disease, the cardiovascular system becomes affected as a result of the loss of vasculature in destroyed alveolar walls and vasoconstriction and vascular remodeling due to chronic hypoxia. With a limited area for blood flow, pulmonary vascular resistance is increased, leading to increased right ventricular afterload and development of pulmonary hypertension. This accelerates the development of right ventricular failure, which is referred to as cor pulmonale in the setting of lung disease. Right heart gallop, distended neck veins, hepatojugular reflux, and leg edema characterize cor pulmonale.

Diagnosis and Differential Diagnosis

Diagnosis

Pulmonary function tests, especially spirometry, are essential for the diagnosis of COPD. Classically, the diagnosis of COPD has been made using GOLD criteria, which defines COPD as an FEV₁/FVC ratio of less than 0.70 on post-bronchodilator spirometry. However, the American Thoracic Society (ATS)/European Respiratory Society (ERS) guidelines are coming into favor for diagnosing COPD. ATS/ERS defines COPD as FEV₁/FVC ratio less than the lower limit of normal based on the patient's sex and age. Although some degree of reversibility of the obstruction may be detected with bronchodilators, the obstructive defect is not entirely reversible in COPD. This characteristic and the consistent and progressive nature of the expiratory flow limitation

TABLE 16.2 GOLD Criteria

GOLD 1/mild COPD	FEV ₁ ≥80% predicted
GOLD 2/moderate COPD	FEV ₁ ≥50% but less than 80% predicted
GOLD 3/severe COPD	FEV ₁ ≥30% but less than 50% predicted
GOLD 4/very severe COPD	FEV ₁ <30% predicted

represent key features that help distinguish COPD from asthma, a major differential diagnostic consideration. The severity of disease and prognosis can be estimated by the FEV₁, as detailed in Table 16.2.

An FEV₁ of about 1 L (usually 50% predicted) suggests severe obstruction and, in the case of COPD, predicts a mean survival rate of 50% at 5 years. For a better predictor of mortality than FEV₁ alone, the BODE index can be used: *body mass index, degree of obstruction as measured by FEV₁, modified Medical Research Council dyspnea score, and exercise capacity as denoted by 6-minute walk distance.*

Lung volumes should be measured along with pulmonary function testing because the limitation to expired airflow and decreased elastic recoil lead to lung hyperinflation, as evidenced by increased RV, FRC, and, ultimately, TLC.

Destruction of alveoli decreases the surface area for gas exchange in emphysema. This loss of surface area, coupled with bronchial obstruction and altered distribution of ventilated air, results in ventilation-perfusion inequality or mismatch, a cause of hypoxemia. Hyperinflation leads to expansion of lung zone 1, the region of the lung in which alveolar pressure exceeds pulmonary arterial pressure. This process increases physiologic dead space because alveolar units ventilate areas that are not perfused. Hypercarbia can be avoided by increasing the minute ventilation, even with substantial ventilation-perfusion mismatching. However, eventually, the metabolic costs of increased ventilation become excessive, and respiratory muscles fatigue. Over time, chemoreceptors reset, allowing the level of partial pressure of carbon dioxide in arterial blood (Paco₂) to rise. Since Paco₂ is equal to alveolar partial pressure of carbon dioxide (PACO₂), the higher the Paco₂, the more CO₂ is exhaled with every breath, which increases the efficiency of ventilation. Significant individual variation is observed in relationship between the degree of mechanical impairment and in the magnitude of increase in Paco₂. Derangements in gas exchange can be detected by measuring arterial blood gases, by showing a decrease in DLCO, or by evaluating hemoglobin oxygen desaturation during exertion. The degree of decrease in DLCO correlates well with the radiologic extent of emphysema in COPD.

Chest radiography may fail to reveal abnormalities during the early stages of COPD, but in later stages, radiographic studies show hyperinflation, hyperlucency, flattening of the diaphragms, and bulbous changes in lung parenchyma (E-Fig. 16.6). Pleural abnormalities, lymphadenopathy, and mediastinal widening are not characteristic of emphysema and should point to other diagnoses, such as lung cancer. Computed tomography is more sensitive than plain radiography because it allows for a more detailed evaluation of the lung parenchyma and surrounding structures. Computed tomography is useful in assessing the distribution of emphysema (E-Fig. 16.7) in patients for whom operative interventions such as lung volume reduction surgery are being contemplated (see later discussion). High-resolution CT is highly sensitive for the detection of occult emphysema and can reveal the pattern of emphysematous changes. Electrocardiography might show evidence of right ventricular strain. Echocardiography can reveal evidence of right ventricular hypertrophy or dilation and can often provide an estimate of pulmonary arterial pressures in patients with advanced COPD. A high blood hemoglobin level might reveal erythrocytosis in the setting of chronic hypoxemia, whereas increased white

E-Fig. 16.6 Anterior-posterior (*left*) and lateral (*right*) chest radiographs show changes caused by severe chronic obstructive pulmonary disease, including hyperinflation, increased anterior-posterior diameter, flattened diaphragms, and enlarged pulmonary arteries.

E-Fig. 16.7 Computed tomographic scan shows paraseptal distribution of emphysema.

blood cell counts might suggest infection. The arterial blood gas analysis may show hypoxemia, hypercarbia, or both, whereas acidemia due to acute hypercarbia may be present during an exacerbation.

Differential Diagnosis

The differential diagnosis of COPD includes the other major obstructive lung disorders: asthma, bronchiectasis, and the bronchiolar disorders. Asthma can occur at any age and sometimes overlaps with COPD, such as in patients with childhood asthma who smoke as adults. However, patients with COPD are typically older than 40 years of age and have a lengthy smoking history, whereas patients with asthma often have a history of atopy, have more variable symptoms that are often worse at night, and typically have marked improvements in lung function after bronchodilator administration. Patients with asthma may have normal pulmonary function during periods in which their asthma is well controlled, whereas those with COPD demonstrate ongoing airway obstruction even during periods of relative clinical stability.

It can be difficult to distinguish COPD with chronic bronchitis from bronchiectasis, and HRCT is necessary to assess for the abnormal bronchial dilation that is diagnostic of bronchiectasis.

Bronchiolar disorders can also be difficult to distinguish from COPD but should be considered in patients with risk factors, such as connective tissue disease or occupational exposures. Again, more sophisticated testing, such as HRCT with inspiratory and expiratory views to demonstrate peripheral areas of gas trapping and centrilobular nodules consistent with mucus impaction of the small airways, or even lung biopsy, may be needed to diagnose bronchiolitis.

Nonpulmonary causes of dyspnea on exertion, such as congestive heart failure or coronary artery disease, should also be considered in the differential diagnosis of COPD.

Treatment and Prevention

Because a cure for COPD does not exist, the best approach to this condition is prevention. Most cases of COPD in the United States are caused by cigarette smoking. Therefore, an appropriate major emphasis has been placed on the development of community education programs that focus on smoking prevention and promote smoking cessation. Legislative measures banning smoking in various public settings and levying increased taxes on cigarettes have been used to diminish the effects of environmental or second-hand exposure to tobacco smoke and to discourage smoking. Although smoking cessation interventions are effective in only a minority of patients, smoking cessation decreases mortality in patients with COPD who do succeed in quitting.

Most patients who are successful at smoking cessation have had at least one prior failed attempt, so physicians should encourage smoking cessation with at least brief interventions at every opportunity, even in patients who have tried but failed to quit in the past. Long-term physician and group support increase the success of cessation attempts, and pharmacologic smoking cessation aides, including nicotine replacement with gum or transdermal patches, bupropion, and varenicline, may provide additional benefit. Although there is considerable interest in the potential benefits and risk of E-cigarettes, further study is required to define its role.

Pharmacologic Therapies

After a diagnosis of COPD is established, therapy is guided primarily by symptoms of dyspnea and frequency of exacerbations. Dyspnea is assessed using subjective scoring systems. Patients are considered to be higher risk if they have a high dyspnea score or if they have had either one hospitalization for COPD or two exacerbations not requiring hospitalization in the past year. Overall treatment is directed at avoiding complications such as exacerbations, relieving airflow obstruction

through use of bronchodilators, and providing supplemental oxygen to patients with hypoxemia. Commonly used inhaled bronchodilators include sympathomimetic agents (β_2 -adrenoreceptor agonists) and anticholinergic agents. Ipratropium bromide, a short-acting anticholinergic agent, is effective at decreasing dyspnea and improving FEV₁ in COPD. Albuterol is the most commonly used β_2 -agonist; its bronchodilator effect is rapid in onset and relatively short lived. In practice, a combination of albuterol and ipratropium is frequently prescribed because these agents produce greater benefits when used in combination than when used individually.

Short-acting agents are typically prescribed for patients with mild disease or intermittent symptoms on an as-needed basis. Short-acting bronchodilators can be delivered by metered-dose inhaler (MDI) or by nebulizer. The MDI offers advantages of portability and ease of administration and convenience. When used correctly with a spacer, MDIs are as effective as nebulizers in delivering the drug. Nebulization has no advantage over the use of MDIs in the long-term management of obstructive lung disease except in patients who are unable to use an MDI properly.

Long-acting bronchodilators are effective for maintenance therapy in patients who have at least moderate COPD. Long-acting agents include the long-acting β_2 -agonists (LABAs), which are available in once- or twice-daily formulations, and the long-acting anticholinergic/muscarinic antagonists (LAMAs), which are administered once daily. There have been several large studies evaluating the efficacy of long-acting bronchodilators and inhaled corticosteroids (ICS) in COPD, as detailed in Table 16.3. Initiation of either a LABA or a LAMA is reasonable for patients with COPD who require a long-acting bronchodilator. In more advanced disease, there is some evidence of additional benefits from the combination of a LABA and a LAMA. Tachycardia, hypokalemia, and tremor are potential adverse effects of LABAs, whereas dry mouth and urinary retention may occur with LAMA administration.

Current data suggest that the chronic use of inhaled corticosteroids improves symptoms and decreases the frequency of exacerbations.

TABLE 16.3 Studies Evaluating the Efficacy of LABA, LAMA, and ICS

TORCH (2007): LABA/ICS vs ICS or LABA vs placebo	<ul style="list-style-type: none"> • n = 6112 • Length of study: 3 years • LABA/ICS associated with fewer COPD-related hospitalizations • No mortality benefit
INSPIRE (2007): LABA/ICS vs LAMA	<ul style="list-style-type: none"> • n = 1323 • Length of study: 2 years • No difference in exacerbation rates • More hospitalizations and deaths in LAMA group
UPLIFT (2008): LAMA vs placebo	<ul style="list-style-type: none"> • n = 5993 • Length of study: 4 years • No difference in decline of FEV₁
SPARK (2013): LABA/LABA vs LAMA or LABA	<ul style="list-style-type: none"> • n = 2224 • Length of study: 64 weeks • LABA/LABA was associated with fewer exacerbations than single agent
FLAME (2016): LABA/LAMA vs LABA/ICS	<ul style="list-style-type: none"> • n = 3362 • Length of study: 1 year • LABA/LAMA was associated with fewer COPD-related hospitalizations

Inhaled long-acting corticosteroids (e.g., beclomethasone, budesonide, fluticasone propionate) should be considered for individuals with COPD and a history of exacerbations but should not be used as monotherapy. Inhaled corticosteroids are less clearly effective in COPD than in asthma, and pneumonia occurs more frequently in patients with COPD treated with inhaled corticosteroids. Inhaled corticosteroids can be combined with LABAs; the combination salmeterol with fluticasone in patients with moderate to severe COPD was shown to improve health-related quality of life and to reduce exacerbations to a greater extent than either component alone.

Systemic use of corticosteroids is indicated during acute exacerbations, and intravenous corticosteroids are useful in the acute setting. Intravenous corticosteroids have also proved effective for the management of acute exacerbations of most obstructive lung diseases, including asthma (Fig. 16.4). Patients with acute exacerbations are usually transitioned from intravenous to oral steroids within 72 hours. While oral steroids were historically tapered over 14 days, more recent research suggests that a 5-day “burst” of steroids without a taper is noninferior to traditional tapering regimens. Other agents with anti-inflammatory capabilities, such as leukotriene inhibitors, are not indicated for treatment of COPD.

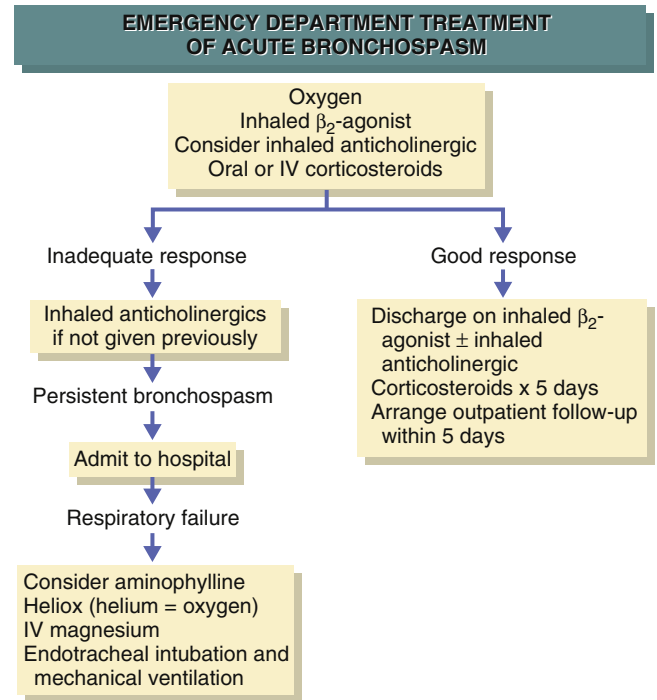

Theophylline, a methylxanthine, is a weak systemic sympathomimetic agent with a narrow therapeutic window. It is not a first-line drug in the treatment of COPD, although long-acting derivatives with improved safety profiles have been developed. Theophylline preparations have some anti-inflammatory activity and may provide additional bronchodilation in patients with COPD who do not respond adequately to inhaled β -agonists. When these preparations are used, blood concentrations should be maintained in the lower end of the therapeutic range (between 8 and 12 $\mu\text{g/mL}$). Toxicity is common at concentrations higher than 20 $\mu\text{g/mL}$. The metabolism of theophylline is decreased by many commonly used drugs (e.g., erythromycin), and toxic serum concentrations of theophylline can be reached quickly when these other drugs are administered unless the theophylline dose is adjusted appropriately. Toxic effects of theophylline may be observed in the gastrointestinal, cardiac, and neurologic systems. Severe theophylline toxicity can be fatal, and treatment with charcoal hemoperfusion may be required.

Phosphodiesterase type 4 (PDE4) inhibitors have been investigated for the treatment of COPD, and an oral PDE4 inhibitor was recently approved as add-on therapy for treatment of severe COPD with chronic bronchitis and a history of exacerbations. PDE4 inhibitors act to inhibit breakdown of cyclic adenosine monophosphate (cAMP), resulting in a weak bronchodilator effect (approximately 50 mL improvement in FEV₁); they should not be used as acute bronchodilators. However, roflumilast was demonstrated to reduce exacerbation rates in patients who had severe COPD with chronic bronchitis and a history of exacerbation in the prior year and were not using inhaled corticosteroids. Adverse effects include weight loss, nausea and loss of appetite, and an increase in psychiatric adverse reactions including suicidality.

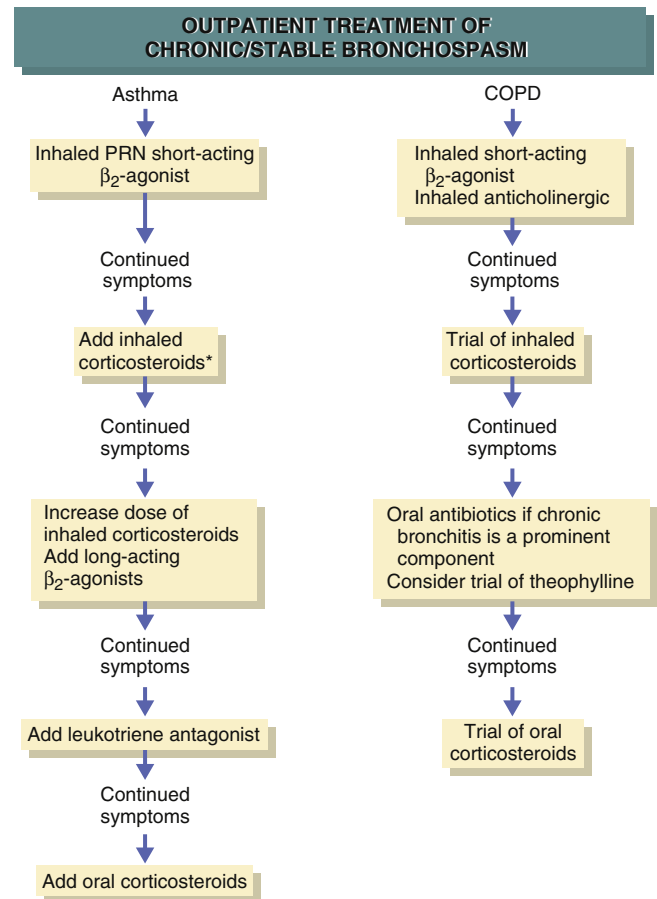

Oxygen Therapy and Mechanical Ventilation

Continuous oxygen therapy has been shown to improve survival in patients with COPD and hypoxemia. Oxygen supplementation is recommended once the partial pressure of oxygen in arterial blood (Pao_2) drops below 55 mm Hg or the hemoglobin oxygen saturation decreases to 88%. Oxygen supplementation is indicated at higher levels of Pao_2 if end-organ damage, such as pulmonary hypertension, is present.

Oxygen therapy is frequently necessary for treatment of acute exacerbations of obstructive lung disease. In patients who hypoventilate chronically and therefore have an elevated Paco_2 , elevating the inspired oxygen content may acutely worsen hypercarbia by inhibiting

A

B

Fig. 16.4 Algorithms for the treatment of bronchospasm in patients in the emergency department (A) and in outpatients with stable disease (B). IV, Intravenous; PRN, as needed. *Leukotriene antagonists could be considered.

the hypoxic ventilatory drive and by promoting the dissociation of carbon dioxide from oxygenated hemoglobin (the Haldane effect). High-flow oxygen has been shown to be harmful in the setting of pre-hospital emergency treatment for COPD. Therefore, oxygen should be closely titrated to maintain normoxia and to avoid either hypoxemia or excessively elevated P_{aO_2} . An oxygen saturation of 90% to 92% is a reasonable target in the absence of further data. During exacerbations of COPD leading to hypercarbic respiratory failure, noninvasive positive airway pressure ventilation has proved useful in reducing the work of breathing, alleviating diaphragm fatigue, and reducing the need for endotracheal intubation and mechanical ventilation.

Antibiotics

Exacerbations of airway obstruction may result most often from viral infections but also from bacterial infection. The most common bacterial pathogens in COPD are *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Moraxella catarrhalis*. Management of acute exacerbations with dyspnea and increased volume and purulence of mucus should include empiric administration of antibiotics, which have been shown to improve the success rate in exacerbation treatment. The role of chronic prophylactic antibiotic use in COPD is uncertain, and a trial of oral azithromycin resulted in a reduction in exacerbations but an increased risk of hearing loss. Immunization with influenza vaccines directed at specific epidemic strains reduces exacerbations of COPD. Pneumococcal vaccination is also recommended in patients with COPD.

Nonpharmacologic Therapies

Multiple airway clearance techniques aid in clearing of airway secretions, but their effectiveness in the management of emphysema and other obstructive lung diseases in adults is questionable. If needed, chest physiotherapy and postural drainage might be useful in patients with chronic bronchitis and increased sputum production. Few data support the use of specific mucolytics or expectorant agents for patients with COPD.

Patients with pulmonary disease of sufficient severity to compromise normal activities of daily living commonly demonstrate improved quality of life and less subjective dyspnea when enrolled in a comprehensive, high-quality pulmonary rehabilitation program. Pulmonary rehabilitation has not been shown to improve objective measures of pulmonary function, to affect the rate of decline in lung function, or to improve survival. However, it has been shown to improve the quality of life in motivated patients. An important part of pulmonary rehabilitation is nutritional assessment and careful attention to maintaining adequate nutrition. Malnutrition and cachexia are common in later stages of obstructive lung disease, and they result in decreased respiratory muscle strength and compromised immune function.

The role of surgery in COPD is generally limited. Bullectomy, lung volume reduction surgery (LVRS), and lung transplantation are all potentially effective surgical options for selected patients. Resection of nonfunctional areas of lung (e.g., bullectomy) may allow for compressed functional areas to expand and may improve symptoms, airflow, and oxygenation by improving ventilation-perfusion matching in a subgroup of patients. In addition, resection of bullae can decrease lung volumes, resulting in enhanced diaphragmatic function and decreased work of breathing. The best candidates for LVRS are those with predominantly upper lobe disease who have a low exercise tolerance despite rehabilitation and are without other major comorbidities. This subgroup may have reduced mortality after LVRS. In general, a high surgical mortality risk exists in patients referred for LVRS who have an FEV_1 or DLCO of less than 20% predicted and in those who have more homogeneous distribution of emphysema. Patients with

high surgical risk may be candidates for endoscopic placement of endobronchial valves (EBV), which were FDA approved in 2018. EBVs are one-way valves that aim to deflate emphysematous regions of the lung by allowing air to flow out of but not into the affected alveoli.

Single or bilateral lung transplantation is an option for patients with end-stage airflow obstruction. The average survival after lung transplantation is 4 to 5 years. Rejection, viral infections, transplant-associated lymphoproliferative disease, and late occurrence of bronchiolitis obliterans remain significant problems, but the procedure can improve the quality of life in properly selected patients.

Palliative Care

Although the disease course can be unpredictable, discussion of end-of-life issues with the patient is an important component of longitudinal care as COPD progresses to an advanced stage. Preparation of advance directives regarding use of intensive care measures at the end of life may be desirable. Opioid narcotics can be highly effective for relieving dyspnea in patients with terminal complications of COPD.

Prognosis

COPD is a chronic and progressive disease with a variable and typically prolonged clinical course. As discussed previously, measurement of lung function (FEV_1 % predicted) has prognostic significance, and use of the multifactorial BODE index can improve prognostication compared with use of FEV_1 alone. Patients who have frequent exacerbations of COPD appear to have more rapid loss of lung function than those without exacerbations, suggesting that frequent exacerbations result in a worse clinical course.

At present, aside from smoking cessation and the addition of long-term oxygen therapy for patients with hypoxemia, interventions to improve survival in COPD are limited. No pharmacologic therapy for COPD has been definitively demonstrated to improve survival. In mild COPD, mortality is frequently related to comorbidities such as ischemic heart disease and lung cancer; in more advanced stages, a greater proportion of patients die from respiratory causes.

BRONCHIOLAR DISORDERS

Definition and Epidemiology

The bronchioles are defined as the small noncartilaginous airways (<2 mm in diameter). The bronchiolar disorders encompass a spectrum of diseases of widely varying causes primarily affecting these small airways. Bronchiolar disorders can be associated with cigarette smoking. For example, small airways disease contributes significantly to the syndrome of COPD. Respiratory bronchiolitis is also commonly found incidentally in smokers. However, bronchiolar disorders with etiologies other than cigarette smoking also exist. Bronchiolar disorders are associated with patchy inflammation and epithelial injury, fibrosis, mucoid impaction, or obliteration of the bronchioles (E-Fig. 16.8). These changes result in airflow limitation due to increased airway resistance.

Acute bronchiolitis related to respiratory syncytial virus infection is epidemic among infants and young children, but primary bronchiolar disorders, including infectious or postinfectious bronchiolitis, are rare in the adult general population and tend to affect specific patient populations.

Pathology

The pathology of the bronchiolar disorders is complex. A variety of terms are used to describe or classify the various histopathologic patterns of small airways disease, including *cellular bronchiolitis* (inflammatory cell infiltration of the small airway wall resulting in small

E-Fig. 16.8 Arrows point to normal bronchiole (*left*) and bronchiole narrowed by inflammation and remodeling in a patient with bronchiolitis (*right*). (Courtesy Dr. Charles Kuhn.)

airway narrowing), *follicular bronchiolitis* (formation of abundant lymphoid follicles in close apposition to the small airways, resulting in airway compression), *obliterative* or *constrictive bronchiolitis* (fibrosis surrounding the small airways resulting in narrowing of the affected airways), and *bronchiolitis obliterans* (formation of endoluminal fibrous lesions, sometimes called *Masson bodies*, obstructing the small airway lumen). The histopathologic pattern of small airways disease may suggest a likely underlying etiology; for example, follicular bronchiolitis is often, although not exclusively, seen in the context of Sjögren's syndrome.

Clinical Presentation

In general, the bronchiolar disorders manifest nonspecifically with dyspnea, which may be severe or progressive, and in some cases accompanied by cough or sputum production. The physical examination may reveal inspiratory squeaks or wheezes but may be surprisingly normal. The possibility of a bronchiolar disorder should be considered in particular settings. For example, bronchiolitis may complicate the course of rheumatoid arthritis, Sjögren's syndrome, or inflammatory bowel disease.

Diffuse panbronchiolitis is a rare idiopathic disorder most common in Japan that is characterized by cough with purulent sputum, sinusitis, and dyspnea. Recurrent respiratory infections with bacterial organisms such as *Pseudomonas aeruginosa* complicate the course of diffuse panbronchiolitis.

Bronchiolitis obliterans can be a clinical syndrome (in addition to a histopathologic term) that is associated with chronic allograft rejection after lung transplantation, graft-versus-host disease after allogeneic hematopoietic stem cell transplantation, and occupational toxin exposures. For example, occupational clusters of bronchiolitis obliterans have been described after exposure to diacetyl, a flavoring chemical used in the manufacture of microwave popcorn. Constrictive bronchiolitis can be seen in war veterans who were exposed to burn pits in Iraq or Afghanistan.

Diagnosis and Differential Diagnosis

In general, the bronchiolar disorders cause an obstructive pattern of expiratory airflow limitation on pulmonary function testing without evidence of reversibility. The bronchiolitis obliterans syndrome is diagnosed clinically by a decline in FEV₁ of 20% from a stable baseline value on serial testing after lung transplantation. HRCT is valuable in the diagnosis and assessment of the bronchiolar disorders. Characteristic findings on HRCT include centrilobular nodules or tree-in-bud opacities, reflecting impacted inflammatory exudates or sloughed epithelial cells in the bronchioles. A "mosaic attenuation" pattern, with decreased attenuation in geographic regions of lung reflecting areas of air trapping distal to obstructed bronchioles, is often seen on inspiration. CT scanning during the expiratory phase can confirm that this finding is caused by air trapping rather than decreased perfusion from pulmonary vascular disease. Lung biopsy may be of limited value because of the scattered, patchy nature of the abnormalities present in the bronchiolar disorders. The differential diagnosis includes COPD, which also causes poorly reversible obstruction on spirometry.

Treatment

Treatment of the bronchiolar disorders is challenging. Acute bronchiolitis typically resolves without treatment; bronchodilators and steroids are not clearly beneficial, although they are often prescribed. The bronchiolitis obliterans syndrome responds poorly to increased immunosuppression and is a frequent cause of death after lung transplantation. Azithromycin has been reported to increase FEV₁ in the

bronchiolitis obliterans syndrome. Macrolide antibiotics have also been reported to positively affect the clinical course of diffuse panbronchiolitis, possibly reflecting immunomodulatory or antifibrotic effects of these medications. Lung transplantation may be necessary in progressive bronchiolitis obliterans, and retransplantation has sometimes been performed in patients affected by the bronchiolitis obliterans syndrome after transplant rejection.

Prognosis

These disorders may be self-limited, as in acute bronchiolitis caused by respiratory syncytial virus, or relentlessly progressive and fatal, as in the bronchiolitis obliterans syndrome occurring after lung transplantation.

BRONCHIECTASIS

Definition and Epidemiology

Bronchiectasis (E-Fig. 16.9) is defined as an abnormal dilation of the bronchi (the large airways containing cartilage within their walls) resulting from inflammation and permanent destructive changes of the bronchial walls. The incidence of bronchiectasis is unknown, but it may affect more than 100,000 individuals in the United States and is more frequent in older age groups. There is likely a higher incidence of bronchiectasis in developing countries where there are lower childhood vaccination rates and a higher prevalence of pulmonary tuberculosis.

Pathology

Bronchiectasis may be localized to a bronchial segment or lobe of the lung, or it may be diffuse. The involved bronchi are abnormally dilated and demonstrate chronic inflammation within the bronchial wall with neutrophilic inflammation and bacterial colonization and infection in the bronchial lumen. The inflammation in bronchiectasis is associated with structural changes in the walls of the bronchi, including destructive changes affecting the elastic fibers, smooth muscle, and cartilage. As with COPD, there is also involvement of the small airways. Small airway obstruction leads to increased resistance to airflow that results in airflow obstruction despite the dilation of the larger airways. The classic pathologic classifications of bronchiectasis are *tubular* (the most common form, in which there is smooth dilation of the bronchi), *varicose* (dilated bronchi with indentations reminiscent of varicose veins), and *cystic* (end-stage bronchiectasis with dilated bronchi ending in sac-like structures resembling clusters of grapes).

Bronchiectasis is hypothesized to result from an environmental insult leading to bronchial damage in a susceptible host. This in turn leads to impaired infection clearance, bacterial colonization and infection or reinfection, ongoing inflammation of the airways, and further bronchial damage, creating a classic vicious cycle. An inciting infection, sometimes occurring in childhood, is thought to initiate the development of bronchial damage leading to bronchiectasis in many cases (postinfectious bronchiectasis). This may be a viral infection (e.g., measles), a necrotizing pneumonia (e.g., *Staphylococcus aureus* pneumonia), tuberculosis, or infection with an atypical mycobacteria (e.g., *Mycobacterium avium-intracellulare*). Because infections such as *M. avium-intracellulare* also complicate the course of bronchiectasis, determination of whether a mycobacterial infection was an initiator or a consequence of bronchiectasis may be difficult.

Localized bronchiectasis may also result from anatomic obstruction by an endobronchial foreign body, tumor, or broncholith or from extrinsic compression by lymphadenopathy. Right middle lobe syndrome, for example, results from narrowing of the right middle lobe bronchial orifice, often by lymph node enlargement in the setting of tuberculosis, which leads to localized bronchiectasis distal to the site

E-Fig. 16.9 Cystic bronchiectasis with enlarged airways (*arrow*).

of obstruction. Anatomic obstruction results in chronic or recurrent bacterial infections and inflammation leading to bronchial distortion and destruction over time.

Diffuse bronchiectasis can result from various impairments in host defenses that create a vulnerability to persistent or recurrent lung infection leading to bronchial damage. For example, bronchiectasis may occur with congenital defects that impair mucus clearance in the airways such as CF (discussed later) or primary ciliary dyskinesia, a rare inherited abnormality of the ciliary microtubules (the classic triad of sinusitis, situs inversus, and infertility is diagnostic of Kartagener's syndrome, a form of primary ciliary dyskinesia). Immunodeficiency states, such as hypogammaglobulinemia in combined variable immunodeficiency, may also result in bronchiectasis. α_1 -Antitrypsin deficiency is also associated with bronchiectasis. Bronchiectasis also complicates certain connective tissue disorders such as rheumatoid arthritis.

Finally, bronchiectasis overlaps with the more common obstructive lung disorders, COPD and asthma. Certain patients with COPD also have bronchiectasis, often in the lower lobes. Allergic bronchopulmonary aspergillosis is a condition that occurs in asthmatics with hypersensitivity to aspergillus fungi. It is associated with central bronchiectasis, high levels of immunoglobulin E (IgE), and precipitins for *Aspergillus* species.

Clinical Presentation

Patients with bronchiectasis exhibit chronic cough and copious, sometimes foul-smelling sputum. The sputum produced may be greater in volume and purulence than with COPD or asthma. Shortness of breath and fatigue may also be present. Blood-streaked sputum is common, and massive hemoptysis may occur during the course of bronchiectasis. Localized crackles and clubbing may be present. Periodic exacerbations due to infection with bacterial pathogens, including *H. influenzae* and *P. aeruginosa*, are common. Nontuberculous mycobacterial colonization or infection may also occur. Pulmonary function tests typically show mild to moderate obstruction. Evidence of bronchial hyperresponsiveness may occur.

Diagnosis and Differential Diagnosis

Chest radiographs may be normal or may show increased interstitial markings. The classic finding is parallel lines in peripheral lung fields, described as "tram tracks," which represent thickened bronchial walls that do not taper from proximal to distal sites. However, HRCT is more sensitive for the detection of dilated airways and is the diagnostic test of choice in the evaluation of suspected bronchiectasis. Bronchiectasis on HRCT is diagnosed by demonstration of lack of airway tapering, airways that are larger in diameter than their accompanying blood vessel, and the presence of visible bronchi at the lung periphery (outer 1 to 2 cm of the lung). Bronchoscopy may be indicated in localized bronchiectasis to assess for endobronchial abnormalities or foreign body. Sputum can be cultured to assess for fungal or mycobacterial organisms that may be causative or for identification of specific bacterial pathogens during exacerbations. Once the diagnosis of bronchiectasis is established, investigation to determine the underlying cause, such as assessment of immunoglobulin levels to rule out combined variable immunodeficiency, is indicated.

The differential diagnosis includes chronic bronchitis and COPD, asthma, and, in the setting of hemoptysis and clubbing, lung cancer.

Treatment

Treatment of the underlying cause of the bronchiectasis should be undertaken if possible. An anatomic obstruction, such as from a foreign body or benign tumor, should be relieved. Atypical mycobacterial

infection should be treated with an appropriate multidrug regimen in symptomatic patients after confirmation of the diagnosis with multiple smears and cultures. Allergic bronchopulmonary aspergillosis is typically treated with corticosteroids; addition of azole antifungals may also be beneficial. Bacterial exacerbations of bronchiectasis should be treated with a broad-spectrum antibiotic that is effective against the likely pathogens, such as amoxicillin or, in patients known to be colonized or infected by *Pseudomonas*, a fluoroquinolone. Aerosolized antibiotics are of benefit to suppress bacterial growth in bronchiectasis associated with CF and may be beneficial in non-CF bronchiectasis if *Pseudomonas* infection is present or if frequent exacerbations occur. Chronic administration of macrolide antibiotics has been shown to reduce inflammation and exacerbations in bronchiectasis but may also promote development of macrolide-resistant bacteria. Immunoglobulin supplementation may aid in the host defense against bacterial infection in individuals with hypogammaglobulinemia.

Airway clearance and postural drainage are the mainstays of treatment in bronchiectasis (discussed in further detail under CF). Bronchodilators may provide symptomatic relief. Massive hemoptysis should be managed with airway protection and identification of the bleeding site; bronchial artery angiography with embolization of the causative bleeding vessels can be life-saving. The role of surgery is mainly in resection of obstructing lesions that are causing distal bronchiectasis, in removal of a badly damaged isolated segment of bronchiectatic lung, and, on occasion, as a salvage therapy in resection of a site with uncontrolled hemorrhage.

Prognosis

The prognosis of patients with bronchiectasis is generally thought to be favorable, although deterioration of lung function over time has been shown to occur. Quality of life may be affected adversely, for example by chronic production of copious sputum or frequent exacerbations. Massive hemoptysis is an emergency situation that requires intensive management and may be fatal.

CYSTIC FIBROSIS

Definition and Epidemiology

CF is an autosomal recessive genetic disorder that results from mutations in the *CFTR* gene. CF affects about 30,000 children and adults in the United States and 70,000 worldwide. This disorder affects many organs, including the lungs, pancreas, and reproductive organs, although most mortality related to CF is due to lung disease. It is the most common lethal genetic disorder in the Caucasian population, with a carrier frequency of about 1 in 29, affecting 1 in 3300 live births. About 1000 new cases of CF are diagnosed each year. Although 75% of patients with CF are diagnosed during their first two years of life, some patients are not diagnosed until adulthood. The prognosis has improved significantly with recent advances in therapy. Before 1940, infants with CF rarely lived to their first birthday, but today more than half of the CF population in the United States is older than 18 years of age. Currently, the median predicted life span for a person with CF is about 37 years.

Pathology

CF results from pathogenic mutations in both alleles of a single gene, *CFTR*, which encodes the CF transmembrane conductance regulator (CFTR), a cAMP-regulated chloride channel that is present on the apical surface of epithelial cells (E-Fig. 16.10). The most common mutation is the $\Delta F508$ mutation, a three-base-pair deletion that results in absence of the phenylalanine residue at the 508 position of the protein. However, more than 1900 mutations in CFTR have been identified to

E-Fig. 16.10 Proposed structure of the CFTR chloride channel.

date. These mutations are categorized into five different classes based on their effects on CFTR. Class I and II mutations result in CFTR that is not present on the cell surface due to impaired translation or protein misfolding. Class III and IV mutations are associated with CFTR that is present on the cell surface but has abnormal function due to a gating defect or decreased conductivity. Class V mutations are associated with reduced expression of normally functioning CFTR.

Abnormal, reduced, or absent CFTR protein results in defective chloride transport and increased sodium reabsorption in airway and ductal epithelia; this leads to abnormally thick and viscous secretions in the respiratory, hepatobiliary, gastrointestinal, and reproductive tracts. The thick secretions do not easily clear from the airways, resulting in respiratory symptoms, and cause luminal obstruction and destruction of exocrine ducts in other organs, leading to exocrine organ fibrosis and dysfunction, including pancreatic damage.

Poor airway clearance predisposes CF patients to recurrent bacterial infection and eventual colonization with microorganisms such as *S. aureus* and *H. influenzae*, followed by *P. aeruginosa* in ensuing years. Persistent inflammation and infection cause bronchial wall destruction and bronchiectasis. Mucus plugging of small airways results in postobstructive cystic bronchiectasis and parenchymal destruction, progressive airflow obstruction, and eventually hypoxemia. The course of CF may additionally be complicated by the development of allergic bronchopulmonary aspergillosis or by nontuberculous mycobacterial infection. Colonization and infection with multidrug-resistant organisms such as the *Burkholderia cepacia* complex may occur in advanced CF, creating challenging management issues. The most common cause of death in CF is respiratory failure.

Clinical Presentation

Neonatal screening programs for CF exist nationwide in the United States to identify infants with possible CF who should undergo further testing (e.g., genotyping). Infants with CF may have meconium ileus or failure to thrive with steatorrhea. Salty-tasting skin may be noticed by caregivers. Patients with CF typically have chronic cough with thick sputum production, wheezing, and dyspnea. Pancreatic insufficiency and diabetes are common, and male patients may have azoospermia. Nasal polyps are often present, and clubbing is typical.

CF should be considered in the differential diagnosis of patients with unexplained chronic sinus disease, bronchiectasis, pancreatitis, malabsorption, or male infertility associated with absence of the vas deferens. Pulmonary function tests demonstrate hyperinflation and obstruction, with or without a bronchodilator response. Chest imaging studies show hyperinflation, bronchial wall thickening, and bronchiectasis.

Diagnosis and Differential Diagnosis

Measurement of the concentration of chloride in sweat (sweat test) is used to diagnose CF. The diagnosis is considered definitive if the clinical picture is consistent with CF and if the chloride concentration measured in a certified laboratory is greater than 60 mEq/L on at least two occasions. Genotyping can also confirm the diagnosis if known mutations are identified in both gene alleles and may be used if sweat testing is equivocal.

Treatment

The hallmark of CF treatment is aggressive airway hygiene. A typical airway clearance routine includes a series of therapies in the following order: First, patients use bronchodilators such as albuterol or ipratropium. Next, patients can use nebulized hypertonic (7%) saline to hydrate and loosen secretions, followed by aerosolized recombinant human deoxyribonuclease I (Dornase alfa) to decrease sputum viscosity. Then

patients should utilize a mechanical airway clearance technique. The specific technique is usually determined by patient preference. Available options include a vibratory vest, intrapulmonary percussive ventilation, or manual chest physiotherapy. The goal of the mechanical airway clearance techniques is to induce productive cough to clear mucous from the airways as much as possible. Lastly, patients can administer inhaled antibiotics (if applicable), such as tobramycin, colistin, or aztreonam, followed by inhaled steroids such as fluticasone propionate or budesonide.

Inhaled antibiotics are reserved for patients who are colonized with *Pseudomonas*. Inhaled tobramycin has been available as a nebulized solution since 1997 and as a dry powder inhaler since 2013. Inhaled tobramycin is typically prescribed as a 28-day course every other month. More recently, inhaled colistin and aztreonam have become available and can be used during tobramycin “off-months” or as alternatives to tobramycin if the patient is experiencing intolerable side effects or if their *Pseudomonas* resistance pattern warrants alternate therapy. Chronic anti-inflammatory therapy with azithromycin may be helpful in certain patients with CF.

Since 2012, there have been significant advancements in the treatment of CF due to the development of CFTR modulator drugs. As of 2019, there are three modulator therapies available, ivacaftor (Kalydeco®), lumacaftor/ivacaftor (Orkambi®), and tezacaftor/ivacaftor (Symdeko®). Ivacaftor is used in patients with class III genetic mutations. Ivacaftor binds CFTR causing the defective channel to remain open thus enabling chloride transport. In a large clinical trial, ivacaftor reduced sweat chloride by about 50%, increased FEV₁ by about 10%, and cut the incidence of pulmonary exacerbations in half. Ivacaftor can also be used in certain patients with class V mutations by increasing chloride transport through functioning CFTR to compensate for the reduced expression of these proteins.

Lumacaftor aids proper folding of CFTR and is used in combination with ivacaftor to treat patients who are homozygous for $\Delta F508$ (class II mutation). Lumacaftor/ivacaftor was shown in clinical trials to improve FEV₁, increase BMI, and reduce pulmonary exacerbations. A common side effect of lumacaftor-ivacaftor is chest discomfort.

Tezacaftor can also be used in combination with ivacaftor in homozygous $\Delta F508$ patients who cannot tolerate lumacaftor/ivacaftor due to side effects. In addition, tezacaftor/ivacaftor can also be used in patients with certain class II mutations other than $\Delta F508$.

The first triple combination drug, Trikafta, was developed by adding elxacaftor to ivacaftor/tezacaftor. Trikafta was FDA approved in 2019 for patients with at least one $\Delta F508$ mutation. It was shown to be superior to the other CF modulator therapies in improvement of lung function and quality of life as well as reduction in sweat chloride and frequency of exacerbations. As with other obstructive lung diseases, the ultimate therapy for patients with CF and end-stage lung disease is bilateral lung transplantation.

Prognosis

Although CF is still considered to be a fatal disease, significant advancements in therapy have led to considerable improvement in median survival time.

ASTHMA

Definition and Epidemiology

Asthma is described by the Global Initiative for Asthma as “a chronic inflammatory disorder of the airways in which many cells and cellular elements play a role. The chronic inflammation is associated with airway hyperresponsiveness that leads to recurrent episodes of wheezing, breathlessness, chest tightness, and coughing, particularly at night or in the early morning. These episodes are usually associated with

widespread but variable airflow obstruction within the lung that is often reversible either spontaneously or with treatment.”

The incidence of asthma is highest in children, but it affects all ages and occurs worldwide, with a preponderance of the disease in developed industrialized countries. Asthma affects millions of individuals worldwide. In the United States in 2017, 7.9% of the population (approximately 25,000,000 persons) were estimated to have asthma according to the Centers for Disease Control and Prevention. The prevalence of asthma has increased markedly over recent decades. Nevertheless, after rising in the late 20th century, the number of deaths from asthma has declined since 2000. Asthma death rates are higher in older age groups, females, and blacks.

Pathology

Underlying chronic airway inflammation is considered to be a major pathogenic feature of asthma. Patients with asthma have higher numbers of activated inflammatory cells within the airway wall, and the epithelium is typically infiltrated with eosinophils, mast cells, macrophages, and T lymphocytes, which produce multiple soluble mediators such as cytokines, leukotrienes, and bradykinins. Airway inflammation in asthma is typified by a type 2 helper T-cell (T_H2) response with predominantly eosinophilic inflammation, but some patients with severe asthma exhibit neutrophilic airway inflammation and cytokine production more characteristic of T_H1 inflammation.

The hallmark of asthma is airway hyperresponsiveness—a tendency of the airway smooth muscle to constrict in response to levels of inhaled allergens or irritants that would not typically elicit such a response in normal hosts. Inhaled allergens provoke airway mast cell degranulation by binding to and cross-linking IgE on the mast cell surface. Mast cell degranulation leads to the release of chemical mediators, which cause acute bronchoconstriction and thus increased airway resistance and wheezing as well as mucus hypersecretion (E-Fig. 16.11). Disruption of the continuity of the ciliated columnar epithelium and increased vascularity and edema of the airway wall also follow antigen exposure. In addition to allergens, factors such as stimulation of irritant receptors, respiratory tract infections, and airway cooling can provoke bronchoconstriction in asthmatic individuals. Airway cooling appears to be responsible for exercise-induced bronchoconstriction as well as some wintertime asthma attacks.

Asthma is associated with airway wall remodeling, which is characterized by hyperplasia and hypertrophy of smooth muscle cells (E-Fig. 16.12), edema, inflammatory infiltration, angiogenesis, and increased deposition of connective tissue components such as type I and type III collagen. This last effect leads not only to a thickening of the sub-epithelial lamina reticularis (E-Fig. 16.13) but also to an expansion of the entire airway wall. Airway remodeling may begin fairly early in the course of the disease. Whether inflammation leads to remodeling or whether these processes represent two independent manifestations of the disease is unknown. Pulmonary function does seem to decline at an accelerated rate in patients with asthma, and airway wall remodeling may play a role in this functional loss. Over time, airway wall remodeling may lead to irreversible airflow limitation, which can worsen the disease by rendering bronchodilator drugs less effective. In this way, airway wall remodeling may make the clinical distinction between asthma and COPD difficult.

The cause of asthma is unknown, but it is likely to be a polygenic disease influenced by environmental factors. Atopy is strongly linked to asthma. Exposure to indoor allergens such as dust mites, cockroaches, furry pets, and fungi is a significant factor; outdoor pollution and other irritants, including cigarette smoke, are also important.

Current concepts of asthma pathogenesis include a focus on impairment of the shift from a T_H2 -predominant immunity to a T_H1

immune response early in life. Paradoxically, in the developed world, the perpetuation of T_H2 immune responses and the development of inappropriate allergic responses may be related to a relative lack of exposure of the immune system to appropriate infectious antigenic stimuli in childhood, the so-called hygiene hypothesis. Farming, for example, appears to be protective against the development of asthma and allergic disease, possibly in part because of the increased exposure to microbial antigens eliciting a T_H1 response. Increased exposure to other children (as in daycare settings) and less frequent use of antibiotics may also decrease asthma risk. On the other hand, asthma is common in poor urban settings in which there is heavy exposure to allergic antigens from dust mites and cockroaches. The timing and roles of particular environmental exposures in utero and in early life in the pathogenesis of asthma and allergic diseases remain to be fully elucidated, and there is no current theory that completely explains asthma pathogenesis or the recent increased incidence of asthma. The interplay of other aspects of modern life, such as changes in the microbiome, with regard to asthma propensity continues to be explored.

Several genetic polymorphisms have been associated with asthma, including variations in the β -adrenergic receptor leading to diminished responsiveness to β -agonists. Identification of other genetic polymorphisms that are important in asthma is a subject of ongoing research. Although asthma is more common in male children than in female children, the prevalence of asthma changes after puberty, and it is more common in adult women than in men. These facts, along with evidence of variation in asthma symptoms during the menstrual cycle and during pregnancy, suggest possible hormonal influences on asthma pathogenesis.

Asthma can be induced by workplace exposures in persons having no previous history of asthma (occupational asthma). Certain substances, such as isocyanates (used in spray paints) and Western red cedar wood dust, are provocative agents for the development of occupational asthma. Obesity has been linked to a higher incidence of asthma though the mechanisms by which obesity may influence asthma development remain unclear. Other potentiators of acute bronchospasm include viral infections, gastroesophageal reflux disease (GERD), and exposure to gases or fumes. These disorders may play a role in asthma development and may be targeted for therapy in some cases of asthma.

Clinical Presentation

Major symptoms of asthma are wheezing, episodic dyspnea, chest tightness, and cough. The clinical manifestations vary widely, from mild intermittent symptoms to catastrophic attacks resulting in asphyxiation and death. Although wheezing is not a pathognomonic feature of asthma, in the setting of a compatible clinical picture, asthma is the most common diagnosis. Often symptoms worsen at night or during the early hours of the morning. Other associated symptoms are sputum production and chest pain or tightness. Patients may exhibit only one or a combination of symptoms, such as chronic cough only (cough-variant asthma). Wheezing may occur several minutes after exercise (exercise-induced bronchoconstriction). Physical examination typically shows evidence of wheezing, although findings may be normal in between symptomatic periods. Rhinitis or nasal polyps may be present. In the case of an acute episode of bronchospasm or an exacerbation, the clinician may find that the patient has difficulty talking, is using accessory muscles of inspiration, has pulsus paradoxus, is diaphoretic, and has mental status changes ranging from agitation to somnolence. In patients with these findings, treatment should be immediate and aggressive.

Diagnosis and Differential Diagnosis

A diagnosis of asthma requires documentation of bronchial hyperreactivity and reversible airway obstruction. The history may provide sufficient documentation because most patients complain of characteristic periodic episodes of wheezing and other symptoms that respond to use of a bronchodilator. However, spirometry is recommended to assess formally for expiratory flow limitation, and reversibility is demonstrated by repeat spirometry after bronchodilator administration. At least 12% and 200 mL improvement in FEV₁ after bronchodilator use indicates reversibility. Because asthma is episodic, airflow limitation is variable and patients may exhibit symptoms at a time when spirometry cannot be performed. Peak expiratory flow measurements can be performed at home and may be helpful in establishing evidence of variability in expiratory flow.

Depending on the circumstances, formal testing for airway hyperactivity by bronchoprovocation challenge may be necessary. A stimulant with bronchoconstrictor activity, most commonly methacholine, is applied to the patient's airway. Methacholine, a synthetic form of acetylcholine, is preferred to histamine because there are fewer systemic side effects. Exercise can also be used to trigger an attack. Although most patients with or without asthma develop some degree of airflow limitation during bronchoprovocation testing, those with asthma develop airflow limitation at much lower doses. For a methacholine challenge, the concentration of methacholine required to produce a 20% decline in FEV₁ from baseline is reported. Although a positive bronchoprovocation challenge result is not by itself diagnostic of asthma, a negative result is helpful in ruling out asthma as a diagnosis.

Lung volume measurements may show hyperinflation during active disease, but the DLCO is typically normal or even elevated. During acute exacerbations of asthma, analysis of arterial blood gases is useful to determine gas-exchange status. A chest radiograph should be obtained if a concern for pulmonary infection exists, but routine chest radiography is not necessary. Fleeting or migratory infiltrates on chest radiographs in a patient with difficult asthma should suggest the possibility of allergic bronchopulmonary aspergillosis. Blood tests in asthma might reveal eosinophilia and increased levels of IgE. Skin tests might be useful to identify household products or other antigens that could precipitate asthma attacks in a specific patient.

The differential diagnosis includes tracheal disorders, respiratory tract tumors and foreign bodies, COPD, and bronchiectasis. In patients whose primary presenting complaint is chronic cough, the differential diagnosis includes other causes of chronic cough, such as GERD and postnasal drip. A major differential consideration in patients not responding to typical asthma treatment is vocal cord dysfunction.

Treatment

Simple, inexpensive peak expiratory flow meters can be used at home to monitor airflow obstruction. A diary should be maintained, and a clear written plan should be in place for using symptoms and peak flow information to intervene early in exacerbations and to tailor long-term therapy for optimal control of symptoms. Short-acting β -agonists are used for acute relief of symptoms such as wheezing. However, the cornerstone of maintenance therapy in all but mild intermittent asthma is administration of inhaled corticosteroids, which are highly effective in improving asthma control. Long-acting β -agonists may be added for additional symptomatic control as needed. LABAs should not be used as a monotherapy for asthma control because they do not control airway inflammation and increased mortality has been demonstrated with this therapeutic approach. However, these medications may

be added to inhaled corticosteroids to provide additional symptom control.

Alternatively, leukotriene modifiers can be used in maintenance therapy, although they appear to be somewhat less effective than inhaled corticosteroids (see Fig. 16.4). Theophylline preparations may have additional benefit in some patients, but the narrow therapeutic window and modest efficacy of this drug limits its value. Recent evidence suggests that use of long-acting anticholinergics in patients with poor control on LABAs and inhaled corticosteroids may increase the time to exacerbation and provide additional bronchodilation. Oral or intravenous corticosteroids are used during acute asthma exacerbations. Long-term use of oral corticosteroids should be avoided, if possible, given the various side effects associated with chronic glucocorticoid administration.

Patients with severe refractory asthma who frequently require systemic corticosteroids might benefit from a monoclonal antibody therapy. Targets of monoclonal antibodies include IgE (omalizumab), IL-5 (mepolizumab, reslizumab), and IL-4 (dupilumab). Patients with poorly controlled asthma are candidates for anti-IgE therapy if they have elevated total IgE levels and positive allergy skin or radioallergosorbent testing (RAST). Patients are candidates for anti-IL-5 or anti-IL-4 therapy if they have peripheral eosinophilia.

Allergen avoidance is a reasonable measure in asthma, although the effects of specific interventions, such as mattress barrier protection to reduce dust mite exposure, appear limited. Treatment of associated conditions that may exacerbate asthma, such as allergic rhinitis and GERD, may be clinically beneficial and may aid in achieving asthma control. Bronchial thermoplasty is a new endoscopic technique in which radiofrequency energy delivered in a series of treatments is used to destroy airway smooth muscle. It has been shown to reduce exacerbations and improve quality of life in the months following treatment.

Acute severe asthma, or status asthmaticus, is an attack of severe bronchospasm that is unresponsive to routine therapy. Such attacks may be sudden (hyperacute asthma) and can be rapidly fatal, often before medical care can be obtained. In most cases, however, patients have a history of progressive dyspnea over hours to days, with increasing bronchodilator use. Treatment of status asthmaticus should be aggressive, including administration of nebulized bronchodilators and intravenous steroids. Heliox can be used in severe causes of asthma, which is a mixture of oxygen and helium (typically 70% helium and 30% oxygen) that promotes laminar flow rather than turbulent flow of gas through the airways. Continuous monitoring of blood oxygen saturation by pulse oximetry should be performed, often supplemented by arterial blood gas analysis to evaluate for hypercarbia. A rising PaCO₂ in a patient with asthma is an ominous sign and may portend need for ventilatory support. Noninvasive ventilation has been used successfully to decrease the work of breathing and avoid the need for endotracheal intubation in patients with exacerbations of asthma, but intubation and mechanical ventilation are necessary for the management of respiratory failure in status asthmaticus. Mechanical ventilation of the patient with status asthmaticus can be extremely challenging and may require the use of paralytic agents to control the breathing pattern or even use of inhaled general anesthesia to relieve bronchospasm. Lastly, if a patient is unable to maintain adequate oxygenation with maximal ventilator support, extracorporeal membrane oxygenation (ECMO) can be considered.

Prognosis

The prognosis in most patients with asthma is excellent. Although there is no cure, most patients can achieve appropriate control of their asthma.

Interstitial Lung Diseases

Abhinav Kumar Misra, Matthew D. Jankowich, Barry S. Shea

OVERVIEW

The interstitial lung diseases (ILDs) are a heterogeneous group of non-malignant and noninfectious lung diseases characterized by varying amounts of inflammation and/or fibrosis (scarring) of the lung parenchyma. The lung involvement in these disorders is often diffuse but can occur in a wide array of patterns. The disease process can involve any part of the anatomic lung interstitium, including that within the alveolar walls, the intra- and interlobular septa, and the airways. However, it can also involve the air spaces and airway lumens themselves, and therefore the term *interstitial* lung disease is somewhat misleading. *Diffuse parenchymal* lung disease (DPLD) is the more accurate name for this collection of disorders, but for the sake of convention, we will refer to them as ILDs throughout this chapter.

Well over 100 distinct ILDs have been described, and there is no universally accepted classification system. One useful way of approaching

ILDs is to consider them as all belonging to one of three broad categories: (1) exposure-related ILDs, (2) ILDs attributable to systemic diseases, and (3) idiopathic ILDs (Table 17.1). Exposure-related ILDs can be broadly thought of as those ILDs caused by environmental and occupational exposures (e.g., hypersensitivity pneumonitis, pneumoconiosis), iatrogenic exposures (e.g., drug-induced ILD, radiation pneumonitis or fibrosis), or intentional exposures (e.g., cigarette smoking, inhalational drug use). The most common systemic diseases known to cause ILD are the connective tissue diseases (e.g., rheumatoid arthritis, systemic sclerosis, and polymyositis/dermatomyositis), but there are many others, including the vasculitides, amyloidosis, sarcoidosis, and a variety of genetic conditions (e.g., lysosomal storage diseases). Idiopathic ILDs are those for which a specific cause is unknown or not identified. Most of the idiopathic ILDs fall into a group of clinicopathologic entities known as the idiopathic interstitial pneumonias (IIPs), but there are some additional isolated ILDs that are also idiopathic (e.g., eosinophilic PNA, pulmonary alveolar proteinosis).

TABLE 17.1 Categories of Interstitial Lung Diseases

Idiopathic ILDs	Exposure-Related ILDs	Systemic Disease-Associated ILDs
Idiopathic interstitial pneumonias	Environmental and occupational exposures	Connective tissue diseases
Idiopathic pulmonary fibrosis (IPF)	Hypersensitivity pneumonitis (see Table 17.3)	Rheumatoid arthritis
Idiopathic nonspecific interstitial pneumonia (NSIP)	Pneumoconioses	Systemic sclerosis
Acute interstitial pneumonia (AIP)	Silicosis	Polymyositis and dermatomyositis
Cryptogenic organizing pneumonia (COP)	Asbestosis	Sjögren syndrome
Respiratory bronchiolitis–interstitial lung disease (RB-ILD)	Coal-worker’s pneumoconiosis	Systemic lupus erythematosus
Desquamative interstitial pneumonia (DIP)	Berylliosis	Mixed connective tissue disease
Idiopathic lymphoid interstitial pneumonia (LIP)	Talc pneumoconiosis	Vasculitides
Idiopathic pleuroparenchymal fibroelastosis (IPPF)	Hard metal pneumoconiosis	Granulomatosis with polyangiitis (GPA)
Eosinophilic pneumonia (acute and chronic)	Iatrogenic exposures	Microscopic polyangiitis (MPA)
Pulmonary alveolar proteinosis	Radiation-induced lung injury	Eosinophilic granulomatosis with polyangiitis (EGPA)
	Drug-induced lung injury (see Table 17.4)	Anti-glomerular basement membrane (anti-GBM) disease
	Antineoplastic therapies	Pauci-immune pulmonary capillaritis
	Biological agents	Sarcoidosis
	Cardiovascular drugs	Amyloidosis
	Antimicrobials	Lymphangioleiomyomatosis (LAM)
	Anti-inflammatory agents	Neurofibromatosis
	Intentional exposures	Hermansky-Pudlak syndrome
	Cigarette smoking	Inborn errors of metabolism
	Pulmonary Langerhans cell histiocytosis (PLCH)	Niemann-Pick disease
	Vaping associated pulmonary illness (VAPI)	Gaucher’s disease
	Illicit drug use	
	“Crack lung”	
	Foreign body granulomatosis	
	Inhalational talcosis	

Because ILDs comprise a broad spectrum of disorders, the symptoms, exam findings, and physiologic, radiographic, and histologic abnormalities associated with them can vary greatly. Dyspnea on exertion and chronic cough are the two most common symptoms encountered in ILD patients, although these are nonspecific. These symptoms can often be insidious and progressive, and in many cases they can be present for months to years before a diagnosis is made. Exertional dyspnea can lead to exercise limitation, and in many cases patients, family members, and providers attribute such limitations to other factors, including aging, weight gain, and deconditioning. The presence of unexplained and gradually progressive dyspnea on exertion, with or without a persistent dry cough, should alert the clinician to the possibility of ILD. Other symptoms, such as wheezing, chest pain, hemoptysis, or constitutional symptoms are less common but can occur, and when present these symptoms may be clues to a specific diagnosis or class of ILDs. Most forms of ILD are chronic and progressive, but others can have more acute or subacute presentations and can be difficult to distinguish from infectious pneumonia. Waxing and waning symptoms can occur and are often associated with ILD caused by intermittent exposures. Some patients are asymptomatic and are diagnosed with ILD as an incidental finding on chest imaging done for other reasons (e.g., lung cancer screening).

Basic demographic factors such as age, sex, and race can provide some clues in determining potential causes of ILD. For example, idiopathic pulmonary fibrosis (IPF) is more common in men than in women and its incidence increases with age; it is only very rarely diagnosed in individuals under the age of 50 years. In contrast, connective tissue disease–associated ILD (CTD-ILD) tends to be more common in women and can occur often in young adults and even in the pediatric population. Inherited forms of ILD (Gaucher disease, Nieman-Pick disease) are also more likely in younger patients. Sporadic lymphangiomyomatosis (LAM) occurs almost exclusively in premenopausal women, sarcoidosis occurs more frequently in African Americans, and pulmonary Langerhans cell histiocytosis (LCH) is more common in young or middle-aged male smokers.

The history can further narrow the differential diagnosis for suspected ILD. Important factors to specifically query include rash, skin thickening, arthritis, myalgias or proximal muscle weakness, dysphagia, and Raynaud's phenomenon, any of which may suggest an underlying connective tissue disease. If a patient with ILD carries a known diagnosis of connective tissue disease, the work-up may be limited if imaging findings are typical of the pulmonary manifestations of that disease. A history of severe or poorly controlled asthma for a patient with radiographic infiltrates and constitutional symptoms should lead to consideration of eosinophilic granulomatosis with polyangiitis (EGPA), whereas a history of severe sinus disease should raise the possibility of granulomatosis with polyangiitis (GPA).

A detailed exposure history, including both domestic and occupational environmental exposures, is also important when evaluating a patient with ILD. For example, routine exposure to domestic birds, hot tubs, molds, or farming environments may suggest hypersensitivity pneumonitis. Home visits can also be informative here. Although the pneumoconioses due to asbestos and silica exposure are becoming much less common with modern safeguards and restrictions, these diseases continue to manifest long after exposure. High-technology manufacturing has particular hazards, such as beryllium exposure leading to berylliosis in susceptible individuals.

A medication exposure history is also important, and drug-induced ILD should be considered for all patients with diffuse lung disease seen on imaging. Smoking history is important because several ILDs are seen almost exclusively in cigarette smokers, including respiratory bronchiolitis–associated interstitial lung disease, desquamative

interstitial pneumonia, and pulmonary LCH. Cigarette smoking and inorganic dust exposure also appear to be risk factors for the development of IPF. Acute and subacute ILD has also been described as a consequence of smoking or inhaling a variety of substances, including marijuana, synthetic cannabinoids, “crack” cocaine, and more recently electronic cigarettes.

Physical exam findings can also vary greatly. The most common finding is the presence of inspiratory crackles on lung exam, often most pronounced in the lung bases. Wheezing can be heard and can be a clue towards specific diagnoses (e.g., hypersensitivity pneumonitis), or it can be a sign of concomitant asthma or COPD. Some patients exhibit digital clubbing, focal enlargement of the terminal aspects of the fingers and/or toes with an unclear pathogenesis. Although this finding should prompt the clinician to suspect the presence of ILD, it can also be seen in other conditions, and it is of unknown significance. Exam findings of pulmonary hypertension with cor pulmonale (peripheral edema, loud P₂) can be seen in more advanced disease or can suggest the presence of a disorder known to cause both ILD and pulmonary vascular disease (e.g., systemic sclerosis). Similarly, extrapulmonary exam findings, such as synovitis, sclerodactyly, telangiectasias, mechanic's hands, muscle weakness, or lymphadenopathy can also provide important clues to a potential cause of ILD. In some cases the physical exam, including lung auscultation, can be entirely normal.

Pulmonary function testing (PFT) in ILDs generally reflects the pattern and severity of the disease process. Since most ILDs involve some combination of alveolar wall thickening and loss of functional air spaces, impaired gas exchange (reduced diffusion capacity for carbon monoxide, DLCO) and evidence of restriction (reduced total lung capacity, TLC) are the most common abnormalities seen. The ratio of forced expiratory volume in 1 second to forced vital capacity (FEV₁/FVC) is generally preserved (i.e., no obstruction to airflow), although obstruction can also be seen when there is prominent airways involvement, such as with hypersensitivity pneumonitis, sarcoidosis, and lymphangioliomyomatosis. An isolated reduction in the DLCO may be the only obvious PFT abnormality in early or mild disease. In these cases the oxygen saturation may be normal at rest, but exercise oximetry may reveal the presence of exertional hypoxemia. Routine laboratory testing is often normal but some abnormalities, if present, can provide important clues to a specific diagnosis (e.g., peripheral eosinophilia, elevated serum creatinine). Detailed serologic testing to look for evidence of an underlying autoimmune or other systemic disease known to cause ILD is often performed.

Plain radiographs of the chest can provide evidence suggesting the presence of ILD, and in some cases can also help to establish a more definitive diagnosis, but high-resolution computed tomography (HRCT) of the chest provides much more detailed information and is almost always indicated in these cases. A variety of abnormalities can be seen on HRCT in ILD, including reticular, ground-glass, nodular, and consolidative opacities, mosaic attenuation, and honeycombing, and specific combinations and distributions of these abnormalities can often provide useful information when trying to determine a specific diagnosis. Certain HRCT patterns can often allow the diagnostic considerations to be significantly narrowed, and in some cases the HRCT pattern can be essentially pathognomonic for a particular disease. For example, a finding of bilateral, upper lung zone predominant peribronchovascular opacities with perifissural nodules and mediastinal and hilar lymphadenopathy would be highly suggestive of ILD due to sarcoidosis. Hypersensitivity pneumonitis (HP), pneumoconiosis, and lymphangioliomyomatosis also tend to be upper lung zone predominant ILDs. Pulmonary LCH has a characteristic pattern of irregular nodules and thick-walled cysts in the mid to upper lung zones bilaterally, that when seen in a young-to-middle-aged active cigarette

smoker can be viewed as confirmatory of the diagnosis. Other forms of ILD are often more pronounced in the lower lung zones, and there can be other features that suggest different diagnoses (e.g., honeycombing with IPF and subpleural sparing with NSIP). The presence of bilateral calcified pleural plaques can be strongly suggestive of asbestosis as the cause of ILD.

In many cases of ILD, a definitive diagnosis can be made on the basis of the medical history, physical exam, laboratory and physiological testing, and HRCT, often in the context of a multidisciplinary approach. However, in some cases this information is insufficient, and a lung biopsy is needed to obtain a lung tissue sample for histologic evaluation. Surgical lung biopsy (SLB), typically using a thoracoscopic approach, is the preferred method for evaluating most forms of ILD. Bronchoscopic transbronchial lung biopsy (TBLB) is less invasive but yields much smaller fragments of tissue, typically too small to allow appropriate examination of the lung architecture. TBLB is not recommended for the assessment of suspected IPF and many other forms of chronic fibrosing ILD, but it can be useful for diagnosing certain ILDs, most notably sarcoidosis and HP. Transbronchial lung cryobiopsy, which is less invasive than SLB but provides larger samples of lung tissue than those obtained with TBLB, is currently in use in many centers, but its exact role in tissue diagnosis of ILD remains unclear.

The lung's response to injury is relatively stereotyped, and particular biopsy patterns of injury, such as usual interstitial pneumonia or granulomatous inflammation, are seen in a variety of disorders. Interpretation of lung biopsy results must be done in the appropriate context and with incorporation of clinical and imaging data. For example, a biopsy result of usual interstitial pneumonia may carry a different prognosis in the setting of rheumatoid arthritis-associated ILD than in the setting of IPF.

Management of ILD depends on the specific disease, and treatments appropriate to specific entities are discussed throughout this chapter. Historically, pharmacologic therapy has largely consisted of glucocorticoids and other immunosuppressive agents, an approach that seems to be effective for those ILDs with a significant inflammatory component but is of unclear benefit when fibrosis predominates. More recently, antifibrotics have been developed that appear to be effective at slowing the progression of IPF and some other chronic fibrotic ILDs. Other key aspects of ILD management include exposure avoidance (particularly for exposure-related ILDs, such as HP, smoking-related ILD, and drug-induced ILD), supplemental oxygen, and pulmonary rehabilitation. Lung transplantation can be performed in patients who have advanced disease that is expected to severely limit life expectancy, but unfortunately many patients are not candidates for lung transplant due to age or other comorbidities. Even then there is a scarcity of suitable donor lungs available such that every year many patients die while on lung transplant waiting lists.

The remainder of this chapter is organized around the three broad categories of ILDs described above: idiopathic ILDs, exposure-related ILD, and ILDs due to systemic diseases.

IDIOPATHIC INTERSTITIAL LUNG DISEASES

Idiopathic Interstitial Pneumonias

The idiopathic interstitial pneumonias (IIPs) are a group of ILDs of unknown origin, each of which has distinct clinicopathologic features. For several decades, these conditions were generally considered to be different variations of idiopathic pulmonary fibrosis (IPF). However, with growing appreciation that the different radiographic and histologic patterns of disease had distinct clinical presentations, natural histories, and responses to treatment, they were formally reclassified as IIPs by the American Thoracic Society (ATS) and European Respiratory

TABLE 17.2 Idiopathic Interstitial Pneumonias (IIPs)

Major IIPs	
Chronic fibrosing	Idiopathic pulmonary fibrosis (IPF) Idiopathic nonspecific interstitial pneumonia (NSIP)
Acute/Subacute	Cryptogenic organizing pneumonia (COP) Acute interstitial pneumonia (AIP)
Smoking-related	Respiratory bronchiolitis–interstitial lung disease (RB-ILD) Desquamative interstitial pneumonia (DIP)
Rare IIPs	Idiopathic lymphoid interstitial pneumonia (LIP) Idiopathic pleuroparenchymal fibroelastosis (IPPF)
Unclassifiable IIP	

Society (ERS) in 2002. This classification scheme was updated in 2013, at which time these entities were divided into major IIPs, rare IIPs, and unclassifiable IIPs (Table 17.2). The 6 major IIPs are IPF, idiopathic nonspecific interstitial pneumonia (NSIP), respiratory bronchiolitis–associated interstitial lung disease (RB-ILD), desquamative interstitial pneumonia (DIP), cryptogenic organizing pneumonia (COP), and acute interstitial pneumonia (AIP), and these can be further characterized as chronic fibrosing IIPs (IPF and NSIP), smoking-related IIPs (RB-ILD and DIP), and acute/subacute IIPs (COP and AIP) (see Table 17.2). Rare IIPs include idiopathic lymphoid interstitial pneumonia (LIP) and idiopathic pleuroparenchymal fibroelastosis (PPFE). Some patients have idiopathic interstitial lung disease that does not meet criteria for any of these entities, and they are considered to have unclassifiable IIP.

Idiopathic Pulmonary Fibrosis

Definition, epidemiology, and pathogenesis. IPF has been defined in a consensus statement as a “specific form of chronic, progressive fibrosing interstitial pneumonia of unknown cause, occurring primarily in older adults, limited to the lungs, and associated with the histopathologic and/or radiologic pattern of usual interstitial pneumonia (UIP).” It is the most common of the IIPs, with an estimated incidence of 16.3 per 100,000 person years and prevalence of 42.7 per 100,000 people in the United States as of 2000, which translates to an estimated 89,000 individuals in the United States living with IPF at that time. The incidence of IPF appears to be increasing worldwide. There are likely many factors contributing to this increasing incidence, and one factor may be the overall aging of the world's population. Age is the single biggest risk factor for IPF, as many studies have shown that the incidence and prevalence increases steadily during each decade of life. It is only rarely diagnosed before the age of 50 years. Cigarette smoking has also been strongly associated with the development of IPF, as up to two thirds of IPF patients are current or former smokers. Other potential risk factors include exposure to inorganic and organic dusts and gastroesophageal reflux disease (GERD), the latter of which may lead to repetitive lung injury from recurrent microaspiration.

There is growing understanding of the role that genetics plays in IPF. Numerous genetic polymorphisms have been found to increase the risk of developing IPF. Most notably, a common polymorphism in the promoter region of the *MUC5B* gene has been found to confer a 5-fold and 18-fold increased risk of developing IPF when one or two copies of the risk allele are present, respectively. The fact that a family history of pulmonary fibrosis has also been increasingly recognized as

an important risk factor for IPF also underscores the important genetic contribution to the disease. Some studies have suggested that up to 20% of cases may be familial (i.e., occurring in two or more first-degree relatives). The nomenclature of the familial form(s) of the disease is evolving; it has been referred to as familial IPF, familial pulmonary fibrosis (FPF), and familial interstitial pneumonia (FIP), the latter term reflecting the fact that in some cases the radiographic and/or histologic pattern of disease can be more suggestive of one of the other types of IIP rather than IPF. The familial form of the disease is often inherited in mendelian fashion, and specific causative mutations have been identified in 20% to 30% of these families, most commonly in the telomerase complex genes but also in the surfactant protein genes.

The pathogenesis of IPF is complex. Although it was for many years thought of as a disease driven by chronic inflammation, the paucity of inflammation seen on histologic sample from IPF lungs and the lack of response to aggressive anti-inflammatory therapy challenged this notion. It is now thought instead to be a disease characterized by aberrant or dysregulated wound-healing responses to repetitive lung injury. This current paradigm of IPF pathogenesis suggests that a complex interaction between host susceptibility (aging, genetics) and environmental factors (cigarette smoking, inhaled particulates, etc.) is ultimately what leads to the development of IPF. This shift in the understanding of IPF as being driven by aberrant wound-healing rather than chronic inflammation has also been important in leading to the discovery of effective therapies for this disease, as discussed below.

Pathology. The underlying histopathologic pattern found in the lungs of patients with IPF is called *usual interstitial pneumonia* (UIP). The characteristic histologic features of UIP include scar tissue deposition that is predominantly peripheral and patchy, with areas of fibrosis interspersed with areas with relatively normal lung (Fig. 17.1), along with fibroblastic foci, which are areas of active fibroblast proliferation and are thought to be the “leading edge” of fibrosis development. There is generally a paucity of inflammation, and in areas of more advanced fibrosis, microscopic honeycombing is often seen. Importantly, this UIP pattern can be seen in other disorders (e.g., connective tissue disease–related ILD and asbestosis), and therefore the diagnosis of IPF depends on not only identifying UIP, but also ruling out known causes of that histologic pattern (i.e., IPF is *idiopathic* UIP).

Clinical presentation. IPF is characterized by progressive accumulation of scar tissue in the lungs. As a consequence, patients typically present with insidious, gradually worsening dyspnea on exertion and a nonproductive cough. Symptoms are frequently present for 1 to 2 years before a diagnosis is made, although in some cases they can progress more slowly or more rapidly. Some patients with IPF are asymptomatic, and the disease is discovered because of abnormal physical exam findings or as an incidental finding on chest imaging studies done for other reasons (e.g., lung cancer screening).

Physical examination often reveals inspiratory crackles in the bases of both lungs, indicating the predominant site of scarring. Clubbing may exist, but extrapulmonary findings are generally absent. With increased scar deposition, the lungs become stiffer, as evidenced by decreased compliance. Pulmonary function tests show decreased lung volumes consistent with a restrictive process, and the DLCO is generally reduced. Impaired oxygenation in IPF, initially with exercise and later at rest, often requires long-term oxygen supplementation.

The chest radiograph shows reticular opacities that are most predominant at the bases and the periphery of the lungs. HRCT allows better visualization of the lung and is useful in evaluating the extent and pattern of disease. The classic HRCT findings of IPF are bilateral, subpleural reticular opacities that are more pronounced in the lower lung zones, along with areas of radiographic honeycombing and traction bronchiectasis and bronchiolectasis (Fig. 17.2) in the absence of

Fig. 17.1 Pulmonary fibrosis in idiopathic pulmonary fibrosis with usual interstitial pneumonia pathology that is adjacent to normal lung parenchyma. (Courtesy Dr. Charles Kuhn.)

Fig. 17.2 Typical usual interstitial pneumonia (UIP) pattern of abnormality seen on chest computed tomography (CT) of a patient with IPF, demonstrating patchy, bilateral areas of subpleural reticulation, traction bronchiectasis and bronchiolectasis, and honeycombing.

significant ground-glass opacification, nodules, consolidation, or other features that suggest an alternative diagnosis. When these features are present on an HRCT in the absence of other abnormalities that suggest an alternative diagnosis (e.g., extensive ground-glass opacification, diffuse nodules or areas of consolidation), then a confident diagnosis of a UIP pattern can often be made without the need for a lung biopsy. In other cases when the HRCT pattern is not as definitive, a lung biopsy may be required to help distinguish UIP/IPF from other types of ILD.

Diagnosis and differential diagnosis. IPF is diagnosed on the basis of typical clinical, radiographic (HRCT), and if available, pathologic features (i.e., biopsy showing a UIP pattern). Other potential causes of ILD, such as connective tissue disease, hypersensitivity pneumonitis, and asbestosis, must be ruled out as best as possible by the history, examination, and selected laboratory testing. When an HRCT scan shows the typical UIP pattern described above (lower lung zone predominant, subpleural reticular opacities with areas of honeycombing) and no feature to suggest an alternative diagnosis, a diagnosis of IPF can be made without the need for a surgical lung biopsy. If honeycombing is

absent on HRCT or atypical features such as ground-glass infiltrates, consolidation, diffuse nodules, or extensive air trapping are found, the radiographic diagnosis becomes less certain. In these cases, a lung biopsy may be indicated, and incorporation of the clinical, HRCT, and histologic information are then needed to make a diagnosis of IPF. Multidisciplinary discussion during the diagnostic process, with input from experienced clinicians, radiologists, and pathologists, is ideal.

Treatment. For decades there were no pharmacologic therapies that were proven to be helpful at slowing the progression of IPF. However, with improved understanding of IPF pathogenesis (described above), many novel therapies that target aberrant wound-healing responses have been studied in IPF. Two such therapies, pirfenidone (multiple mechanisms of action) and nintedanib (inhibits intracellular signaling of fibroblasts), have been shown in large randomized controlled trials to slow IPF progression by approximately 50%. In 2014, these drugs became the first ever to be approved by the US Food and Drug Administration (FDA) for treatment of IPF. Importantly, neither nintedanib or pirfenidone reverses established fibrosis or even completely stops the progression of the disease. Therefore, these treatments do not cure IPF, nor do they alleviate the symptoms of breathlessness or coughing, both of which can be debilitating. As such, the search for other potentially effective therapies for IPF is an area of intense ongoing investigation.

Because IPF is a progressive disease, even despite the availability of effective antifibrotic therapies, lung transplantation should be considered for patients with IPF. Many patients with IPF are not candidates for lung transplantation because of age, comorbidities, or other factors, but for those who are candidates, lung transplant may offer a chance at prolonged survival and improved quality of life. The median survival rate after lung transplant is only about 5.8 years, but this is steadily improving and still compares favorably to the expected survival of IPF patients at or near the top of lung transplant waiting lists, which is likely only weeks to months. Because of the unpredictable nature of disease progression in IPF, early referral for transplantation evaluation should be considered.

Prognosis. IPF is a progressive disease, and historically it has carried a poor prognosis. Median survival is often reported to be 2 to 3 years from the time of diagnosis. It is likely that the median survival will be prolonged in the era of antifibrotic therapy, but as stated, these therapies still do not cure the disease. There is considerable heterogeneity in the pace of progression in IPF, as the rate of lung function decline varies greatly between different individuals with the disease and even within any given patient over time. Furthermore, some patients with IPF experience acute or subacute respiratory deterioration in the absence of any clinically apparent superimposed cause (e.g., heart failure, pulmonary embolism, pneumonia). These episodes of acute deterioration are referred to as acute exacerbations of IPF and are associated with a very poor prognosis. HRCT findings include new ground-glass opacities and/or consolidation superimposed on the background of pulmonary fibrosis. Histologically, evidence of acute lung injury (i.e., diffuse alveolar damage) can be found on the background of UIP. These patients are often treated with high doses of steroids and/or other immunosuppressant medications, although data supporting such approaches are lacking. Mortality for IPF patients hospitalized with acute exacerbations is very high (50% to 90%).

Other Idiopathic Interstitial Pneumonias

The other major chronic fibrosing IIP is idiopathic nonspecific interstitial pneumonia (NSIP). This condition exhibits a histologic picture that is distinct from that of UIP/IPF and is characterized by diffuse, uniform infiltration of the lung interstitium with varying amounts of chronic (lymphoplasmacytic) inflammation and fibrosis, in contrast to the patchy, heterogeneous pattern seen in UIP. It is sometimes characterized

as either cellular NSIP or fibrotic NSIP depending on the predominance of either inflammation or fibrosis, although it is not clear if these are truly distinct entities. As a clinical entity, idiopathic NSIP is not as well defined as IPF, and as a result it is not as well studied either. As with IPF, patients with idiopathic NSIP usually present with progressive dyspnea and cough, and HRCT typically reveals diffuse, bilateral, peripheral reticular opacities, although ground-glass opacities are often more prominent with NSIP and honeycombing is generally absent. In many instances, distinguishing between IPF and idiopathic NSIP by HRCT alone can be difficult. The prognosis for NSIP is much better than for IPF, with a 5-year survival rate of greater than 82% in one series. It may be responsive to immunosuppressive therapy, and although data are lacking, a trial period with such agents can be considered. Lung transplantation should be considered in these patients if they exhibit progressive disease. Importantly, the same NSIP histologic pattern may occur in other conditions, most notably connective tissue disorders (e.g., systemic lupus erythematosus, rheumatoid arthritis, polymyositis), and therefore the identification of a histologic pattern of NSIP should prompt a detailed search for these conditions, which occasionally can otherwise be occult.

Cryptogenic organizing pneumonia (COP) and acute interstitial pneumonia (AIP) are classified as acute/subacute IIPs. Patients with COP exhibit subacute onset of dyspnea and/or cough, often with associated constitutional symptoms. Radiographically, patients with COP typically have areas of air space consolidation, often multifocal and bilateral, that mimic infectious pneumonia. Concomitant ground-glass opacities are also common. Histologically, COP is characterized by patchy areas of organizing pneumonia, which is accumulation of granulation tissue (a loose collection of fibrin, fibroblasts, collagen, and inflammatory cells) within the distal air spaces (alveoli and alveolar ducts), with or without extension into the respiratory and terminal bronchioles (bronchiolitis obliterans). COP is generally very responsive to corticosteroid therapy, often with complete resolution, but it can also relapse when steroids are stopped. The histologic pattern of organizing pneumonia (OP) can be seen in a variety of conditions, specifically connective tissue diseases, acute/subacute hypersensitivity pneumonitis, inhalational exposures, and drug-induced ILD, so as with NSIP, a histologic finding of OP should prompt a thorough evaluation for known causes before it is classified as an idiopathic process.

Acute interstitial pneumonia (AIP) is an IIP that is characterized by the rapid onset and progression of dyspnea and hypoxemia. Symptoms and radiographic opacities develop over days to a few weeks, invariably leading to respiratory failure. Many patients report a prior illness suggesting an upper respiratory infection with constitutional symptoms. The histologic pattern shows diffuse alveolar damage with hyaline membrane formation with or without organization. These patients can therefore be thought of as having acute respiratory distress syndrome (ARDS) of unknown cause. Although a trial of high-dose steroids with or without additional immunosuppressants is generally recommended, data indicating efficacy for this approach are lacking. Mortality rates for AIP are high at approximately 50%. Most survivors have a good long-term prognosis, although in some instances they experience persistent severe lung fibrosis. Occult connective tissue disease—most notably polymyositis/dermatomyositis—can present with an acute respiratory illness that mimics AIP, and this association may account for the fact that some patients clearly improve with aggressive treatment.

Desquamative interstitial pneumonia (DIP) is a rare idiopathic pneumonia usually seen in younger individuals. It is associated in most cases with a history of cigarette smoking. Patients exhibit a progressive shortness of breath and bilateral infiltrates on chest radiographs. The HRCT pattern shows extensive ground-glass infiltrates, and a biopsy is often required for diagnosis. Tissue histologic findings show the accumulation of so-called smoker's macrophages, which contain

yellow-brown pigment and fill the alveolar spaces, and some degree of interstitial inflammation and fibrosis.

Respiratory-bronchiolitis interstitial lung disease (RB-ILD) and DIP are classified as smoking-related IPs. Although these are classified as “idiopathic” ILDs, all cases of RB-ILD and the vast majority of cases of DIP are seen in cigarette smokers. RB-ILD and DIP are thought to represent a spectrum of illness, as both are characterized by abnormal accumulation of pigment-laden macrophages. The histologic finding of RB-ILD—accumulation of these macrophages in the lumens of the respiratory bronchioles—is considered a universal finding in active smokers and considered an asymptomatic/subclinical process. When the extent of macrophage accumulation becomes more extensive, involves the peribronchiolar air spaces, and/or causes symptoms or radiographic findings, it is referred to as RB-ILD. When the macrophage accumulation is even more extensive and involves the air spaces more diffusely, it is referred to as DIP. The prognosis for RB-ILD is generally excellent, with complete resolution occurring with smoking cessation alone. For DIP, the prognosis is more variable. Smoking cessation is still the mainstay of treatment, but many patients often also require treatment with corticosteroids. Some patients unfortunately develop progressive pulmonary fibrosis despite this approach. Very rare cases of DIP have been described in nonsmoking adults, although secondhand cigarette smoke and other inhalational exposures have been implicated.

Idiopathic lymphoid interstitial pneumonia (LIP) and idiopathic pleuroparenchymal fibroelastosis (PPFE) are classified as rare IIPs. LIP is characterized by extensive, relatively homogenous lymphoid infiltration of the interstitium, often with numerous lymphoid follicles. On HRCT, LIP is characterized by the combination of diffuse ground-glass opacity and frequently numerous thin-walled cysts. In many instances, LIP may be part of a spectrum of pulmonary lymphoproliferative disorders or true lymphoma. The vast majority of histologic LIP cases are associated with other conditions (e.g., connective tissue disease, HIV) and therefore are not truly idiopathic. Idiopathic pleuroparenchymal fibroelastosis (PPFE) is a relatively recently described entity characterized by dense, elastotic fibrosis of the pleura and subpleural lung parenchyma. HRCT typically shows patchy areas of subpleural, dense, plaque-like consolidation, often predominantly in the upper lung zones. Spontaneous pneumothorax is common. It is typically progressive and unresponsive to steroids or other immunosuppressive treatments. Idiopathic PPFE is still poorly understood, and the PPFE pattern has been described in a variety of conditions, including as a complication of both stem cell transplant and lung transplant. Additional rare histologic patterns of ILD have been described, such as acute fibrinous organizing pneumonia (AFOP) and bronchiolocentric pulmonary fibrosis and inflammation, but whether or not these represent distinct IIPs is still unclear. AFOP may exist along a clinical spectrum that includes AIP and COP, and bronchiolocentric patterns of ILD may be predominantly exposure-related. Lastly, there are some cases of IIP that, despite multidisciplinary discussion and review of clinical, HRCT, and histologic findings, do not fit into any of the clinicopathologic entities described above, and these are often referred to as unclassifiable IIP.

Other Idiopathic ILDs

Eosinophilic Pneumonia

Acute eosinophilic pneumonia (AEP) and chronic eosinophilic pneumonia (CEP) are two clinically distinct idiopathic forms of ILD characterized by eosinophilic infiltration of the lung parenchyma. AEP is typically characterized by fever, a nonproductive cough, and dyspnea that progresses over several days to weeks, often leading to acute respiratory failure. This disease typically affects male smokers between the ages of 20 and 40 years who are otherwise healthy. Chest imaging

Fig. 17.3 Photographic negative of pulmonary edema in chronic eosinophilic pneumonia.

reveals diffuse bilateral pulmonary infiltrates. Eosinophilia is often not found in the peripheral blood initially but may occur 7 to 30 days after onset. Abundant eosinophils can be found in BAL fluid, and a level of greater than 25% of all nucleated cells is helpful in making the correct diagnosis. Although lung biopsy is typically not required to make the diagnosis, it can show eosinophilic infiltration with acute and organizing diffuse alveolar damage. Treatment with corticosteroids typically offers rapid and complete clinical and radiographic resolution without recurrence or residual sequelae.

Chronic eosinophilic pneumonia is an idiopathic disease predominantly of middle-aged women with a history of asthma. Also called *prolonged pulmonary eosinophilia*, this illness is characterized by a productive cough, dyspnea, malaise, weight loss, night sweats, and fever associated with progressive peripheral lung infiltrates that have been described as resembling the photographic negative of pulmonary edema on chest radiographs (Fig. 17.3). On presentation, most patients with chronic eosinophilic pneumonia have a peripheral eosinophilia of greater than 30% and BAL fluid eosinophilia. Histologic examination shows eosinophils and histiocytes in the lung parenchyma and interstitium, but minimal fibrosis. There is often histologic overlap with organizing pneumonia (OP). Spontaneous remissions have been reported, but respiratory failure can develop. Typically, treatment with corticosteroids is rapidly effective, but unlike AEP relapses are common and therefore prolonged therapy is often required.

Both AEP and CEP are diagnoses of exclusion, and other causes of eosinophilic lung infiltration must be ruled out, including fungal and parasitic infections, drug-induced ILD, connective tissue disease-ILD, EGPA, and hypereosinophilic syndrome (HES).

Pulmonary Alveolar Proteinosis

Pulmonary alveolar proteinosis (PAP) is a rare disorder in which lipoproteinaceous material accumulates within the alveoli due to impaired surfactant metabolism by alveolar macrophages. There are a variety of forms of PAP, which occurs more frequently in middle-aged patients and in current or former smokers. Primary PAP is due to impaired granulocyte-macrophage colony-stimulating factor (GM-CSF) signaling and can occur as an autoimmune disease due to neutralizing antibodies against GM-CSF, or as a hereditary disease due to mutations in GM-CSF receptor mutations. Secondary PAP occurs in conditions in which there is a functional impairment or decrease in the number of alveolar macrophages, as seen in various hematologic malignancies

(e.g., leukemia), inhalation of toxic dusts (e.g., silica, aluminum), or after allogeneic bone marrow transplantation. PAP also has congenital forms that typically present in the neonatal period and are caused by various mutations that lead to dysregulated or defective surfactant production. Lung biopsy in PAP shows intra-alveolar accumulation of eosinophilic, acellular material staining positive with the periodic acid–Schiff (PAS) stain, which is consistent with surfactant.

Patients with PAP may be asymptomatic, or they may have progressive dyspnea on exertion, malaise, low-grade fever, and cough. Examination may reveal clubbing. The chest radiograph typically shows bilateral perihilar opacities. The CT scan may show diffuse ground-glass opacities with prominent thickening of the intralobular and interlobular septa, creating a pattern called “crazy paving,” although this is a nonspecific finding that can be seen in many other forms of lung disease. The course of PAP may be complicated by opportunistic lung infection. BAL fluid can establish the diagnosis because it has a milky, opaque appearance. The fluid contains large, foamy alveolar macrophages and extracellular surfactant material that stains positive with PAS. Surgical or transbronchial lung biopsy may also be performed to establish the diagnosis if the BAL is nondiagnostic.

Asymptomatic patients with PAP and those with mild symptoms require no immediate treatment. Sequential whole lung lavage with warmed saline is indicated for patients with hypoxemia or severe dyspnea, and in up to 40% of patients it may be required only one time. Limited lobar lavage may be performed in milder disease. GM-CSF administration in patients with acquired PAP may be beneficial. Rituximab has been used in refractory PAP. The prognosis of autoimmune PAP is good, with excellent survival since the introduction of whole lung lavage.

EXPOSURE-RELATED ILDS

Environmental and Occupational Interstitial Lung Disease

Several environmental and occupational exposures may cause ILD, and these are generally classified as hypersensitivity pneumonitis (HP) and the pneumoconioses. Pneumoconioses are lung diseases resulting from the inhalation of mineral dusts, including silica, coal dust, or asbestos. HP is typically caused by the inhalation of organic dusts.

Hypersensitivity Pneumonitis

Definition and epidemiology. HP (also called *extrinsic allergic alveolitis*) is a relatively common ILD resulting from an abnormal immune response in the lungs to various inhaled agents, typically organic antigens. This immune response consists of both humoral and cellular components and causes a pattern of airway-centered inflammation and/or fibrosis. Potential antigens are diverse, ranging from bacterial, fungal, and animal proteins to low-molecular-weight chemicals that can act as haptens (Table 17.3). Host susceptibility seems to play an important role, because the vast majority of individuals subject to a particular exposure do not develop HP. The mechanisms contributing to host susceptibility are unclear but likely include genetic, environmental, and epigenetic factors. Although evocative descriptions have been given to occupational forms of this disease (e.g., paprika splitter’s lung resulting from sensitivity to inhaled paprika dust contaminated with *Mucor stolonifer*), more routine exposures may occur in everyday life, such as hot tub water contaminated by mycobacterium avium complex (MAC), antigens from pet birds, or even common mold spores. The incidence and prevalence of HP are not well known and vary considerably based on many factors, such as geographic conditions, prevalent industries, and host mix. There is likely significant underdiagnosis of HP. For reasons that are unclear,

TABLE 17.3 Hypersensitivity Pneumonitis: Partial List of Common Etiologic Agents

Antigen	Source	Diseases
Bacteria	Moldy hay Sugar cane Compost Contaminated water	Farmer’s lung, bagassosis, mushroom-worker’s lung, humidifier lung, summer-type HP, composter’s lung
Fungi	Moldy hay, cork, bark, cheese or wood dust Grains Compost Contaminated water or ventilation systems	Farmer’s lung, suberosis, malt-worker’s lung, maple bark-splitter’s lung, humidifier lung, summer-type HP, composter’s lung, sequoiosis, wood pulp-worker’s disease, miller’s lung
Mycobacteria	Contaminated water Metal cutting fluid	Hot tub lung, humidifier lung, swimming pool lung, machine-worker’s lung
Animal proteins	Bird droppings, serum proteins, and feathers Pituitary powder Rat urine or serum proteins Fish meal	Pigeon breeder’s lung, bird fancier’s lung, feather duvet lung, duck fever, poultry-worker’s lung, pituitary snuff-taker’s lung, laboratory-worker’s lung, fish meal-worker’s lung
Chemicals	Isocyanates Anhydrides Bordeaux mixture	Chemical worker’s lung, epoxy resin lung, vineyard-sprayer’s lung

active cigarette smoking has been associated with a decreased risk of developing HP.

Pathology. Typical lung biopsy findings in HP demonstrate an airway-centered (i.e., bronchiolocentric) chronic inflammatory process involving the interstitium and air spaces, along with poorly formed granulomas containing multinucleated giant cells (Fig. 17.4). These findings are classically associated with the subacute form of the disease. In chronic HP there is generally considerable fibrosis and often features of fibrosing NSIP or UIP patterns in addition to areas of granulomatous and airway-centered inflammation. It is rare that lung biopsies are obtained in the acute form of HP, as it often resolves quickly, but histologic findings more associated with acute lung injury (along the diffuse alveolar damage organizing pneumonia (DAD-OP) spectrum) have been described in that setting.

Clinical presentation. HP can be classified as acute, subacute or chronic, although there can be considerable overlap between these forms. Acute HP usually presents with cough and dyspnea within hours after an intense exposure to a provocative antigen, often with prominent constitutional symptoms (e.g., fever, chills, malaise), and symptoms last for up to 24 hours. At the time of presentation, acute HP can be difficult to differentiate from bacterial or viral infection. Subacute HP is characterized by the gradual onset of cough and dyspnea, often with fatigue, anorexia, and weight loss, in response to prolonged lower level or intermittent antigen exposure. With intermittent exposure, symptoms of subacute HP may wax and wane. Chronic HP develops even more slowly than the subacute form, typically with insidious and gradually progressive cough and dyspnea and less variation in symptoms over time. Chronic HP is also thought to occur in response to sustained lower level antigen exposure, but it remains unclear if it represents the progression of prolonged, untreated subacute HP, or if subacute and chronic HP represent different host responses (inflammatory vs. fibrotic) to antigen-triggered immune-mediated lung injury.

Fig. 17.4 (A) Poorly formed granulomas (*arrow*) in a patient with hypersensitivity reaction to a chemotherapy drug (low magnification). (B) Poorly formed granuloma (*arrow*) in a patient with a hypersensitivity reaction to a chemotherapy drug (high magnification).

Fig. 17.5 CT image from a patient with hypersensitivity pneumonitis demonstrating diffuse, poorly formed, centrilobular nodules.

Tachypnea, hypoxemia, and diffuse inspiratory crackles are common physical exam findings in acute and subacute HP. Diffuse wheezes may also be present. Inspiratory crackles are also common in chronic HP, and these patients may also have digital clubbing. Hypoxemia with exertion may occur in earlier stages of chronic HP, with resting hypoxemia developing as the disease progresses. Pulmonary function tests usually show a restrictive pattern with abnormal gas exchange in subacute and chronic HP, although obstructive or mixed patterns are sometimes seen.

Chest radiographs in HP are characterized by nonspecific infiltrates, often in the middle and upper lung fields, although plain radiography may be normal in acute HP due to the fleeting nature of the disease. HRCT scanning is more sensitive than chest radiography and typically reveals ground-glass opacities, poorly formed centrilobular nodules (Fig. 17.5), and mosaic attenuation and air trapping patterns resulting from airway obstruction. Chronic HP may have architectural distortion with traction bronchiectasis and honeycombing and may be difficult to differentiate from IPF.

BAL findings are nonspecific but may demonstrate a lymphocytic alveolitis with a low CD4:CD8 ratio, although these findings seem to be less sensitive and specific for chronic compared to subacute disease. Patients with HP may have circulating IgG antibodies (serum precipitins) to the offending antigen, but these are not sufficiently sensitive nor specific for the diagnosis. The specific

antigen may not be known or may not be tested for with standard test panels.

Diagnosis. An appropriate exposure, clinical history, BAL, and HRCT imaging findings can suggest the diagnosis, but a lung biopsy may be necessary for confirmation in some cases. Transbronchial biopsy has a relatively high yield for diagnosing subacute HP, but surgical lung biopsy is often required to differentiate chronic HP from other chronic fibrosing ILDs, such as IPF and NSIP.

Treatment and prognosis. For acute and subacute HP, clinical improvement often occurs with separation from the offending exposure, if it is identified. A typical clinical course of acute/subacute HP is improvement in the hospital setting (often with empiric antibiotics for presumed infection), followed by relapse when the patient returns to her or his prehospitalization environment. This waxing and waning pattern of illness can often be an important clue to the diagnosis of HP. The prognosis for acute and subacute HP is favorable, particularly if the offending antigen can be identified and the exposure eliminated. Corticosteroids can help relieve symptoms and accelerate recovery in subacute HP or in more severe cases of acute disease. Corticosteroids and/or other immunosuppressants are also often administered to patients with chronic HP, but data indicating efficacy are lacking. Even with aggressive immunosuppressive therapy, many patients with chronic HP continue to experience gradual worsening of their disease. The presence of fibrosis in HP is a poor prognostic indicator. In fact, chronic (fibrotic) HP often behaves similarly to IPF, with many patients progressing to lung transplantation or death from pulmonary fibrosis. As a result, there is great interest in the potential role of antifibrotic therapy for chronic HP. Identification of the offending antigen is of critical importance in HP, but even then antigen avoidance can be financially or psychologically challenging for patients in the setting of occupational, pet, or residential exposures.

Pneumoconioses

The pneumoconioses are fibroinflammatory lung diseases that result from the inhalation and accumulation of inorganic and mineral dusts in the lungs. The risk and extent of these diseases are related to the intensity and cumulative amount of exposure over time. Prevention of the pneumoconioses through occupational safeguards or, in the case of asbestos, legislative bans on use, is important because there are no effective treatments for these diseases.

Silicosis is caused by exposure to crystalline silica (silicon dioxide), which results in an inflammatory and fibrotic reaction and the formation of the characteristic silicotic nodule. Crystalline silica is abundant in nature, most commonly in the form of quartz, and is present in stone, sand, and concrete. Occupations with a higher likelihood of

exposure to silica include mining, stone cutting, carving, polishing, foundry work, and abrasive clearing (e.g., sandblasting). Although exposure is usually chronic (over years), accelerated and acute disease manifestations have been described in the setting of heavier short-term exposures.

Acute silicosis is rare and the consequence of high-level silica exposure over a relatively short period of time. It is characterized by alveolar filling with silica dust and surfactant material, causing a pattern of disease that closely resembles pulmonary alveolar proteinosis (described above). Chronic silicosis results in simple nodular silicosis, and progressive massive fibrosis, which is characterized by extensive bilateral apical fibrosis resulting from the confluence of many silicotic nodules.

Patients with silicosis may have dyspnea or may be relatively asymptomatic but require further evaluation of an abnormal chest radiograph. Chest radiographs in uncomplicated silicosis show upper lobe nodular opacities, which may be subtle, whereas progressive massive fibrosis results in marked architectural distortion of the upper lobes (Fig. 17.6). Hilar node enlargement may be accompanied by “eggshell” nodal calcification. Pulmonary function tests in simple nodular silicosis may be normal or show a mixed obstructive or restrictive pattern, whereas progressive massive fibrosis is typically associated with severe restriction and hypoxemia. Patients with silicosis are at elevated risk for tuberculosis and should be screened for latent tuberculosis infection; there is also an association between silicosis and rheumatoid arthritis.

Coal worker’s pneumoconiosis is an uncommon cause of pulmonary fibrosis, occurring in workers exposed to coal dust and graphite. Usually, the patients are exposed while working in underground mines. Coal worker’s pneumoconiosis results in the formation of pigmented lesions in the lung surrounded by emphysema, called *coal macules*. Progressive massive fibrosis may subsequently occur. Most patients have chronic cough, which is usually productive, resulting from bronchitis related to coal exposure or to tobacco. The chest radiograph shows diffuse, small, rounded opacities. As with silicosis, there is an association with rheumatoid arthritis. Caplan’s syndrome is the occurrence of multiple, large, sometimes cavitary lung nodules in association with rheumatoid arthritis after coal dust exposure.

Asbestosis results from chronic exposure to asbestos, which is a fibrous silicate used for insulation, for friction-bearing surfaces, and to strengthen materials. The inhaled asbestos fibers are deposited in the lungs, where the small fibers may be phagocytosed and cleared through lymphatics to the pleural space, but the longer fibers are often retained. Asbestos exposure typically leads to pleural disease characterized by

pleural plaques, effusion, and fibrosis, but it does not necessarily affect the lung parenchyma. If it does, it is called *asbestosis*, with interstitial lung fibrosis resulting from asbestos exposure.

Asbestosis is characterized by a gradual onset of dyspnea. As with other pneumoconioses, the risk and severity of disease are related to the extent and duration of exposure. Asbestosis is often diagnosed after exposure has ceased, and disease progression may continue in the absence of ongoing exposure because of the reaction to retained asbestos fibers in the lung. The clinical presentation, pulmonary function tests, and imaging studies are similar to those for restrictive lung diseases such as IPF. However, the detection of significant pleural disease is useful in distinguishing this illness from other ILDs.

The diagnosis of asbestosis is made from the history of exposure and demonstration of concomitant pleural plaques and lower lobe predominant fibrotic changes on the chest radiograph or CT scan. In uncertain cases, the demonstration of asbestos in tissue specimens may be necessary. Asbestos bodies are the characteristic finding and consist of asbestos fibers coated by iron-containing (ferruginous) material. Asbestos exposure increases the incidence of malignancy, including lung carcinoma and mesothelioma, especially among people who also smoke. No specific treatment for asbestosis exists.

Berylliosis results from exposure to beryllium, a rare metal useful in modern, high-technology industries. Exposure to beryllium can lead to an acute chemical bronchitis and pneumonitis or chronic beryllium disease. Chronic beryllium disease is characterized by a granulomatous pneumonitis that is difficult to distinguish from sarcoidosis. The diagnosis is made by history of exposure, histologic examination, and laboratory confirmation using the beryllium lymphocyte proliferation test that is available at specialized centers. Corticosteroids may be useful in the treatment of berylliosis, but patients should avoid further exposure to beryllium.

Drug and Radiation-Induced ILD

A large number and variety of drugs can induce adverse reactions in the lung, often in the form of ILD (Table 17.4). These reactions vary in severity from self-limited hypersensitivity reactions to acute respiratory distress syndrome (ARDS) resulting in respiratory failure and even death. Together, this group of illnesses is often referred to as drug-induced lung injury (DILI). A high index of suspicion is needed to make the association between a drug and a pulmonary reaction, and a careful review of medications and other pharmacologic substances used by a patient is necessary in the setting of diffuse lung disease.

The clinical presentation of a drug-induced ILD is often non-specific, with cough and dyspnea accompanied by radiographic

Fig. 17.6 Architectural distortion of the upper lobes in a patient with silicosis.

TABLE 17.4 Common Medications Associated With Drug-Induced Interstitial Lung Disease

Class	Drug	Class	Drug
Antineoplastic Cytotoxic agents	Bleomycin	Immune checkpoint inhibitors	Osimertinib
	Bortezomib		Panitumumab
	Busulfan		Rituximab
	Carmustine		Trametinib
	Chlorambucil		Trastuzumab
	Cyclophosphamide		Atezolizumab
	Cytarabine		Avelumab
	Docetaxel		Durvalumab
	Doxorubicin		Ipilimumab
	Etoposide		Nivolumab
	Fludarabine	Pembrolizumab	
	Gemcitabine	Other Biologic Agents	Adalimumab
	Hydroxyurea		Anakinra
	Ifosfamide		Etanercept
	Irinotecan		Infliximab
	Lomustine		Tocilizumab
	Melphalan	Cardiovascular	Amiodarone
	Methotrexate		Captopril
	Mitomycin-C		Flecainide
	Oxaliplatin		Hydralazine
	Paclitaxel		Procainamide
	Pemetrexed		Quinidine
	Procarbazine		Statins
	Temozolomide		Sotalol
	Thalidomide		Tocainide
	Vinblastine		Antimicrobial
	Molecularly targeted agents	Bevacizumab	
Brigatinib		Sulfasalazine	
Erlotinib		Anti-inflammatory	Cyclophosphamide
Ceritinib			Gold
Cetuximab			Leflunomide
Crizotinib			Methotrexate
Dasatinib			Sulfasalazine
Gefitinib			
Imatinib			

opacities. Fevers can be present, and peripheral eosinophilia is sometimes found. Pulmonary function tests, if performed, usually reveal decreases in diffusion capacity and often show a restrictive pattern. ILD caused by medications usually does not produce a unique radiographic or histologic pattern of lung injury but may result in a variety of nonspecific reactions, including eosinophilic pneumonia, a hypersensitivity pneumonitis-type pattern, organizing pneumonia (OP), diffuse alveolar damage (DAD), nonspecific interstitial pneumonia (NSIP), and pulmonary fibrosis. Drug-induced systemic lupus erythematosus (SLE) can result in an acute pneumonitis, and pleural and pericardial effusions may also be present. Because the clinical presentation of patients with drug-induced ILDs lacks specificity, these are typically diagnoses of exclusion.

There are settings in which drug-induced lung disease may be especially relevant and should be strongly considered in the differential diagnosis. They include the use of antineoplastic therapy, patients with an acute SLE-like illness, and patients using specific agents known to induce pulmonary toxicity, such as methotrexate, amiodarone or nitrofurantoin. All types of antineoplastic therapy have been associated with lung toxicity and ILD, ranging

from classic cytotoxic agents (e.g., bleomycin, gemcitabine, taxanes), molecularly targeted therapies (e.g., tyrosine kinase inhibitors, EGFR inhibitors), and more recently immune checkpoint inhibitors (ICIs, e.g., nivolumab, pembrolizumab, ipilimumab). It has been estimated that up to 20% of patients receiving antineoplastic therapy develop some form of lung toxicity. Diagnosis of drug-induced ILD and identification of the offending medication can be challenging in patients receiving antineoplastic therapy because infection and chemotherapy-induced heart failure may result in similar symptoms and radiographic findings, and combination treatment with multiple agents (and radiation) is common. Biologic agents, such as tumor necrosis alpha (TNF- α) inhibitors and rituximab, have also rarely been associated with the development of drug-induced ILD. Because these drugs are often used to treat autoimmune conditions that are themselves associated with ILD (e.g., rheumatoid arthritis), in many cases it can be difficult to definitively assign a causal relationship between the drug exposure and the ILD. An online reference website (<http://www.pneumotox.com>) is available that tabulates the reported pulmonary toxicities of various drugs and is searchable by drug name and pattern of lung involvement.

Drug-induced ILD may be dose dependent, as with bleomycin, for which the risk of lung toxicity increases with cumulative doses exceeding 450 U. Amiodarone lung disease typically occurs with dosages greater than 400 mg per day. In other cases (e.g., with biologic or molecularly targeted therapies or immune checkpoint inhibitors) these reactions can be idiosyncratic and can occur either early or late in the treatment course. Synergistic lung toxicities may occur. For example, exposure to high levels of inspired oxygen may precipitate bleomycin lung injury and should be avoided if possible in exposed patients. Treatment of drug-induced ILD consists of discontinuation of the offending agent, glucocorticoids, and supportive care.

ILD can also be caused by ionizing radiation and is referred to as radiation-induced lung injury (RILI). There are two distinct types of RILI, radiation pneumonitis and radiation fibrosis, and these can occur in any patient undergoing thoracic irradiation for treatment of malignancy (e.g., lung or breast cancer, thoracic lymphoma). The main risk factors are the total dose of radiation delivered to the lung and volume of lung irradiated. Concurrent chemotherapy, particularly those that are known to sensitize tumors to radiation therapy, can also increase the risk of RILI. Interestingly, preexisting ILD also seems to confer an increased risk of RILI, suggesting that there may be host factors (e.g., genetics, prior environmental exposures) that predispose an individual to developing inflammatory or fibrotic reactions to a variety of insults to the lung.

Radiation pneumonitis usually develops within the first 3 months following irradiation, whereas radiation fibrosis typically presents much later (greater than 6 months). Symptoms are nonspecific and included dyspnea and a dry cough. Constitutional symptoms (fevers, malaise) may also be present. The physical exam typically reveals inspiratory crackles. Chest radiographs typically show hazy opacities in acute pneumonitis or reticulonodular opacities when fibrosis is present. HRCT imaging is generally done and provides more detailed information, demonstrating ground-glass opacities and areas of consolidation in radiation pneumonitis and reticular opacities, traction changes, and architectural distortion in the setting of radiation fibrosis. Although not always present, a “straight line effect”—the presence of radiographic or CT opacity that terminates abruptly, with a demarcation border that does not respect normal anatomic boundaries (Fig. 17.7)—is virtually pathognomonic for RILI. There are reports of RILI

Fig. 17.7 CT image from a patient with lung fibrosis due to prior mediastinal radiation. There is a sharp demarcation between the fibrotic and normal lung (arrow) that crosses the major fissure, representing the “straight-line” effect.

occurring outside of the radiation field, but the mechanisms for more widespread lung injury after radiation are unknown. Bronchoscopy with BAL and/or lung biopsy can be helpful for ruling out infection or other processes (e.g., progression of cancer), but otherwise these modalities have little role in the diagnosis of RILI since the BAL fluid characteristics and histologic features are nonspecific.

Treatment of symptomatic, moderate-to-severe radiation pneumonitis typically consists of an extended course (4–6 weeks) of high-dose glucocorticoids, followed by gradual tapering. There can often be significant improvement in symptoms, lung function, and radiographic abnormalities in the subacute setting. However, those patients who develop radiation lung fibrosis generally do not improve, and corticosteroids (or other treatments) are generally ineffective.

Intentional Exposures

Cigarette Smoking

Cigarette smoking is well known to be the primary cause of chronic bronchitis and emphysema, collectively referred to as chronic obstructive pulmonary disease (COPD). It is also a risk factor for idiopathic pulmonary fibrosis (IPF), as described above. Although much less common than COPD, several types of ILD can also be directly caused by cigarette smoking, specifically respiratory bronchiolitis–interstitial lung disease (RB-ILD), desquamative interstitial pneumonia (DIP), and pulmonary Langerhans cell histiocytosis (PLCH). These are sometimes collectively referred to as smoking-related interstitial lung disease, and in many cases radiographic and histologic features of two of these entities can coexist. Despite their causal association with cigarette smoking, RB-ILD and DIP are also classified as idiopathic interstitial pneumonias (IIPs) and are discussed earlier in this chapter. Therefore, we will limit our discussion here to PLCH.

Pulmonary Langerhans cell histiocytosis

Definition and epidemiology. Pulmonary Langerhans cell histiocytosis (PLCH), formerly called *eosinophilic granuloma* or *pulmonary histiocytosis X*, is a rare ILD that is most common in middle-aged adults and seen almost exclusively in cigarette smokers. It is characterized by an abnormal infiltration of Langerhans cells, which are specific types of dendritic cells, into the lung parenchyma. Although a multisystem Langerhans cell disease related to clonal proliferation of Langerhans cells occurs in children, isolated pulmonary LCH in adult smokers does not appear to be a clonal neoplastic disorder.

Pathology. Pulmonary LCH results in the formation of cysts and nodules in the lungs. The accumulation of activated Langerhans cells results in stellate nodular infiltrates around the small airways, with eventual destruction and dilation of the airway walls, resulting in cystic changes in the lung parenchyma. Smoking may alter local immune signaling, attracting the Langerhans cells to the lungs, or it may cause local proliferation and increased survival of Langerhans cells in the lungs. Biopsy of the lung demonstrates multiple stellate lung nodules that may be cellular or fibrotic, containing Langerhans cells that stain for Cd1a and S100. Electron microscopy may reveal Birbeck granules, distinctive racquet-shaped structures in the Langerhans cells.

Clinical presentation. Patients may be asymptomatic or may exhibit constitutional symptoms, dyspnea on exertion, and cough, possibly with hemoptysis. Spontaneous pneumothorax may also occur. Pulmonary function tests show impaired diffusion capacity, and an obstructive or restrictive pattern may be seen. Chest imaging shows nodules that may be cavitory and cysts that predominate in the middle and upper lung zones. Classic HRCT findings are bilateral, mid and upper lung zone predominant, irregular nodules and “bizarre,” thick-walled cysts (Fig. 17.8).

Fig. 17.8 CT image from a patient with pulmonary Langerhans cell histiocytosis (PLCH) demonstrating numerous thick-walled cysts (solid arrows) and irregularly shaped nodules (dashed arrows).

Diagnosis and differential diagnosis. When the classic CT pattern described above is seen in a middle-aged cigarette smoker, PLCH can generally be diagnosed without the need for a lung biopsy. The differential diagnosis includes other cystic lung diseases, such as lymphangioleiomyomatosis (LAM), lymphocytic interstitial pneumonia (LIP), and Birt-Hogg Dubé syndrome, sarcoidosis, emphysema, and other smoking-related ILDs. The presence of coexisting emphysema or other smoking-related ILD (e.g., DIP) can sometimes confound the diagnosis on imaging alone.

Treatment and prognosis. The main treatment is tobacco cessation. Corticosteroids and cytotoxic agents are sometimes employed as adjunctive therapy. Lung transplantation may be considered in cases of advanced disease. In contrast to systemic LCH, pulmonary LCH is not a neoplastic disorder, and spontaneous regression may occur with smoking cessation. Although some patients have a benign course, others develop progressive disease or complications such as pulmonary hypertension, which may be fatal.

Other Exposures

Illicit drugs such as heroin and cocaine commonly produce adverse pulmonary reactions. Substances such as talc may be injected or inhaled inadvertently during the use of illicit drugs, resulting in pulmonary vascular or interstitial disease. Heroin use typically results in pulmonary edema or aspiration injury rather than ILD. Cocaine use can produce a variety of pulmonary effects, including organizing pneumonia, alveolar hemorrhage, and diffuse alveolar damage. “Crack lung” is a clinical diagnosis typified by dyspnea, hemoptysis, and pulmonary infiltrates occurring in the setting of crack cocaine use. Recently, the United States has seen an outbreak of acute ILD in the setting of electronic cigarette use or vaping, termed vaping-associated pulmonary illness (VAPI) or e-cigarette associated lung injury (EVALI). These cases have typically occurred in younger individuals and seem to be more common with the use of THC-containing e-cigarettes. A variety of patterns of lung injury have been seen, and many cases have been severe, with progression to ARDS and even death. The specific cause(s) of lung injury from e-cigarette use are currently unknown, but some cases have been linked to chemical additives (such as vitamin E acetate) in some e-cigarette products.

ILD DUE TO SYSTEMIC DISEASES

Interstitial lung disease can be a manifestation of a wide variety of systemic diseases (see Table 17.1), but by far the most common are the connective tissue diseases (CTDs). Several vasculitides, which like CTDs are characterized by autoimmunity, also can cause ILD. Sarcoidosis is commonly thought of as a lung disorder, but it is in fact a multisystem disease that frequently involves the lung in a variety of different ways. In this chapter, we will discuss ILD associated with CTDs, the vasculitides, sarcoidosis, and lastly a more rare condition, lymphangioleiomyomatosis (LAM).

Connective Tissue Diseases

CTDs (also known as collagen vascular diseases, systemic rheumatic diseases) are a group of multisystem disorders characterized by dysregulation of the immune system (i.e., “autoimmunity”) leading to inflammation and/or fibrosis of many different organ systems. ILD is a common manifestation of many CTDs, most notably systemic sclerosis (SSc), rheumatoid arthritis (RA), the idiopathic inflammatory myopathies (polymyositis/dermatomyositis; PM/DM), Sjögren’s syndrome (SS), and mixed connective tissue disease (MCTD) (Table 17.5). Lung disease is a major cause of morbidity and mortality in these conditions. Chronic ILD is relatively uncommon in systemic lupus erythematosus (SLE), which usually is complicated by acute pneumonitis or diffuse alveolar hemorrhage. A finding of chronic ILD in a patient with SLE should prompt evaluation for MCTD or overlap syndromes (e.g., RA-SLE overlap).

Some patients presenting with ILD already have established CTD diagnoses, or the presence of CTD-ILD is discovered as a result of screening these high-risk patient populations. In other cases, a thorough history and physical examination may reveal abnormalities that strongly suggest an underlying CTD, such as inflammatory arthritis or joint deformities, myalgias or muscle weakness, sicca symptoms, esophageal dysmotility, Raynaud’s phenomenon, rashes or other skin changes. In some cases, however, it appears that ILD can be the first sign of an otherwise occult CTD, with other manifestations of the disease not developing until months or even years later. This phenomenon of ILD preceding other CTD symptoms or signs is best described in RA and PM/DM, and the presence of an evolving CTD may be suspected based on the presence of circulating autoantibodies in the setting of ILD. For this reason, the evaluation of patients with newly diagnosed ILD typically involves routine serologic testing aimed at identifying evidence of occult CTD. Lastly, there are some patients with ILD who have circulating autoantibodies and/or clinical features that suggest a possible autoimmune process but do not meet criteria for any defined CTD. Terms that have been used to describe these entities include “lung-dominant” CTD, form fruste of CTD, or autoimmune-featured ILD. Recently, the term interstitial

TABLE 17.5 Frequency of Interstitial Lung Disease in Connective Tissue Diseases

Connective Tissue Disease	Incidence of ILD
Systemic sclerosis	50-60%
Rheumatoid arthritis	10-15%
Polymyositis/dermatomyositis	20-80%
Mixed connective tissue disease	50-60%
Sjögren’s syndrome	10-20%
Systemic lupus erythematosus	5-10%

pneumonia with autoimmune features (IPAF) has been proposed, along with specific classification criteria, to better study and define this patient population. It remains to be seen whether the clinical course of those who could be classified as having IPAF more closely mimics that of defined CTD-ILD or that of the idiopathic interstitial pneumonias described above.

Lung biopsy is not typically indicated for the diagnosis of ILD in the setting of an established CTD, but when performed, the histologic patterns of ILD are similar to those seen with the IIPs. Nonspecific interstitial pneumonia (NSIP) is overall the most common histology associated with CTD-ILD, but usual interstitial pneumonia (UIP) and organizing pneumonia (OP) are also not uncommon. In some cases, there is a mix of histologic patterns (e.g. NSIP-OP overlap). HRCT patterns typically correspond to the histologic pattern.

Clinical manifestations of CTD-ILD are nonspecific but generally include exertional dyspnea and dry cough. CTD-ILD may be relatively asymptomatic, manifesting as an incidental finding on imaging or only detected as a consequence of aggressive screening with HRCT. Lung examination in patients with CTD-ILD may reveal bibasilar crackles, and pulmonary function tests often show a restrictive pattern with decreased diffusion capacity. If obstruction is identified on pulmonary function testing, airway manifestations of the connective tissue disorder, such as obliterative bronchiolitis in the setting of rheumatoid arthritis, must be considered. In the majority of cases of CTD-ILD, particularly with SSc and RA, the symptoms are chronic and slowly progressive, and this typically correlates with NSIP and/or UIP histologic and HRCT patterns of abnormality. More subacute symptoms can be seen with OP-like manifestations of CTD-ILD (often in RA or PM/DM). Importantly, acute fulminant presentations of CTD-ILD can also be seen, often with rapid progression to respiratory failure/ARDS. This is most often seen in PM/DM, where the histologic and HRCT patterns are often suggestive of diffuse alveolar damage (DAD) or a combination of DAD and OP, or in SLE, where DAD or capillaritis with DAH can be seen.

Other non-ILD forms of lung involvement can occur in CTD and may sometimes provide clues to the underlying diagnosis. The presence of pulmonary hypertension that does not seem to be attributable to the ILD itself is suggestive of SSc or MCTD, and the presence of pleural effusions suggests the possibility of SLE. Severe respiratory muscle weakness can occur in PM/DM and can contribute to dyspnea, PFT abnormalities, and respiratory failure. Lastly, pharyngeal muscle weakness (PM/DM) and/or esophageal dysfunction (SSc) can lead to recurrent aspiration.

Corticosteroids and other immunosuppressive drugs targeting the underlying disease process are generally considered the mainstay of treatment for CTD-ILD, although in most cases data from large, randomized controlled trials are lacking. Cyclophosphamide and mycophenolate have both been shown to be beneficial at slowing the progression of SSc-ILD, and smaller studies have suggested benefit to other treatment strategies in SSc and other CTDs (e.g., rituximab, azathioprine, calcineurin inhibitors, etc). In general, the likelihood of a response to immunosuppressive therapy seems to be somewhat determined by the pattern of ILD, similar to that seen in the IIPs (OP > cellular NSIP > fibrotic NSIP > UIP). As a group, CTD-ILDs are felt to be more responsive to treatment than IPF. However, because in many cases CTD-ILD can be predominantly a fibrotic process that is chronic and progressive (e.g., SSc-ILD and RA-ILD with a UIP pattern), there is a great deal of interest in using the newer antifibrotic agents developed for IPF in these patients, too. Indeed, a recent randomized controlled trial demonstrated

that the antifibrotic drug nintedanib was able to successfully slow the progression of SSc-ILD.

Vasculitides

The vasculitides represent a group of entities characterized by inflammation of blood vessel walls, leading to loss of vascular integrity, bleeding, and tissue ischemia. They include GPA, microscopic polyangiitis (MPA), EGPA, pauci-immune pulmonary capillaritis, anti-glomerular basement membrane (anti-GBM) disease, and CTD-associated vasculitis. Many of the vasculitides that affect the lungs are associated with circulating autoantibodies directed against neutrophil cytoplasmic antigens (i.e., antineutrophil cytoplasmic antibodies [ANCA]). Two major immunofluorescent patterns can be seen in ANCA testing: diffuse staining throughout the cytoplasm (cANCA) or perinuclear staining (pANCA). Specific antigens that ANCAs are directed against include proteinase 3 (PR3), typically causing the cANCA pattern, and myeloperoxidase (MPO), which typically causes the pANCA pattern.

GPA is a systemic necrotizing granulomatous vasculitis that often involves the small and medium-sized vessels of the upper airway, the lower respiratory tract, and the kidney. Although this triad is not always seen at initial presentation because only 40% of those affected have renal disease at that time, 80% to 90% of patients eventually develop glomerulonephritis. The most frequent manifestations of this illness are pulmonary, as highlighted by cough, chest pain, hemoptysis, and dyspnea. Constitutional symptoms such as fever and weight loss and symptoms due to involvement of the skin, eye, heart, nervous system, and musculoskeletal system are also common.

Chest imaging may show bilateral disease and infiltrates that evolve over the course of the illness. Lung nodules are common and may cavitate. Effusions and adenopathy are uncommon. Sinus films or CT scans can diagnose upper airway involvement. The diagnosis of GPA is supported by clinical findings and by circulating ANCAs, which are seen in 90% of patients. The remaining 10% of patients are ANCA negative. In ANCA-positive patients, antibodies are usually in a cANCA pattern and are directed against PR3; however, 10% to 20% may have pANCA patterns with anti-MPO antibodies.

Tissue biopsy at a site of active disease is usually needed to confirm a diagnosis of GPA. A renal biopsy is preferred because it is easier to perform and more often diagnostic. In the absence of renal involvement, a lung biopsy should be considered. Pathologically, GPA is characterized by small and medium-sized vessel necrotizing vasculitis and granulomatous inflammation. Special stains and cultures should be performed to exclude infections that can produce similar findings.

MPA is a form of systemic necrotizing small vessel vasculitis that universally affects the kidneys, whereas pulmonary involvement occurs in only 10% to 30% of patients. This rare condition has a prevalence of 1 to 3 cases per 100,000 people, but it is the most common cause of pulmonary-renal syndrome. MPA often is heralded by a long prodromal phase, characterized by constitutional symptoms followed by the development of rapidly progressive glomerulonephritis. In patients who develop lung involvement, diffuse alveolar hemorrhage (DAH) due to capillaritis is the most common manifestation. Joint, skin, peripheral nervous system, and gastrointestinal involvement also can be seen.

Seventy percent of patients with MPA are ANCA positive, and most are in a pANCA pattern with anti-MPO antibodies. Because pANCA/anti-MPO and cANCA/anti-PR3 antibodies can occur in MPA and GPA, these diseases cannot be distinguished based on their ANCA pattern. However, they can be distinguished pathologically because MPA is characterized by a focal, segmental necrotizing vasculitis affecting venules, capillaries, arterioles, and small arteries without clinical or pathologic evidence of necrotizing granulomatous inflammation. The absence or paucity of immunoglobulin localization in vessel walls distinguishes

MPA from immune complex–mediated small vessel vasculitis such as Henoch–Schönlein purpura and cryoglobulinemic vasculitis.

Treatments for GPA and MPA are similar. Combination therapy with corticosteroids and cyclophosphamide is the standard of care to induce remission. Plasma exchange is added in cases of severe disease and provides better renal outcomes. Azathioprine or methotrexate can be substituted for cyclophosphamide if remission is achieved. Rituximab may be used for induction of remission in place of cyclophosphamide or for relapsing disease.

EGPA (formerly known as Churg–Strauss syndrome) is characterized by the triad of asthma, hypereosinophilia, and necrotizing vasculitis. Many other organ systems, including the nervous system, skin, heart, and gastrointestinal tract, may be involved. The vasculitis can be associated with skin nodules and purpura. Although DAH and glomerulonephritis may occur, they are much less common than in the other small vessel vasculitides. Morbidity and mortality often result from cardiac or gastrointestinal complications or status asthmaticus and respiratory failure.

ANCA are less helpful in the diagnosis of EGPA because only 50% of patients are ANCA positive. Anti-MPO antibodies are more commonly seen in these patients. Pathologically, a necrotizing small vessel vasculitis and an eosinophil-rich inflammatory infiltrate with necrotizing granulomas are seen. Most patients respond well to corticosteroids, but other immunosuppressants such as cyclophosphamide may be required for patients with refractory disorders.

Other causes of pulmonary capillaritis include the connective tissue diseases (particularly SLE), pauci-immune pulmonary capillaritis, and anti–glomerular basement membrane (anti-GBM) disease (i.e., Goodpasture’s syndrome). Pauci-immune pulmonary capillaritis is characterized by neutrophilic infiltration of the alveolar septae with negative ANCA testing and no other systemic manifestations of vasculitis. Goodpasture’s syndrome causes DAH associated with glomerulonephritis due to anti-GBM antibodies to the α_3 chain of type IV collagen that is also found in the lung basement membrane. More than 90% of patients with Goodpasture’s syndrome have anti-GBM antibodies detectable in the serum. For those without circulating antibodies, the diagnosis may be confirmed by lung biopsy, although the kidney is the preferred site. Up to 40% may also be ANCA positive, primarily with anti-MPO antibodies. Pathologically, linear deposition of antibody along the alveolar or glomerular basement membrane is visible by direct immunofluorescence. The treatment of Goodpasture’s syndrome is plasmapheresis and immunosuppression. The disease is fatal if left untreated.

Sarcoidosis

Definition and Epidemiology

Sarcoidosis is a multisystem granulomatous disorder of unknown cause. The lungs and thoracic lymph nodes are frequent sites of involvement. Sarcoidosis is relatively common, with a prevalence of 1 to 40 cases per 100,000 people worldwide. A higher incidence of sarcoidosis is reported among Scandinavian, German, and Irish individuals residing in northern Europe. In the United States, the prevalence rates of sarcoidosis are 10.9 cases per 100,000 white individuals and 35.5 cases per 100,000 African Americans, with women in both groups being more frequently affected. Because sarcoidosis may be asymptomatic, the true prevalence may be higher. Sarcoidosis typically occurs in individuals between 10 and 40 years old.

Pathology and Pathophysiology

Sarcoidosis is characterized by the formation in tissues of noncaseating granulomas that organize in an inner core of epithelioid histiocytes, CD4⁺ T lymphocytes, and giant cells, which are surrounded by a rim of lymphocytes, fibroblasts, and connective tissue (Fig. 17.9).

Fig. 17.9 Subepithelial noncaseating granuloma, which is characteristic of sarcoidosis, from an endobronchial biopsy.

Granulomas are found in the airways or lung parenchyma in more than 90% of patients with sarcoidosis. Granulomatous angitis may also be found in the lungs. The upper respiratory system, lymph nodes, skin, and eyes are commonly involved. Virtually any other organ may be affected, including the liver, bone marrow, spleen, musculoskeletal system, heart, salivary glands, and nervous system.

The granulomas may be clinically silent or, if extensive, may disrupt normal organ structure and function. The cause of these lesions is unknown, but given the frequency of lung involvement, inhaled antigens ranging from bacteria (especially mycobacteria and *Propionibacterium*) to environmental substances have been hypothesized to trigger the onset of granulomatous inflammation. This inflammation may be self-limited or may be propagated, possibly by repeated exposure to the unknown antigen or because of defective immune regulation.

Familial susceptibility to sarcoidosis exists, and alleles of human leukocyte antigen (HLA) genes involved in antigen presentation and a mutation in the butyrophilin-like 2 gene (*BTNL2*), a possible immunoregulatory gene, have been associated with susceptibility to sarcoidosis. A single causative antigen initiating granuloma formation may not exist, and sarcoidosis instead may represent a stereotypical inflammatory reaction to various antigens in a genetically susceptible host.

Sarcoidosis is associated with abnormal immune function as evidenced by cutaneous anergy and as exhibited in lung by an increased ratio of CD4⁺ to CD8⁺ T lymphocytes and increased concentrations of pro-inflammatory cytokines such as interferon- γ , interleukin-12, and tumor necrosis factor- α (TNF- α). These derangements can be detected in the bronchoalveolar lavage (BAL) fluid and are consistent with an imbalance in the production of type 1 (T_H1) and type 2 (T_H2) helper T-cell cytokines, favoring the production of the former and promoting persistent inflammation. Sarcoidosis may occur in the setting of immunomodulatory therapy, especially with interferon- α , or the immune reconstitution syndrome, occurring after initiation of antiretroviral therapy for human immunodeficiency virus (HIV) infection, highlighting the role of immune imbalances in the disorder.

Clinical Presentation

The clinical presentation of patients with sarcoidosis varies. The disease is frequently detected incidentally on routine chest radiographs of asymptomatic individuals. Others may have diverse acute or chronic symptoms. Patients may develop well-described acute syndromes such as Löfgren syndrome, which includes erythema nodosum, fever, arthritis, and hilar adenopathy, or uveoparotid fever (i.e., Heerfordt

Fig. 17.10 Hilar adenopathy in a patient with sarcoidosis (arrows). (A) Chest radiograph. (B) Chest computed tomography scan. (Courtesy Dr. Rafael L. Perez.)

syndrome), which exhibits the triad of uveitis, parotitis, and facial nerve palsy. Both syndromes are associated with better outcomes than for other clinical presentations of sarcoidosis.

In many cases, symptoms are vague and chronic, and they may include systemic symptoms such as low-grade fevers, fatigue, night sweats, or joint pains. Respiratory manifestations, including shortness of breath, wheezing, dry cough, and chest pain, occur in one third to one half of patients. Skin manifestations include erythema nodosum, plaques, nodules, and lupus pernio, a violaceous, often disfiguring, nodular lesion of the nose and cheeks. Ocular symptoms are also common, and the onset of uveitis may eventually lead to the diagnosis of sarcoidosis when granulomatous extraocular organ involvement is uncovered. Neurosarcoidosis may manifest with cranial nerve palsies or with headache in the setting of lymphocytic meningitis. Sarcoidosis can involve the heart, resulting in a cardiomyopathy. Arrhythmias and sudden cardiac death can occur as a result of the disruption of the conducting system by granulomatous infiltration. Pulmonary hypertension may result from pulmonary fibrosis or directly from granulomatous vasculitis.

In 90% of patients, the chest radiograph shows abnormalities that include bilateral hilar adenopathy (Fig.17.10), parenchymal opacities, or both. The radiographic changes characteristic of sarcoidosis have been classified as stages 0 through IV (Table17.6), but this staging system does not imply a typical chronologic progression. However, stage I patients have a better prognosis for resolution than those with more advanced stages of disease.

As in other ILDs, computed tomography (CT) is more sensitive for the detection of parenchymal abnormalities, and it more clearly demonstrates the extent of mediastinal adenopathy. Typical HRCT findings include bilateral, mid and upper lung zone predominant peribronchovascular opacities emanating from the hila, along with extensive micronodules that can be seen within the lung parenchyma and running along the interlobular septae, fissures, and pleural surfaces (Fig.17.11). Positron emission tomography (PET) or gallium-67 scans may reveal other sites of organ involvement.

Pulmonary function tests show restriction, obstruction, or mixed deficits. Liver involvement may cause mild elevation of transaminase levels, and cirrhosis and liver failure have been reported, although they are rare. Hypercalcemia and hypercalciuria may be detected and are caused by increased intestinal absorption of calcium as a result of increased conversion of vitamin D to its active form in sarcoid granulomas. Kidney stones may result from the abnormal calcium metabolism. Elevated levels of angiotensin-converting enzyme (ACE) are common but are not specific. The use of ACE levels in the diagnosis or management of sarcoidosis is controversial.

TABLE 17.6 Radiographic Staging of Sarcoidosis

Stage	Radiographic Findings
0	Normal radiograph
I	Adenopathy without parenchymal abnormality
II	Adenopathy and parenchymal disease

Fig. 17.11 CT image from a patient with sarcoidosis demonstrating bilateral, upper lung zone predominant peribronchovascular opacity and extensive micronodules.

Diagnosis

The diagnosis of sarcoidosis depends on a typical clinical, radiographic, and histologic picture and is a diagnosis of exclusion. Patients with classic syndromes such as the Löfgren syndrome or uveoparotid fever may not require biopsy; however, most patients require tissue biopsy of an affected organ. Tissue samples show non-caseating granulomas, but because this finding is nonspecific, careful attention should be given to ruling out other causes of granulomatous inflammation (e.g., mycobacterial infection) through stains and cultures.

Necrotizing granulomas have rarely been reported in sarcoidosis, but this finding should prompt an intense search for infection. In

contrast to most ILDs, in which tissue diagnosis requires open lung biopsy, the granulomas in sarcoidosis can be identified in skin nodules or in lymph nodes. Due to frequent lung and lymph node involvement, bronchoscopy is commonly used to diagnose sarcoidosis. Results of bronchoscopy with transbronchial lung biopsy are positive for 50% to 60% of patients, but the procedure poses the risks of hemorrhage and pneumothorax. Because airway involvement is common, endobronchial biopsies may also demonstrate granulomas. However, there is increasing evidence that transbronchial needle aspiration of mediastinal and hilar lymph nodes using endobronchial ultrasound guidance may have a higher diagnostic yield for granulomas than conventional bronchoscopic techniques.

As mentioned above, sarcoidosis is a multisystem disease, so careful attention must be paid to potential signs and symptoms of extra-pulmonary involvement. After the diagnosis is made, all patients should have an ophthalmologic evaluation to assess for ocular involvement and an ECG to look for conduction abnormalities. Further cardiac testing, including Holter monitoring, echocardiography, or cardiac magnetic resonance imaging (MRI) should also be done depending on the presence of symptoms (e.g., palpitations) or ECG abnormalities. PET scanning can also be helpful for detecting active cardiac involvement from sarcoidosis. Additional imaging studies and/or tissue biopsies may be needed when symptoms or basic lab testing suggests other organ involvement (e.g., headaches, abnormal liver function tests, etc.).

Treatment

Corticosteroids are the mainstay of therapy, although they are not required in all patients with sarcoidosis because many patients are minimally symptomatic and may undergo spontaneous remission. Whether corticosteroids alter the disease course is uncertain. However, corticosteroid therapy should be considered in patients with extra-pulmonary organ involvement, respiratory symptoms, or evidence of progressive pulmonary disease. In patients with pulmonary involvement, oral prednisone at a dosage of 20 to 40 mg per day is typically initiated and maintained for a 4- to 6-week course before being slowly tapered over a course of 3 to 6 months. Some patients may experience remission with this treatment approach and may be managed off therapy for an extended period of time. For patients with disease that is refractory to corticosteroids, or for those who experience disease worsening when steroids are tapered, additional treatments should be considered. Methotrexate is the most commonly used steroid-sparing agent in sarcoidosis, but leflunomide, azathioprine, and mycophenolate have also been used. Anti-TNF- α inhibitors (e.g., infliximab) can also be used for refractory disease, and there are some small studies to support this approach in individuals with refractory sarcoidosis or with extra-pulmonary involvement.

Prognosis

The course of sarcoidosis varies. Spontaneous remission is common, and death and disability occur rarely, making decisions regarding treatment initiation difficult. The acute sarcoidosis syndromes tend to remit and not recur. However, about one third of patients with sarcoidosis have chronic, progressive disease, and some patients develop pulmonary fibrosis or other end-organ damage.

Lymphangioleiomyomatosis

Definition and Epidemiology

Lymphangioleiomyomatosis is a rare, slowly progressive, multisystem disorder resulting in cystic interstitial lung disease and kidney angiomyolipomas that occurs in either a sporadic form or in association with tuberous sclerosis complex (TSC-LAM). Sporadic LAM occurs almost exclusively in women of childbearing age.

Pathology

The disease is characterized by extensive infiltration of the lungs and lymphatics with growths of smooth muscle–like lymphangioleiomyomatosis cells. Mutations in the *TSC1* or *TSC2* gene, which encodes tumor suppressor proteins that normally act as inhibitors of protein synthesis and cell growth, may result in tuberous sclerosis or lymphangioleiomyomatosis. Mutations in *TSC2* are associated with greater disease severity.

Clinical Presentation

Dyspnea and spontaneous pneumothorax are the most common presentations, with chylous pleural effusions and hemoptysis also occurring. These clinical presentations result from lung parenchymal destruction, airway narrowing, and lymphatic obstruction caused by the abnormal proliferation of the smooth muscle–like cells.

Imaging studies show an interstitial pattern with middle and upper lung predominance; multiple, thin-walled cystic lesions; and characteristically preserved lung volumes. Pleural effusion or pneumothorax may be seen on imaging. CT of the abdomen may reveal fat-containing kidney lesions consistent with angiomyolipomas. Pulmonary function tests typically show a progressive obstructive pattern, although mixed obstruction and restriction may also be seen.

Diagnosis

Although the clinical features coupled with characteristic imaging are often diagnostic, lung biopsy may be necessary in some cases. It demonstrates interstitial nodules composed centrally of spindle-shaped cells that stain for smooth muscle cell actin and for HMB-45, an antibody to the melanocytic glycoprotein 100, with staining involving the alveolar walls, lobular septa, venules, small airways, and pleura.

Treatment

Treatment involves management of pleural complications, including the use of pleurodesis to prevent recurrent pneumothorax or effusion, bronchodilator and oxygen therapy, and avoidance of pharmacologic estrogens, which may exacerbate the disease. Progesterones have been used in an attempt to modulate disease progression, but efficacy data are limited.

Because the products of the *TSC1* and *TSC2* genes normally act as inhibitors of the mammalian target of rapamycin (mTOR), pharmacologic mTOR inhibitors such as sirolimus and everolimus have been studied in lymphangioleiomyomatosis. Sirolimus stabilized lung function in lymphangioleiomyomatosis, and sirolimus and everolimus treatment resulted in angiomyolipoma shrinkage. Lung transplantation can be performed in patients with severe pulmonary dysfunction.

Prognosis

Lymphangioleiomyomatosis is a slowly progressive disease that can result in potentially fatal complications, especially respiratory failure.

SUMMARY

The interstitial lung diseases (ILDs), or *diffuse parenchymal lung diseases* (DPLDs), are a heterogeneous group of nonmalignant and noninfectious lung diseases characterized by varying amounts of inflammation and/or fibrosis (scarring) of the lung parenchyma. ILDs manifest with a wide range of overlapping clinical presentations, radiographic findings, and histologic abnormalities. Because of the similarities shared by many ILDs and the rarity of most of these conditions, establishing a definitive diagnosis can often be difficult and requires the incorporation of a detailed history, physical exam, imaging, and

histologic data. Although there is no universally accepted classification system for ILDs, it can be useful to think of these entities as falling into the three broad categories of exposure-related ILDs, ILDs attributable to systemic diseases, and idiopathic ILDs.

The treatment approach for ILDs generally revolves around treating the underlying illness (if present) and removal of offending exposures (if identified), as well as suppressing inflammation in those settings where inflammation is thought to play a prominent role. However, pulmonary fibrosis is a characteristic feature of many ILDs, and fibrosis often progresses despite these approaches. Fortunately, we are now starting to see the emergence of treatments that target the aberrant wound-healing processes that are thought to contribute to the development of lung fibrosis. Antifibrotic treatments are now available for idiopathic pulmonary fibrosis (IPF) that slow the progression of this otherwise fatal disease process, and these treatments may also be effective for other types of fibrotic ILD. However, until therapies are developed that can completely arrest—and ideally even reverse—fibrogenesis, lung transplantation remains the only option for a chance at prolonged survival for many patients afflicted with IPF and other ILDs.

Pulmonary Vascular Diseases

Christopher J. Mullin, James R. Klinger

INTRODUCTION

Pulmonary vascular disease is a broad term for any disease that affects the blood vessels of the lungs. These diseases are a heterogeneous group of disorders with multiple causes, but most can be categorized as diseases of either pulmonary embolism or pulmonary hypertension. Some pulmonary vascular diseases, such as idiopathic pulmonary arterial hypertension (PAH), directly affect the pulmonary vessels, whereas other forms of pulmonary vascular disorders are compensatory responses to elevation of pulmonary venous pressure or recurrent hypoxia due to chronic heart and lung diseases. This chapter discusses pulmonary hypertension and pulmonary thromboembolism, with a focus on pulmonary arterial hypertension (PAH) and chronic thromboembolic pulmonary hypertension (CTEPH).

The normal pulmonary vasculature is a high-flow, low-resistance system with very high capacitance that can accept the entire output of the right ventricle with only slight increases in pressure. The right ventricle (RV) in health is well adapted to the pulmonary circulation and matches the cardiac output of the left ventricle with one fifth of the energy expenditure. However, the RV is unable to tolerate large increases in afterload, which occur acutely in the setting of pulmonary thromboembolism and more subacutely or chronically in pulmonary hypertension. As such, right ventricular function is important in the clinical manifestations, diagnosis, treatment, and prognosis of pulmonary vascular diseases.

❖ For a deeper discussion on this topic, please see Chapter 75, "Pulmonary Hypertension," in *Goldman-Cecil Medicine*, 26th Edition.

PULMONARY HYPERTENSION

Definition and Epidemiology

Normal pulmonary arterial pressure (PAP) in healthy adults at rest is about 25/10 mm Hg with a mean PAP (mPAP) of 14.3 mm Hg \pm 3.0 mm Hg. Thus, mPAP above 20 mm Hg is two standard deviations above the mean and generally considered to be abnormal. However, mPAP increases slightly with age and is difficult to measure accurately due to limitations in normalizing intravascular pressure to atmospheric pressure. For these reasons, PH is usually defined as mPAP greater than or equal to 25 mm Hg. In 1998, the World Symposium on Pulmonary Hypertension proposed a classification of pulmonary hypertension that grouped diseases with similar pathologic and hemodynamic characteristics. In the most recent version of this classification (Table 18.1), PH is divided into five groups: (1) Pulmonary arterial hypertension (PAH), meant to infer disease of the pulmonary arteries, (2) pulmonary hypertension due to elevated pulmonary venous pressure caused by left-sided heart disease, (3) pulmonary hypertension due to chronic hypoxia or lung disease, (4) pulmonary hypertension

caused by chronic pulmonary emboli, and (5) pulmonary hypertension attributable to unclear or multifactorial mechanisms.

The most common types of pulmonary hypertension are WHO Groups 2 and 3. In one study, nearly 75% of adult cases of PH were due to left heart disease and 10% due to chronic lung disease. However, much of the attention on pulmonary vascular disease has focused on WHO Group 1 PAH. Despite representing a small minority of cases, PAH is the most severe form of pulmonary hypertension and often afflicts relatively young otherwise healthy individuals. Without treatment, median survival is about 3 years. In early registries, the peak incidence of PAH occurred in the fourth decade of life, but it can be seen at all ages and it affects women two to three times more frequently than men. The cause of PAH is unknown, but disease classification has been further subdivided into idiopathic PAH, heritable PAH, and associated PAH (APAH) in which PAH is associated with one of several diseases. Heritable PAH is caused primarily by mutations in the gene for bone morphogenetic protein receptor type 2 (*BMPR2*) representing nearly three quarters of the cases of familial PH and approximately 20% of patients with idiopathic PAH. Mutations in other related genes within the transforming growth factor- β family including (activin receptor-like kinase 1 [*ALK1*]) and endoglin (*ENG*) have also been described.

Idiopathic PAH is extremely rare with an incidence estimated at 1 to 10 in 1,000,000. However, APAH is not uncommon in patients with connective tissue disease, especially the limited cutaneous form of scleroderma and mixed connective tissue disease where it can be seen in up to 14% of patients. PAH also occurs in 2% to 3% of patients with portal hypertension and 0.5% of patients with HIV infection. It is also seen in patients exposed to methamphetamines, particularly the anorectic drug phentermine/fenfluramine, and is a common sequel of congenital heart diseases that result in significant left-to-right intracardiac shunt. Pulmonary veno-occlusive disease (PVOD) and pulmonary capillary hemangiomatosis (PCH) constitute a rare subgroup of PH that is characterized by vascular remodeling and occlusion of small pulmonary veins and venules, leading to severe hypoxia and in some cases interstitial edema.

Pulmonary Arterial Hypertension

Pathophysiology

Although the pathogenic mechanisms responsible for PAH are not well understood, the vascular remodeling associated with it has been well described. Prominent features include an obliterative vasculopathy characterized by medial vascular smooth muscle hypertrophy, adventitial thickening, and proliferation of pulmonary vascular endothelial cells. In situ thromboses of small pulmonary arteries and areas of perivascular inflammation are also frequently observed. Plexiform lesions consisting of abnormal proliferation of endothelial cells causing near complete obstruction of the vascular lumen of distal pre-acinar arterioles with areas of recanalization are considered pathognomonic of the

TABLE 18.1 World Health Organization Classification of Pulmonary Hypertension**Group 1: Pulmonary Arterial Hypertension (PAH)**

- Heritable PAH
- Drug- and toxin-induced
- PAH associated with:
 - Connective tissue disease
 - Human immunodeficiency virus infection
 - Portal hypertension
 - Congenital heart disease
 - Schistosomiasis

Long-term responders to calcium-channel blockers

PAH with overt features of venous/capillary involvement (pulmonary veno-occlusive disease or pulmonary capillary hemangiomatosis)

Persistent pulmonary hypertension of the newborn

Group 2: Pulmonary Hypertension Due to Left Heart Disease

- Heart failure with preserved left ventricular ejection fraction
- Heart failure with reduced left ventricular ejection fraction
- Valvular heart disease
- Congenital/acquired cardiovascular conditions leading to post-capillary PH

Group 3: Pulmonary Hypertension Due to Lung Diseases and/or Hypoxia

- Obstructive lung disease
- Restrictive lung disease
- Other lung diseases with mixed restrictive and obstructive pattern
- Hypoxia without lung disease
- Developmental lung diseases

Group 4: Pulmonary Hypertension Due to Pulmonary Arterial Obstructions

- Chronic thromboembolic pulmonary hypertension
- Other pulmonary artery obstruction: sarcoma, other malignant or nonmalignant tumors, arteritis without connective tissue disease, congenital pulmonary artery stenosis, parasites

Group 5: Pulmonary Hypertension With Unclear and/or Multifactorial Mechanisms

- Hematologic disorders: chronic hemolytic anemia, myeloproliferative disorders
- Systemic and metabolic disorders: sarcoidosis, pulmonary Langerhans cell histiocytosis, glycogen storage disease, Gaucher disease, neurofibromatosis
- Others: chronic renal failure with or without hemodialysis, fibrosing mediastinitis
- Complex congenital heart disease

Modified from Simonneau G, Montani D, Celermajer DS, et al. Haemodynamic definitions and updated clinical classification of pulmonary hypertension. *Eur Respir J* 2019; 53: 1801913.

disease E-Fig. 18.1). In some cases, vascular remodeling extends into pulmonary capillaries and proximal pulmonary veins. These varied changes result in narrowing of the vascular lumen and are thought to contribute to the increase in pulmonary vascular resistance and pressure. In addition, numerous changes in vascular cell function have been described. Pulmonary vascular endothelial cells show decreased expression of vasodilators such as prostacyclin and nitric oxide and increased expression of pulmonary vasoconstrictors such as thromboxane and endothelin. Pulmonary vascular smooth muscle becomes hypertrophic and proliferative leading to muscularization of distal normally non-muscularized vessels. Adventitial fibroblasts display an inflammatory phenotype that may induce changes in smooth muscle cell growth. Finally, the loss of distal pulmonary vessels due to abnormal apoptosis of pulmonary vascular endothelial cells is also likely to contribute to the pathogenesis of PAH. It is unclear if the obliterative vascular remodeling characteristic of PAH is the primary cause of the disease or a compensatory response to the increase in blood flow through the remaining vessels. A leading hypothesis is that PAH is caused by a double hit mechanism, the first being vascular injury resulting in loss of distal pulmonary vessels and the second being the deregulation of vascular repair mechanisms that lead to abnormal pulmonary vascular remodeling.

Clinical Presentation

The initial presentation of PAH is often subtle. Initial symptoms include dyspnea on exertion, fatigue or exertional lightheadedness. As the disease progresses, right ventricular failure causes peripheral edema, decreased appetite, ascites, and occasionally exertional chest pain. Severity of PAH is often classified by the degree of exercise impairment using a WHO modification of the New York Heart Association functional class as follows: class I, asymptomatic; class II, symptoms with normal activity; class III, symptoms with less than normal activity; and class IV, symptoms with any physical activity or at rest.

Chest radiographs may reveal prominent pulmonary arteries or right ventricular enlargement (E-Fig. 18.2). Pulmonary function testing usually shows normal spirometry, but diffusing capacity can be reduced reflecting the restricted circulation and decreased surface area available for gas exchange. Plasma brain natriuretic peptide levels rise as right ventricular pressure increases and a fall in oxygen saturation in response to exercise is often seen.

Diagnosis and Clinical Evaluation

The diagnosis of PAH depends on exclusion of other underlying heart or lung diseases that might cause pulmonary hypertension. Because PAH is

E-Fig. 18.1 The plexiform lesion is an abnormal proliferation of pulmonary endothelial cells seen only in the setting of pulmonary arterial hypertension (hematoxylin and eosin stain). (Courtesy Dr. Charles Kuhn.)

E-Fig. 18.2 The chest radiograph shows an enlarged right main pulmonary artery (*arrow*), which resulted from pulmonary artery hypertension.

TABLE 18.2 Medications for Treatment of Pulmonary Arterial Hypertension

Drug Class	Drug Name	Route of Administration	Mechanism of Action
Endothelin receptor antagonist	Ambrisentan	Oral	Inhibits vasoconstriction by blocking endothelin
	Bosentan	Oral	
	Macintentan	Oral	
Phosphodiesterase type 5 inhibitor	Sildenafil	Oral, intravenous	Promotes vasodilation by delaying metabolism of intracellular cGMP
	Tadalafil	Oral	
Prostacyclin derivative	Epoprostenol	Intravenous, inhaled ^a	Promotes vasodilation by increasing intracellular cAMP
	Iloprost	Inhaled, intravenous infusion ^a	
	Treprostinil	Oral, inhaled, subcutaneous infusion, intravenous infusion	
Prostacyclin receptor agonist	Selexipag	Oral	Activates prostacyclin receptor
Soluble guanylyl cyclase stimulator	Riociguat	Oral	Promotes vasodilation by increasing cGMP synthesis

^aCurrently no commercial preparation available for this route of administration in the United States.

extremely rare in healthy individuals, every effort should be made to look for connective tissue disease, portal hypertension, HIV infection, congenital heart disease, chronic pulmonary emboli, or history of exposure to a potentially causative drug or toxin. Most patients should have pulmonary function testing to exclude obstructive or restrictive defects and measure oxygen saturation. Nocturnal hypoxemia from sleep-disordered breathing should be considered. A lung ventilation/perfusion scan should be done to exclude chronic pulmonary embolism and blood tests for screening for autoimmune disease, HIV, or liver dysfunction should be obtained. Left heart disease is usually evaluated by echocardiography, but in some patients, additional studies to assess coronary artery disease or infiltrative cardiomyopathies may be needed. Although rare, PCH and PVOD should be considered, the latter characterized by severe hypoxemia, decreased DLCO, and a triad of centrilobular nodules and ground-glass opacities and thickened interlobular septa on high-resolution chest CT.

Transthoracic echocardiography is often the first step in excluding left-sided heart disease and when used with Doppler ultrasound can provide an estimate of pulmonary artery systolic pressure. In addition, it provides important information on right atrial and ventricular size and function and the relative degree of right- versus left-sided filling pressure by examining the position of the interatrial and interventricular septa. Finally, the presence of significant intracardiac shunts can often be detected.

Definitive diagnosis of PAH requires right heart catheterization to confirm increased mPAP and assess left-sided filling pressure via measurement of pulmonary artery occlusion pressure. Hemoglobin oxygen saturation should be measured in the superior or inferior vena cava, right atrium, and pulmonary artery to exclude significant left-to-right shunt. In patients with PAH, pulmonary vasoreactivity should be tested by administration of a short-acting selective pulmonary vasodilator such as inhaled nitric oxide or intravenous epoprostenol. A decrease in mPAP of 10 mm Hg or greater to a mPAP less than 40 mm Hg without a decrease in cardiac output is considered a positive response and identifies a small group of PAH patients who can often be treated successfully with a calcium-channel blocker.

Treatment

In the last 25 years, five classes of drugs have been approved for the treatment of PAH (Table 18.2). These drugs act primarily as semiselective pulmonary vasodilators, although antimitogenic properties that may slow pulmonary vascular remodeling have also been described. There are insufficient data to compare the relative efficacy of the different drug classes, but in general most treatment guidelines agree on several points: (1) In the absence of severe right heart failure, patients with a positive response to pulmonary vasodilator testing should be given a trial of calcium-channel blocker, usually nifedipine. (2) Patients with the greatest risk of death,

including those in WHO functional class IV, should be treated with continuous intravenous infusion of a prostacyclin derivative. (3) Patients with less advanced PAH such as those in functional class II or III should be treated with a combination of a phosphodiesterase type 5 inhibitor (PDE5) inhibitor and an endothelin receptor antagonist (ERA). Patients who are unable to tolerate this combination or who do not improve while taking it should be considered for treatment with soluble guanylate cyclase (sGC) stimulators in place of a PDE5 inhibitor or use of an inhaled or oral prostacyclin derivative or a prostacyclin receptor agonist.

Response to treatment is assessed by (1) symptomatic improvement as measured by change in functional class, (2) objective improvement in exercise capacity as assessed by 6-minute walk distance or cardiopulmonary exercise testing, (3) enhanced right ventricular function as assessed by echocardiogram or cardiac MRI and brain natriuretic peptide levels, and when necessary, (4) pulmonary hemodynamics assessed by repeat right heart catheterization.

Other interventions include supplemental oxygen to keep resting oxygen saturation greater than 90%, judicious use of diuretics to reduce peripheral edema and right ventricular overload, and a supervised exercise program such as pulmonary rehabilitation. The role of anticoagulation to prevent thrombosis in situ remains controversial, but some guidelines recommend low-level anticoagulation unless patients are at increased risk of bleeding. Patients who remain in or progress to functional class IV despite maximum medical therapy should be considered for lung transplantation. Current treatment guidelines also recommend consideration of referral of PAH patients to regional centers with experience in managing this disease.

OTHER TYPES OF PULMONARY HYPERTENSION

Pulmonary hypertension is a normal complication of any left-sided heart disease that increases pulmonary venous pressure such as left ventricular systolic or diastolic dysfunction or valvular heart disease. Pulmonary hypertension is also a common development of chronic lung disease, especially those that are associated with hypoxemia. These conditions have been called *secondary pulmonary hypertension* but now are usually referred to as WHO Group 2 and 3 PH (see Table 18.1). Hypoxic pulmonary vasoconstriction contributes to increased pulmonary vascular resistance in chronic or recurrent hypoxia. Long-standing hypoxia causes vascular remodeling that is similar to plexogenic pulmonary arteriopathy but does not include in situ thrombosis or formation of plexiform lesions (E-Fig. 18.3).

Due to the association of increased mortality when PH is present in patients with chronic heart and lung disease, there is considerable

Normal lung

Emphysema

E-Fig. 18.3 Hypertrophy of smooth muscle in the media of an artery (*arrow*) in a patient with emphysema is compared with that of a normal artery (*arrow*). (Courtesy Dr. Charles Kuhn.)

interest in using PAH medications for the treatment of WHO Groups 2 and 3. There is currently insufficient evidence to suggest that any of the currently available medications are beneficial in these other types of pulmonary hypertension. Considering their high costs and ability to worsen gas exchange and pulmonary edema formation, their use in patients who do not have Group 1 PAH is not recommended, and treatment should be directed at the underlying heart or lung disease.

PULMONARY THROMBOEMBOLISM

Definition and Epidemiology

Pulmonary thromboembolism refers to the passage of a clot from the venous system or the right ventricle into a pulmonary artery. Several other materials can embolize to the pulmonary arterial bed, including air, fat, amniotic fluid, tumor, or injected foreign bodies (e.g., talc). These embolic phenomena have different risk factors and clinical manifestations but occur much less commonly than venous thrombosis with pulmonary thromboembolism.

Pulmonary thromboembolic disease is a relatively common entity, with an incidence ranging from 400,000 to 650,000 cases per year in the United States. The deep veins of the femoral and popliteal systems of the lower extremities are the most common sources of venous thrombosis, but upper extremity thrombosis and right heart thrombi can also embolize to the lung. Predisposing factors for pulmonary embolism are the same as those for venous thrombosis and include venous stasis, hypercoagulability, and endothelial injury, as well as congenital or acquired prothrombotic disorders (e.g., activated protein C deficiency, factor V Leiden).

❖ For a deeper discussion on this topic, please see Chapter 75, “Pulmonary Hypertension,” in *Goldman-Cecil Medicine*, 26th Edition.

Pathophysiology

An acute pulmonary thromboembolism can obstruct a branch of the pulmonary artery, resulting in an increased \dot{V}/\dot{Q} ratio. This increases overall dead space ventilation, which can lead to inefficient excretion of carbon dioxide, potentially raising the partial pressure of carbon dioxide in arterial blood (P_{aCO_2}). Blood flow is shifted from the obstructed site to other areas, leading to \dot{V}/\dot{Q} mismatch, shunting, and hypoxemia.

Right ventricular dysfunction is commonly encountered in acute pulmonary thromboembolism, occurring when a substantial portion of the pulmonary vascular bed is occluded and there is an acute increase in PAP. Approximately 5% of patients present with cardiogenic shock from right ventricular failure, and somewhere between 30% and 70% of normotensive patients will have right ventricular dysfunction on transthoracic echocardiography, which is associated with a worse prognosis.

Clinical Presentation and Diagnosis

Common symptoms of pulmonary thromboembolism include shortness of breath, chest pain, hemoptysis, and syncope. When the diagnosis of acute pulmonary embolism is suspected, risk factors such as recent immobilization or surgery, malignancy, or a prior history of venous thrombosis should be clinically documented, and a validated clinical scoring system, such as the Wells or Geneva score, can be used to assess the pretest probability of pulmonary embolism. The most common physical examination findings are tachycardia and tachypnea, and chest examination may be normal or may reveal isolated crackles or even diffuse wheezing. Edema of the extremities, especially if the edema is asymmetrical, may indicate venous thrombosis. Signs of right ventricular strain, such as an increased pulmonary component

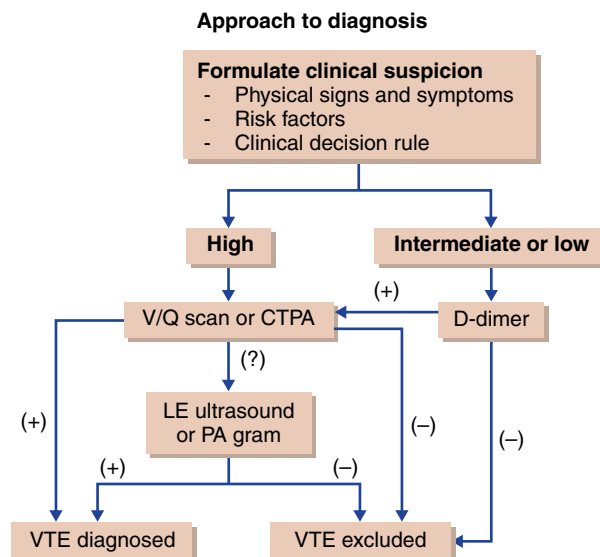

Fig. 18.1 A proposed diagnostic algorithm for the diagnosis of acute pulmonary embolism (PE). Clinical suspicion, often with the use of clinical decision rules, can determine if patients should proceed directly to an imaging study such as CT pulmonary angiography (CTPA) or ventilation-perfusion (V/Q) scan when the pretest probability is high. D-dimer testing is recommended in patients with a lower clinical suspicion for acute PE, where a negative D-dimer is a sensitive test and can exclude the diagnosis of venous thromboembolism (VTE).

of the second heart sound or a palpable right ventricular heave, can be observed in massive pulmonary embolus.

The electrocardiogram may show atrial tachyarrhythmias or evidence of right heart strain as shown by a new right bundle branch block or right ventricular strain pattern that mimics inferior myocardial infarction. The chest radiograph is often normal but may show atelectasis, isolated infiltrates, or a small pleural effusion, but in most cases, is not sufficiently sensitive to diagnose a pulmonary embolism.

Chest CT angiography is the main imaging modality used for the diagnosis of acute pulmonary embolism, although \dot{V}/\dot{Q} scan and pulmonary angiography are used in certain clinical settings (Fig. 18.1). CT angiography provides a noninvasive, rapid, and sensitive way to detect pulmonary emboli (E-Fig. 18.4), and most diagnostic algorithms combine CT pulmonary angiography with clinical suspicion, D-dimer determination, and assessment of the lower extremities for deep vein thrombosis by CT or ultrasound.

However, for individuals with absolute or relative contraindications to CT angiography, the \dot{V}/\dot{Q} scan provides an alternative approach. A *high-probability* \dot{V}/\dot{Q} scan, characterized by multiple perfusion defects in areas of normal ventilation, is more than 90% accurate in diagnosing pulmonary embolism. A *normal* \dot{V}/\dot{Q} scan excludes pulmonary embolism in essentially all cases. The test is less reliable when interpreted as *low*, *intermediate*, or *indeterminate* probability. In these circumstances, pulmonary embolism is observed in 4% to 66% of patients, and in these situations the diagnostic certainty depends on the pretest probability of pulmonary embolism. With improvements in CT angiography, pulmonary angiography is now performed very infrequently but could be considered when other tests are inconclusive, a high likelihood of pulmonary embolism exists, and there is a need for diagnostic certainty.

Risk Stratification and Treatment

Once acute pulmonary thromboembolism is diagnosed, risk stratification is essential to guide treatment decisions. This typically incorporates

E-Fig. 18.4 Computed tomography angiography shows a saddle embolus entering both right and left (*arrow*) pulmonary arteries. (Courtesy Dr. Charles Kuhn.)

clinical appearance, vital signs, validated PE risk scores, and RV function assessed by imaging modalities and cardiac biomarkers. Acute PE that causes hemodynamic instability is referred to as massive PE or high-risk PE and warrants immediate consideration of reperfusion therapies. In acute PE patients who present without shock or hemodynamic instability, multimodal risk stratification is used to identify patients at low and intermediate risk, the latter typically defined by signs of RV dysfunction on CT or echocardiography, or elevated levels of troponin or B-type natriuretic peptide (BNP).

Treatment of acute PE centers on supportive care, systemic anticoagulation, and consideration of reperfusion therapy. Unless there are contraindications, systemic anticoagulation should be started after the diagnosis of acute PE is established. Intravenous unfractionated heparin or subcutaneous low-molecular-weight heparin (LMWH) are typically the preferred agents. For patients with a contraindication to anticoagulation, an inferior vena cava filter should be placed. Reperfusion therapies include systemic thrombolysis and surgical thrombectomy and are indicated in massive PE. The use of systemic thrombolytics in intermediate risk PE remains controversial and is not practiced routinely. Catheter-directed thrombolysis and catheter embolectomy are other available reperfusion therapies that are less well studied and not recommended for routine use.

After stabilization and clinical improvement, patients are transitioned to their long-term anticoagulation therapy. Options for anticoagulation include vitamin K antagonists such as warfarin, non-vitamin K oral anticoagulants (NOACs), such as apixaban or rivaroxaban, or LMWH. NOACs have increasingly become the preferred oral anticoagulant due to their safety profile and ease of use, but risks and benefits of each agent should be discussed with patients to allow for individualized decision making. Duration of anticoagulation for an acute pulmonary embolism is at least 3 months, after which extended therapy can be considered based on clinical risk factors (e.g. provoked vs. unprovoked event) and bleeding risk.

Chronic Thromboembolic Pulmonary Hypertension

Chronic thromboembolic pulmonary hypertension (CTEPH) is a distinct type of pulmonary hypertension, classified as WHO group 4 PH. CTEPH is characterized by incomplete or abnormal resolution of acute pulmonary thromboembolism such that residual emboli become organized and fibrotic. This develops in approximately 4% of patients after acute pulmonary embolism. However, nearly half of CTEPH cases occur in patients without a prior history of venous thromboembolism. The diagnosis of CTEPH requires precapillary pulmonary hypertension on RHC in the presence of chronic/organized flow limiting thrombi/emboli in the elastic pulmonary arteries after at least 3 months of effective anticoagulation (E-Fig 18.5). Unlike other forms of pulmonary hypertension, the mainstay of treatment is surgical. Pulmonary endarterectomy (PEA) is performed via median sternotomy with cardiopulmonary bypass, after which deep hypothermic circulatory arrest allows for visualization, identification of the dissection plane, and complete endarterectomy. PEA is often curative, and is associated with improved symptoms, hemodynamics, and survival.

In patients for whom PEA is not feasible, medical therapy with pulmonary vasodilators, namely riociguat, has been shown to be effective in improving hemodynamics and functional capacity. Balloon pulmonary angioplasty is an emerging therapeutic option for CTEPH patients with inoperable disease or in whom the risk-to-benefit ratio of PEA is not favorable.

PROSPECTUS FOR THE FUTURE

Numerous advances in our understanding of pulmonary vascular biology over the last 35 years have markedly enhanced understanding of the pathogenesis of pulmonary hypertensive disorders and have led to the development of therapies that slow disease progression, increase functional capacity, and increase quality of life. However, most pulmonary vascular diseases are not curable and result in decreased survival. New therapies designed to prevent the loss of healthy vessels and reverse vascular remodeling are needed before substantial gains in disease reversal and cure can be achieved. Cellular mechanisms that regulate endothelial apoptosis, angiogenesis, and perivascular inflammation appear to have potential as future therapeutic targets. Modulation of sex hormones, cellular bioenergetics, and epigenetic factors may be other promising approaches. Little is understood about the adaptive changes of the right ventricle to chronically increased afterload. Furthermore, studies are needed in the area of genetic predisposition to thromboembolic disease and vascular dysfunction leading to thrombus formation as well as the determination of appropriate follow-up evaluation for patients after acute PE and who might benefit from screening for chronic thromboembolic disease. Finally, national studies currently underway that seek to provide deep phenotyping of pulmonary vascular disease and establish national biobanks and patient registries should provide important tools to help investigators find more effective therapies for these devastating diseases.

Disorders of the Pleura, Mediastinum, and Chest Wall

Eric J. Gartman, F. Dennis McCool

PLEURAL DISEASE

The pleura is a thin membrane that covers the entire surface of the lung, inner surface of the rib cage, diaphragm, and mediastinum. There are two pleural membranes: the visceral pleura, which covers the lung; and the parietal pleura, which lines the rib cage, diaphragm, and mediastinum. A layer of mesothelial cells lines both pleural surfaces. The closed space in between the surface of the lung and the chest cavity is called the *pleural space*. A small amount of fluid normally resides in this space and forms a thin layer between the pleural surfaces. Pleural fluid serves as a lubricant for the visceral and parietal pleurae as they move against each other during inspiration and expiration.

The blood vessels in the visceral pleura are supplied from the pulmonary circulation and have less hydrostatic pressure than the blood vessels in the parietal pleura, which are supplied by the systemic circulation. The pressure in the pleural space is subatmospheric during quiet breathing. Fluid is filtered from the higher-pressure vascular structures into the pleural space. The normal fluid turnover is about 10 to 20 mL per day, with 0.2 to 1 mL remaining in the pleural space. Pleural fluid usually contains a small amount of protein and a small number of cells that are mostly mononuclear cells. Although both parietal and visceral pleurae contribute to pleural fluid formation, most of the fluid results from filtration of the higher-pressure vessels supplying the parietal pleura.

After the fluid enters the pleural space, it is drained from the pleural space by a network of pleural lymphatics located beneath the mesothelial monolayer. The lymphatics originate in stomas on the parietal pleural surface. In abnormal circumstances of increased fluid production or impaired removal, fluid can accumulate in the pleural space. Factors that promote the entry of fluid into the pleural space include an increase in systemic venous pressure, an increase in pulmonary venous pressure, an increase in permeability of pleural vessels, and a reduction in pleural pressure. Conditions that increase hydrostatic pressure can be seen in congestive heart failure; changes in pleural membrane permeability can be seen in various inflammatory states or malignancy; and a reduction in pleural pressure can be seen with atelectasis. Occasionally, microvascular oncotic pressure may be sufficiently reduced to promote fluid entry into the pleural space in patients with hypoalbuminemia. Factors that block lymphatic drainage and interfere with the egress of fluid from the pleural space include central lymphatic obstruction and obstruction of lymphatic channels at the pleural surface by tumor.

Pleural Effusion

Pleural effusion is the accumulation of fluid in the pleural space. Pleural effusions usually are detected by chest radiography; however, the volume of fluid in the pleural space must exceed 250 mL to be visualized

on a chest radiograph. When an effusion exists, there is blunting of the costophrenic angle on a posteroanterior chest film, which represents a fluid meniscus that can be detected posteriorly on the lateral chest radiograph, and fluid occasionally can be demonstrated in the minor or major fissures (E-Figs. 19.1 and 19.2). Apparent elevation or changes in the contour of the diaphragm on a posteroanterior chest film may signify a subpulmonic effusion, so called because it retains the general shape of the diaphragm without blunting the costophrenic angle; however, it is evident on the lateral film.

A decubitus chest radiograph can be obtained to determine whether the fluid is free flowing or loculated. Computed tomography (CT) of the chest provides better definition of the pleural space than plain radiography. Chest CT is particularly useful in defining loculated effusions and in differentiating pulmonary parenchymal abnormalities from pleural abnormalities, atelectasis from effusion, and loculated effusion from lung abscess or other parenchymal processes (E-Fig. 19.3). The edge of a parenchymal process usually touches the chest wall and forms an acute angle (0-90 degrees), whereas that of an empyema is usually an obtuse angle (90-180 degrees).

Thoracentesis is a procedure in which fluid is aspirated from the pleural space. To help minimize procedural complications and assist in needle placement, ultrasound or CT guidance should be used to direct the thoracentesis catheter into the pleural space.

Classifying pleural effusions as transudates or exudates greatly assists with the differential diagnosis. The approach to pleural effusions is outlined in E-Fig. 19.4. Further analysis of pleural fluid may provide a definitive diagnosis (e.g., malignancy); however, even without a definitive diagnosis, pleural fluid analysis can be useful in excluding possible causes of disease such as infection.

Transudates

Effusions that accumulate due to changes in oncotic and hydrostatic forces usually have a low protein content and are called *transudates* (Table 19.1). Congestive heart failure is the most common cause of a transudate, and the effusions are typically bilateral. If the effusion is unilateral, it involves the right hemithorax in most instances. Effusions due to heart failure almost universally are related to dysfunction of the left side of the heart, although they rarely can result from right heart failure (e.g., advanced pulmonary arterial hypertension).

Transudative effusions may be seen in cirrhosis, nephrotic syndrome, myxedema, pulmonary embolism, superior vena cava obstruction, and peritoneal dialysis. In patients with cirrhosis, the effusions are often right-sided, and the mechanism may be related to flow from the peritoneal space across diaphragmatic defects into the pleural space (i.e., hepatic hydrothorax). Transudative effusions are typically small to moderate sized and rarely require drainage to improve symptoms.

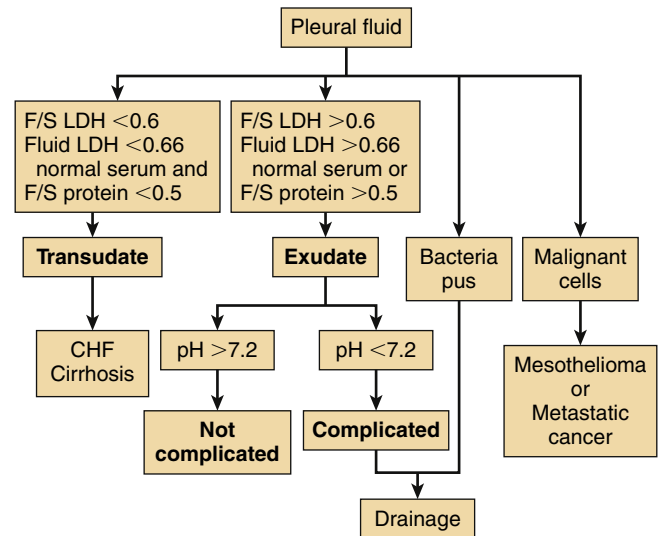

E-Fig. 19.1 Posteroanterior and lateral chest radiographs show a large, right pleural effusion (arrow) and left upper lobe mass (double arrows).

E-Fig. 19.2 Computed tomography of the patient in E-Fig. 19.1 shows a large, right pleural effusion (arrow) and left upper lobe mass (double arrows).

E-Fig. 19.3 Computed tomography demonstrates a pleural effusion (arrow) and atelectasis (double arrows).

E-Fig. 19.4 Work-up for pleural effusion. CHF, Congestive heart failure; F/S, fluid/serum; LDH, lactate dehydrogenase.

TABLE 19.1 Causes of Pleural Effusions

Conditions Associated With Transudates

Ascites
 Cirrhosis
 Congestive heart failure
 Hypoalbuminemia
 Intra-abdominal fluid
 Malnutrition
 Nephrotic syndrome
 Peritoneal dialysis

Conditions Associated With Exudates

Asbestosis
 Chylothorax
 Collagen vascular disease
 Complications of abdominal surgery
 Dressler's syndrome (myocardial infarction, cardiomy)
 Drug-induced lupus
 Empyema
 Hemothorax
 Infection
 Intra-abdominal pathologic abnormalities (abscess)
 Lymphedema
 Malignancy (primary lung cancer, lymphoma, metastatic cancer)
 Meigs' syndrome (benign ovarian tumor)
 Myxedema
 Pancreatitis
 Parapneumonic causes (pneumonia, lung abscess, bronchiectasis)
 Pulmonary embolism and infarction
 Rheumatoid arthritis (pleurisy)
 Ruptured esophagus
 Subphrenic abscess
 Systemic lupus erythematosus
 Trauma
 Uremia
 Urinothorax

Exudates

Exudative effusions occur when there is an alteration in vascular permeability or pleural fluid resorption. They can be observed in inflammatory, infectious, or neoplastic conditions.

To distinguish an exudate from a transudate, one of three criteria must be fulfilled: (1) An exudate must have a pleural fluid-to-serum protein ratio greater than 0.5; (2) a pleural fluid-to-serum lactate dehydrogenase (LDH) ratio must be greater than 0.6; or (3) a pleural fluid LDH level must be greater than two thirds of the upper limit of normal (Table 19.2). When all three criteria are met, the sensitivity, specificity, and positive predictive value exceed 98% for defining an exudative effusion.

Measuring pleural fluid cholesterol may also help to distinguish an exudate from a transudate. Pleural fluid cholesterol is derived from degenerating cells within the pleural space and from vascular leakage due to increased permeability. A cholesterol level greater than 45 mg/dL is consistent with an exudative effusion.

Exudative effusions are commonly caused by infection. Parapneumonic effusion typically occurs in patients with bacterial pneumonia and can be further classified as an uncomplicated or complicated effusion.

TABLE 19.2 Differentiation of Exudative and Transudative Pleural Effusions

Characteristic	Exudate	Transudate
Pleural fluid-to-serum protein ratio	>0.5	<0.5
Pleural fluid LDH level	> $\frac{2}{3}$ of the upper limit of normal	< $\frac{2}{3}$ of the upper limit of normal
Pleural fluid-to-serum LDH ratio	>0.6	<0.6

LDH, Lactate dehydrogenase.

Uncomplicated parapneumonic effusions do not require drainage and respond to antibiotic therapy alone used for treatment of the underlying pneumonia. In contrast, complicated parapneumonic effusions do not respond to antibiotic therapy alone and require drainage to prevent the formation of an empyema. The transition from uncomplicated to complicated can occur extremely rapidly, within a 24-hour period in some cases.

Typically, an uncomplicated parapneumonic effusion has a pH level greater than 7.3, a glucose level greater than 60 mg/dL, and an LDH level less than 1000 IU/L. A pH level of less than 7.2 usually identifies a complicated effusion. However, this finding is not specific for infection, and the cause may be malignancy, rheumatoid arthritis, or trauma with esophageal disruption causing an associated reduction in pH level.

Complicated exudative effusions require drainage to avoid development of loculation, cutaneous fistulas, bronchopleural fistulas, or fibrothorax. The findings of pus or bacteria by Gram stain or culture confirms the diagnosis of empyema and requires immediate drainage. The injection of fibrolytic agents and DNase into the pleural space can augment full drainage of infected pleural effusions; however, treatment of complicated pleural effusions occasionally requires surgical intervention and lung decortication.

Primary tuberculosis in endemic areas may be associated with pleural effusion in up to 30% of patients. The effusion is caused by increased vascular permeability of the pleural membrane because of a hypersensitivity reaction, not direct infection. Typically, the pleural fluid is lymphocyte predominant and acid-fast stain and culture negative. Adenosine deaminase levels greater than 50 U/L may be helpful in identifying tuberculous pleural effusions. Tuberculous empyema is distinct from a tuberculous pleural effusion and can occur when there is an extension of infection from the thoracic lymph nodes into the pleural space or hematogenous spread of tuberculosis to the pleural space.

Malignant effusions are the second most common cause of exudative pleural effusions and confer a poor prognosis. Seeding of the parietal or visceral pleura with malignant cells can change vascular permeability and impede resorption, resulting in effusion formation. However, the finding of a pleural effusion in an individual with malignancy does not necessarily imply that there is a malignant process in the pleural space. Effusions in these individuals may be caused by atelectasis, postobstructive pneumonia, hypoalbuminemia, pulmonary emboli, or complications from irradiation or chemotherapy.

The most common cause of malignant effusion is lung cancer, followed by breast cancer and lymphoma. An effusion that is bloody suggests a malignant process; however, other causes of bloody pleural effusions include trauma, asbestos exposure, tuberculosis, collagen vascular disease, and thromboembolic disease. To confirm the diagnosis of malignancy, cytologic examination of the fluid is needed. Malignant cells can be seen in 60% of malignant effusions on the first thoracentesis. Sensitivity rises to 80% if three separate samples are obtained. If needed, a biopsy

of the pleura may be useful in identifying a malignancy. Biopsies may be obtained via medical thoracoscopy, surgical video-assisted thoracoscopy or, less optimally, in a blinded fashion through a Cope or Abrams needle.

A low pleural fluid pH has prognostic and therapeutic implications for patients with malignant effusions. Patients with a low pleural fluid pH due to malignancy tend to have shorter survival times and poorer responses to chemical pleurodesis. Recurrent malignant pleural effusions may improve with chemical pleurodesis with talc or tetracycline derivatives, but effectiveness varies and a complete response is achieved in little more than 50% of patients. Alternatively, many patients with recurrent malignant effusions have tunneled indwelling pleural catheters placed, allowing intermittent drainage, relief of symptoms, and possibly mechanical pleurodesis over time.

Systemic inflammatory disorders such as rheumatoid arthritis and lupus erythematosus can be associated with exudative effusions. Rheumatoid pleural effusions are a common intrathoracic manifestation of rheumatoid disease and may be seen in as many as 5% of patients. Rheumatoid factor titers in pleural fluid are often greater than 1:320, and the pleural fluid glucose level is less than 60 mg/dL (or the pleural fluid-to-serum glucose ratio is less than 0.5). However, a low glucose level also may be found in complicated parapneumonic effusions or empyema, malignant effusion, tuberculosis pleurisy, lupus pleuritis, and esophageal rupture. In systemic lupus erythematosus, 15% to 50% of patients have pleural effusions, and the pleural fluid antinuclear antibody titer is greater than 1:160.

Measuring pleural fluid amylase concentrations may further refine the differential diagnosis for an exudative effusion. Finding a pleural amylase level greater than the upper limit of normal for serum amylase is consistent with acute pancreatitis, chronic pancreatic pleural effusion, esophageal rupture, or malignancy. Pancreatic disease is associated with pancreatic amylase isoenzymes, whereas malignancy and esophageal rupture are characterized by a predominance of salivary isoenzymes.

Pneumothorax

Pneumothorax is the accumulation of air in the pleural space. In this instance, pleural pressure becomes positive and there is compression of underlying lung. Patients with pneumothorax typically have acute onset of dyspnea. Findings include tachycardia, decreased breath sounds, decreased tactile fremitus, a pleural friction rub, subcutaneous emphysema, hyperresonance, and a tracheal shift to the opposite side.

The diagnosis can be made by obtaining an upright chest radiograph, and rapid assessment can be achieved with point-of-care ultrasound. Typically, the visceral pleura separates from the parietal pleura, and air can be seen between the visceral pleural lining and the rib cage. An end-expiratory radiograph increases the density of lung while reducing its volume, highlighting the difference between the lung parenchyma and the pleural gas.

Management of a significant pneumothorax usually requires insertion of a thoracostomy tube and suction followed by water-seal drainage. However, if the pneumothorax is small and the patient is not in distress, observation alone may be indicated. If there is not a continuing air leak, as from a bronchopleural fistula, the pleural air is reabsorbed into the blood with resolution of the pneumothorax.

A tension pneumothorax is a medical emergency that requires immediate decompression by placement of a chest catheter. A tension pneumothorax occurs when pleural pressure reaches levels sufficient to cause mediastinal shift, compression of the vena cava and heart, and hemodynamic compromise. This physiology implies an ongoing leak of air into the pleural space.

Pneumothorax is often associated with blunt or penetrating trauma. With penetrating trauma, air may leak into the pleural space through the chest wall or the lung. Mechanical ventilation has also

been associated with pneumothorax. Patients with underlying lung disease receiving mechanical ventilation may acutely develop a pneumothorax. A sudden rise in peak airway pressures with a reduction in breath sounds can alert the clinician to this complication.

Pneumothorax may occur spontaneously or result secondarily from underlying lung disease. Typically, spontaneous pneumothorax occurs in tall, young, thin men, presumably a result of rupture of apical blebs. Underlying lung diseases that can be complicated by pneumothorax include emphysema, cystic fibrosis, granulomatous inflammation, necrotizing pneumonia, pulmonary fibrosis, and lung abscess. Catamenial pneumothorax occurs in women who have subpleural and diaphragmatic endometriosis, with rupture of the endometrial nodules at the time of menstruation causing pneumothorax.

Mesothelioma

Malignant mesotheliomas are neoplasms arising from the serosal membranes of the body cavities. Eighty percent of mesotheliomas originate in the pleura. Individuals usually are older than 55 years, and there is an association with asbestos exposure in the distant past. Symptoms include shortness of breath, chest pain, and weight loss.

The most common radiologic finding is a large, unilateral pleural effusion that may completely opacify the hemithorax. There may be circumferential pleural thickening, usually associated with various amounts of calcified pleural plaque and effusions. CT of the chest is the most accurate noninvasive method for assessing stage and progression of mesothelioma. Pleural fluid cytology frequently is insufficient for diagnosis, and the most efficient way of obtaining tissue is by CT-guided core biopsy or thoracoscopy.

The overall prognosis for patients with malignant mesothelioma is poor. No particular therapy has emerged as superior to supportive therapy alone in terms of survival.

MEDIASTINAL DISEASE

Lesion Location

The mediastinum is the central part of the thoracic cavity between the lungs that contains the heart and aorta, esophagus, trachea, lymph nodes, and thymus. The mediastinum is bordered by the two pleural cavities laterally, the diaphragm inferiorly, and the thoracic inlet superiorly. The mediastinal space can be divided into three compartments: anterior, middle, and posterior. The localization of mediastinal masses in one of these compartments assists in the differential diagnosis (Fig. 19.1).

The anterior mediastinal compartment is anterior to the pericardium and includes lymphatic tissue, the thymus, and the great veins. Lesions most commonly found in the anterior mediastinum are thymomas, germ cell tumors, lymphomas, intrathoracic thyroid tissue, and parathyroid lesions. Thymomas comprise 20% of mediastinal neoplasms in adults, and they are the most common anterior mediastinal primary neoplasm in adults. Symptoms due to myasthenia gravis may affect one third of patients with thymomas. Middle mediastinal lesions include tracheal masses, bronchogenic and pericardial cysts, enlarged lymph nodes, and proximal aortic disease (i.e., aneurysm or dissection). Posterior mediastinal masses include neurogenic tumors and cysts, meningocele, lymphoma, aneurysm of the descending aorta, and esophageal disorders such as diverticula and neoplasms.

Patients with systemic lymphoma often have mediastinal involvement, and 5% to 10% of patients with lymphoma have primary mediastinal lesions at clinical presentation. Mediastinal cysts can arise in the pericardium, bronchi, esophagus or stomach, thymus, and thoracic duct, and although benign, they can produce compressive symptoms. Lung cancer often presents with metastatic mediastinal adenopathy and is a sign of advanced stage.

Fig. 19.1 Masses of the mediastinum and their anatomic locations.

Treatment of a mediastinal mass depends on the underlying pathology. Many require surgical resection, irradiation, chemotherapy, or careful monitoring over time.

Mediastinitis

Inflammation of the mediastinal structures can be acute or chronic. Acute mediastinitis is a rapidly progressive condition due to infection, and it most commonly complicates cardiothoracic surgical procedures or occurs as a result of trauma. Chest imaging studies may show a widening of the mediastinum, pneumothorax, or hydrothorax. Treatment requires microbiological identification, antibiotics, pleural drainage, and mediastinal evacuation.

Chronic mediastinitis (i.e., fibrosing mediastinitis) is a progressive illness that results from fungal or granulomatous infections, neoplasms, radiotherapy, occasionally drugs (such as methysergide), or it may be idiopathic. Patients usually remain asymptomatic until vascular, respiratory, or neurologic structures are affected; tracheobronchial narrowing is the most common manifestation. Diagnosis and treatment often require surgical intervention, although no treatment is highly successful.

CHEST WALL DISEASE

The chest wall is composed of the bony structures of the rib cage, the articulations between the ribs and the vertebrae, the diaphragm, and other respiratory muscles. Normal function of this ventilatory pump is needed to bring oxygen from the atmosphere into the body. A wide variety of chest wall and neuromuscular disorders can result in dysfunction of the ventilatory pump. These disorders typically result in a restrictive dysfunction characterized by a reduction in total lung capacity and vital capacity with a normal residual volume. Hypoventilation may ensue, resulting in hypercapnia, atelectasis, and hypoxemia.

Fig. 19.2 Schematic depiction of the lines constructed to measure the Cobb angle of scoliosis (A) and kyphosis (B).

Skeletal Disease

Kyphoscoliosis and ankylosing spondylitis are disorders that involve the spine and its articulations. Pectus excavatum involves the sternum, flail chest affects the ribs, and obesity adds to the soft tissue mass of the chest wall. These disorders primarily affect the respiratory system by stiffening its tissues. Of these disorders, kyphoscoliosis produces the most severe restrictive impairment, and ankylosing spondylitis and pectus excavatum cause little respiratory compromise.

Kyphoscoliosis refers to a group of disorders characterized by excessive spinal curvature in the lateral plane (i.e., scoliosis) and sagittal plane (i.e., kyphosis). The degree of curvature can be assessed by measuring the Cobb angle (Fig. 19.2). Greater degrees of spinal curvature are associated with greater restriction and an increased risk of respiratory failure (E-Fig. 19.5).

Kyphoscoliosis may be idiopathic, caused by neuromuscular disease, or associated with congenital vertebral malformations. Idiopathic kyphoscoliosis is the most common form, usually manifesting in late childhood or early adolescence and affecting females more than males (ratio of 4:1). It is thought to be a multigene condition with an autosomal or sex-linked inheritance pattern and variable phenotypic expression. A defect in the chromatin-remodeling gene (*CHD7*) has been associated with idiopathic kyphoscoliosis.

For a given degree of spinal deformity, individuals with kyphoscoliosis due to a neuromuscular disease have more respiratory impairment than those with idiopathic kyphoscoliosis. Factors that contribute to respiratory failure in patients with kyphoscoliosis include inspiratory muscle weakness, underlying neuromuscular disease, sleep-disordered breathing, and airway compression due to distortion of lung parenchyma and twisting of airways.

Treatment consists of general supportive measures such as immunizations against influenza and pneumococci, smoking cessation, maintenance of a normal body weight, supplemental oxygen, and treatment of respiratory infections. It is important to recognize nocturnal hypoventilation because it can be treated with noninvasive positive-pressure ventilation. This is typically delivered through a nasal or full face mask. Indications for instituting noninvasive ventilation include symptoms suggesting nocturnal hypoventilation, signs of cor pulmonale, nocturnal oxymoglobin desaturation, or an elevated daytime Paco_2 .

Obesity

Obesity is a major health problem that affects children and adults throughout the world. Body fat usually constitutes 15% to 20% of body mass in healthy men and 25% to 30% of body mass in healthy women. In cases of obesity, the body fat content may increase by as much as 500% in women and 800% in men. The degree of obesity can be assessed by the body mass index, which is the ratio of body weight (BW) in kilograms to the square of the height (Ht) in meters (BW/Ht^2). Individuals with a BMI between 18.5 and 24.9 kg/m^2 are normal, and those with a BMI greater than 40 kg/m^2 are considered severely or morbidly obese.

E-Fig. 19.5 A patient with post-polio syndrome had severe kyphoscoliosis, and Harrington rods were placed to correct the spinal curvature.

Reductions in functional residual capacity and expiratory reserve volume are the most common pulmonary function abnormalities in obesity, whereas vital capacity and total lung capacity may be only minimally reduced. Obesity promotes breathing at low lung volumes, which reduces lung compliance and increases the work of breathing. A subgroup of individuals with obesity hypoventilate and become hypercapnic. When obesity is associated with hypoventilation, it is called the obesity-hypoventilation syndrome (i.e., Pickwickian syndrome). The mechanism underlying hypoventilation is unknown but may result from factors that reduce respiratory center chemosensitivity, such as hypoxia, sleep apnea, or adipokines such as leptin. The most important consequences of chronic hypoventilation are hypoxemia and pulmonary hypertension.

Nocturnal noninvasive positive-pressure ventilation can help to reverse these abnormalities. Weight loss is the optimal therapy, but it is not always attainable, and long-term weight loss maintenance is even more difficult. Pharmacotherapy or bariatric surgery should be considered for obese individuals who do not achieve weight control with conventional methods (i.e., diet, enhanced physical activity, and behavioral therapy).

Diaphragm Paralysis

The diaphragm separates the thorax from the abdomen and is the major muscle of inspiration. Diaphragm weakness or paralysis can involve one or both hemidiaphragms. Unilateral diaphragm paralysis is more common than bilateral diaphragm paralysis. The most frequent causes of unilateral paralysis include traumatic phrenic nerve injury, herpes zoster infection, cervical spinal disease, and compressive tumors. Patients may be asymptomatic, or the abnormality may be discovered as an incidental finding of an elevated hemidiaphragm on a chest radiograph (Fig. 19.3). The diagnosis is confirmed by seeing on fluoroscopy a paradoxical upward motion of the affected diaphragm during a vigorous sniff maneuver. There is no specific treatment for this disorder, but recovery after the initial injury occasionally occurs. When the patient has disabling symptoms and significant elevation of the diaphragm is seen on the chest radiograph, surgical plication of the diaphragm may provide some relief of symptoms.

Bilateral diaphragm paralysis is most often seen in the setting of a disease producing generalized muscle weakness or motor neuron disease such as amyotrophic lateral sclerosis. Pulmonary function test results are associated with severe restrictive impairments. When the patient assumes the supine position, there may be a further reduction ($\leq 50\%$) in vital capacity. It is not surprising that orthopnea is an especially prominent symptom, and patients often have difficulty sleeping

Fig. 19.3 Computed tomography of a patient with unilateral right hemidiaphragm paralysis and associated right lower lobe atelectasis.

in the supine position. Patients also complain of dyspnea when bending or lifting objects.

Bilateral diaphragm paralysis can be difficult to diagnose. Restriction evidenced by pulmonary function test results is nonspecific, as is the finding of low lung volumes on chest radiographs. Fluoroscopic sniff testing (i.e., diaphragm fluoroscopy) can yield false-negative and false-positive results. Measurement of transdiaphragmatic pressure is the gold standard, but it is somewhat invasive, requiring placement of catheters in the esophagus and stomach. Alternatively, B-mode ultrasound of the diaphragm in the zone of apposition is a very useful noninvasive means of diagnosing diaphragm paralysis, as it can directly assess the thickening of the diaphragm muscle (or lack thereof).

Treatment should address the underlying disease, which may or may not be reversible. If paralysis is idiopathic or caused by neuralgic amyotrophy (i.e., brachial plexus neuritis), more than 50% of individuals may recover. Phrenic nerve pacing may be used in patients with spinal cord injuries above C3, and noninvasive positive-pressure ventilation can be used to treat patients with nocturnal hypoventilation. Diaphragm plication is not indicated in patients with bilateral diaphragm paralysis.

PROSPECTUS FOR THE FUTURE

Numerous advances can be expected in treating individuals with pleural, mediastinal, and chest wall diseases. Progress in pleural fluid analysis using novel biomarkers and nucleic acid amplification tests may lead to more rapid and accurate diagnosis of tuberculous pleural effusions. Assays of pleural fluid tumor markers and chromosome analysis are promising developments for the differentiation of malignant from nonmalignant effusions. Mesothelioma remains resistant to traditional therapeutic approaches, but evolving technology centered on gene therapy may produce a new treatment modality.

Better visualization of mediastinal structures can be achieved as magnetic resonance imaging (MRI) evolves and becomes more routinely applied to examination of the chest. Molecular tracers targeting tumor receptors or proteins may be used with MRI and positron emission tomography imaging techniques to better differentiate malignant from benign mediastinal masses.

Noninvasive nocturnal ventilation remains a cornerstone of therapy for patients with chest wall and neuromuscular diseases, but compliance can be problematic. Continued evolution of techniques to deliver nocturnal noninvasive ventilation may improve compliance with treatment, and application of this technique to patients with obesity-hypoventilation syndrome may reduce morbidity and mortality for them.

Patients with diaphragm paralysis due to high cervical spinal cord lesions may benefit from advances in intramuscular diaphragm pacing. This technique may provide an alternative means of treating respiratory failure in these individuals and others with diaphragm paralysis.

For a deeper discussion on this topic, please see Chapter 92, “Diseases of the Diaphragm, Chest Wall, Pleura, and Mediastinum,” in *Goldman-Cecil Medicine*, 26th Edition.

Respiratory Failure

Andrew E. Foderaro, Abhinav Kumar Misra

INTRODUCTION

The principle function of our lungs and respiratory system is gaseous exchange, absorption of oxygen and elimination of carbon dioxide produced by the body. Sudden inability to perform one or both of these functions leads to acute respiratory failure (ARF). Impairment of oxygen absorption will manifest as hypoxemia (arterial oxygen tension (P_{aO_2}) <55-60 mm Hg) where impairment of carbon dioxide elimination (ventilation) is manifested by hypercapnia and respiratory acidosis (arterial carbon dioxide tension (P_{aCO_2}) >45 mm Hg). ARF is one of the most common causes for admission to an intensive care unit (ICU). The annual incidence of ARF in the United States is around 330,000 cases and carries significant short-term and long-term morbidity and mortality. Mortality rises with age, comorbidities, shock, or the presence of multiorgan failure. With an aging population in the United States the incidence of ARF is expected to rise.

PATHOPHYSIOLOGY

Respiratory failure can be classified as acute when derangements happen over hours to days or chronic when derangements occur more slowly over a longer period of time. Acute on chronic implies acute deterioration in someone with preexisting chronic respiratory failure. The respiratory system consists of two distinct parts: the lung (the gas exchanging organ) with the lung parenchyma and alveolar capillary interface, and the ventilatory pump comprising the lung and the chest wall (the respiratory muscles and airways that control ventilation).

Respiratory control is maintained by central neuronal respiratory centers in the medulla oblongata including the dorsal (DRG) and ventral respiratory groups (VRG). The DRG stimulates the diaphragm and intercostal muscles to contract causing inspiration and when activity ceases results in expiration. The VRG is involved in the forced inspiration and expiration through accessory muscles. The second respiratory center is located in the pons and consists of the pneumotaxic and apneustic center. These neurons are involved in control of rate and depth of breathing. Along with the central control there are peripheral chemoreceptors located in carotid bodies as well as aortic bodies constantly monitoring acidity and P_{aO_2} levels. Upon stimulation of respiratory muscles, the muscles contract generating a negative (subatmospheric) intrapleural pressure. This establishes a pressure gradient leading to flow of air towards alveoli where oxygen diffuses across the alveolar-capillary interface and forms oxyhemoglobin. The oxygen delivery to tissues is not only dependent on respiratory mechanics but also on hemoglobin and cardiac output.

Efficient gas exchange in our lungs is dependent on alveolar ventilation and pulmonary blood flow. This ratio is known as the ventilation-perfusion (\dot{V}/\dot{Q}) ratio. When there is alveolar ventilation without blood flow and thus without gas exchange this is referred to as dead

space ventilation. Dead space consists of anatomic dead space (upper airway) as well as physiologic dead space (ventilation exceeding perfusion). In the case of physiologic dead space the \dot{V}/\dot{Q} ratio is approaching infinity. Increased physiologic dead space ventilation can be seen when the alveolar-capillary interface is disrupted such as in emphysema, when pulmonary blood flow is reduced such as in low cardiac output, or when alveoli are overdistended due to positive-pressure ventilation. Alternatively, blood flow exceeding ventilation could lead to a portion of blood flow not partaking in gas exchange leading to intrapulmonary shunt. True shunt is when the \dot{V}/\dot{Q} ratio is equal to 0. The fraction of cardiac output that does not partake in gas exchange is known as the shunt fraction, which is usually less than 10%. Increased shunt fraction can be seen when small airways are occluded (e.g., asthma), alveoli are collapsed (e.g., atelectasis), in alveolar filling diseases (e.g., pneumonia, pulmonary edema), or by bypassing the capillary bed (e.g., arteriovenous malformations).

Ideally, the oxygen that is present in the alveoli will equilibrate with the arterial blood. The difference between partial pressures of oxygen in alveolar space and arterial blood is known as the A-a gradient. This can be easily calculated with the help of the alveolar gas equation:

$$A-a \text{ gradient} = P_{AO_2} - P_{aO_2}$$

$$P_{AO_2} = P_{iO_2} - (P_{aCO_2}/RQ)$$

Here, P_{AO_2} represents partial pressure of oxygen in the alveolar space, P_{aO_2} represents partial pressure of oxygen in the arterial blood, P_{iO_2} is partial pressure of oxygen in inhaled gas, P_{aCO_2} is partial pressure of carbon dioxide in alveolar space, and RQ is the respiratory quotient (the ration of CO_2 production to O_2 consumption). In a healthy subject eating a mixed diet, the respiratory quotient is 0.8. Furthermore, P_{aCO_2} can be replaced by partial pressure of carbon dioxide in arterial blood (P_{aCO_2}) as CO_2 diffuses efficiently.

$$P_{A}O_2 = F_{iO_2} (P_A - P_{H_2O}) - (P_{aCO_2}/RQ)$$

F_{iO_2} is the fraction of oxygen, P_A is atmospheric pressure, and P_{H_2O} is partial pressure of water vapor. Thus, for a normal healthy young person breathing room air at sea level the A-a gradient equation would be as follows:

$$A-a \text{ gradient} = [F_{iO_2} (P_A - P_{H_2O}) - (P_{aCO_2}/RQ)] - P_{aO_2}$$

$$A-a \text{ gradient} = [0.21 (760 - 47) - 40/0.8] - 90 = 10$$

Of note, the A-a gradient increases as a function of age. When patients are ventilated, their mean airway pressure needs to be added to atmospheric pressure to factor in the positive-pressure ventilation.

TABLE 20.1 Classification of Respiratory Failure

Organ System	Disease Entity
Respiratory	Upper airway obstruction
	Airway obstructive disease
	COPD
	Asthma
	Pulmonary parenchyma
	Pneumonia
	ARDS
	ILD flare
	Pulmonary hemorrhage
	Alveolar proteinosis
Pulmonary Vascular	Pulmonary thromboembolism
	Pulmonary hypertension
	Right-to-left intrapulmonary shunts
Cardiac	Cardiogenic pulmonary edema
	Right-to-left intracardiac shunts
Neuromuscular	Myasthenia gravis
	ALS
Central Nervous System	Guillain-Barré syndrome
	Decrease respiratory drive
	Sedative medications
	Opioids
	Brain stem insult
	Space occupying lesion
	CVA
	Trauma

TABLE 20.2 Mechanisms That Cause Lower Partial Pressure in the Arterial Blood (PaO₂)

Etiologies of Hypoxia	Observed A-a Gradient
Low inspired oxygen	Normal
Hypoventilation	Normal
Ventilation-perfusion mismatch	Elevated
Shunt	Elevated
Diffusion Impairment	Elevated

CLASSIFICATION OF RESPIRATORY FAILURE

There are several ways to classify respiratory failure. A brief classification based on organ system can be found in [Table 20.1](#).

Type I Hypoxemic Respiratory Failure

Mechanisms that cause lower PaO₂ are listed in [Table 20.2](#). The first two mechanisms, low inspired oxygen and hypoventilation, lead to low PaO₂ through low P_AO₂, thus the A-a gradient is normal. It is usually easy to eliminate the first two mechanisms in the clinical setting. Hypoventilation can be ruled out if hypercarbia is not present on arterial blood gas as the elevated P_ACO₂ leads to increased P_ACO₂ and lower PaO₂ (see the alveolar gas equation above).

The other three mechanisms result in an elevated A-a gradient. V/Q mismatch and shunt are essentially a part of the same spectrum with shunt reflecting the extreme version of V/Q mismatch. Administering supplemental oxygen will improve PaO₂. Supplemental oxygen cannot correct hypoxemia induced by pure shunt because the blood is completely bypassing the alveoli either physically or functionally. Impaired

diffusion is usually not clinically very important because oxygen transport across the alveolar-capillary interface is not diffusion limited even in individuals with preexisting interstitial disease.

Type II Hypercarbic Respiratory Failure

This represents incapability of the lungs to remove a sufficient amount of CO₂, due to either lower alveolar ventilation or, less commonly, higher production of carbon dioxide due to hyper-metabolic states such as sepsis, overfeeding, or fever. Minute ventilation is the product of respiratory rate and tidal volume. The dead space ventilation, both anatomic (in upper airways) and physiologic (areas where ventilation exceeds perfusion), does not take part in elimination of CO₂. Total alveolar ventilation is determined by the difference between total minute ventilation and dead space ventilation. As a result, both decreased tidal volume and increased dead space will lead to hypercarbia.

There are three major causes of ventilatory or hypercarbic failure: (1) Reduced central respiratory drive due to sedatives, drug overdoses or pathologic state of the medulla; (2) Mechanical defect in the chest wall (e.g., kyphoscoliosis, flail chest), disorders of the nerves or neuromuscular junctions such as myasthenia gravis, amyotrophic lateral sclerosis, or disorders of the respiratory muscles (e.g., myopathies); (3) Muscular fatigue usually seen when working against increased inspiratory load such as when hyperinflation is present or increased rate such that these muscles are no longer able to generate sufficient negative pleural pressure to maintain tidal volumes or required respiratory rate. Various etiologies of acute hypercarbic respiratory failure are summarized in [Table 20.3](#).

TABLE 20.3 Causes of Hypercarbic Respiratory Failure

Etiology	Clinical Situation	
Depressed CNS drive	Drugs: sedatives, opioids	
	Brain stem/medulla lesions	
	Sleep-disordered breathing	
	Hypothyroidism	
	Neuromuscular transmission impairment	Spinal cord injury
		Phrenic nerve injury
		Demyelinating illness: ALS
		Neurotoxins: tetanus, botulism
		Neuromuscular junction disorders (e.g., myasthenia gravis, organophosphate poisoning)
		Muscle abnormalities: degenerative myopathies
Chest wall disease		Kyphoscoliosis
		Flail chest
		Obesity
		Pleural disruption: pneumothorax, pleural effusion
	Diaphragmatic rupture	
	Pulmonary disease	Upper airway obstruction
		Obstructive diseases
		Asthma
		COPD
		Alveolar filling process
Pulmonary edema		
Atelectasis		
Pulmonary thromboembolism		
Bronchiectasis		

Clinical Manifestations

Common clinical manifestations of acute respiratory failure include tachycardia, tachypnea, anxiety, and cyanosis. For a patient to have cyanosis they must have 3 to 5 g/dL of deoxygenated hemoglobin, which usually corresponds to 80% peripheral capillary oxygen saturation (SpO_2). Patients may not be tachypneic if they are medicated with sedatives or opioids. Altered mental state is also a common finding. In the setting of acute hypercarbia, patients may experience increased somnolence, headaches, slurred speech, and eventually coma.

Chest radiography is an essential tool and shows one of three findings: (1) Normal or relatively normal, in which case etiologies such as airway disorders, right-to-left shunts, pulmonary embolism, and neuromuscular disorders come to the forefront; (2) Focal infiltrates as are seen with pneumonia or aspiration; (3) Diffuse infiltrates as can be seen in acute respiratory distress syndrome (ARDS) and interstitial lung disease flares. Initial evaluation for suspected respiratory failure should also include blood gas testing evaluating for presence of hypoxia. If hypoxia is present, calculating the A-a gradient can help point us in the direction of etiologic process. If a patient is hypercarbic, is that enough to cause hypoxemia? In this case, A-a gradient should remain normal. If A-a gradient is elevated it is likely \dot{V}/\dot{Q} mismatch or shunt is playing a role. These are usually the most common causes of respiratory failure.

Principles of Management

The differential diagnoses for acute respiratory failure are extensive; hence the specific management strategies depend on correcting the underlying cause. As part of the initial management it should be ensured that the airway is patent and the patient is breathing and has stable circulation. Strategies to supplement oxygen and improve oxygenation and ventilation remain cornerstones of supportive care until the etiology resolves.

Oxygen Delivery Systems

A large number of oxygen delivery systems exist. Each of these systems is characterized by the mechanism of delivery, some of which limit the concentration of oxygen (FiO_2) that can be delivered. Normal inspiratory flow rate at rest is 15 L/min, which is intermixed with the flow provided by the O_2 delivery device. Nasal cannula is one of the most commonly and widely accepted delivery systems. These provide 1 to 6 L/min of 100% FiO_2 , which is mixed with room air. At rest these can provide an FiO_2 of 24% to 40% (nasal cannula oxygen intermixed with room air). Even though this modality is widely accepted by patients, its use has limitations in the acute setting due to inability to achieve high concentrations of FiO_2 . Standard face masks are reservoir systems with 100 to 200 mL of reservoir around the patient's face. These use 5 to 10 L of flow to provide 35% to 50% FiO_2 to patients, which is variable depending upon the flow rate at which the patient is actually breathing. These need a minimum flow of around 5 L to clear exhaled gases. When an air entrainment device is attached, the FiO_2 can be regulated regardless of the flow. Air entrainment works by creating a high velocity stream of gas by narrowing the outlet of the oxygen, creating a pull that leads to room air getting mixed with oxygen. The greater the flow, the greater the force to pull room air, therefore keeping FiO_2 constant. This phenomenon was earlier thought to be due to the Venturi effect, lending these masks the name Venturi masks or Venti masks. These masks provide 24% to 50% FiO_2 in a constant fashion irrespective of the flow rates.

Non-rebreather masks are another form of reservoir system with attached reservoir bags of 600 to 1000 mL. As long as the bag is inflated, patients breathe air primarily contained in the bag. The masks are equipped with one-way expiratory ports to allow expired air to leave but don't allow room air to mix with oxygen in the reservoir bag. In ideal settings these masks can provide high FiO_2 up to 100%; however, due to leaks because of inadequate seal the true FiO_2 is often closer to 80%.

TABLE 20.4 Physiologic Benefits of HFNC

Improved oxygenation
Decreased anatomic dead space
Decreased carbon dioxide generation
Generation of positive nasopharyngeal and tracheal airway pressure
Increased lung volumes
Improved work of breathing
Preconditioning of inspired gas (heated and humidified)
Better secretion clearance
Superior comfort
Reduced room air entrainment

High-Flow Nasal Cannula

High-flow nasal cannula (HFNC) can provide up to 40 to 60 L/min of heated and humidified gas. An oxygen blender connected to the circuit enables precise titration of FiO_2 ranging from 21% to 100%. In order to actually match this to alveolar FiO_2 , flow from the HFNC should be equal to the patient's flow. HFNC also creates a flow-dependent clearance of carbon dioxide from upper airways. In randomized trials HFNC has been shown to generate positive airway pressure between 0.35 (mouth open) and 0.69 (mouth closed) cm H_2O of pressure for every 10 L/min of flow. This pressure is higher in the expiratory phase of respiration, almost behaving like positive end-expiratory pressure (PEEP). It helps in recruitment of alveoli and may be more pronounced in people with higher BMI. HFNC has been shown to improve lung compliance, reduce respiratory rate, and increase tidal volume by as much as 10%. The heated and humidified nature of inhaled gas leads to increased mucociliary clearance as shown in patients with bronchiectasis. Physiologic effects of HFNC are summarized in [Table 20.4](#).

The principles and mechanism of action make HFNC a very promising oxygen delivery device. In multiple prospective observational studies, it has been associated with reduction in respiratory rate, heart rate, use of accessory muscles, and dyspnea scores in ICU patients and is often better tolerated than bilevel positive airway pressure ventilation devices. Parke and colleagues conducted a prospective randomized trial in ICU patients with mild to moderate hypoxemic ARF and demonstrated fewer desaturations and less need of noninvasive ventilation (NIV) compared to face masks. However, until recently the effect of HFNC on intubation rates and mortality was not known. In the FLORALI trial, HFNC was shown to have lower mortality and higher ventilator-free days, albeit in secondary analyses. In contrast to the FLORALI trial, results of the HOT-ER trial concluded that HFNC was not superior to conventional oxygen therapy, although the intubation rate in the HFNC group was lower at 5.5% versus 11.6% in the conventional oxygen therapy group but did not reach statistical significance ($P = 0.053$). In a meta-analysis HFNC was associated with a much lower rate of intubation and as such HFNC should be considered first-line therapy in patients for acute hypoxemic respiratory failure.

In other population groups, retrospective studies found no difference in mortality between HFNC and NIV in immunosuppressed patients with ARF. In patients with cancer and patients who had a lung transplant HFNC was associated with lower mortality and lower intubation rates when compared to conventional oxygen therapy. HFNC was ineffective as a rescue therapy when NIV and conventional oxygen therapy had failed, suggesting benefit of early use. In 2014, Maggiore and colleagues showed that HFNC at 50 L/min for 48 hours when applied to a high-risk patient population who passed a spontaneous breathing trial but had a Pao_2/FiO_2 ratio of less than 300 had much lower reintubation rates at 3.8% versus 21% (Venturi mask).

Expanding on this trial, in 2016 Hernandez et al. showed this to be true even in a lower-risk population with reintubation rates being 4.9% in HFNC compared to 12.2% in conventional therapy group. Number needed to treat to prevent 1 reintubation was 14. HFNC has not been shown to be superior to conventional therapy or NIV in postcardiac surgical patients or postabdominal surgery patients. It can be used as a preoxygenation tool during intubation.

Patients who are failing HFNC need to be promptly intubated for invasive mechanical ventilation. Delaying intubation for greater than 48 hours has been shown to be associated with increased mortality. Poor prognostic signs include persistent tachypnea, hypoxia, asynchronic breathing, acidosis with pH less than 7.25, nonpulmonary organ failure or hypotension.

Mechanical Ventilation

Until the 1950s the “iron lung” and other forms of negative-pressure ventilation were the most common forms of mechanical ventilation, especially outside of the anesthesia suite. However, during the polio epidemic in Europe in 1955, the mortality benefit as well as safety outside of anesthesia suites of invasive positive-pressure ventilation was demonstrated, leading to increased use of positive-pressure ventilation. In the 1980s, noninvasive ventilation began to be used for patients with chronic respiratory failure and eventually moved from the outpatient to the inpatient setting. Since then it has become increasingly popular with as much as a 400% increase in use compared to 20 years ago.

Noninvasive Ventilation

NIV is the provision of ventilatory assistance to the lung without use of invasive interface such as endotracheal intubation. NIV uses a variety of noninvasive interfaces including oronasal masks, full face masks, and nasal prongs. Success of NIV depends on the tolerability of the interface as well as the seal provided by the interface. There are essentially two modes of ventilation: constant positive airway pressure (CPAP) and bilevel positive airway pressure (BiPAP).

CPAP provides a constant positive pressure while the patient breathes spontaneously. The degree of ventilatory support provided by this mode is limited. It does not lead to an increase in tidal volumes. It does provide benefit in patients without obstructive lung disease such as obesity hypoventilation and patients with cardiogenic pulmonary edema. BiPAP provides two different pressures during different phases of respiration. During inspiration it provides a higher pressure called inspiratory positive airway pressure (IPAP) and during expiration it maintains a lower airway pressure, which it maintains constantly, called expiratory positive airway pressure (EPAP). The EPAP essentially is the same as CPAP, with IPAP providing a pressure difference that assists during inspiration and provides ventilatory support. Because both of these modalities raise mean airway pressure they help with alveolar recruitment to a certain degree and have a role in providing hemodynamic support to patients with heart failure.

NIV has distinct advantages over invasive mechanical ventilation. Importantly, it eliminates intubation and it eliminates the risk of upper airway trauma by intubation. In addition, it reduces patient discomfort, lowers risk of ventilator-associated pneumonia (VAP), and preserves airway clearance. Patients can be provided breaks from ventilation to allow communication and normal eating and drinking. There are multiple specific etiologies where NIV has become first-line therapy, which are discussed below. There are specific clinical situations where NIV is contraindicated and clinicians should move to invasive mechanical ventilation (IMV). These are summarized in [Table 20.5](#).

TABLE 20.5 Contraindications for Noninvasive Ventilation (NIV)

Absolute Contraindications	Relative Contraindications
Cardiopulmonary arrest	Hemodynamically unstable
Facial surgery/trauma	Encephalopathy
Upper airway obstruction	Agitated or uncooperative
Vomiting	Unable to protect airway
Upper GI bleeding	Excessive secretions
	Multiple organ failure
	Swallowing impairment
	Inability to physically remove the mask

Hypercapnic respiratory failure. There are strong recommendations to use NIV in cases of acute COPD exacerbations with mild and moderate ARF with pH between 7.25 and 7.35 and Paco_2 of greater than 45 despite standard medical therapy. Early initiation of NIV has been shown to lower rates of intubation and the length of hospitalization as well as mortality. Though pH is the most important determinant, other clinical factors such as tachypnea, severity of dyspnea, and use of accessory muscles should also be considered. Although the mechanism of respiratory failure during asthma exacerbations resembles COPD exacerbation, the airway obstruction is less homogeneous and there is a higher risk of dynamic hyperinflation. Evidence to use NIV in this case is not as convincing. There is probably a narrow window to trial NIV and if respiratory failure does not improve to go ahead with invasive MV.

In patients with bronchiectasis such as cystic fibrosis patients, NIV has been shown to reduce the load on respiratory muscles as well as improve alveolar hypoventilation. NIV should be started if patients have hypercapnia either in the stable phase or during an exacerbation. It may be valuable supportive therapy as a bridge to lung transplantation. Similar to this patient population, in patients with neuromuscular disease respiratory pump impairment plays a pivotal role in alveolar hypoventilation. This usually presents initially as nocturnal hypoventilation, gradually getting worse as the disease progresses and leading to inspiratory muscle weakness, decreased chest wall compliance, and failure to clear secretions. Combining NIV with airway clearance therapies may delay intubation.

Hypoxemic respiratory failure. Several studies since the 1980s have looked at NIV in patients with cardiogenic pulmonary edema. Use of both forms of NIV (CPAP and BiPAP) have shown decreased mortality rate and decreased need for intubation in patients with ARF due to cardiogenic pulmonary edema and has been recommended as first-line therapy in the ATS 2017 guidelines. However, NIV should be used with caution in patients with acute coronary syndromes and cardiogenic shock because there is a slightly higher chance of myocardial infarction.

Guidelines recommend use of NIV in postsurgical patients who develop ARF. Use of both CPAP and BiPAP reduces intubation rates, nosocomial infections, as well as mortality once surgical complications have been ruled out.

Given the lower risk of VAP, NIV has been suggested in patients who are immune compromised with pooled analyses showing benefit and lower intubation risks. However, some studies have shown benefit of HFNC compared to NIV. In patients with ARF of unknown etiology NIV is not recommended. There are multiple disadvantages to consider, and the positive effects of NIV on alveolar recruitment are lost with any interruptions in therapy. NIV can mask clinical deterioration and delay intubations as well as cause lung injury if tidal volumes are too high. In patients with severe hypoxia with $\text{Pao}_2/\text{FiO}_2$ ratio of less than 150, use of NIV has been shown to have higher mortality.

TABLE 20.6 Risk Factors for Failure of NIV

Acute hypercarbic RF	Poor neurologic score: GCS <11 Tachypnea: >35 breaths/min pH <7.25 APACHE score >29 Asynchronous breathing Excessive air leak Agitation Excessive secretions Poor tolerance Poor adherence to therapy No initial improvement within first 2 hrs of noninvasive ventilation No improvement in pH Persistent tachypnea, tachycardia Persistent hypercapnia
Acute hypoxic RF	Diagnosis of ARDS or pneumonia Age >40 yr Hypotension: systolic blood pressure <90 mm Hg Metabolic acidosis: pH <7.25 Low PaO ₂ /FiO ₂ ratio <150 Failure to improve oxygenation within first hour of noninvasive ventilation

Success of NIV is dependent on underlying disease. Disorders such as COPD exacerbation and cardiogenic edema are more responsive than hypoxemic respiratory failure of unknown etiology. Baseline severe acidosis (pH <7.25), severe hypoxia, respiratory distress with persistent high respiratory rate greater than 25, and nonpulmonary organ failure have been associated with NIV failure. Various risk factors for failure of NIV are summarized in [Table 20.6](#).

Invasive mechanical ventilation. IMV is positive-pressure ventilatory assistance with the help of a tracheostomy or endotracheal tube connected to a ventilator. In the United States around 800,000 patients receive IMV annually. The fundamental operation of a ventilator involves four phases: (1) The trigger phase initiates the breath. This can be controlled by changing preset triggers such as flow or pressure in the circuit or by time (time-triggered) when the ventilation is completely controlled. (2) The target phase where the pressure or flow is maintained by the ventilator. (3) The cycling phase determines the end of the inspiratory phase. Once the variable—flow or pressure—reaches the preset value, the expiration phase starts. (4) The expiration phase is usually passive while maintaining a preset pressure (PEEP).

The simplest mode of ventilation is assist-control ventilation where the patient provides the initial trigger for a flow-targeted volume-cycled (volume assist-control ventilation, or VC) or pressure-targeted time-cycled (pressure assist control ventilation, or PC) ventilation. Both of these modes are usually on a simple feedback loop, so that if the patient's respiratory rate is too low then the ventilator will provide the set number of breaths per minute. When the patient's respiratory rate is higher, all breaths will be triggered by the patient and will get the set ventilatory assistance. Another simple mode is the pressure support mode (PS), where the patient triggers every breath. Apart from preset pressure assistance there is no cycling variable set and the patient controls the duration of the breath.

IMV is often lifesaving but it is fraught with complications. Many of these complications can be avoided and minimized. Initiation of IMV involves endotracheal intubation, which is a

critical procedure. Prior to intubation patients need to be evaluated for factors that could indicate presence of a difficult airway. Preoxygenation is essential and use of rapid-sequence intubation with sedative and neuromuscular blocking agents increases the rate of successful intubation. Following placement of an endotracheal tube IMV is not well tolerated in most fully awake patients, hence the need for sedation. Sedation agents are associated with their own complications; for example, long-term use of benzodiazepines, especially in the form of continuous infusions, has been linked with delirium and poor long-term outcomes.

In addition to sedation-related complications, ventilators can provide 100% FiO₂, which can cause oxygen toxicity when used inappropriately. Hyperoxemia has been linked to poor outcomes in patients suffering from strokes or cardiac illness.

Positive-pressure ventilation can cause direct pressure-related injuries from three mechanisms: barotrauma, volutrauma, and atelectrauma. Barotrauma is an increase in pressure in the airways that can lead to alveolar or distal airway rupture leading to air leaks and pneumothorax or pneumomediastinum. Volutrauma can lead to overdistension of alveoli, causing alveolar-capillary interface disruption leading to inflammation. In the 1980s, the first studies showed diffuse parenchymal infiltrates from high inflation volumes. Atelectrauma occurs during the expiratory phase when small airways can collapse, especially in cases where lung compliance is markedly reduced. Repetitive opening and closing of alveoli and small airways can lead to damage to airway epithelium and inflammation.

Weaning From Ventilation

As the underlying cause of respiratory failure improves, attempts need to be made to get the patient off of MV as soon as possible. Determining when a patient can be removed from ventilation is challenging. In the ICU, several studies have shown bedrest negatively affects musculoskeletal, cardiovascular, and respiratory systems. Profound weakness is common in ICU patients, persists beyond hospitalization, and is linked with reduced post-ICU survival. Recent guidelines recommend liberation from MV using protocols for sedation and weaning and mobilizing patients as early as possible. Daily use of spontaneous breathing trials (SBT) has not only been shown to be safe but also shown to reduce weaning times from ventilation when compared to gradual lowering of ventilator settings. For a SBT to be successful, a patient needs to be able to spontaneously breathe with no or minimal ventilator support for at least 30 mins, not be apneic, not be persistently tachypneic (>35 breaths/min), and remain hemodynamically stable without increased work of breathing. Minimizing sedation agents have been shown to reduce duration of ventilation. Daily interruption of sedation as well as stopping sedation prior to SBT increase the chances of successful SBT. Risk factors for unsuccessful extubation are listed in [Table 20.7](#).

TABLE 20.7 Risk Factors for Failed Extubation

Failure of two or more SBTs Chronic heart failure Weak cough Stridor postextubation Hypercarbia during SBT or after extubation PaCO ₂ >45 Age >65 APACHE score >12 on day of extubation Pneumonia as cause of ARF

SPECIFIC CLINICAL SITUATION: ACUTE RESPIRATORY DISTRESS SYNDROME

ARDS is one of the most severe forms of hypoxemic respiratory failure. Based on several observational studies, the incidence of ARDS has been estimated to be about 7 per 100,000. In 2012 a panel of experts established the Berlin definition of ARDS. ARDS is characterized by acute hypoxic respiratory failure from acute diffuse inflammatory lung injury. This leads to increased vascular permeability, increased lung weight, and loss of aerated lung tissue, resulting in decreased lung compliance. The lung injury can be direct (e.g., inhalational injury or multifocal pneumonia) or indirect (e.g., pancreatitis or severe sepsis).

For a patient to be defined as having ARDS the onset must be within 1 week of a known clinical insult or new or worsening respiratory symptoms. Based on the degree of hypoxia, severity of ARDS was quantified as mild when P_{aO_2}/F_{iO_2} ratio was between 200 to 300 mm Hg on PEEP of 5 or higher via invasive or noninvasive MV, moderate ARDS with a P_{aO_2}/F_{iO_2} ratio less than 200 mm Hg, and severe with a P_{aO_2}/F_{iO_2} ratio less than 100 mm Hg.

The majority of the cases of ARDS occur in the setting of predisposing clinical risk factors such as bacterial pneumonia, severe sepsis, severe trauma, drug or alcohol overdose, systemic inflammation (e.g., acute pancreatitis), and massive aspiration. These risk factors can be divided into those that cause direct lung injury and those that cause indirect lung injury likely via inflammatory cytokines. It is estimated that 30% to 40% of patients with severe sepsis will go on to develop ARDS. Direct inhalational injury, acute exacerbation of interstitial lung disease, burns, head trauma, and near-drowning are less common causes of ARDS.

ARDS is a complex and heterogeneous disorder with a pathophysiology that is only partially understood. During the initial phase, described as the exudative phase, after exposure to a risk factor, there is injury to the type I pneumocytes and disruption of the alveolar capillary interface. This leads to leakage of protein-rich plasma into the alveolar spaces, release of proinflammatory cytokines (e.g., IL1, IL8, TNF- α) and lipid mediators such as leukotriene B, and neutrophilic accumulation, resulting in predominantly dependent alveolar edema. Unlike cardiogenic edema, which is mostly due to hydrostatic forces, the alveolar fluid is rich in proteins leading to dysfunction of the surfactant activity and a proteolytic process. The process leads to diminished aeration, atelectasis, decreased lung compliance, intrapulmonary shunting, increased physiologic dead space, and significant hypoxemia. The chest radiograph at this stage shows diffuse bilateral alveolar and interstitial opacities that are nonspecific and difficult to distinguish from cardiogenic pulmonary edema, multifocal pneumonia or diffuse alveolar hemorrhage. As ARDS improves there is organization of alveolar exudates and a shift from neutrophilic to lymphocyte predominant pulmonary infiltrate. Type II pneumocytes proliferate and repair the alveolar basement membrane, differentiate into type I pneumocytes, and synthesize surfactant.

In most patients ARDS will resolve after the acute phase. Rarely, some patients enter a fibrotic phase. In these patients there is extensive interstitial fibrosis and disruption of normal pulmonary architecture as well as pulmonary vascular intimal changes predisposing them to pulmonary hypertension and right ventricular failure. This leads to a prolonged phase of decreased lung compliance and oxygenation and prolonged need for continued MV. This phase can last for weeks and is complicated by nonpulmonary organ dysfunction, deconditioning, and hospital-acquired infections.

General principles of management of ARDS patients include recognition and treatment of underlying causes and secondary illnesses. Patients with ARDS frequently require mechanical ventilation for

support. Historically, these patients were ventilated with tidal volumes set at 12 to 15 mL/kg. However, in 2000 the ARDS Network published the results of their first study comparing tidal volumes of 6 mL/kg versus 12 mL/kg and revealed a 9% absolute reduction in mortality in the lower tidal volume group. Along with the mortality benefit, both ventilator-free days and organ failure-free days were also increased in the low tidal volume group. Currently the American Thoracic Society in conjunction with the European Respiratory Society recommends using lower tidal volumes of 4 to 8 mL/kg of predicted ideal body weight and lower inspiratory pressures ($P_{plat} < 30$ mm Hg).

Further, although higher PEEP may improve alveolar recruitment, oxygenation, and prevent atelectrauma, there are risks of alveolar overdistension, increased intrapulmonary shunt, and hemodynamic effects. There have been multiple studies comparing high PEEP with lower PEEP, including studies from ARDS Network comparing average PEEP of 13 versus 8 with similar clinical outcomes. None of these studies showed evidence of barotrauma related to higher PEEP. In an individual patient meta-analysis from three randomized controlled trials, patients with moderate or severe ARDS ($P_{aO_2}/F_{iO_2} < 200$ mm Hg) had significant mortality benefit from higher PEEP while patients with mild ARDS did not have statistically significant benefit.

There have been multiple studies addressing fluid management in ARDS. The ARDS Network conducted a large multicenter randomized controlled trial looking at a liberal fluid strategy versus a conservative fluid strategy targeting lower intravascular pressures. Patients in the conservative group had a higher number of ventilator-free days, better oxygenation, and did not have a higher incidence of shock or need for dialysis. The 2010 ACURASYS trial looking at neuromuscular blockade for patients in moderate to severe ARDS showed a lower incidence of barotrauma and higher adjusted overall survival. However, the 2019 ROSE trial did not show a similar benefit between the two groups. From a physiological perspective, neuromuscular blockade needs to be administered when patient-ventilator desynchronies exist. However, some patients' ventilatory pattern predisposes them to ventilator-induced lung injury despite use of sedation strategies.

Rescue therapies need to be applied to patients in the setting of refractory hypoxia. Prone positioning was initially shown to improve oxygenation but not affect mortality in several small studies; however, in prespecified subgroup analyses of these studies, prone position for greater than 12 hours a day in patients with moderate to severe ARDS showed mortality benefit. This was subsequently confirmed in the PROSEVA trial, in which proning led to a mortality benefit in patients with severe ARDS. Hence, proning is recommended by ATS in patients with severe ARDS. Other rescue therapies such as inhaled nitric oxide can improve oxygenation in some patients. This therapy can also lead to loss of hypoxia-induced vasoconstriction in poorly ventilated portions of the lung, leading to worsening oxygenation. Extracorporeal membrane oxygenation (ECMO) refers to circulation of blood externally over a gas exchanger to oxygenate blood and eliminate carbon dioxide. This was first studied in the 1970s and did not show any benefit; however, mortality from ARDS at that time was close to 90% in both arms of the study. In 2009 the CESAR trial was published, which showed a mortality benefit in the treatment arm; however, 25% of the patients in the treatment arm ended up getting conservative management. There were no fixed ventilation protocols for patients in the control arm, therefore it was difficult to predict how much benefit was attributable to ECMO. Another randomized trial in 2018 did not show mortality benefit using ECMO versus reserving it as a rescue therapy with conventional lung-protective ventilation.

Transitions in Care From Pediatric to Adult Providers for Individuals With Pulmonary Disease

Kate E. Powers, Debasree Banerjee, Robin L. McKinney

INTRODUCTION

With advances in technology and pharmaceuticals, more than 90% of children born with life-shortening diseases will survive to adulthood. The transition of care from pediatric to adult providers is high risk, with the potential for poor clinical outcomes. There are few resources and limited formal education for pediatric and adult providers on transition of care for individuals with underlying pulmonary disease. This gap in knowledge among health care providers has significant effects on patient outcome, including accelerated progression of disease and increased health care cost.

The Society for Adolescent Health and Medicine defines transition in care as “the purposeful, planned movement from adolescents and young adults with chronic physical and medical conditions from child-centered to adult-oriented health care systems.” Despite the recognized need for detailed and active measures to ensure the transfer of patient care, there are no standardized approaches for transition of care for individuals with underlying pulmonary disease. Many individuals experience gaps of care during the transfer phase of transition before definitively establishing care with an adult provider. These gaps in care are multifactorial including individual, cultural, geographic, logistic, and financial etiologies. Adolescents and young adults may lack the skill or neurocognitive development to fully assume management of their own care. This is further compounded by moving away from home, loss of insurance as a dependent, and lack of engagement of family or caretakers in adult practices. If not adequately planned for, parents’ lack of legal right of their child at the age of majority significantly impacts care and consent in neurocognitively impaired individuals. Fragmented care may lead to poor health maintenance, decreased adherence to medical therapies, and avoidance of medical intervention in earlier stages of illness. An organized transition process establishes individual trust in new adult providers, especially for young adults with chronic disease. A smooth transition of health care allows for developmentally appropriate care in a system that can support the individual patient throughout life.

Our goal for this chapter is to illustrate successful methods to transition adolescents and young adults with underlying pulmonary disease and those chronically critically ill individuals into adult clinics utilizing specific pulmonary disease examples.

CYSTIC FIBROSIS AND OTHER MUCOCILIARY DISEASES

Cystic fibrosis (CF) is an autosomal recessive genetic multisystem disease with primary involvement occurring in the respiratory and gastrointestinal tracts. Mucus plugging, inflammation, and bacterial

infections lead to lung damage with progressive small airway obstruction and lung scarring known as bronchiectasis that eventually contributes to worsening lung function and respiratory failure. In the gastrointestinal and hepatobiliary tracts as well as the exocrine pancreas, inspissation of viscous secretions leads to intestinal obstruction, cholestasis, and fat and protein malabsorption. CF affects approximately 30,000 individuals in the United States and 70,000 worldwide. It is the most common life-shortening inherited disease in Caucasians but impacts all races and ethnicities. CF is caused by mutations in a gene on chromosome 7 that encodes the CF transmembrane conductance regulator (CFTR) protein. The CFTR protein primarily functions as a chloride and bicarbonate receptor responsible for the movement of fluid into and out of epithelial cells lining the respiratory tract, biliary tree, intestines, vas deferens, sweat ducts, and pancreatic ducts. As of 2017, the median predicted survival is about 50 years. Improvement in survival has resulted from specialized care centers, early diagnosis, timely screening, therapies to optimize pulmonary function and nutrition as well as clinical care guidelines to standardize symptom-based treatments. Newly developed CFTR modulator therapies target the basic defect in CF and are now clinically available for more than 60% of the US CF population. Although modulator therapies cannot reverse existing disease, they have already further altered the CF-disease trajectory improving overall health, quality of life, and survival.

With improved survival into adulthood, successful transition and transfer of individuals from pediatric to adult CF programs is essential. A timeline for recommended CF-related milestones has been developed to support an individual with CF and his or her parent or support person through transition. CF R.I.S.E. (Responsibility. Independence. Self-care. Education.) is a transition resource that includes patient assessments and checklists, care team progress reports, and educational resource guides to optimize the transition process over time.

Specific educational goals are established by age: early school age (6-9 years old), late elementary and middle school (10-12 years old), early high school (13-15 years old), late high school (16-18 years old) and young adults (18-25 years old). Modules assist individuals with CF and their families to better understand the disease, CF-related care including medications and therapies, as well as planning for the future (Table 21.1).

Primary ciliary dyskinesia (PCD) is an autosomal recessive disease with more than 30 different genetic variants, characterized by congenital impairment of mucociliary clearance. These defects lead to ciliary immotility, ciliary dyskinesia or ciliary aplasia. Considerable variation exists in the clinical presentation of PCD, but most present in childhood with recurrent upper and lower respiratory infections. It is characterized by chronic cough, bronchiectasis, chronic rhinosinusitis, and recurrent otitis media. Individuals with PCD generally live an active

TABLE 21.1 Specific Educational Goals by Age

Milestones	6-9 Years Old	10-12 Years Old	13-15 Years Old	16-18 Years Old	18-25 Years Old
Understanding CF	Basics of CF	Many aspects of CF care	Most aspects of CF	All aspects of CF	Understands and learns about all adult-related CF care issues
Managing CF care Clinic visits	Able to answer some questions about general health status and symptoms with support person's input	Able to independently answer more questions	Independently answers most questions	Independently takes the lead including answering questions	Plans for and takes the lead
Health status	Begins to identify and report changes in symptoms or health to a parent/support person	Proactively identifies and reports changes in health and symptoms to parent/support person	Reports health/symptom changes to parents and care team	Implements recommended nutrition/treatment changes after clinic and hospital visits	Implements recommended nutrition/treatment changes after clinic and hospital visits
Coordination of care		Can report to care team all of the health care providers seen outside CF center	Can report to care team all of the health care providers seen outside CF center, reasons for and outcomes from those appointments	Works with parent to coordinate care with health care providers outside CF Center	Coordinates all care with health care providers outside CF center
Insurance and financial			Begins to watch parent/support person order medication and supplies and starts to call for their own refills when needed	Monitors medications and supplies and calls in refills	Monitors medications and supplies, calls in refills, owns all medication and insurance-related management and reaches out to parent/support person if questions arise
Transfer to adult care				Participates in key meetings and fills out paperwork associated with transfer	Participates in key meetings and fills out paperwork associated with transfer
Taking CF treatments and therapies Taking treatments	Begins taking steps towards remembering to take and carry pills and enzymes; Helps to set up nebulizer and airway clearance equipment; Takes and participates in all treatments with close oversight	Responsible for remembering to take and carry enzymes; Independently performs airway clearance with some oversight; Knows and sticks to treatment plan expectations	Independently administers enzymes and airway clearance; Responsible for following treatment plan in school and while on vacation with some supervision	Primarily responsible for taking all treatments with little parental supervision	Completely responsible for taking all treatments with little parental/support person supervision
Medication management		Begins tracking and sorting all medicines and proper storage plan for medicines	Tracks and sorts all medicines and tells parent when medicine is running low	Tracks and sorts all medications; demonstrates and calls for refills when medicine is running low	Responsible for tracking and sorting all medicines and identifying need for refills
Living with CF Planning for future	Pictures a future as an adult	Pictures a future and is able to talk about hopes and dreams	Begins to plan for future (big picture) and plan for how CF may impact future life plan and adulthood	Actively plans for future including college life, work, and/or living independently	Actively plans for future
Anxiety and depression	Aware of anxious or sad feelings and alerts a parent/support person	Can identify feelings of sadness and anxiety and bring to the attention of a parent/support person	Can identify warning signs of anxiety and depression and alert parent/support	Can identify warning signs of anxiety and depression and alert parent/support person	Can identify warning signs of anxiety and depression and alert parent/support person

TABLE 21.1 Specific Educational Goals by Age—cont'd

Milestones	6-9 Years Old	10-12 Years Old	13-15 Years Old	16-18 Years Old	18-25 Years Old
Exercise	Participates in sports, exercise, or other health activities	Maintains an exercise routine/participates in sports of other healthy activities	Maintains an exercise routine/participates in sports or other healthy activities	Works with care team to develop an exercise routine	
Self-advocacy	Can answer very basic questions about CF from family, friends, and teachers	Has a short statement to answer basic questions about CF	More comfortable independently answering common questions from peers/others about CF	Able to answer questions from peers/others about CF	Able to answer questions from peers/others about CF
Support system	Understands the importance of a support system of peers with CF	Understands the importance of a support system and starts to develop a group of peers with CF	Understands the importance of and starts to develop a support system of peers with CF	Understands the importance of and utilizes a support system of peers with CF	Understands the importance of and utilizes a support system of peers with CF

life and have a normal lifespan. The rate of lung function decline is much slower than that with CF. Similar to CF, individuals with PCD benefit from implementation of a preventative airway clearance regimen to mobilize retained pulmonary secretions. Retained pulmonary secretions can be corrosive leading to chronic inflammation, recurrent infections, and bronchiectasis.

Bronchiectasis is a structural abnormality characterized by abnormal dilatation and distortion of the bronchial tree with resultant chronic obstructive lung disease. A range of pathophysiologic and disease processes other than CF contribute to bronchiectasis, and most include some combination of bronchial obstruction and infection. Bronchiectasis is frequently associated with atelectasis, emphysema, pulmonary fibrosis, and bronchial vasculature hypertrophy. Improving airway clearance and preventing further airway damage are the cornerstones of therapy. Prognosis and outcome in non-CF related bronchiectasis depends primarily on the underlying etiology. Prediction of outcomes is limited, but with early diagnosis and appropriate therapies, including a preventative airway clearance regimen, lung function in children can stabilize or improve over time. Non-CF related bronchiectasis typically progresses much more slowly than CF-related bronchiectasis and often improves if an airway clearance regimen is implemented to minimize retained pulmonary secretions.

Consensus guidelines for transitioning individuals with PCD or non-CF related bronchiectasis from pediatric to adult providers have not been established to date. Both benefit from continued implementation of a preventative airway clearance regimen to mobilize pulmonary secretions.

ASTHMA AND BRONCHOPULMONARY DYSPLASIA

Asthma and bronchopulmonary dysplasia (BPD) are two of the most common chronic lung diseases in pediatrics. While adult health care providers will likely have experience and be comfortable managing asthma, BPD is a disease that few will be familiar with. BPD results from premature birth with an incidence of 10,000 to 15,000 new cases annually in the United States.

In premature infants, the type II pneumocytes of the lung are underdeveloped and produce insufficient quantities of surfactant, a surface-active substance produced by specific alveolar epithelial cells that helps to decrease surface tension and prevent alveolar collapse. This disorder is called respiratory distress syndrome (RDS). The treatment of RDS is administration of exogenous surfactant and corticosteroids to enhance lung maturation. To sustain life while allowing maturation, mechanical ventilation and oxygen supplementation are required but contribute to the development of BPD.

BPD is defined as the need for 30% or greater oxygen and/or positive pressure at 36 weeks postgestational age (PGA) or discharge, in infants born before 32 weeks gestational age. The neonatal and pediatric provider is likely to be more familiar with the immediate sequela and morbidity associated with BPD than adult health care providers who may inherit an individual years after symptoms have become silent. Birth history is often overlooked by both pediatric and adult health care providers but may provide health information relevant well into adulthood. BPD is often clinically silent by age four, but there is increasing evidence that abnormal spirometry can be detected in early childhood and significantly contributes to adult diseases including chronic obstructive pulmonary disease (COPD) and asthma.

Recent studies challenge the traditional teaching that lung function continuously improves from birth until the third decade of life. Evidence suggests childhood illnesses such as BPD and asthma can contribute to lower-than-expected lung function. Given this lower-than-expected lung function, pathology such as COPD is more likely to occur earlier in life and potentially have a more severe course.

It is essential for pediatric providers to begin early with age-appropriate conversations on the management of asthma in preparation for transfer and transition of health care in adolescence and young adulthood. A minority of patients with moderate to severe childhood asthma will experience remission as they enter adulthood. The majority of individuals will have persistent symptoms. There is an association between severe asthma in childhood with decreased peak lung function and a more rapid decline of lung function compared to children without asthma that ultimately leads to COPD later in life. Pediatric and adult providers should be aware of these long-term outcomes, appropriately monitor lung function, and manage symptoms accordingly to try and prevent long-term lung remodeling leading to persistent disease.

DIFFUSE LUNG DISEASE (INTERSTITIAL LUNG DISEASE)

Diffuse lung disease (DLD) consists of a diverse group of disorders that impact the pulmonary parenchyma and interfere with gas exchange reflecting a spectrum of underlying pathology. These disorders are associated with extensive alteration of alveolar and airway architecture in addition to interstitial changes, therefore the term DLD is now preferred to ILD. Childhood interstitial lung disease (chILD) is still a term utilized when DLD is suspected based on clinical and radiologic features without an established etiology. Some conditions that cause DLD are similar in children and adults, they occur in different proportions, and certain diseases are unique to infants. All diseases are rare in childhood.

For many forms of DLD, treatment options are limited and often include medications with unproven efficacy and substantial side effects. Lung transplantation is an option for children with severe and progressive disease without a response to therapy. Consensus guidelines for transitioning individuals with DLD from pediatric to adult providers have not been established to date. Given the spectrum of underlying pathology and possible post-lung transplant status, individuals with DLD benefit from a focused transition of care.

INDIVIDUALS WITH TECHNOLOGY DEPENDENCE OR OTHER SPECIAL HEALTH CARE NEEDS

Children and youth with special health care needs (CYSHN) is defined as those who have one or more chronic physical, developmental, behavioral, or emotional condition requiring additional health and related services beyond that of children generally. Approximately 750,000 CYSHN transition into adulthood annually. While these individuals make up a small fraction of the pediatric patient population, they utilize the largest fraction of health care resources. Individuals with technology dependence include those who have tracheostomy dependence requiring part- or full-time mechanical ventilatory support.

Home oxygen therapy is often required in children with chronic respiratory conditions including CF, BPD, sleep-disordered breathing, sickle cell disease, pulmonary hypertension with and without congenital heart disease, and DLD. Despite a lack of empirical evidence regarding implementation, monitoring, and discontinuation of supplemental oxygen therapy, an expert panel through the American Thoracic Society published clinical practice guidelines in 2018. Optimal implementation includes age-appropriate oxygen equipment to maintain acceptable oxygen saturations according to age and respiratory condition and pulse oximetry.

Important steps to optimal transfer and transition include updating insurance status to reflect the coordination of special services with durable medical equipment companies and qualifying patients for certain state or national services. Adult providers frequently have a more patient-centered than family-centered approach to care than pediatric counterparts. Adolescence and young adulthood is often a time of educational transition with variation in access and medical support provided for children and youth with special health care needs. Lack of disease-specific education and few evidence-based guidelines may contribute to adult pulmonologists' limited expertise caring for an individual with technology dependence. General pediatric recommendations for improving transition include the preparation of a transition plan written in early adolescence starting at age 14. This plan includes individual patient and family perspectives, anticipated health care services the individual will need, and a financial plan. It should include preventative as well as disease-specific therapies and insurance coverage strategies for the transition period to decrease gaps of care.

IMPORTANCE OF A SUCCESSFUL TRANSITION

Data from 10 years ago suggested that more than 500,000 adolescents with special health care needs in the United States reach adulthood annually. As life expectancy for individuals with chronic lung disease, technology dependence or other special health care needs has increased, so has the need for a guided, structured transfer and transition of care and transition from pediatric to adult-focused care. The transition of individuals from pediatric to adult care should begin years before the actual transfer. The transition process should include individual- and family-specific education, patient understanding of disease including

TABLE 21.2 Multilevel Suggestions for Transition of Health Care

Patient level	<ul style="list-style-type: none"> Begin discussions of transition early in life Develop a road map in preparation for transition readiness, disease knowledge, and skills assessment to share with patients and families Create a personalized medical summary to ensure seamless continuity of care, especially where an electronic medical record is not shared by pediatric and adult programs
CF team level	<ul style="list-style-type: none"> Create an open and transparent dialogue between the pediatric and adult CF programs Develop a working transitional care policy at all levels of the multidisciplinary team (include input from patients and parents) Create a registry of eligible patients and a plan to discuss them periodically Identify outcome measures to monitor progress and success, including establishment of best practices and communication among pediatric and adult care teams
Institutional level	<ul style="list-style-type: none"> Seek institutional leadership buy-in Collaborate with other hospital programs focused on transition Invest in EMR systems with patient access to personal health records and built-in transition tools

rationale for therapies and overall prognosis, as well as a patient readiness assessment indicating if the patient can independently manage therapies and navigate the health care system.

The goals of a planned transition are to improve quality of life, maximize independence, and minimize interruption in care as a patient transfers from pediatric to adult primary and subspecialty care. A designated transition coordinator or champion allows for streamlined communication between health care providers and helps to ensure individual access to medications, interventions, and medical devices through to establishment of care with the adult provider. Although no single process for transition will work in all health care systems, it is essential that an approach that best meets the needs of patient populations and fits within the health care system constraints be established (Table 21.2).

Transition of health care is a complex process involving multiple factors for which a multidisciplinary care team will provide the best chance for success for the individual patient and family (Table 21.3).

Effective transition of care can prevent the deterioration of chronic health conditions while engaging the adolescent to become involved and take over their own care. Poor transition of care has been associated with missed health care visits, loss to follow-up, poor compliance with medications, and increased morbidities. All of these lead to increased emergency care utilization and worse outcomes. Research has identified obstacles that can make transition challenging, including the limited number of capable providers for adults, lack of individual readiness, cognitive disability, instability of mental health (anxiety/depression), and communication issues between pediatric and adult providers.

CF is an example of a chronic pulmonary disease in which much effort has been placed into implementing models to optimize the process of transition. The CF Foundation supported the training of additional providers and developed Adult Care Consensus Guidelines to provide goals and help standardize care. Research and

TABLE 21.3 Multidisciplinary Care Team for Transition of Health Care

Multidisciplinary Care Team	Focus for Transition Assessment
Physician/nurse practitioner	Supervising overall transfer and transition process
Registered nurse/care coordinator	Supporting communication of transfer and transition process
Registered dietician	Nutrition and supplementation knowledge, food insecurity risk
Clinic facilitator	Scheduling transfer; meet-and-greet adult team; supplying documents
Pharmacist	Medication knowledge
Behavioral psychologist	Mental/emotional strengths and any barriers to transition
Clinical social worker	Psychosocial strengths and any barriers to transition
Respiratory therapist	Airway clearance knowledge
Physical therapist	Physical activity knowledge as relates to airway clearance
Child life specialist	Age-appropriate disease education and tools for medication adherence

quality improvement projects have identified areas that can make transition a success:

- Make transition to adult care a gradual process.
- Remember that parents and caregivers also are going through a transition.
- Pediatric and adult care teams should work together to improve transition.

Developing a transition program is critically important and does not develop without committed individuals and institutions. Finally, there needs to be pediatric and young adult focused research to better establish guidelines for care that are applicable to this special population.

Preoperative and Postoperative Care

22 Preoperative and Postoperative Care, 240

Preoperative and Postoperative Care

Kim A. Eagle, Kwame Dapaah-Afriyie, Arkadiy Finn

INTRODUCTION

More than 40 million people undergo noncardiac surgical procedures in the United States annually. A general medical and focused cardiovascular preoperative risk assessment involves evaluation of pertinent medical problems with an emphasis on those conditions that may become exacerbated in the perioperative period. Emerging evidence-based practices dictate that the physician should thoughtfully perform an individualized evaluation of the surgical patient to provide an accurate preoperative risk assessment, risk stratification, and modification of risk parameters that can then provide the framework for optimal perioperative risk reduction strategies.

The perioperative period is associated with hemodynamic changes due to surge in sympathetic activity, fluid shifts and their associated effect on the renin-angiotensin system (RAS), and effect of exposure to anesthetic agents.

Assessment of patients' functional status, exercise tolerance, and other preexisting comorbidities are core components of perioperative management. Patients younger than 50 years of age and having no significant medical comorbidities are at very low risk for developing perioperative complications. The increasing prevalence of medical conditions in the surgical patient warrants review of the perioperative approach to those conditions that may pose significant risk. This chapter reviews preoperative and postoperative cardiovascular and medical risk assessment that targets intermediate- to high-risk patients to strategically guide perioperative preventive therapies for optimal outcome.

CARDIAC DISEASE

Preoperative and Postoperative Cardiac Care

It is estimated that the incidence of cardiac complications after noncardiac surgical procedures is between 0.5% and 1%. In other words, 200,000 to 400,000 people will experience perioperative cardiac complications annually. Moreover, more than 25% of these patients will die. Patients who survive a postoperative myocardial infarction (MI) are twice as likely to die in the following 2 years as are patients with uneventful surgical procedures. Emerging evidence-based practices dictate that the physician should thoughtfully perform an individualized evaluation of the surgical patient to provide an accurate preoperative risk assessment, risk stratification, and modification of risk parameters that can then provide the framework for optimal perioperative risk reduction strategies. This section reviews preoperative and postoperative cardiovascular risk assessment that targets intermediate- to high-risk patients to strategically guide perioperative preventive therapies for optimal outcome.

IDENTIFICATION OF PATIENTS WITH ELEVATED RISK

The preoperative evaluation includes an assessment of the risk associated with the planned surgery or procedure. Low-risk procedures (e.g., colonoscopy, cataract surgery) are associated with a less than 1% risk of major adverse cardiovascular events (MACE) of death or MI. Those procedures with a MACE risk of 1% or greater are classified as conferring higher risk. Simple standardized preoperative screening questionnaires have been developed for the purpose of identifying patients at intermediate to high risk who may benefit from a more detailed clinical evaluation (Table 22.1).

TABLE 22.1 Standardized Preoperative Questionnaire^a

1. Age, weight, and height
2. Are you
 - a. Female and 55 years of age or older or male and 45 years of age or older?
 - b. If yes, are you also 70 years of age or older?
3. Do you take anticoagulant medications ("blood thinners")?
4. Do you have or have you had any of the following heart-related conditions?
 - a. Heart disease
 - b. Heart attack within the last 6 months
 - c. Angina (chest pain)
 - d. Irregular heartbeat
 - e. Heart failure
5. Do you have or have you ever had any of the following?
 - a. Rheumatoid arthritis
 - b. Kidney disease
 - c. Liver disease
 - d. Diabetes
6. Do you get short of breath when you lie flat?
7. Are you currently on oxygen treatment?
8. Do you have a chronic cough that produces any discharge or fluid?
9. Do you have lung problems or diseases?
10. Have you or any blood member of your family ever had a problem with any anesthesia other than nausea?
 - a. If yes, describe
11. If female, is it possible that you could be pregnant?
 - a. Perform pregnancy test
 - b. Please list date of last menstrual period

^aUniversity of Michigan Health System patient information report. Patients who answer yes to any of questions 2 through 9 should receive a more detailed clinical evaluation.

From Tremper KK, Benedict P: Paper "preoperative computer," *Anesthesiology* 92:1212-1213, 2000.

Evaluation of such surgical patients should always begin with a thorough history and physical examination including a 12-lead resting electrocardiogram (ECG) in accordance with the American College of Cardiology/American Heart Association (ACC/AHA) guidelines. A determination of the urgency of the surgery should be included in the history because truly emergent procedures are associated with unavoidably higher rates of morbidity and mortality.

Perioperative risk assessment begins with an assessment of the urgency of the noncardiac surgery; emergency surgery should not be delayed but may not allow for in-depth risk stratification. Preoperative testing should be done only for specific clinical conditions based on the history. Healthy patients of any age who are undergoing elective surgical procedures and have no coexisting medical conditions should not need any testing unless the degree of surgical stress could result in unusual changes from the baseline state. The history should focus on symptoms of occult cardiac disease.

PREOPERATIVE CARDIAC RISK ASSESSMENT

During the perioperative risk assessment of patients undergoing noncardiac surgery, there are active cardiac conditions that should be evaluated and treated in accordance with the ACC/AHA guidelines. These conditions include unstable coronary artery disease (CAD), decompensated heart failure, severe arrhythmia, and severe valvular disease (notably severe aortic stenosis and symptomatic mitral stenosis).

Assessment of exercise tolerance in preoperative risk stratification and precise prediction of in-hospital perioperative risk is most applicable in patients who self-report worsening exercise-induced cardiopulmonary symptoms, patients who may benefit from noninvasive or invasive cardiac testing regardless of the scheduled surgical procedure, and patients with known CAD or with multiple risk factors and the ability to exercise. For the prediction of perioperative events, “poor” exercise tolerance has been defined as inability to walk four blocks and climb two flights of stairs or as inability to meet a metabolic equivalent (MET) level of 4 (Table 22.2). Highly functional symptomatic patients (i.e., those who are able to achieve a functional capacity ≥ 4 METS

TABLE 22.2 Functional Status

Excellent (Activities Requiring >7 METS)

Carry 24 lb up eight steps
Carry objects that weigh 80 lb
Outdoor work (shovel snow, spade soil)
Recreation (ski, basketball, squash, handball, jog or walk 5 mph)

Moderate (Activities Requiring >4 but <7 METS)

Have sexual intercourse without stopping
Walk at 4 mph on level ground
Outdoor work (garden, rake, weed)
Recreation (roller-skate, dance, foxtrot)

Poor (Activities Requiring <4 METS)

Shower/dress without stopping, strip and make bed, dust, wash dishes
Walk at 2.5 mph on level ground
Outdoor work (clean windows)
Recreation (golf, bowl)

MET, Metabolic equivalent.

Modified from Hlatky MA, Boineau RE, Higginbotham MB, et al: A brief self-administered questionnaire to determine functional capacity (the Duke Activity Status Index), *Am J Cardiol* 64:651-654, 1989.

without symptoms, as when climbing a flight of stairs or running a short distance) rarely require noninvasive testing or intervention to lower the risk of noncardiac surgery.

If the patient has poor functional capacity or is symptomatic, physicians often use risk indices derived from empirical multivariable predictive models based on clinical assessment of risk factors to identify patients with elevated perioperative cardiac risk. Based on prospective comparison studies, the Revised Cardiac Risk Index (RCRI) is favored by many given its accuracy and simplicity (Table 22.3). A newer predictive model is the National Surgical Quality Improvement Program (NSQIP) risk calculator, which is based on multiple clinical predictors. The RCRI relies on the presence or absence of six identifiable predictive factors: high-risk surgery (suprainguinal vascular, intrathoracic, or intraperitoneal surgery), ischemic heart disease, congestive heart failure (CHF), cerebrovascular disease, diabetes mellitus (requiring insulin therapy), and renal failure (with a serum creatinine concentration >2.0 mg/dL). Each of the RCRI clinical predictors, if present, is assigned 1 point. The risk for cardiac events (i.e., MI, pulmonary edema, ventricular fibrillation or primary cardiac arrest, and complete heart block) can then be predicted. A patient with an RCRI score of 0 has an estimated risk of 0.4% to 0.5% for major cardiac complications; the risk is 0.9% to 1.3% for someone with a score of 1, 4% to 6.6% with a score of 2, and 9% to 11% with a score of 3 (Fig. 22.1). Cardiac risk particularly increases with the presence of two or more predictors and is greatest with three or more. The clinical utility of the RCRI is that it identifies patients who are at higher risk for cardiac complications and helps determine whether they may benefit from further risk stratification with noninvasive cardiac testing or from initiation of preoperative preventive medical management.

TABLE 22.3 Revised Cardiac Risk Index: Clinical Markers

1. High-risk surgical procedures
2. Ischemic heart disease
 - a. History of myocardial infarction
 - b. Current angina considered to be ischemic
 - c. Requirement for sublingual nitroglycerin
 - d. Positive exercise test
 - e. Pathologic Q waves on ECG
 - f. History of PTCA and/or CABG with current angina considered to be ischemic
3. Congestive heart failure
 - a. Left ventricular failure by physical examination
 - b. History of paroxysmal nocturnal dyspnea
 - c. History of pulmonary edema
 - d. S_3 gallop on cardiac auscultation
 - e. Bilateral rales on pulmonary auscultation
 - f. Pulmonary edema on chest radiography
4. Cerebrovascular disease
 - a. History of transient ischemic attack
 - b. History of cerebrovascular accident
5. Diabetes mellitus
 - a. Treatment with insulin
6. Chronic renal insufficiency
 - a. Serum creatinine concentration >2 mg/dL

Fig. 22.1 Bar graph shows the predicted risk for cardiac events during surgery according to a patient's Revised Cardiac Risk Index score.

Preoperative Noninvasive Cardiac Testing for Risk Stratification

Evidence discourages widespread application of preoperative noninvasive cardiac testing for all patients. Rather, a selective approach based on clinical risk categorization appears to be both effective and cost-effective. No testing is recommended if it might delay surgical intervention for urgent or emergent conditions.

On a rare occasion, coronary revascularization offers the potential benefit of improving outcomes in high-risk patients—that is, patients with acute coronary syndromes, those with left main CAD, those with two-vessel coronary disease who have significant proximal left anterior descending artery stenosis (and either ischemia on noninvasive testing or reduced left ventricular ejection fraction), and those with three-vessel coronary vessel disease and an ejection fraction of less than 50%. Routine prophylactic coronary revascularization should not be performed in patients with stable CAD before noncardiac surgery. An RCRI score of 3 or higher in a patient with severe myocardial ischemia suggestive of left main or three-vessel disease should lead to consideration of coronary revascularization before noncardiac surgery in appropriate patients.

Noninvasive cardiac testing is most appropriate if it is anticipated that the patient will meet guidelines for initiation of additional medical therapy or coronary angiography and coronary revascularization in the event of a positive test. Noninvasive stress testing of patients with three or more clinical risk factors and poor functional capacity (<4 METS) who require vascular surgery is reasonable, provided that the result might change future management. When feasible, exercise stress testing is the modality of choice and offers the benefit of an objective assessment of functional capacity. Pharmacologic stress tests may be performed instead of exercise tests; they are typically reserved for patients with functional limitations.

Dobutamine echocardiography and nuclear perfusion testing for purposes of identifying patients at risk for perioperative MI or death have excellent negative predictive values (near 100%) but poor positive predictive values (<20%). Therefore, a negative study is reassuring, but a positive study is still only a weak predictor of a “hard” perioperative cardiac event. Which higher-risk patients are most likely to benefit from preoperative noninvasive cardiac testing and treatment strategies to improve outcomes is not well defined.

Preoperative Invasive Cardiac Testing for Risk Stratification

Recommendations for perioperative coronary angiography are similar to those for patients with suspected or known CAD in general and should conform to the ACC/AHA guidelines for coronary angiography. This procedure should be considered for patients who are at high

risk for adverse outcomes based on the presence of unstable angina, angina refractory to medical treatment, high-risk results on noninvasive testing, or a nondiagnostic test in a high-risk patient undergoing high-risk noncardiac surgery. It should be considered on an individual basis for those with extensive ischemia revealed during noninvasive testing, for those at intermediate risk undergoing high-risk surgery for whom test results are nondiagnostic, for those convalescing from MI who require urgent noncardiac surgery, and for those with perioperative MI. In patients who have a high clinical risk (RCRI >3) and high-risk features on noninvasive cardiac testing, diagnostic cardiac catheterization should be considered (see Fig. 22.1).

PREOPERATIVE RISK MODIFICATION TO REDUCE PERIOPERATIVE CARDIAC RISK

Coronary Revascularization

Retrospective analyses of the Coronary Artery Surgery Study (CASS) registry and the Bypass Angioplasty Revascularization Investigation (BARI), along with prospective study of patients enrolled in the Coronary Artery Revascularization Prophylaxis (CARP) trial, have shown that prophylactic coronary revascularization with either coronary artery bypass grafting (CABG) or percutaneous coronary intervention (PCI) provides no short-term or mid-term benefit for patients without left main disease or multivessel CAD in the presence of poor left ventricular systolic function. Evidence is lacking to support elective coronary revascularization as a primary strategy for perioperative risk reduction in intermediate-risk patients undergoing major noncardiac surgery.

Recommendations for PCI are similar to those for patients with suspected or known CAD and should conform to the ACC/AHA guidelines. Recommendations by the AHA/ACC Society for Cardiovascular Angiography and Intervention, the American College of Surgeons, and the American Dental Association Science Advisory Committee are for a 30- to 45-day delay of surgery in patients taking thienopyridine dual antiplatelet therapy after bare-metal coronary stent placement and a 365-day wait after placement of a drug-eluting stent. Some studies indicate that the duration of dual antiplatelet therapy may be shortened to less than 1 year in selected patients receiving newer-generation stents (such as everolimus- or zotarolimus-eluting stents).

Currently, studies suggest that optimal medical therapy is the preferred strategy for intermediate- to high-risk patients with RCRI scores of 2 or higher who are without documented severe myocardial ischemia. As stated previously, the CARP trial demonstrated that preoperative coronary revascularization strategies to reduce perioperative cardiovascular risk did not offer significant benefit compared with excellent medical treatment in intermediate- to high-risk patients undergoing vascular surgery. However, high-risk patients with left main coronary stenosis, severe aortic stenosis, left ventricular ejection fraction of 20% or less, or unstable coronary symptoms were excluded from that trial. In many of these patients, coronary or valve surgery may be indicated on its own merit, without factoring in the noncardiac surgery. Therefore, coronary revascularization may be appropriate if diagnostic catheterization reveals left main disease or multivessel disease and depressed ejection fraction.

Using the information obtained from the composite algorithm (Fig. 22.2), a key decision is whether the risk for perioperative cardiac events is sufficiently low to proceed with surgery. For patients identified to be at high cardiac risk who are not candidates for coronary revascularization, the physician may decide to perform an operation that is thought to be less stressful such as a less extensive major plastic reconstruction, laparoscopic versus open procedures or alternative palliative procedures, or attempt to modify cardiac risk by additional intraoperative and perioperative therapies.

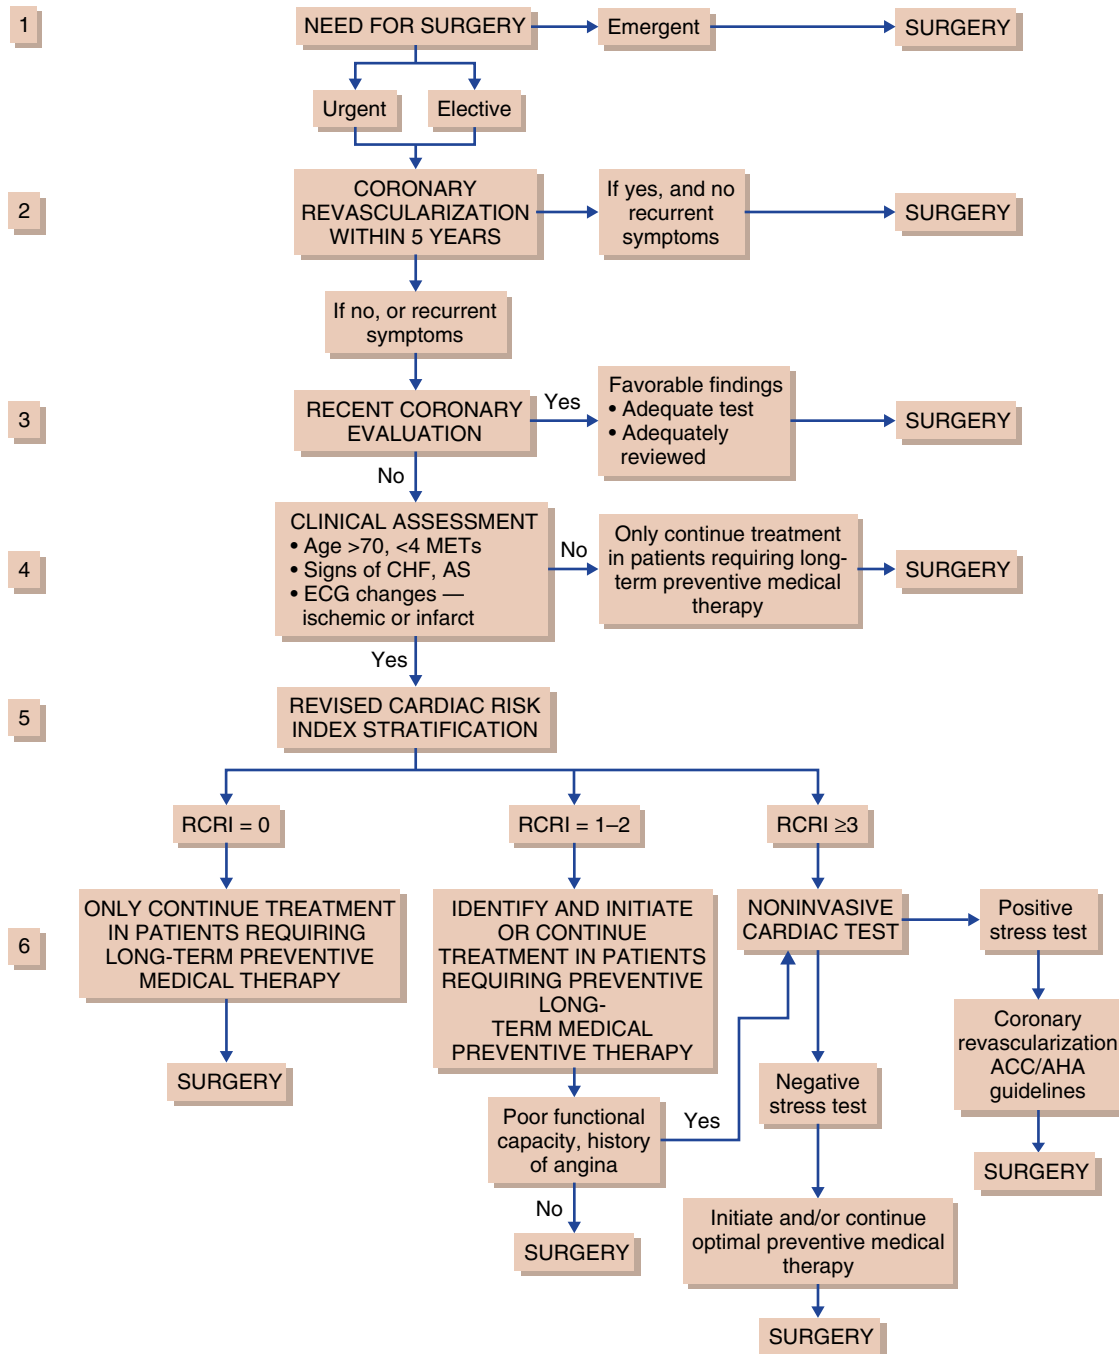

Fig. 22.2 Stepwise clinical evaluation algorithm for diagnostic cardiac catheterization. (1) Emergency surgery; (2) prior coronary revascularization; (3) prior coronary evaluation; (4) clinical assessment; (5) Revised Cardiac Risk Index; (6) risk modification strategies. Preventive medical therapy includes β -blocker and statin therapy. ACC, American College of Cardiology; AHA, American Heart Association; AS, aortic stenosis; CHF, congestive heart failure; ECG, electrocardiogram; MET, metabolic equivalent; RCRI, Revised Cardiac Risk Index.

β -Adrenergic Antagonists

There is uncertainty about the effectiveness and safety of perioperative β -blockade in patients undergoing noncardiac surgery. The ACC/AHA guidelines focusing on recommendations for perioperative β -blocker therapy limit class I recommendations to patients undergoing surgery who are already receiving β -blockers to treat angina, symptomatic arrhythmias, or hypertension. Class IIb recommendations are given for the initiation of β -blocker therapy prior to surgery in those with

intermediate- or high-risk myocardial ischemia noted on preoperative noninvasive stress testing (level of evidence C) and patients with three or more RCRI risk factors (level of evidence B).

The Perioperative Ischemic Evaluation (POISE) trial addressed the benefit versus risk of perioperative β -blockade. The POISE trial randomized 8351 intermediate- to high-risk patients older than 45 years of age to receive either a long-acting oral metoprolol succinate (metoprolol CR) or placebo in the perioperative period. The results showed that the

incidence of cardiac death, nonfatal MI, or cardiac arrest was reduced in the metoprolol group compared with placebo. However, there was an increased incidence of mortality and stroke in the metoprolol group compared with the placebo group. Stroke was associated with perioperative hypotension, bleeding, atrial fibrillation, and a history of stroke or transient ischemic attack. The POISE trialists highlighted the importance of a clear risk and benefit assessment for the initiation of preoperative β -blockers (see Fig. 22.2).

Preexisting β -blockade should be continued because withdrawal might increase perioperative mortality. If β -blockers are newly initiated in appropriately selected higher-risk patients undergoing noncardiac surgery, they should be carefully titrated and not abruptly initiated on a high-dose regimen in order to avoid hypotension or bradycardia.

HMG-CoA Reductase Inhibitors (Statins)

Prospective and retrospective evidence supports the perioperative prophylactic use of 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors (statins) for reduction of perioperative cardiac complications in patients with established atherosclerosis. Statins should be continued in patients who are already on statin therapy and undergoing noncardiac surgery. A class IIa indication is assigned to the use of statins for patients undergoing vascular surgery with or without clinical risk factors.

Angiotensin-Converting Enzyme Inhibitors

Angiotensin-converting enzyme inhibitors (ACEIs) and angiotensin II-receptor blockers (ARBs) are frequently prescribed for the management of hypertension, CHF, chronic renal failure, and ischemic heart disease. Evidence supports the discontinuation of these agents for 24 hours before noncardiac surgery because of adverse circulatory effects after induction of anesthesia in patients on these medications (hypotension) that may result in the need for vasopressin agonists for management of the ensuing refractory hypotension.

Oral Antithrombotic Agents

Evidence-based recommendations regarding perioperative use of aspirin, clopidogrel, other antiplatelet agents, or combination therapy to reduce cardiac risk currently lack clarity. A substantial increase in perioperative bleeding and transfusion requirement in patients receiving dual antiplatelet therapy has been observed. The discontinuation of clopidogrel for 5 days and aspirin for 5 to 7 days before major surgery to minimize the risk of perioperative bleeding and transfusion must be balanced with the potentially increased risk for an acute coronary syndrome, especially in high-risk patients including those with recent coronary stent implantation. If clinicians elect to withhold aspirin before surgery, it should be restarted as soon as possible postoperatively, especially after vascular graft procedures. (See further information on anticoagulants and surgery later in chapter.)

POSTOPERATIVE CARDIAC RISK ASSESSMENT

Monitoring for Myocardial Infarction

Although there are no standard criteria for their diagnosis, most perioperative MIs occur within the first 3 days after noncardiac surgery. Although an ECG is recommended in the setting of signs or symptoms suggestive of myocardial ischemia, MI, or arrhythmia in the postoperative period, the usefulness of postoperative screening with ECGs is uncertain. Measurement of serum cardiac biomarkers should be reserved for patients at high risk and for those who demonstrate ECG changes, symptoms of myocardial ischemia, new arrhythmias, unexplained shortness of breath, or hemodynamic evidence of cardiovascular dysfunction.

NONCARDIAC SURGERY IN PATIENTS WITH SPECIFIC CARDIOVASCULAR CONDITIONS

Valvular Heart Disease

All patients undergoing noncardiac surgery should be assessed especially for aortic stenosis by physical examination and by two-dimensional echocardiography for any suspicious murmur. Symptomatic severe stenosis represents an active cardiovascular condition that should be evaluated and managed before elective surgery is undertaken. Appropriately selected patients can be managed with valve replacement or valvuloplasty as a bridge to noncardiac surgery.

Less is known about the perioperative risks associated with mitral stenosis and mitral regurgitation in patients undergoing noncardiac surgery. Usually, a preoperative history and physical examination, chest radiograph, or ECG provides clues to the diagnosis, which can be confirmed by echocardiography. Accurate diagnosis may help optimize intraoperative anesthetic strategies, choice of pharmacologic interventions and invasive monitoring, and postoperative medical management. Patients with severe mitral stenosis are likely to benefit from balloon mitral valvuloplasty or surgical intervention before high-risk surgery.

Patients with aortic or mitral valvular regurgitation benefit from volume control and afterload reduction. In aortic insufficiency, it is thought that faster heart rates are better tolerated than slow ones because slow heart rates lead to increased diastolic filling and can exacerbate left ventricular volume overload.

Arrhythmias and Conduction Defects

Ventricular and atrial arrhythmias historically are recognized as predictors of perioperative cardiac complications. Therefore, identification of a preoperative arrhythmia warrants a careful evaluation for the presence and severity of underlying ischemic heart disease, cardiomyopathy, or other conditions that may contribute to perioperative complications. In general, asymptomatic arrhythmias or conduction defects warrant only observation and maintenance of an optimal metabolic state.

Congestive Heart Failure and Left Ventricular Dysfunction

CHF has been identified as a significant marker of cardiac risk in noncardiac surgery. Every effort should be made to identify the etiology of CHF and optimally control it preoperatively because it is a known risk factor for postoperative cardiac complications. Close monitoring of volume status is needed to avoid perioperative decompensation. Intravenous inotropic agents, vasodilators, or both may be useful for a short duration in the perioperative period to prevent or treat CHF, depending on the situation.

RENAL DISEASE

Renal dysfunction affects critical excretory and synthetic functions required for homeostasis. The major ensuing clinical effects include hypertension, volume overload, and electrolyte derangements.

Hypertension

A well-controlled blood pressure is desirable to reduce perioperative cardiovascular complications. The goal is to have blood pressure within an acceptable range based on current guidelines. Non-urgent procedures should be delayed for adequate BP control to be attained.

The stress response in the perioperative period does increase the incidence of so-called “white coat hypertension.” These patients do not require aggressive lowering of blood pressure that can result in

reduced perfusion to the brain and kidneys, resulting in cerebrovascular accidents and acute kidney injury, respectively.

Antihypertensives (Medications)

- ACEIs, ARBs, and renin antagonists' effect on the RAS have been associated with intraoperative hypotension and should be held on the day of surgery. These can be resumed within 48 hours based on patients' blood pressure, volume status, and renal function
- Diuretics should ideally be held in the perioperative period except in patients with evidence of volume overload. The need for patients to be NPO and associated volume losses during surgery usually result in hypovolemia. Diuretics often need to be adjusted perioperatively to reduce risk of acute kidney injury.
- α -Blockers and β -blockers should not be stopped abruptly except in patients who are hypotensive. These medications are associated with rebound hypertension when stopped abruptly. Doses should rather be reduced and holding parameters instituted in cases of hypotension in order to prevent hypertensive crisis associated with rebound hypertension.
- Calcium-channel blockers and vasodilators can be stopped abruptly if not required for optimization of blood pressure.

Acute Kidney Injury

Refer to the Kidney Disease: Improving Global Outcomes (KDIGO) classification of acute kidney injury (AKI).

Kidney injury can be due to prerenal, intrarenal or postrenal etiologies. Perioperative AKI occurs in about 1% of patients, but risk is much higher in patients having vascular and/or cardiac procedures and in patients with chronic kidney disease, cirrhosis, and heart failure. AKI in the perioperative period is often due to fluid losses, fluid shifts to other body compartments, and/or activation of the RAS. It is essential for the etiology of preoperative AKI to be elucidated and addressed before proceeding with elective surgery. It is critical to maintain euolemia, while aiming to keep electrolytes—especially serum potassium, magnesium, and sodium—within normal limits.

Management

Prerenal AKI patients typically respond to IVF and measures to ensure adequate renal perfusion by preventing hypotension.

Intrarenal AKI patients require consultation from nephrology colleagues to ensure adequate and timely management to prevent progression of the underlying AKI condition and for initiation of renal replacement therapy if needed.

Postrenal insufficiency is due to obstructive uropathy typically due to BPH, urethral stenosis or calculi. Renal ultrasound or CT of the abdomen and pelvis provides information about the nature and severity of the obstruction. Consultation from urology colleagues is often required.

In all patients with AKI, maintaining adequate renal perfusion by keeping spontaneous bacterial peritonitis (SBP) greater than 110 mm Hg is critical, and avoidance of potential nephrotoxins is essential.

Chronic Kidney Disease (CKD)

Refer to the KDIGO classification for staging.

The majority of the perioperative complications are of cardiac etiology. As much as possible, euolemic status needs to be attained before surgical procedures are performed. Patients on dialysis need to be dialyzed at least 24 hours before the planned procedure. Patients on peritoneal dialysis who require laparotomy often need temporary conversion to hemodialysis to maintain required volume status and address electrolyte abnormalities.

For non-dialysis dependent patients, adequate renal perfusion needs to be maintained and potential nephrotoxins avoided to prevent worsening of CKD.

Nephrotic Syndrome

Maintenance of adequate volume status and renal perfusion is important. Diuretic doses may need to be adjusted. For patients on corticosteroids (prednisone >5 mg daily) for the management of this condition, it should be assumed that their hypothalamic-pituitary-adrenal (HPA) axis is at least partially compromised. Stress dose corticosteroids given as hydrocortisone 100 mg IV every 8 hours, with a transition to an oral regimen in 24 to 48 hours, and then continuing with the usual dose during the perioperative period is usually an appropriate plan.

Renal Transplant Medicine

Immunosuppressive medications should be continued perioperatively. For patients who are unable to take oral medications such as cyclosporine, IV cyclosporine should be given; the dose required is a third of the oral dose.

Monitoring of drug serum levels is essential in view of potential drug-drug interactions.

HEPATIC DISEASE

Acute and chronic liver diseases (Fig. 22.3) can lead to hepatic dysfunction that may worsen perioperatively because of anesthetic agents and hemodynamic effects of a surgical procedure. The major

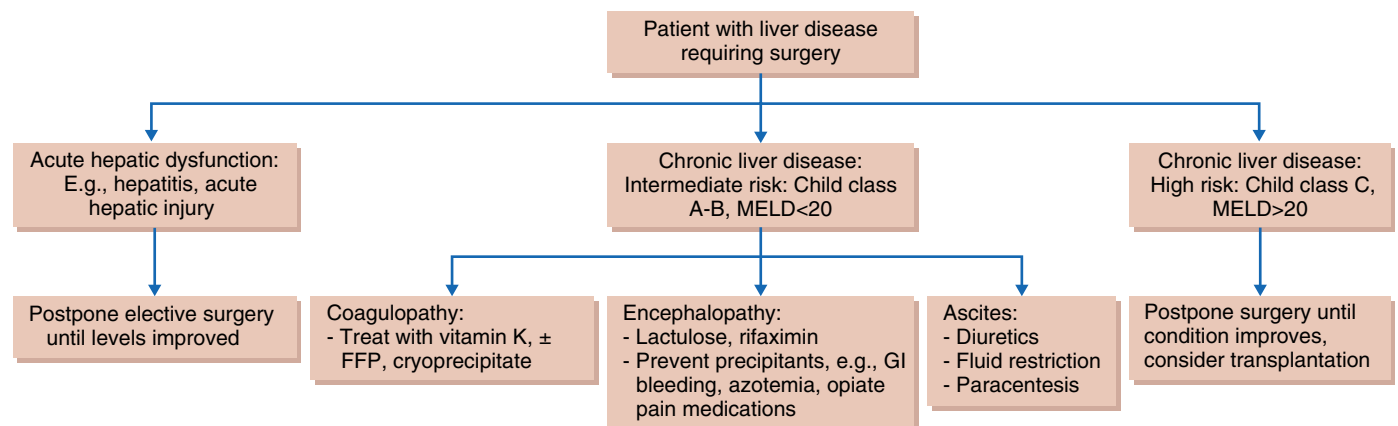

Fig. 22.3 Approach to preoperative risk stratification and interventions in patients with liver disease.

concerns are drug-induced hepatotoxicity, precipitating decompensation of liver cirrhosis and/or development of fulminant liver failure. Perioperative management involves treatment of the complications of liver disease, including coagulopathy, ascites, encephalopathy, and malnutrition.

- Elective procedures in patients with asymptomatic hepatic dysfunction should be postponed pending additional evaluation and reassessment of operative risk.
- Patients with acute hepatic inflammation or hepatocellular and/or cholestatic injury should have elective procedures postponed until there is evidence of recovery.
- Patients with chronic liver disease with preserved hepatic function require close monitoring although their operative risk is minimal.

Cirrhosis is a chronic liver disease, which results in impaired synthetic and metabolic functions.

SBP antibiotic prophylaxis is required for patients with low ascitic fluid protein levels (<1 g/L) for the duration of hospitalization perioperatively. Additional indications for SBP prophylaxis include prior history of SBP and patients with evidence of upper gastrointestinal blood loss.

Patients with ascites due to portal hypertension who may require therapeutic paracentesis will need albumin infusion if more than 5 L is drained to reduce risk for AKI, and the rapid reaccumulation of ascitic fluid.

Diuretic regimens should be adjusted as needed to help maintain required volume status and to keep serum electrolytes within normal limits.

Precipitants of hepatic encephalopathy in patients with cirrhosis need to be avoided as much as possible. Elective procedures in patients who are encephalopathic should be postponed while their clinical condition is managed with the aid of a hepatologist.

Coagulopathy is one of the primary features of chronic advanced liver disease. The etiology is often multifactorial, including hepatic synthetic dysfunction, thrombocytopenia, malnutrition, and the effect of cholestasis on vitamin K absorption. The following measures should be taken to address coagulopathy in the perioperative period.

1. Vitamin K supplementation with or without fresh-frozen plasma (FFP) is often used to correct coagulopathy before surgery. Use of FFP is mainly limited to instances where massive blood transfusion (>4 units) raises concern for dilutional coagulopathy.
2. Cryoprecipitate can address hypofibrinogenemia if serum fibrinogen is less than 100 mg/dL.
3. Platelet transfusion can be used to attain a desired serum platelet level depending on the type of surgical procedure, greater than 50,000 μ L for most surgical interventions, but greater than 100,000 μ L for neurosurgical procedures.
4. NR values tend to be elevated due to hepatic dysfunction, but this does not confer any antithrombotic properties due to the concept of rebalanced hemostasis. Patients who require deep vein thrombosis (DVT) prophylaxis should still receive subcutaneous heparin or other pharmacologic interventions to reduce DVT risk.

The Model for End-Stage Liver Disease (MELD) and Child-Pugh score/classification (also referred to as Child criteria) have been used for risk assessment of patients with liver disease. The MELD score is calculated using total bilirubin, international normalized ratio (INR), and serum creatinine. This results in four MELD levels, with scores greater than 25 indicating highest mortality risk. Child-Pugh scores are calculated using five clinical measures: total bilirubin, serum albumin, prothrombin time (PT), ascites, and hepatic encephalopathy. The scoring of these clinical measures results in classification of patients in Child class A, B, or C. Patients in class C have the highest mortality risk.

More recently, the integrated MELD score (iMELD), which incorporates serum sodium level for MELD scores less than 12, has been

adapted and has been shown to have a better prognostic strength compared with the MELD or Child-Pugh scores.

Surgery is contraindicated in patients with Child-Pugh class C, high MELD/iMELD score (>20), acute hepatitis, severe coagulopathy, or severe extrahepatic manifestations of liver disease (e.g., acute renal failure, hypoxia). Avoid surgery, if possible, in patients with a MELD score of greater than or equal to 18 or Child-Pugh class B unless they have undergone a thorough preoperative evaluation and preparation.

- Use sedatives and neuromuscular blocking agents cautiously.
- Optimize nutrition and medical therapy for cirrhotics:
 - Correct coagulopathy with vitamin K with or without FFP to achieve an INR less than 1.6.
 - The goal platelet count is greater than 50 to 100×10^3 /L. This may vary depending on the type of surgical procedure.
 - Address ascitic fluid volume to reduce risk of abdominal wall herniation, wound dehiscence, and compartment syndrome.
- Postoperatively, emphasis should be placed on:
 - Signs of acute liver failure, including worsening jaundice, encephalopathy, and ascites.
 - Monitoring for and correction of renal dysfunction and/or electrolyte abnormalities.
 - Some patients may require IV tranexamic acid to address postoperative bleeding due to the altered fibrinolytic system.

PULMONARY DISEASE

The major components of effective preoperative care are measures to prevent or reduce perioperative complications including pulmonary infections, exacerbation of underlying pulmonary disease, hypoxic hypercarbic respiratory episodes, and avoidance of pulmonary embolism.

For asymptomatic patients there is generally no need for preoperative chest radiographs or pulmonary function tests (PFTs). Preoperative PFTs are, however, essential in patients who are scheduled to have lung resection procedures to help predict postoperative lung function.

Patients with unexplained dyspnea need to be evaluated before having surgical procedures that require general anesthesia.

A combined cardiopulmonary risk index is proposed for risk stratification of pulmonary complications. Pulmonary risk factors have been added to the Goldman Cardiac Risk Index; patients with a combined score of greater than 4 points (of a total of 10) are 17 times more likely to develop complications. These pulmonary risk factors include the following:

- Obesity (i.e., body mass index >27 kg/m²)
- Cigarette smoking within 8 weeks of surgery
- Productive cough within 5 days of surgery
- Diffuse wheezing within 5 days of surgery
- FEV₁/FVC ratio less than 70% and PaCO₂ greater than 45 mm Hg

In the preoperative history and physical exam, patients should be screened for obstructive sleep apnea (OSA). Adequate management of OSA is critical to prevent cardiopulmonary and neurovascular complications. The commonly used tool is the STOP-BANG score. A formal sleep study is needed in high-risk patients who are scheduled for elective procedures.

COPD/Bronchial Asthma

Patients with these conditions should have their treatment regimen optimized and be instructed to continue with their medications up to the morning of their procedures. Patients with features of exacerbation should be started on systemic corticosteroids. Planned procedures should be rescheduled if possible.

HPA axis suppression should be assumed to be present in patients who have received systemic steroids for more than 3 weeks in the past 6 months. These patients should receive stress-dose coverage perioperatively.

There is no role for prophylactic perioperative use of antibiotics. Elective procedures should be cancelled in patients with active infections.

Obstructive Sleep Apnea

Patients require CPAP (continuous positive airway pressure) perioperatively. Blood gas monitoring is required.

Smoking cessation does reduce pulmonary complications and should be encouraged several weeks before planned elective procedures.

Breathing exercises including use of incentive spirometry are worthwhile risk-reduction measures that should be used.

Postoperative management is based on:

- Appropriate use of antibiotics to treat infections
- Use of high-dose steroids of management of flare-up of underlying lung diseases
- Maintenance of adequate oxygenation.

Prevention of Venous Thromboembolism

In patients undergoing major orthopedic surgery such as hip and knee joint replacement, venous thromboembolism (VTE) prophylaxis with low-molecular-weight heparin (LMWH), adjusted dose warfarin, apixaban, rivaroxaban or aspirin should be initiated postoperatively and continued for a period of up to 35 days. Placement of inferior vena cava filters is unlikely to offer added benefit to patients with contraindications to thromboprophylaxis. Patients undergoing nonorthopedic surgeries should be risk stratified for VTE and those at high risk receive prophylaxis with LMWH or low-dose unfractionated heparin. See American College of Chest Physicians guidelines in the suggested readings section.

ENDOCRINE DISEASE

Diabetes Mellitus

Diabetes mellitus is a common condition requiring preoperative management because uncontrolled diabetes is associated with hyperglycemic crises, infection, reduced wound healing, and increased mortality. Optimal perioperative glucose targets vary but generally fall between 80 to 180 mg/dL. Evaluation includes known complications of diabetes including neuropathy, chronic kidney disease, and heart disease. Hemoglobin A_{1C} measurement will correlate with recent (1-3 months) blood glucose levels and may be helpful with assessment of hyperglycemia risk. Oral and noninsulin injectable medications are generally continued until the morning of surgery at which time they are temporarily discontinued. Long-acting basal insulin is continued but may require dose reduction by 20% to 30% if a fasting period is required. Withholding of long-acting insulin in type 1 diabetics may result in onset of ketoacidosis and should be avoided. Short-acting insulin doses may be reduced or temporarily eliminated depending on oral intake restrictions. Intraoperative and postoperative monitoring of blood glucose via fingerstick (every 2-4 hours) will help identify occurrence of hypo- or hyperglycemia. Long- and short-acting insulin should be used to treat and prevent hyperglycemia while being mindful of the patient's insulin sensitivity to avoid hypoglycemia. Transition back to home regimen may begin when the patient is clinically stable, resumes steady oral intake and no further procedures/operations are planned (see [Chapter 68](#)).

Thyroid Disease

Hypo- and hyperthyroidism are each associated with worsening of associated symptoms, morbidity, and even death. Although routine laboratory screening is not recommended, evaluation should be done when symptoms of thyroid dysfunction are noted in patient assessments. Mild to moderate hypothyroidism should be treated with preoperative oral levothyroxine. Treatment of severe hypothyroidism including myxedema coma include IV levothyroxine and IV liothyronine and postponement of elective surgery until thyroid hormone levels are stable. Untreated hyperthyroidism may result in postoperative thyroid storm, which is characterized by tachycardia, confusion, fever, and cardiovascular collapse. Patients with thyrotoxicosis should be treated with β -blockers and antithyroid medications preoperatively (see [Chapter 65](#)).

Adrenal Insufficiency and Long-Term Corticosteroid Use

The adrenal glands produce cortisol and various catecholamines in response to stimulation from the HPA axis. Patients receiving long-term exogenous corticosteroids (20 mg daily of prednisone or equivalent for >3 weeks) are considered at risk of adrenal insufficiency due to HPA axis suppression. Because surgery is a state of induced stress, an IV corticosteroid regimen (intravenous hydrocortisone 50-100 mg and up to three times daily) is required with a plan to taper to routine doses based on hemodynamic response (see [Chapter 66](#)).

HEMATOLOGIC DISEASE

Screening for disorders of bleeding hemostasis includes questions identifying episodes of bleeding diathesis, medications posing high bleeding risk, and family history of hemophilia or other inherited bleeding disorders. Patients with liver disease, end-stage renal disease, and collagen vascular disease may have higher perioperative bleeding risk. Commonly obtained laboratory testing includes PT, INR, activated prothrombin time (aPTT), and platelet count.

Management of anticoagulants and antithrombotics in the perioperative setting is a frequent concern given their frequent use in clinical practice. Perioperative risk of bleeding and thromboembolic events should be evaluated because not all surgical procedures require discontinuation of anticoagulation ([Table 22.4](#)). In situations of high risk of bleeding, the vitamin K antagonist warfarin is held 5 days prior to the planned procedure. Direct oral anticoagulants such as apixaban, dabigatran, and rivaroxaban may be discontinued within 24 to 48 hours of the procedure depending on overall bleeding risk and renal function. In situations of high risk of thromboembolism due to interruption of therapy, bridging therapy may be provided with heparin infusion or LMWH injection until oral therapy may be safely resumed ([Table 22.5](#)). Perioperative management of antithrombotics, such as aspirin, clopidogrel, and other P2Y₁₂ inhibitors should be based upon the indications for antithrombotic use and the type of surgery to be performed as noted in the section on cardiologic disease.

Preoperative anemia is associated with an increase in postoperative transfusion, morbidity, and mortality. A target preoperative hemoglobin is not well established and may depend on the expected blood loss, but most patients will likely tolerate levels as low as 7 g/dL. Screening, work-up, and optimization of anemia should occur with enough lead time to allow for correction and optimization prior to elective surgical procedures.

INFECTIOUS DISEASE

Surgical site infections (SSIs) complicate up to 20% of operations leading to significant morbidity and mortality. SSIs occur within 30 days of surgery and are defined as affecting the superficial, deep or organ/space

TABLE 22.4 Risk Factors for Bleeding and Thrombosis in the Anticoagulated Patient

	INDICATIONS FOR ANTICOAGULATION THERAPY ^a		
	Atrial Fibrillation	Mechanical Heart Valve	VTE
High-risk features for periprocedural bleeding: Consider interruption of therapy	Procedure-related bleeding risk: Consult surgeon or surgical society guidelines for procedure bleeding risk classification. Common high-risk procedures include: vascular surgery, pacemaker lead extraction, kidney biopsy, radical hysterectomy, total hip replacement, and many others. Patient-related bleed risk increased if: Major bleed or intracranial hemorrhage <3 months; thrombocytopenia or abnormal platelet function (uremia and aspirin use); supratherapeutic INR; history of periprocedural bleeding		
High-risk features for perioperative thromboembolism: Consider bridging therapy	<ul style="list-style-type: none"> • CHADS2-Vasc 7+ • CVA/TIA/VTE <3 months prior • Rheumatic valvular heart disease 	<ul style="list-style-type: none"> • Mitral valve prosthesis • CVA/TIA <6 months prior • Cage-ball or tilting disk aortic valve prosthesis 	<ul style="list-style-type: none"> • VTE <3 months prior • Severe thrombophilia (protein C or S deficiency, antiphospholipid syndrome, history of recurrent thrombosis when off anticoagulation)

CHADS2-VASC, Clinical prediction rule for estimating the risk of stroke in patients with nonrheumatic atrial fibrillation.

^aDecisions on bridging therapy are clinically based—evaluate thrombotic risk balanced by patient bleeding risk, consider additional information, and use clinical judgement.

TABLE 22.5 Interruption of Therapy and Bridging of Anticoagulation

	Anticoagulant Class	
	Vitamin K Antagonists	Direct Oral Anticoagulants (DOACs)
	<ul style="list-style-type: none"> • Warfarin 	<ul style="list-style-type: none"> • Dabigatran • Apixaban • Rivaroxaban
Interruption of therapy	<ul style="list-style-type: none"> • INR 2.0-3.0, discontinue 5 days prior to procedure • INR 1.5-1.9, discontinue 3-4 days prior to procedure 	<ul style="list-style-type: none"> • Dependent on creatinine clearance • If renal function is normal, stop 1-2 days prior to surgery
Bridging therapy	<ul style="list-style-type: none"> • Therapeutic UFH or LMWH • Start UFH when INR <2 • UFH: Stop >4 hours prior to procedure • LMWH: Stop 12-24 hours prior to procedure • LMWH use and dosing must be renally adjusted 	<ul style="list-style-type: none"> • Therapeutic UFH or LMWH • Start UFH when INR <2 • UFH: Stop >4 hours prior to procedure • LMWH: Stop 12-24 hours prior to procedure • LMWH use and dosing must be renally adjusted
Reinitiation of therapy	<ul style="list-style-type: none"> • Restart at patient's regular dose • Timing is procedure specific: consult with surgeon (most within 24 hours) 	<ul style="list-style-type: none"> • Will render patient therapeutically anticoagulated within hours • Discuss timing of reinitiation with surgeon/proceduralist (most within 24 hours)
Special considerations	<ul style="list-style-type: none"> • Postprocedure bridging therapy may be considered in patients with moderate or high risk • Discontinue bridging therapy once INR >2.0 	<ul style="list-style-type: none"> • Inability to take PO: may use UFH or LMWH • Obviates need for DVT prophylaxis • Special caution in setting of spinal anesthesia due to risk of hematoma formation

LMWH, Low-molecular-weight heparin; UFH, unfractionated heparin.

areas of the wound. Patient risk factors for SSIs include age, nutritional status, and diabetes while operative risk factors include initial contamination of surgical wound, operative technique, and many others. Perioperative care is focused on prevention through the implementation of care bundles (small sets of straightforward evidence-based interventions) including preoperative antibiotics, hair removal, avoidance of hypothermia, and glycemic control. Preoperative antibiotic coverage should include *Staphylococcus aureus* for clean wounds and expand to cover other organisms depending on wound type and risk of contamination. Skin decontamination with topical agents such as chlorhexidine has become routine but may not confer benefit in all patients.

NEUROLOGIC DISEASE

Neurologic conditions that may become exacerbated in the perioperative period include neuromuscular diseases, Parkinson's disease, and stroke.

Neuromuscular Diseases

Conditions such as myasthenia gravis, amyotrophic lateral sclerosis (ALS), and muscular dystrophies predispose patients to a variety of complications. Myasthenia gravis, an autoimmune disease affecting acetylcholine receptors at the neuromuscular junction that leads to skeletal muscle weakness, may worsen acutely in the perioperative period. Respiratory insufficiency or failure due to myasthenic crisis requires assessment of inspiratory function by measuring the negative inspiratory force at the bedside.

Dysphagia, which accompanies many neuromuscular diseases, may lead to aspiration pneumonitis/pneumonia. Swallow evaluation is necessary in the perioperative setting to mitigate this risk in patients with ALS, which is characterized by motor neuron degeneration and may be complicated by postoperative aspiration pneumonia and respiratory failure. Patients with muscular dystrophies are at risk for cardiac arrhythmias and may require cardiac rhythm monitoring. Malignant hyperthermia syndrome is a rare inherited

condition presenting as perioperative muscle rigidity, fever, and cardiac arrhythmias.

Parkinson's Disease

Parkinson's disease is a common neurodegenerative disorder associated with dyskinesia, dysphagia, dysmetria, and loss of function. Missed doses of levodopa, a common therapy for Parkinson's, may result in fever, dysautonomia, and worsening of Parkinson's disease symptoms. Levodopa therapy should be continued without interruption if possible, depending on the clinical situation. Patients with Parkinson's disease may require longer rehabilitation following surgical procedures.

Stroke

Perioperative stroke incidence is low but carries a high rate of mortality and morbidity. Most perioperative strokes are embolic in mechanism. Risk factors include history of stroke, diabetes mellitus, hypertension, atrial fibrillation, and advanced age. Addressing modifiable risk factors and appropriate management including use of aspirin and statin therapy for known intracranial atheromatous disease should be pursued. In high-risk patients with atrial fibrillation, perioperative bridging of anticoagulation therapy should be considered to minimize risk of stroke.

RHEUMATOLOGIC DISEASE

Autoimmune conditions such as rheumatoid arthritis and lupus are commonly treated with medications aimed at reducing the activity of the immune system. Disease-modifying antirheumatic drugs such as methotrexate, azathioprine, mycophenolate mofetil, which are used in a range of rheumatic conditions, may be continued in the perioperative period. Biologic agents such as adalimumab, infliximab, and other similar agents are thought to raise the risk of perioperative infection and should be held perioperatively. In addition, surgery should ideally be scheduled for the end of the dosing cycle.

SPECIAL NEEDS OF THE GERIATRIC PATIENT

One third of inpatient surgeries in the United States are performed on adults older than age 65. Patients in the geriatric population have a greater risk of perioperative morbidity and mortality. Geriatric preoperative risk assessment should focus on function, cognition, and evaluation of medications, in addition to the systems-based approach in this chapter. Impairment of activities of daily living (ADLs) is directly associated with increased postoperative mortality. Screening for function may be performed with a variety of scales developed for this purpose. Gait speed and the timed Up and Go test are useful objective assessments. Underlying cognitive impairment is an independent risk factor for postoperative delirium. Cognition may be evaluated with the Mini-Cog scale or Montreal Cognitive Assessment. Identification of concerns in the patient's functional status and/or cognition preoperatively may lead to reevaluation of the surgical management plan. Postoperatively, strategies should focus on physical rehabilitation and measures to reduce risk of delirium including minimal use of medications that promote delirium, frequent reorientation, multicomponent interventions, and judicious use of antipsychotic medications.

Review of medications with a view toward postoperative complications should especially include antihypertensives (hypotension), diuretics (volume depletion), diabetes medications (hypo- or hyperglycemia), antithrombotic agents (bleeding or thrombosis), benzodiazepines, opiates, and other sedative hypnotics (sedation and delirium). Indications for each medication should be reviewed and assessment of the risks and benefits should be performed.

SUMMARY

The success of standardized evidence-based preoperative and postoperative risk reduction strategies in patients undergoing noncardiac surgery depends on collaborative teamwork and careful communication among the surgeons, the anesthesiologist, the patient's primary care physician, and the consultant.

The risk for a perioperative cardiac complication varies with the severity of the surgical procedure and with RCRI stratification. A systematic, stepwise approach for preoperative cardiac risk assessment in patients undergoing noncardiac surgery facilitates a decision as to whether the risk for perioperative cardiac events is sufficiently low to proceed with the surgery. The patient's comorbid conditions and risk factors must be assessed for risk of exacerbation and steps taken to reduce risk to the patient in the perioperative period. Postoperatively, close monitoring of the patient's condition is required. Patients who develop complications after the operation will require timely and appropriate interventions by the surgical and medical teams. Finally, cardiac and medical perioperative care are evolving fields and practitioners must strive to keep their knowledge and practices current through literature review and guideline awareness.

For a deeper discussion on this topic, please see Chapters 403, "Preoperative Evaluation," and 405, "Postoperative Care and Complications," in *Goldman-Cecil Medicine*, 26th Edition. ❖

Renal Structure and Function

Orson W. Moe, Javier A. Neyra

INTRODUCTION

The kidney maintains the composition and quantity of body fluids, and kidney failure is manifested by dysfunction of multiple organs. Chronic kidney disease is approaching epidemic proportions worldwide, and acute kidney injury affects a very high percentage of hospital admissions and ambulatory patients, with high rates of morbidity and mortality. The etiologies of these conditions are very diverse and often geographically specific. In addition to loss of glomerular filtration and tubular function, kidney diseases include hypertension, urolithiasis, and a host of electrolyte disorders that do not affect the glomerular filtration rate (GFR) but nonetheless cause significant morbidity and mortality. To understand these conditions, a thorough knowledge of the anatomy and function of the kidney is requisite.

Approximately 25% of the cardiac output is distributed to the kidneys, where the blood is continuously cleansed of toxins. In addition to excretion, the kidney is an important metabolic organ and a source of endocrine molecules. Renal failure represents a disruption of all of these functions. Selected aspects of renal structure and function are reviewed briefly in this chapter to set the foundation for the subsequent chapters that deal with specific renal diseases.

RENAL STRUCTURE

Macroscopic Anatomy

The kidneys are seated against the posterior wall of the abdomen in the retroperitoneal space, rendering them readily accessible for percutaneous biopsy. The lower poles may be palpable on deep inspiration in a lean individual. Each human kidney weighs about 120 to 170 g; is about 11 cm long, 6 cm wide, and 3 cm thick; and is endowed with approximately 1 million nephrons with interindividual variations. The “kidney size” commonly referred to in clinical sonographic reports is actually the cephalocaudal renal length, which is not an accurate surrogate for renal volume and mass and may be influenced by patients’ body habitus. Despite this caveat, renal length is an acceptable clinical surrogate of renal volume.

The kidney is surrounded by a fibrous capsule (anteriorly, Gerota fascia and posteriorly, fascia retro renalis). The renal arteries enter the kidney and the renal vein and ureters leave the kidney in the renal pelvis. The bisected surface consists of the lighter-colored outer *cortex* and the darker inner *medulla* (Fig. 23.1A). A sample from a clinical biopsy typically originates from the cortex in the lower pole. The medulla is divided into outer and inner regions, and the outer medulla is subdivided into outer and inner stripes. The medulla has multiple conical contours, called *pyramids*, with their apices abutting on the renal pelvis as papillae. The contact points of the renal pelvis with the renal

papillae are cup-like structures called *calyces*. Interpolated between the pyramids are centripetal extensions of cortical tissue called *columns of Bertin* (see Fig. 23.1A).

Renal Circulation

Each kidney receives blood from a single renal artery, although supernumerary arteries are present in up to one third of individuals. Just before or after the renal artery enters the kidney, it divides into interlobar arteries that pass between the pyramids of the kidney radially up the columns of Bertin (see Fig. 23.1A). The interlobar arteries further divide into arcuate arteries, which arch along the corticomedullary junction (see Fig. 23.1B). Arcuate arteries give rise to cortical ascending arteries, which bring blood to the glomeruli. Afferent arterioles ramify into glomerular capillaries, distributing blood to individual glomeruli. Features of the renal circulation are summarized in Table 23.1.

The glomerular capillary is the site for glomerular ultrafiltration. Even though the efferent arteriole is downstream from the glomerular capillary, it is not a venule because it has arteriolar walls and is upstream of the second capillary system surrounding the tubules. The peritubular capillaries provide oxygen and nutrients for the kidney, collect the fluid and solutes reabsorbed by tubules to return into the circulation, and deliver the solutes to be secreted by tubule into the tubule fluid. The peritubular capillaries surrounding the cortical and juxtamedullary nephrons originate from the efferent arterioles of cortical and juxtamedullary glomeruli, respectively. In certain pathologic settings, peritubular capillary flow or integrity can be disrupted, decreasing oxygenation and promoting ischemic injury.

The vessels that run parallel to loops of Henle are called *vasa recta* (see Fig. 23.1D) because of their long, straight structures. Blood from the peritubular capillaries is returned to the circulation by a venous system that mirrors the architectural structure of the arterial supply: interlobular vein, arcuate vein, interlobar vein, and renal vein. The parallel countercurrent nature of the vasculature provides the basis for the very high medullary tonicity, which allows urine concentration but also direct arteriovenous diffusion of oxygen, giving rise to the very low oxygen tension in the medulla. This low oxygen tension renders the kidney prone to ischemic injury, which is one of the most common causes of acute kidney injury (see Chapter 29).

Renal Nerves

The capsules of the kidney and the ureters have pain fibers derived from splanchnic nerves. This explains the costovertebral angle pain that occurs when the kidneys are inflamed and during renal colic during kidney stone passage. The renal parenchyma does not have pain fibers but is richly innervated with sympathetic nerves that enter the renal parenchyma with the renal artery. The sympathetic nerves

Fig. 23.1 (A) Gross anatomy of the kidney. (B) Schematic representation of the vasculature within a column of Bertin. (C) Structural components of the glomerulus. (D) Schematic representation of a superficial and a juxtamedullary nephron based on the location of their glomeruli. The tubules are intimately intertwined with the capillary system. The peritubular capillaries come off the efferent arteriole leaving the glomerular capillary. The capillaries that bathe the long descending and ascending limbs of the Henle loop are called the vasa recta due to their straight nature. The tubular segments are named axially: *CCD*, Cortical collecting duct; *CNT*, connecting tubule; *DCT*, distal convoluted tubule; *IMCD*, inner medullary collecting duct; *LOH*, loop of Henle; *OMCD*, outer medullary collecting duct; *PCT*, proximal convoluted tubule; *PST*, proximal straight tubule; *TAL*, thick ascending limb; *tAL*, thin ascending limb; *tDL*, thin descending limb.

TABLE 23.1 Characteristics of the Renal Circulation

Feature	Implications
Few or no anastomoses	Very prone to regional disruption of blood supply
Among the highest blood flow rates per gram of tissue	Lowest oxygen extraction (lowest arteriovenous O_2 difference)
Functional arteriovenous shunts	Solutes and gases (e.g., O_2) can diffuse directly from artery to vein without passing through capillaries
Two capillary systems in tandem	The two capillaries serve completely different functions, in the glomeruli and tubules in sequence

abut on the arterioles (see Fig. 23.1C), stimulate renin release, decrease renal blood flow, and promote renal retention of sodium (Na^+). Renal sympathetic denervation has been proposed as a novel treatment of

resistant hypertension using radiofrequency energy delivered via an intrarenal arterial catheter radially to disrupt the nerve fibers on the renal artery, but thus far the data have not been conclusive.

Walk the Nephron

The functional unit of the kidney is the nephron. Each human kidney has approximately 1 million nephrons. Approximately 30% of these have their glomeruli situated deep in the cortex and are referred to as *juxtamedullary nephrons*; the rest are in the outer cortex and are referred to as *superficial nephrons*. Each nephron is a glomerulus followed by a tubule that ends in the renal pelvis. The surrounding capillaries and the interstitial space are important functional components of the nephron.

Glomerulus

The glomerulus consists of the glomerular vasculature (arterioles and capillaries) supported by the mesangium (mesangial cells and matrix) inside Bowman's capsule (parietal and visceral epithelial cells) (see Fig. 23.1C). The visceral cells of Bowman's capsule are the podocytes, so named because of their numerous "foot processes." The smooth muscle layers of the afferent and efferent arterioles are critical in determining arteriolar tone. The glomerular capillary contacts the mesangium on one side and is separated from the foot processes of the podocytes on the opposite side by the glomerular basement membrane (GBM). The glomerulus filters large volumes of water and small solutes while retaining most of the proteins and all of the cells in the blood. The glomerular filtration barrier is a tripartite structure composed of the capillary endothelium, the GBM, and the podocyte slit diaphragm.

Lining the inside of the GBM is a single layer of fenestrated endothelial cells. The fenestrations (50 to 100 nm in diameter) provide a barrier to negatively charged large molecules in the blood. The GBM contains laminin, type IV collagen, entactin (nidogen), and proteoglycans that restrict movement of large molecules (e.g., albumin) from the capillary into Bowman's space. The GBM contains dense negative charges due to glycoproteins with sialic acid residues that restrict the passage of anionic plasma solutes. It can be the site of deposition of immunocomplexes that cause glomerulonephritis (e.g., membranous glomerulonephritis, membranoproliferative glomerulonephritis, lupus nephritis). Autoantibodies against the GBM cause severe inflammation and loss of filtration. Autoantibodies against a podocyte membrane glycoprotein (M-type phospholipase A2 receptor, PLA2R) can cause antibody-mediated primary membranous nephropathy. The epithelial layer consists of podocytes and the parietal epithelium, which is flat and squamous with few organelles. At the vascular pole, the parietal epithelium is contiguous with a completely different epithelium—the proximal convoluted tubule.

On the visceral side of Bowman's space are the podocytes, which constitute part of the filtration barrier. These cells have a highly interdigitating system of foot processes that rest against the basement membrane. The podocyte cell bodies lie within the extracellular matrix. The spaces between foot processes are filtration slits of approximately 40 nm in diameter bridged by slit diaphragms, which are also negatively charged, contributing to the containment of middle-size negatively charged particles in the capillary. In the last decade, there have been momentous advances in identifying the components of the slit diaphragm complex and understanding their functions. A full discussion is not possible here, but major slit diaphragm-associated proteins include nephrin, podocin, neph-1/2/3, FAT-1, R-cadherin, catenin, CD2AP, ZO-1, and α -actinin 4. Mutations of many of these genes cause congenital proteinuric kidney disease (see Chapter 26).

Tubules

The parietal epithelium of Bowman's capsule becomes the renal tubule (see Fig. 23.1D) as it leaves the glomerulus. The renal tubule is a prototypical polarized epithelium. Its salient characteristics are summarized

in Fig. 23.2. A simple cylinder would not suffice in terms of surface area for transport. In the luminal apical membrane, surface amplification is achieved either by protrusions or by a more extensive form of protrusions called the *brush border* in the proximal tubule. Between cells are structures called *tight junctions*. Although they are called tight junctions, some are truly tight (with high resistance to solute and charge movement), whereas others are quite leaky to solutes. In addition to resistance, these complexes also regulate whether the junction is more permeable to one ion type compared with another selective permeability. On the other side of the tight junction is the intercellular space, which is contiguous with the interstitial space. The basolateral cell membrane on the interstitial-capillary side amplifies its surface area by infoldings into the cell and interdigitations between two cells.

The movement of a solute can be through a cell (transcellular transport) or around the cell (paracellular transport) (see Fig. 23.2A). Solute transport is an energy-consuming process that requires metabolic fuels. There are many kinds of transport proteins (see Fig. 23.2B). ATPases directly couple hydrolysis of adenosine triphosphate (ATP) to transport. Cotransporters (or symporters) move two solutes in the same direction, and countertransporters (antiporters) move two different solutes in opposite directions. Channels function as protein-lined "holes" that allows specific solutes to permeate. Different transporters can also be coupled together to form a new transport system. Finally, there are proteins that protrude outside the cell in the junctional area to provide a conduit for paracellular transport.

Specialized Structures

Interstitialium

The space between the tubules and peritubular capillaries constitutes about 5% to 10% of renal volume and harbors interstitial fibroblasts and dendritic cells. In diseases such as interstitial nephritis (see Chapter 27), the interstitium is full of inflammatory cells, which elaborate cytokines and chemokines that profoundly affect filtration and tubular function. The resident fibroblasts are stellate cells with projections that physically contact tubules and capillaries, provide scaffold support, and secrete and maintain matrix. These cells, when stimulated by cytokines, can transform into myofibroblasts and contribute to interstitial fibrosis, a common pathobiologic feature of kidney disease. Some specialized fibroblasts in the deep cortex are sensors of oxygen and producers of circulating erythropoietin. The dendritic cells are antigen-presenting cells that express major histocompatibility complex (MHC) class II molecules. They are in intimate communication with the renal parenchyma, constantly sampling and responding to the local antigenic environment. Dendritic cells are involved with innate and adaptive immunity and are major players in immunologic homeostasis and diseases of the renal parenchyma.

Juxtaglomerular Apparatus

A unique feature of the nephron is that each thick ascending limb traverses back to and engages in physical contact with its parent glomerulus. The tubular cell at the point of contact is different from the rest of the thick ascending limb and is called the *macula densa*. The tripartite structure comprising the macula densa, the afferent and efferent glomerular arterioles, and the extraglomerular mesangium, a special part of the mesangium that protrudes outside the glomerulus, is called the *juxtaglomerular apparatus* (JGA) (see Fig. 23.1C). The JGA is an important structure in the maintenance of GFR by tubuloglomerular feedback and regulation of afferent arteriole resistance and is the site of endocrine renin production.

Organelles Such as Mitochondria and Endoplasmic Reticulum

The kidney is second to the heart in mitochondrial content and oxygen consumption per unit mass. In addition to their role as the

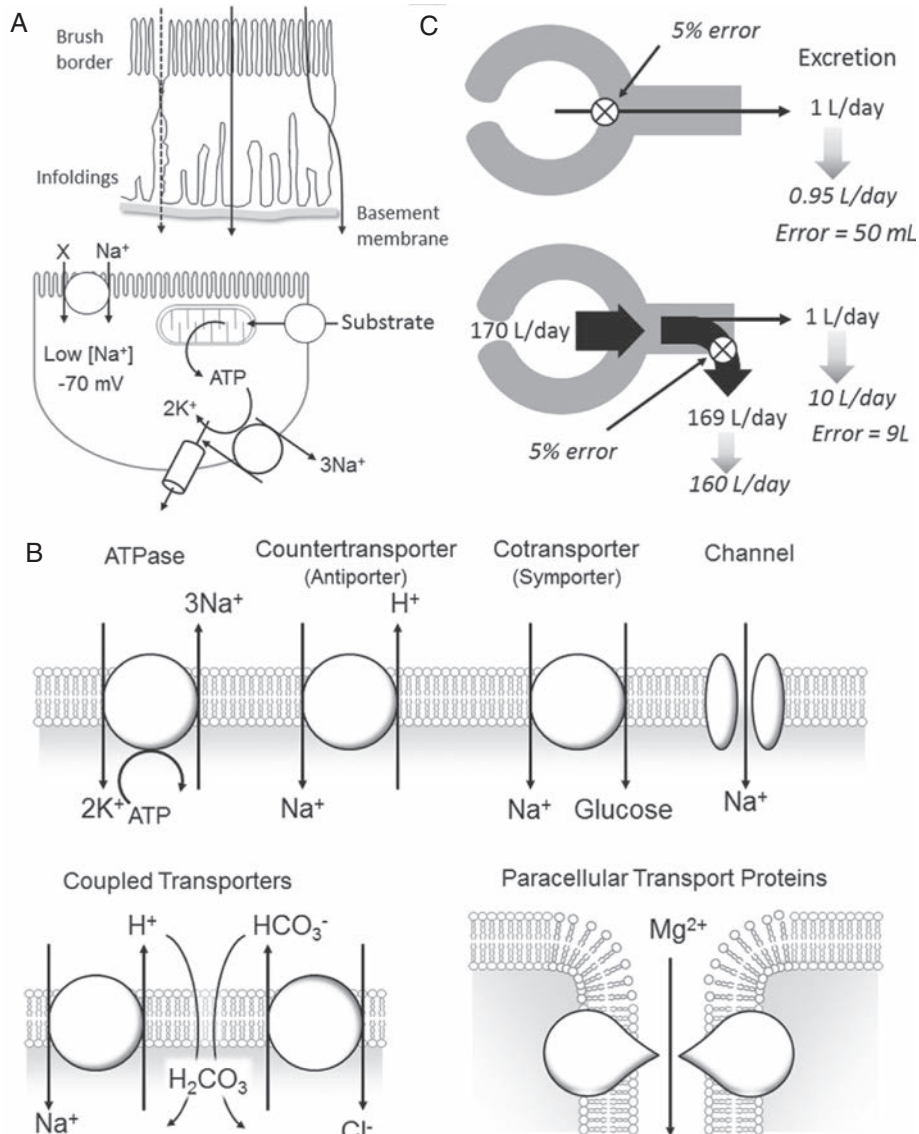

Fig. 23.2 (A) *Top*, Transcellular and paracellular transport of solutes. Solute transport is an energy-consuming process that requires metabolic fuels; a sodium cotransporter and a sodium-potassium countertransporter are shown. (B) Transport proteins. *Top*, Adenosine triphosphatases (ATPases) directly couple ATP hydrolysis to transport. Cotransporters (symporters) move two solutes in the same direction (e.g., Na⁺-glucose cotransporter or sodium-glucose linked transporter [SGLT]), and countertransporters (antiporters) move two different solutes in opposite directions. Channels function as protein-lined “holes” that allow specific solutes to permeate. *Lower left*, Different transporters can be coupled together to form a new transport system. *Lower right*, Proteins that protrude outside the cell in the junctional area provide a conduit for paracellular transport. (C) Comparison of a pure filtration (or secretion) design (*top*) and a filtration-reabsorption design (*bottom*). See text for details.

power generator of a cell, mitochondria serve many roles as regulatory, synthetic, and adaptive functions in the cell. Mitochondria are under complex regulation and undergo a plethora of abnormalities in many kidney diseases. Mitochondria-targeted therapeutics are emerging with the notion that maintenance of mitochondria health can prevent pathogenesis and progression of chronic kidney disease. The endoplasmic reticulum (ER) helps maintain the quality of proteins through the unfolded protein response (UPR) pathway, and ER dysfunction with maladaptive UPR activation is named ER stress. ER stress is now known to be present in a wide variety of kidney diseases, and modulators of ER stress will assume important therapeutic roles.

RENAL FUNCTION

Excretory Function

Renal excretion of a substance can be mediated and modified by one or a combination of three processes: filtration, secretion, and reabsorption. Fig. 23.2C compares two designs—pure filtration (or secretion) and filtration-reabsorption—and their implications in terms of demands on regulation. The filtration-reabsorption mechanism allows high filtration rates to be achieved, and the coupling with reabsorption prevents loss of valuable fluid and electrolytes. This design also enables economy in transport mechanisms through adaptive targeting of key solutes while allowing the rest to be excreted. However, there is a price

to be paid for this configuration. Consider the excretion of 1 L/day by pure filtration (or secretion). If there is a 5% error (reduction in filtration or secretion), only 0.95 L/day will be excreted—a difference of 50 mL. Compare this to a filtration-reabsorption mechanism wherein 170 L/day is filtered and 169 L/day is reabsorbed, resulting in the same 1 L/day excretion. A 5% error (reduction) in reabsorption would result in reabsorption of 160 L/day and excretion of 10 L/day, with an absolute error of 9 L. One consequence of a filtration-reabsorption design is that regulation has to have exquisite fidelity, and even small errors are not tolerated.

Filtration

Filtration occurs exclusively at the glomerulus. The GFR, measured as volume per unit time, has been the standard quantitative surrogate for overall kidney function, although there are many disturbances of renal function that are not associated with a decrease in GFR (e.g., nephrotic syndrome, tubulopathies, renovascular hypertension, kidney stones). Numerically, GFR can be conceptualized as an equation:

$$\text{GFR} = K_f \times (\Delta P - \Delta \Pi)$$

where the ultrafiltration coefficient, K_f , is equal to the surface area for filtration multiplied by the hydraulic permeability; the hydrostatic driving force, ΔP , is the pressure gradient between the glomerular capillary and Bowman's space, which drives fluid to go into Bowman's space to form urine; and the osmotic driving force, $\Delta \Pi$, is the osmotic pressure gradient between the glomerular capillary and Bowman's space, which holds fluid back in the capillary and slows down filtration.

Many renal diseases affect the determinants of GFR. Glomerular disease (see [Chapter 26](#)) decreases K_f by affecting both the filtration surface area and the hydraulic permeability. Changes in ΔP are commonly involved in diseases that reduce GFR. Changes in renal blood flow and more importantly in afferent and efferent arteriolar resistances can drastically affect ΔP and GFR. Functional changes in ΔP , such as pre-renal failure from hypovolemia, hepatorenal syndrome (see [Chapter 29](#)), or intra-abdominal hypertension can radically lower GFR simply by hemodynamic changes without any structural glomerular lesions.

Reabsorption

High GFR, which is required to maintain a high metabolic rate, can be sustained only if there is high reclamation to maintain intravascular volume and prevent circulatory collapse. Tubular reabsorption thwarts the loss of valuable solutes and allows for finer tuning of the water and solutes not reabsorbed. The resulting tubular contents are excreted. In the mammalian kidney, tubular reabsorption assumes critical roles in the regulation of excretion of many solutes ([Table 23.2](#)). A universal mechanism of reabsorption is energy-dependent transepithelial transport, which is mostly Na^+ dependent but can be Na^+ independent. The proximal tubules participate in the reabsorption of all solutes, but some solutes are sequentially reabsorbed by the proximal and distal segments; in these cases, the generic design tends to be high-capacity reabsorption proximally and more of a high-gradient reabsorption for fine tuning distally. The axial difference can occur within the same nephron segment (e.g., early vs. late proximal tubule) or across different segments (e.g., proximal vs. distal nephron segments).

Secretion

Secretion is an ancient mode of excretion that is found in lower-order organisms. Although the human nephron is not primarily secretory in nature, a number of solutes are still handled by secretion. For example, the renal excretion of potassium (K^+), hydrogen ions (H^+), and uric acid involves secretion. Many organic cations and anions are secreted

by the proximal tubule, and so are many exogenous toxins such as xenobiotics. The secretion of creatinine by organic cation transporters in the proximal tubule is the reason why creatinine clearance overestimates GFR. The secretion of furosemide by organic cation transporters in the proximal tubule is why response to this drug is attenuated in settings of renal hypoperfusion and/or proximal tubular damage such in acute kidney injury.

Integrated Models of Excretion

The modes of excretion are coordinated in a precise, complex, and concerted fashion to effect excretion with exquisite accuracy (see [Table 23.2](#)). The kidney is capable of a large range of urinary tonicity (<50 to 1200 mOsm), depending on the need of the organism to excrete or conserve electrolyte-free water. Water is filtered at the glomerulus and is handled isotonicity in the proximal tubule. At the lumen of the distal convoluted tubule, urine is maximally dilute as a consequence of low water permeability throughout the thick ascending limb of Henle. The subsequent fate of the urine determines whether there is electrolyte-free water excretion (dilute urine), achieved by low water permeability of the collecting duct, or electrolyte-free water conservation (concentrated urine), effected by the action of antidiuretic hormone (ADH), which renders the collecting tubule permeable to water.

Na^+ homeostasis basically occurs via filtration-reabsorption; it is regulated by changes in effective arterial blood volume (EABV) mediated by neurohormonal afferent signals (e.g., renin-angiotensin-aldosterone system [RAAS]) that act directly on tubules. In the proximal tubule, Na^+ reabsorption is also regulated by peritubular physical factors. K^+ undergoes an interesting sequence in which the filtered load is largely reabsorbed in the proximal tubule and the thick ascending limb; the final determinant of excretion is secretion by the collecting duct, for which aldosterone and distal Na^+ delivery are major regulators.

Only Ca^{2+} that is not bound to plasma protein is filtered; it is reabsorbed largely via paracellular pathways in the proximal tubule and thick ascending limb and via transcellular pathways in the distal convoluted tubule.

A massive amount of bicarbonate (HCO_3^-) is filtered and must be reclaimed to forestall catastrophic acidosis. H^+ secretion provides the mechanism for HCO_3^- reclamation as well as acid excretion, with the H^+ being carried by urinary buffers such as ammonia.

Metabolic Function

The kidney is a major metabolic organ. It consumes a wide range of fuels, regulates plasma levels of metabolic substrates, and is a major source of gluconeogenesis. Metabolic substrates such as amino acids, glucose, organic anions, and fatty acids are converted to ATP, the universal energy unit for all cells (see [Fig. 23.2A](#)). ATP is directly hydrolyzed by proteins such as Na^+/K^+ -ATPase to create a low intracellular Na^+ concentration ($[\text{Na}^+]$) and a negative interior cell voltage, thus translating the chemical energy into chemical gradients. About 80% to 90% of the oxygen consumption of the kidney can be attributed to Na^+ transport. For example, a protein such as the Na^+ -glucose cotransporter (sodium-glucose linked transporter [SGLT], see [Fig. 23.2B](#)) on the proximal tubule luminal membrane, couples the movement of Na^+ ions to glucose molecule (carrying a net positive charge). The low cell $[\text{Na}^+]$ and negative voltage energize glucose uptake, allowing the proximal tubule to capture most of the filtered glucose that otherwise would be lost in the urine. In normal physiology, this glucose reclamation is beneficial to conserve calories. The pharmacologic inhibition of Na^+ -coupled glucose reabsorption (SGLT-2 inhibitors) leads to low glycosuric threshold and creation of a "glucose sink" to control glycemia. Surprisingly, many additional beneficial cardiovascular and renal effects have been observed with SGLT-2 inhibitors that are not explained by glycemic control.

TABLE 23.2 Solute Excretion

Solute	Filtration	Reabsorption	Secretion	FE (%)	Regulation
Water	Yes	Yes	No	0.3-6.0	Responds primarily to body tonicity but also EABV. ADH is the major regulator of collecting duct water permeability.
Na ⁺	Yes	Yes	No	0.2-2.0	Responds to EABV. Reabsorption is stimulated by sympathetic nerves, angiotensin II, aldosterone; inhibited by atrial natriuretic peptides, dopamine, uroguanylin.
K ⁺	Yes	Yes	Yes	5-20	Responds to total body potassium status. Secretion is controlled primarily by aldosterone and distal Na ⁺ delivery.
Ca ²⁺	Yes	Yes	No	2-10	Responds to serum ionized [Ca ²⁺] and body need for calcium. Major calciotropic hormones include parathyroid hormone, vitamin D, and calcitonin. Renal epithelia directly respond to ionized calcium via the calcium sensing receptor.
Mg ²⁺	Yes	Yes	No	3-5	Responds to total body magnesium status and requirements. Paracrine regulation is via epidermal growth factor.
HCO ₃ ⁻	Yes	Yes	Yes	0.1-0.5	Most bicarbonate reabsorption is to reclaim the filtered load. Responds to systemic acid-base status, which can be mediated by direct sensing by the renal epithelia or via hormonal actions (e.g., angiotensin II, endothelin). Bicarbonate can also be secreted in the collecting duct when alkali excretion is required.
Phosphate	Yes	Yes	No	5-20	Responds to serum phosphate concentration and body phosphate status. Reabsorption primarily resides in the proximal tubule and is regulated by parathyroid hormone and fibroblast growth factor-23.
Glucose	Yes	Yes	No	0.2-0.5	The proximal tubule reclaims almost all filtered glucose except when the filtered load exceeds reabsorptive capacity.
Uric acid	Yes	Yes	Yes	10-50	The cortical proximal tubule performs gluconeogenesis from other organic substrates. Major routes of uric acid clearance are (1) renal excretion and (2) intestinal secretion and uricolysis. Handling of both secretion and reabsorption in the proximal tubule is complex, and regulatory mechanisms are unclear.
Creatinine	Yes	No	Yes	1.0-1.2	Filtered at the glomerulus and secreted by the proximal tubule. The contribution of the tubules to creatinine clearance increases when GFR declines.

ADH, Antidiuretic hormone; EABV, effective arterial blood volume; FE, fractional excretion under normal physiology.

TABLE 23.3 Some Endocrine Hormones Elaborated by the Kidney

Hormone	Source	Function	Drugs
Renin	JGA	Converts angiotensinogen to angiotensin I as an integral part of the renin-angiotensin-aldosterone system	Renin inhibitor ACE inhibitor Angiotensin receptor blocker Mineralocorticoid receptor blocker
1,25(OH) ₂ vitamin D	Mostly proximal tubule	Converts the precursor 25(OH) vitamin D to its active form, 1,25(OH) ₂ vitamin D	25-Hydroxyvitamin D 1,25-Dihydroxyvitamin D Synthetic vitamin D analogues
Erythropoietin	Renal interstitial cells	Stimulates erythropoiesis in the bone marrow	Recombinant human erythropoietin Glycosylated recombinant human erythropoietin Other "EPO mimetic" erythropoiesis-stimulating agents

ACE, Angiotensin-converting enzyme; JGA, juxtaglomerular apparatus.

The amount of filtered organic molecules far exceeds the metabolic consumption by the kidney. Very large amounts of organic metabolic substrates are passively filtered daily; these substrates are not meant to be excreted, but the high GFR and lack of retention at the glomerular capillaries obligate their presence in the glomerular urine. In the proximal tubule, the bulk of the filtered organic molecules are reclaimed from the urine and returned to the systemic circulation. Several thousands of millimoles of amino acids, glucose, and organic cations and anions are retrieved each day by the kidney from the urine.

Metabolic and Endocrine Function

The kidney rivals the liver as a gluconeogenic organ that sustains circulating blood glucose levels. Although there is no doubt that this is a

critical physiologic function, there are no clinical examples of hypoglycemia stemming purely from lack of renal gluconeogenesis.

In addition to the prominent and more obvious roles in solute and water balance, the kidney also is an important endocrine organ. The autocrine and paracrine substances elaborated by the kidney are important for both intrarenal and systemic regulation. Although this subject is not addressed fully here, three of these substances are highlighted because they represent important pharmacologic targets (Table 23.3).

Renin

As the initiating component of the RAAS, renin is important for maintenance of the circulation. The RAAS permits the kidney to have a constant GFR in the face of low and fluctuating salt intake, a property

that is vital for terrestrial existence. Renin is produced by the JGA (see earlier discussion). Despite the benefits and importance of the RAAS in physiology, its continuous and excessive activation in many disease states appears to be maladaptive and contributes to kidney and cardiovascular injury. Pharmacologic blockade of RAAS pathways at various levels has proved beneficial in animal disease models and human clinical studies, and agents to block RAAS signaling are now in clinical use, with others under development (see [Table 23.3](#)).

Vitamin D

1 α -Hydroxylase (cytochrome P-450 isoenzyme 27B1) is found primarily in the proximal tubule, where the major body defense for maintaining phosphate homeostasis is localized. The kidney is one of the most important organs for maintaining calcium and phosphate homeostasis, not just as the major controller of external balance but as an elaborator of systemic factors such as vitamin D and the Klotho protein. Conversion of the precursor 25(OH)-hydroxyvitamin D to its active form, 1,25(OH)₂dihydroxyvitamin D, is achieved not exclusively but substantially in the kidney and is mediated by 1 α -hydroxylase. Vitamin D deficiency is an important complication in chronic kidney disease. Replacement of vitamin D is efficacious in reducing the complications of chronic kidney disease.

Erythropoietin

Erythropoietin, which is produced mainly in the kidney, stimulates erythropoiesis. The erythropoietin-producing cells are strategically located in the cortical interstitium to sense the balance between oxygen delivery and consumption. The current model suggests that upregulation of renal erythropoietin production (mainly by anemia and hypoxia) occurs via an increase in the number of latent

erythropoietin-producing cells. The mechanism of erythropoietin deficiency in kidney disease is not well known, although it does not simply involve destruction of erythropoietin-producing interstitial cells. One possible mechanism is decreased renal oxygen consumption as a consequence of reduced GFR; this results in higher renal tissue oxygen tension and suppression of erythropoietin production. Another theory is direct inhibition of the erythropoietin-producing cells by inflammatory cytokines. Others have proposed transdifferentiation of erythropoietin-producing cells into myofibroblasts and a decrease in the number of interstitial cells that can be recruited to produce erythropoietin.

The use of erythropoiesis-stimulating agents (ESAs) has revolutionized the treatment of anemia associated with chronic kidney disease, but because of incomplete understanding of erythropoietin and erythropoietin receptor biology, the clinical outcome is far from ideal due to inability to tailor the optimal hematocrit for individual patients and uncertainty about possible extra-erythropoietic effects of erythropoietin. The new class of hypoxia-inducible factor prolyl hydroxylase inhibitors as ESAs increases endogenous erythropoietin production.

Approach to the Patient With Renal Disease

Rajiv Agarwal

INTRODUCTION

Chronic kidney disease (CKD) is commonly defined as having an estimated glomerular filtration rate (GFR) of less than 60 mL/min/1.73 m² for at least 3 months. Most patients with CKD are seen in the outpatient setting, and at first consultation an important objective is to uncover the cause of CKD. In the long term the objectives of care are the preservation of kidney and cardiovascular function and the prevention of the long-term complications of CKD. Once kidney function deteriorates to the extent that it can no longer sustain an appropriate quality of life the objective of care evolves to the provision of renal replacement therapy. In some patients, discussion may be about withholding the provision of renal replacement therapy. In contrast to the clinical approach to patients with CKD, most patients with acute kidney injury (AKI) are hospitalized. The focus of their care also starts with accurate determination of the cause of AKI, but over a period of days to weeks it is important to reverse the kidney failure if possible, replace kidney function if needed, and manage the many potential adverse consequences of AKI. Thus, the approach to the care of patients with AKI and CKD are largely non-overlapping and are discussed separately.

Distinction of AKI From CKD

Because of the widespread use of automated systems for serum chemistry analysis, an elevated serum creatinine concentration is the most common initial manifestation of kidney disease. This test is performed as a screen for renal function abnormalities in most metabolic panels; in most cases, an elevated serum creatinine concentration reflects reduced filtration function of the kidney. After ensuring that intravascular volume is appropriate, the approach to the patient depends on whether kidney failure is acute or chronic. Accordingly, the initial step in evaluating an elevated serum creatinine level is to assess the time course and duration of the changes to distinguish AKI from CKD.

A careful history, physical examination, and laboratory evaluation, including imaging studies, are all fundamental to this process. The highest priority is to address acute volume depletion, bleeding, and other causes of intravascular volume loss. Evidence of chronicity may be discovered by searching the records for prior abnormalities of serum creatinine, albuminuria or proteinuria, abnormal urine sediment, or anatomic features such as the presence of multiple cysts in both kidneys discovered on an ultrasound or CT scan. Similarly, a call to the primary care doctor may provide clues to suggest the presence of kidney disease at an earlier time. In the United States, electronic medical record systems are ubiquitous and deep knowledge of this electronic record is often essential to discover the onset date of CKD.

Small kidney size, as assessed by ultrasound, can be highly suggestive of CKD. The size of the kidney depends on the height of the patient, but in general, a kidney length on ultrasound images of less than 9 cm in an adult male is considered small. The presence of normal-sized or

even large kidneys does not exclude the diagnosis of CKD. In fact, it is common in patients with diabetic nephropathy for kidneys to be 11 or 12 cm long. Radiography of clavicles or hands is not commonly performed but may demonstrate renal osteodystrophy and suggest the presence of CKD.

Anemia is common in both AKI and CKD and therefore is not a differentiating feature. However, the presence of secondary hyperparathyroidism points toward CKD. Rarely, if the initial evaluation is unrevealing, a kidney biopsy may be required to distinguish AKI from CKD and to define the etiology of injury.

APPROACH TO THE PATIENT WITH CHRONIC KIDNEY DISEASE

If the elevated creatinine concentration is thought to be chronic in nature, the history and physical examination should focus initially on detection of diabetes mellitus and hypertension, the two most common causes of CKD. In all cases, the evaluation also includes laboratory testing of renal function, serum electrolytes, complete blood count, testing for albuminuria, and microscopic urine sediment analysis. Kidney ultrasound is almost always obtained early in the evaluation to eliminate ureteral or bladder obstruction, a cause of reversible renal failure. In addition, the ultrasound provides important information about kidney size, symmetry, and echogenicity. Kidney biopsy may be needed in some patients, but parenchymal scarring is common in many forms of CKD so the biopsy may not be diagnostic.

Because diabetes and hypertension are common causes of kidney disease, it is important to recognize the associated presentations. To establish a likely diagnosis of diabetic nephropathy, a long-standing history of documented diabetes mellitus is typical. An eye exam that notes diabetic retinopathy often goes hand-in-hand with diabetic nephropathy; however, the absence of diabetic retinopathy does not rule out CKD due to diabetes mellitus. Albuminuria and large kidneys on ultrasound are often seen. However, as many as a third of patients with CKD due to type 2 diabetes mellitus do not have albuminuria. In patients with diabetes mellitus or hypertension, the urinary sediment is usually unremarkable, so the presence of red blood cells (RBCs) casts or a significant number of dysmorphic erythrocytes should initiate a careful evaluation for other causes of CKD.

In cases of hypertensive nephrosclerosis, established hypertension typically antedates the diagnosis of renal failure for many years, and the presence of hypertensive retinopathy or cardiovascular disease (e.g., left ventricular hypertrophy) is common. Proteinuria is typically minimal or absent (<2 g/day), and the kidneys are symmetrically small on ultrasound.

Although hypertension and type 2 diabetes mellitus are common, among patients with CKD it is important not to assume that diabetes

and hypertension are always the cause of CKD. The diagnosis of hypertension or diabetes mellitus as the cause of CKD requires that no other identifiable cause of kidney disease is apparent after a thorough evaluation. Notably, in individuals with hypertension, genes such as *APOL1* have been identified that appear to be associated with a greater risk of renal disease, and genetic analysis may emerge as one approach to identify those most at risk so that strategies for prevention can be tested in the future.

Once a diagnosis of CKD is established, ongoing evaluation is required, because those with CKD are at increased risk for complications such as hypertension, metabolic bone disease, anemia, hyperkalemia, and metabolic acidosis. Furthermore, the initial diagnosis of CKD may be modified over time, such as by the discovery of RBC casts in a patient with diabetes mellitus. AKI may be superimposed on CKD. The assessment of hypertension requires an accurate assessment of blood pressure. Measurements of three readings after quiet rest at intervals of 1 minute using an oscillometric device is now recommended; auscultatory methods utilizing Korotkoff sounds are no longer recommended. If hypertension or volume overload becomes difficult to manage, the dietary intake of sodium can be estimated by 24-hour urine collection. The number of medications prescribed to patients with CKD is substantial, which calls for monitoring for medication adherence. The latter, for instance, may provide clues to lack of control of BP. For a more detailed approach and slightly different opinion on the measurement of the arterial blood pressure, see [Chapter 12](#).

History and Examination

The signs and symptoms of CKD depend on the stage at presentation. Early in the clinical course, nonspecific fatigue is typical, and there may be no discernable clues to CKD on examination, highlighting the need for laboratory screening. As filtration rate declines, the signs and symptoms of CKD become more common and may include pedal edema, facial puffiness, flank pain, polyuria, nocturia, and hypertension. Symptoms referable to uremia, such as nausea, dysgeusia, and vomiting, tend to occur late and should not be relied on to make a diagnosis of early CKD.

Sometimes the manifestations of the primary disease predominate. For example, the presence of fever, arthralgia, and rash in a young woman with renal failure and active urinary sediment is highly suggestive of lupus nephritis; or intravenous drug use, cardiac murmur, vegetations on cardiac valve, and positive blood culture should alert to a possible diagnosis of endocarditis-associated glomerulonephritis. A family history of deafness, hematuria, and CKD can point to the diagnosis of Alport's syndrome; or a history of cerebral hemorrhage due to a ruptured aneurysm may suggest underlying polycystic kidney disease.

Medication history should focus on exposure to nephrotoxins, including long-term use of nonsteroidal anti-inflammatory drugs (NSAIDs), lithium, exposure to cisplatin, and recent escalation of the dose of diuretics. Some nonprescription drugs can lead to CKD (e.g., cocaine-induced glomerulonephritis, Ma Huang–induced ephedrine kidney stones).

Past medical history may clue in to possible etiologies; for example, diabetic retinopathy to diabetic nephropathy; recurrent urinary tract infection to renal calculi; and hepatitis C, infective endocarditis, or Wegner's granulomatosis to glomerulonephritis.

Physical examination can reveal the presence of anemia, skin rash (such as in endocarditis, Fabry's disease, Henoch-Schönlein purpura, or cryoglobulinemia), rales, pericardial or pleural friction rub, pedal edema, abdominal bruit, or enlarged kidneys. Retinal examination is of particular importance and may reveal diabetic retinopathy or changes associated with hypertension; in a patient with rapid deterioration of renal function, retinal examination may show cholesterol emboli or septic emboli, pointing to the existence of cholesterol emboli or bacterial

endocarditis as possible causes. Rectal examination to assess prostate enlargement in men and pelvic examination in women may point to clues to urinary tract obstruction such as a tumor or neurogenic bladder. Examination of the muscle mass is important when interpreting serum creatinine concentration (see later discussion).

The assessment of blood pressure is particularly important. Often, blood pressure is elevated in the clinic but normal at home (*white coat hypertension*). Occasionally, the blood pressure is elevated at home but not in the clinic (*masked hypertension*). In patients who complain of orthostatic symptoms but appear to have normal or high blood pressure in the clinic, home blood pressure measurements or 24-hour ambulatory blood pressure monitoring may be required. The latter may reveal very low blood pressure with orthostatic symptoms, and antihypertensive therapy may need to be modified.

The overall condition of the patient and level of functional status is important in deciding therapies. For example, transplantation may be an option for a patient with correctable cardiovascular disease and dialysis for someone with calcified iliac arteries where kidney transplant may not be possible. However, the physician and the patient's family may share the decision to forego renal replacement in an elderly person with advanced dementia and poor functional status.

Assessment of Kidney Function

Knowledge of both the severity of renal impairment and the rate of change in renal function is important in managing CKD. Rapid deterioration of kidney function over a few weeks to a few months may not reflect native renal disease progression; rather, it may reflect superimposed volume depletion (e.g., escalation in the dose of diuretics), exposure to nephrotoxins (e.g., NSAID use), or urinary tract obstruction. Alternatively, rapid progression of kidney disease may be seen in certain disease states such as malignant hypertension, crescentic glomerulonephritis, microangiopathic hemolytic anemia (thrombotic thrombocytopenic purpura, scleroderma), vasculitides (lupus nephritis, Wegener's granulomatosis), atheroembolic renal disease, or multiple myeloma. In general, a slower progression of decline in kidney failure is anticipated in patients with CKD caused by polycystic kidney disease, hypertension, or diabetes mellitus.

Serum creatinine is the most commonly measured of kidney functions. Along with the assessment of albuminuria, it is an important component for staging CKD ([Fig. 24.1](#)). If estimated GFR is less than 60 mL/min/1.73 m² for 3 months or longer, kidney disease is said to be chronic.

Notably, serum creatinine concentration does not rise to above the population threshold of normal (about 1.3 mg/dL in men and 1.1 mg/dL in women) until approximately 40% of kidney function is lost. In earlier stages of kidney disease, serum creatinine is maintained in the normal range by enhanced tubular secretion of creatinine. This process of creatinine secretion requires cationic transporters, and drugs that compete with creatinine secretion (e.g., cimetidine, triamterene, trimethoprim) may cause elevation of serum creatinine without depressing true GFR. A clinical clue to an impairment in cationic transport of creatinine is the lack of rise in blood urea nitrogen despite an increase in serum creatinine concentration.

With advanced kidney failure, the magnitude of absolute changes in serum creatinine concentration may be more rapid. The relationship between serum creatinine and GFR is nonlinear, accelerating as the GFR declines. This means, for example, that an increase in serum creatinine concentration from 3 to 3.5 mg/dL is associated with a lesser decline in GFR than is a change from 1 to 1.5 mg/dL. Specific knowledge of the baseline level of serum creatinine is important; for example, change from 0.6 to 1.2 mg/dL is still within the normal range in an adult man but actually reflects an approximately 57% loss of GFR.

Prognosis of CKD by GFR and Albuminuria Categories: KDIGO 2012				Persistent albuminuria categories		
				Description and range		
				A1	A2	A3
				Normal to mildly increased	Moderately increased	Severely increased
				<30 mg/g <3 mg/mmol	30–300 mg/g 3–30 mg/mmol	>300 mg/g >30 mg/mmol
GFR categories (ml/min/1.73 m ²) Description and range	G1	Normal or high	≥90			
	G2	Mildly decreased	60–89			
	G3a	Mildly to moderately decreased	45–59			
	G3b	Moderately to severely decreased	30–44			
	G4	Severely decreased	15–29			
	G5	Kidney failure	<15			

Green: Low risk (if no other markers of kidney disease, no CKD); Yellow: moderately increased risk; Orange: high risk; Red: very high risk.

Fig. 24.1 Chronic kidney disease (CKD) nomenclature used by the Kidney Disease Improving Global Outcomes (KDIGO) consortium. CKD is defined as abnormalities of kidney structure or function, present for 3 months or longer, with implications for health. CKD is classified on the bases of cause, glomerular filtration rate (GFR), and albuminuria. (From KDIGO: 2012 clinical practice guideline for the evaluation and management of chronic kidney disease, *Kid Intl Suppl* 3:18, 2013. Available at http://www.kdigo.org/clinical_practice_guidelines/pdf/CKD/KDIGO_2012_CKD_GL.pdf. Accessed June 1, 2014.)

The relationship between GFR and serum creatinine is best interpreted at steady state and not when the GFR is changing rapidly. For example, bilateral nephrectomy in a patient with previously normal kidney function (as might occur in a patient with renal cell carcinoma) results in a drop in GFR from 100 to 0 mL/min. However, serum creatinine would be expected to increase by only about 1 mg/dL/day, and a plateau may not be achieved before 1 week. This delay reflects the fact that the generation of creatinine is insufficient to saturate the volume of distribution of creatinine. A plateau will be reached more rapidly if the rate of creatinine generation is increased, the volume of distribution of creatinine is small, or residual renal function is substantial. Given these variables, it is important to be aware that serum creatinine may be a poor marker of GFR in non-steady-state conditions. Similarly, among patients with end-stage renal disease receiving renal replacement therapy although the laboratory may report eGFR (estimated GFR), this is a poor estimate of GFR given that the creatinine is being removed by extracorporeal means.

There also are several conditions in which serum creatinine may be falsely low in relation to the GFR. Because creatinine generation is dependent on muscle mass, low creatinine generation occurs in diseases associated with sarcopenia, such as motor neuron diseases (amyotrophic lateral sclerosis), wasting illnesses (advanced cancer, tuberculosis, cardiac cachexia), and even malnutrition. Visual examination of muscle mass (thighs, arms, temporal muscles) may therefore be important in the interpretation of serum creatinine concentrations. Other conditions associated with low creatinine generation include cirrhosis and advanced age. Creatinine generation is reduced in sepsis, and kidney function may be worse than is detectable by estimation of GFR through measurement of serum creatinine.

Among patients with severe CKD (e.g., GFR <20 mL/min), creatinine is secreted and urea is absorbed by the tubule. Tubular secretion of creatinine is fortuitously balanced by tubular reabsorption of urea, making measurements of urea clearance and creatinine clearance useful in estimating true GFR. An average of creatinine and urea clearance closely approximates true GFR in such situations.

At steady state—that is, when the patient is neither gaining nor losing weight—the 24-hour urine urea nitrogen measurement can be used to estimate dietary protein intake. In addition to its excretion in urine, nitrogen is lost through the gut, through the skin, and, as non-urea nitrogen, through the kidney in proportion to body weight. It is estimated that 31 mg/kg/day of non-urea nitrogen is excreted in this fashion. Dietary protein intake can be calculated as 6.25 g protein per gram of total daily nitrogen excretion. Accordingly, the formula for dietary protein intake in grams per day is (urine urea nitrogen + 0.031 × body weight in kg) × 6.25.

Although urea by itself is less useful to assess kidney function, it can be helpful in conjunction with the serum creatinine measurement. Urea is reabsorbed by the tubule in sodium-avid states. The normal ratio of urea to creatinine is 10:1. In states of volume depletion such as diuretic use, diarrhea, sweat losses, or third spacing (e.g., leakage of fluid outside the vascular compartment such as in peritoneal cavity [ascites] or pleural space [pleural effusion]), the urea-to-creatinine ratio may be greater than 20:1. Sometimes, ratios greater than 20:1 are also seen in catabolic states (e.g., long-bone fracture, corticosteroid use, burns, sepsis), increased gut protein load (upper gastrointestinal bleeding, high-protein diet), or obstructive uropathy. In contrast, creatinine may rise disproportionately more than urea, for example in advanced cirrhosis, low-protein diets, or states associated with the use of cationic transport inhibitors (e.g., cimetidine).

For many decades, the assessment of creatinine clearance by a 24-hour urine collection has been the mainstay of assessing renal function. However, given that creatinine may be secreted (and not just filtered), this test may overestimate GFR. Furthermore, voiding outside the collection jug is common and may lead to errors in estimating GFR. Although a 24-hour urine collection is not routinely recommended to assess renal function, it may still be useful for estimating GFR in sarcopenic individuals and in those with advanced liver disease. Creatinine clearance can be easily calculated as the urinary flow rate (in mL/min) times the ratio of urinary creatinine to plasma creatinine. A timed collection is needed. Creatinine excretion approximates 15 mg/kg/day. Although this rate is variable (the coefficient of variation from day to day over 28 days on a standard diet varies from 6% to 22%) and depends on meat intake, it can be used to estimate whether urine has been grossly undercollected or overcollected.

Usually, GFR is estimated through the use of equations that account for age in years, race, sex, and serum creatinine. The Modification of Diet in Renal Disease (MDRD) equation uses a creatinine measurement (Scr) that has been calibrated to an isotope dilution mass spectrometry standard:

$$\text{GFR [in mL/min/1.73 m}^2\text{]} = 175 \times (\text{Scr})^{-1.154} \\ \times (\text{Age})^{-0.203} \times 0.742 \text{ [if female]} \times 1.212 \text{ [if black]}$$

A newer equation, called the Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) equation, is less likely to estimate GFR as low if the GFR is higher than 60 mL/min/1.73 m². This equation is more complicated:

$$\text{GFR [60 ml/min/1.73 m}^2\text{]} = 141 \times \min(\text{Scr}/\kappa, 1)^\alpha \\ \times \max(\text{Scr}/\kappa, 1)^{-1.209} \times 0.993^{\text{Age}} \\ \times 1.018 \text{ [if female]} \times 1.159 \text{ [if black]}$$

where Scr is serum creatinine (in mg/dL), κ is 0.7 for females and 0.9 for males, α is -0.329 for females and -0.411 for males, *min* indicates the minimum of Scr/ κ or 1, and *max* indicates the maximum of Scr/ κ or 1. Several calculators to estimate GFR using the CKD-EPI equation or the MDRD equation are available on the World Wide Web or as applications for personal devices.

Assessment of Albuminuria

The assessment of albuminuria is fundamental because it may point to the cause of the CKD. Furthermore, the severity of albuminuria is directly associated with an accelerated progression of CKD and cardiovascular disease. As a result, albuminuria is now used to stage CKD (see Fig. 24.1).

Albumin excretion rate is normally less than 10 mg/24 hr, and an excretion rate of 30 mg/24 hr or higher is considered abnormal and moderately increased. An albumin excretion rate of 300 mg/24 hr or higher is considered severely increased. Albuminuria can be more conveniently assessed by measuring the ratio of urine albumin and urine creatinine concentrations in a spontaneously voided urine specimen. Given that the creatinine excretion rate averages 1 g/day, an albumin-to-creatinine ratio of 30 mg/g creatinine or higher is considered abnormal and moderately increased; a ratio of 300 mg/g creatinine is considered severely increased.

An albumin excretion rate higher than 2200 mg/24 hr (which corresponds to approximately 3000 mg protein/24 hr) is considered nephrotic. Such a degree of albuminuria/proteinuria is often accompanied by edema, hypoalbuminemia, and hyperlipidemia. The combination of these disorders is referred to as the *nephrotic syndrome* and

reflects a profound disorder of glomerular permselectivity. Common causes of nephrotic syndrome in adults are diabetic nephropathy, focal segmental glomerulosclerosis, membranous nephropathy, and amyloidosis. Among children, minimal change nephropathy and focal segmental glomerulosclerosis are important causes of nephrotic syndrome.

Assessment of Blood Pressure

Hypertension is a common accompaniment of CKD, yet the evaluation of hypertension often is performed poorly. Current management of hypertension is directed most often to management of blood pressure measurements obtained during clinic visits. Measurement of BP during clinic visits therefore should be accurately performed. At present, measurement of three readings of BP in the nondominant arm, after seated rest for 5 minutes, is the standard of care. The average of the three readings is used to make clinical decisions regarding the management of hypertension. Despite accurate measurements of BP in the clinic, BP may be falsely higher in the clinic (*white coat hypertension*) or lower in the clinic (*masked hypertension*) compared with 24-hour ambulatory blood pressure measurements. At present, in the United States, the latter technique is mostly limited to research or to management of hypertension in a few difficult cases. However, home blood pressure recordings self-measured by the patient twice daily for about 1 week every month can help diagnose and manage hypertension more effectively. Self-performance of these measurements may promote adoption of a more healthful diet and better medication adherence by the patient, as well as reducing therapeutic inertia on the part of the physician.

An important cause of poor control of BP in patients with or without CKD is poor medication adherence. Pill burden directly relates to nonadherence with medications, and patients with CKD are often prescribed multiple medications. Thus, the assessment of adherence to medications should be a routine part of assessment.

Assessment of Dietary Sodium Intake

At steady state, when body weight is neither increasing nor decreasing, the dietary sodium intake can be judged by 24-hour urine collection. To establish adequacy of urine collection, the measurement of urine creatinine in 24-hour urine sample is important. The creatinine excretion rate in an adequately collected specimen should approach 1 g/day for women and 1.5 g/day for men. Dietary potassium and protein intake can be monitored similarly. Measurement of urine urea nitrogen in the 24-hour urine sample can reveal the adequacy of dietary protein intake. Dietary sodium restriction can improve blood pressure, can enhance the biologic actions of inhibitors of the renin-angiotensin system, and may protect the heart, blood vessels, and kidneys independent of improvement in blood pressure.

Microscopic Urinalysis

Microscopic urinalysis at initial evaluation and on an ongoing basis can reveal vital information about the health of the kidney. Evaluation should be performed by centrifugation of at least 12 mL of a freshly voided specimen. Cells, casts, crystals, and other elements can corroborate the diagnosis of the cause of CKD. Examples are shown in Figs. 24.2 through 24.5. (See also E-Fig. 29.1 and Table 29.3.)

Renal Imaging

Bladder ultrasonography is a tool that can be used to assess residual urine volume. The wide availability of this tool allows diagnosis of bladder outlet obstruction without the need to catheterize the patient.

Fig. 24.2 Cells often found in urine of patients with kidney disease. (A) Sternheimer-Malbin-stained urine sediment (100 \times objective) in a patient with urinary tract infection. *Solid line* shows a leukocyte and *hollow line* indicates bacteria. (B) Sternheimer-Malbin-stained urine sediment (40 \times) in a patient with fungal urinary tract infection. *Solid line* shows a pseudohypha and *hollow lines* indicate leukocytes. (C) Unstained urine sediment (40 \times) shows an oval fat body in a patient with nephrotic syndrome. (D) Sternheimer-Malbin-stained urine sediment (100 \times) in a patient with immunoglobulin A (IgA) nephropathy. *Solid line* shows an acanthocyte characterized by outpouching of the red blood cell (RBC) membrane. (E) Sternheimer-Malbin-stained urine sediment (40 \times) in a patient with IgA nephropathy shows many acanthocytes (*solid line*). When acanthocytes constitute more than 5% of the RBCs, their presence is considered significant. (F) Sternheimer-Malbin-stained urine sediment (100 \times) in a patient with recovering acute tubular necrosis (ATN). *Solid lines* indicate glitter cells. The granules of these leukocytes have a Brownian motion and appear to glitter under the microscope. These cells can be seen in large numbers during the recovery stage of ATN and in patients with urinary tract infection. (G) Sternheimer-Malbin-stained urine sediment (40 \times) shows numerous squamous cells, indicating poor collection technique. (H) Hansel-stained urine sediment (100 \times) shows eosinophils that can be seen in patients with allergic interstitial nephritis, cholesterol emboli, or, sometimes, urinary tract infection.

Fig. 24.3 Tubular cells often found in urine of patients with acute kidney injury. (A) Unstained urine sediment (40 \times objective) in a patient recovering from acute tubular necrosis (ATN). *Solid lines* show intact renal tubular epithelial cells. (B) Same specimen as in A but stained with acridine orange-propidium iodide and viewed with a triple excitation band fluorescence filter (triple-cube). Red cells are dead and green cells are live. Both tubular cells appear viable. Smaller cells are leukocytes. (C) Unstained urine sediment (40 \times) shows several renal tubular cells that appear monomorphic (as in images A and B), indicating acute tubular injury. The *arrow* indicates a binucleate tubular cell. (D) Unstained urine sediment (40 \times) shows several renal tubular cells (*solid lines*) that appear dysmorphic. Instead of being round, the cells are angular. Furthermore, these cells are multinucleated, indicating failure of the cell to divide. Large numbers of dysmorphic renal tubular cells are often seen if the acute tubular injury is substantial. (E) Unstained urine sediment (100 \times) shows two tear-drop-shaped dysmorphic renal tubular epithelial cells (*solid lines*). Because the patient had jaundice, the cells appear to have a color despite lack of staining. (F) Unstained urine sediment (100 \times) shows one dysmorphic, binucleate renal tubular epithelial cell (*line*). This is the same patient as in E. (G) Unstained urine sediment (40 \times) shows severe ATN. No dirty-brown granular casts were seen, but the tubular cells were dysmorphic (*lines*). The large amount of granular debris and absence of casts suggests failure to form Tamm-Horsfall protein and more severe tubular injury. This patient also had jaundice, as is evident from the yellow hue. (H) Unstained urine sediment (40 \times) shows dysmorphic renal tubular epithelial cells (triangular, cigar-shaped, and polygonous), often multinucleated as denoted by *lines*.

Fig. 24.4 Crystals commonly found in urine sediment. All images were made with the use of polarized light and a diffusion interference contrast microscope. (A) Uric acid crystals (40× objective). (B) Calcium oxalate dihydrate crystals (*white lines*) (40×). Large numbers are seen in patients with ethylene glycol poisoning. (C) Calcium oxalate monohydrate crystals (*solid line*) (40×). (D) Magnesium ammonium phosphate crystals, or triple phosphate crystals, are often found in patients with a complicated urinary tract infection (40×). (E) Coffin-lid appearance of magnesium ammonium phosphate crystals (100×). (F) Bilirubin crystals in a patient with acute tubular necrosis and obstructive jaundice (100×). Inset shows 40× view of the bilirubin crystals. (G) Calcium phosphate crystals (40×) in a patient with tumor lysis syndrome. Sequential images (*left to right, top to bottom*) show dissolution of the crystals within a few minutes after urine was acidified by adding 2% perchloric acid. (H) Fiber artifact in the urine is of no clinical significance.

Renal ultrasonography is the most accurate way of determining kidney size. It is commonly performed to detect renal masses, cysts, and evidence of obstruction characterized by dilatation of the pelvicalyceal system and to evaluate the size and shape of the kidneys. The presence

of small kidneys (i.e., <9 cm on both sides) suggests the presence of scarring and therefore CKD. However, kidneys that are larger, typically in the range of 11 to 13 cm, are often seen in conjunction with CKD due to diabetes mellitus, amyloidosis, and multiple myeloma.

Fig. 24.5 Casts in urine. (A) Unstimulated urine sediment (40× objective) in a patient with glomerulonephritis. *Solid line* shows a granular cast, and *hollow line* shows a hyaline cast. (B) Sternheimer-Malbin–stained urine sediment (40×). The *solid line* points to an erythrocyte cast in a patient with immunoglobulin A nephropathy. (C) Unstimulated urine sediment (40×) shows several renal tubular cells and an epithelial cell cast (*solid line*) indicating acute tubular injury. (D) Papanicolaou–stained urine sediment (*solid line*) (100×) shows an epithelial cell cast in an otherwise stable patient with diabetic nephropathy. (E) Unstimulated urine sediment (40×) shows bilirubin–stained granular cast (*solid line*) indicating renal inflammation in a patient with liver disease. (F) Unstimulated urine sediment (10×) shows dirty–brown granular casts (*solid line*) indicative of acute tubular necrosis (ATN). (G) Unstimulated urine sediment (40×) shows severe ATN. No dirty–brown granular casts were seen, but the tubular cells (*solid lines*) were dysmorphic and multinucleated. (H) Sternheimer–Malbin–stained urine sediment (40×) shows a fatty cast (*solid line*) in a patient with nephrotic syndrome.

Therefore, the presence of small kidneys is not required to make a diagnosis of CKD.

The echogenicity of the kidneys is compared with that of liver parenchyma. Typically, the kidneys are less echogenic than the liver. Increased echogenicity of the kidneys suggests the presence of scarring and therefore CKD. Renal ultrasonography can also easily detect the presence of cysts in the kidneys and therefore is a useful technique to detect polycystic kidney disease.

Pulsed Doppler imaging is often used to calculate the resistive index by estimating the systolic and diastolic Doppler velocities in the renal cortex. A resistive index greater than 0.8 suggests that interventional procedures to revascularize the kidney would be unlikely to benefit the patient in terms of improving blood pressure or protecting the long-term decline in kidney function. If the two kidneys differ in size by 1.5 cm, it suggests the presence of renovascular disease in an adult. In children, reflux nephropathy or congenital abnormalities are more common causes of asymmetric kidney size.

Computed tomography (CT) of the kidney is often helpful to evaluate complex cysts. In contrast to simple cysts, complex cysts are suspicious for the presence of malignancy, and CT can evaluate them better than ultrasonography. Likewise, CT is important for evaluating renal masses, stones, retroperitoneal conditions (e.g., hemorrhage, tumor, abscess), and renal vein thrombosis. In morbidly obese people, CT is often used to guide kidney biopsy. The use of contrast agents to assess vascular lesions of the kidney may not be possible if kidney function is compromised due to fear of precipitating AKI. Limiting the volume of the contrast agent and volume repletion before radiocontrast administration may minimize renal injury.

Although *intravenous pyelography* can image the structures in the kidney, contrast CT has taken the place of classic intravenous pyelography in many centers because of the risk of inducing nephrotoxicity in patients with CKD. In contrast, *retrograde pyelography* is often used by urologists to define the site and nature of obstruction within the ureter and the pelvis. In addition, during the procedure, ureteric stones can be removed with the use of a basket device.

Magnetic resonance imaging (MRI) is useful for imaging of the vasculature and therefore for the diagnosis of renal vein thrombosis and renal artery stenosis. Gadolinium-based contrast agents are often used for MRI because of their paramagnetic properties. These agents should be avoided if the GFR is less than 30 mL/min/1.73 m², because in such patients they have been implicated in causing a disabling and untreatable condition called *nephrogenic systemic fibrosis*. It is now believed that the risk of this disabling condition is directly related to the release of free gadolinium from gadolinium-based contrast agents. Stable macrocyclic agents that minimize the release of free gadolinium after administration such as gadoterate acid and gadobutrol are preferred over the older gadolinium-based contrast agents. MRI cannot be performed in patients who have metallic implanted devices with magnetic properties such as pacemakers, artificial joints, or aneurysmal clips. Although nonferrous surgical metal can distort an MRI image, most are safe within the strong magnetic field of an MRI machine. Research now reveals that MRI examination after a total joint replacement is not only possible, but adjusting pulse sequences and parameters often can provide accurate information on soft tissue tissues and causes of joint failure.

After injection of a small amount of radioactive substance, *radionuclide imaging* can be performed to assess renal perfusion and function of the kidneys. One advantage of this technique is that it can assess kidney function and perfusion simultaneously for each kidney. It therefore allows diagnosis of renal artery stenosis, especially when it is performed before and after administration of angiotensin-converting enzyme (ACE) inhibitors.

Renal arteriography is the reference standard for the diagnosis of renal artery stenosis. It involves direct injection of a radiocontrast dye into the renal arteries. In patients with CKD, contrast injection can be limited and carbon dioxide can be injected to avoid nephrotoxicity. This technique is also useful for assessing vascular malformations in the kidney and for making a diagnosis of polyarteritis nodosa. In the latter condition, renal arteriography can detect the presence of microaneurysms.

APPROACH TO THE PATIENT WITH ACUTE KIDNEY INJURY

The initial approach to patients with AKI focuses on the following factors: (1) the evaluation of risk or susceptibility to renal injury, (2) the cause(s) of the AKI, (3) the severity of injury, and (4) the presence of distant organ effects or consequences. In all cases, it is important to evaluate and optimize intravascular volume early in the course, because this is a readily addressable factor that can prevent or minimize further injury.

Evaluation of Risk or Susceptibility to Renal Injury

The risk factors for AKI include, first and foremost, prior existence of CKD; CKD can easily be detected by a low estimated GFR or the presence of albuminuria. Other common risk factors for AKI include advanced age, diabetes mellitus, hypertension (especially when treated with inhibitors of the renin-angiotensin system), chronic liver disease or cirrhosis, and multiple myeloma.

Causes of AKI

AKI is a challenging medical problem, and a careful and stepwise approach to evaluation is essential. This approach is guided by knowledge of the causes of injury, which can be divided into five major groups: ischemia, toxins, obstruction, inflammation, and infection.

Ischemia can be caused by volume loss from the gastrointestinal system (vomiting or diarrhea), the skin (sweating, burns), or the kidneys (diuretics, Addison's disease, and solute diuresis). Comparing the body weight of the patient with those weights recorded in the medical record can be valuable. A substantial decrease in body weight may point toward volume depletion as a possible cause of AKI. Third-space fluid losses, as observed in patients with ascites, pancreatitis, or ileus, can make the diagnosis of volume depletion challenging because such patients may not have an overall loss in body weight. Ischemia is a common cause of AKI due to poor perfusion associated with significant blood loss or sepsis or both. In the setting of ischemia, glomerular hypoperfusion is aggravated when patients are taking inhibitors of the renin-angiotensin system.

Nephrotoxins can be divided into two major groups: endogenous and exogenous. The endogenous toxins include paraproteins, myoglobin, hemoglobin, uric acid (e.g., in tumor lysis syndrome), and bile acids. Exogenous toxins include contrast agents, aminoglycosides, vancomycin, chemotherapeutic agents such as cisplatin, and NSAIDs.

Inflammation can involve the glomerular, interstitial, and vascular compartments. Inflammation of these structures produces glomerulonephritis, interstitial nephritis, and vasculitis, respectively.

Infection is an important cause of injury to the nephron. Infection-associated AKI is often diagnosed in the intensive care unit, where early sepsis can manifest as a fall in urine output followed by an increase in serum creatinine, confirming AKI. The causes of AKI in the setting of sepsis are often multifactorial and include ischemia, direct tubular dysfunction due to sepsis, and concomitant administration of drugs such as nephrotoxic antibiotics (commonly, high doses of vancomycin) and procedures (radiocontrast imaging), often performed to reverse sepsis.

Therefore, declines in urine volume, especially in the intensive care unit, should lead to a diligent search for a focus of infection.

Urinary tract obstruction is often a reversible cause of renal injury and therefore important to diagnose. Although urine output is frequently reduced with obstruction, partial obstruction may be associated with an increase in urine output. Renal ultrasound is useful to diagnose hydronephrosis; urinalysis may reveal hematuria or infection or may be bland. Left untreated, renal atrophy may ensue.

In many ways, the severity of injury is best assessed at the bedside. Oliguric renal failure (100–400 mL urine/24 hr) or anuric renal failure (<100 mL urine/24 hr) has a worse prognosis than nonoliguric renal failure (>400 mL urine/24 hr). A low fractional excretion of sodium or, if the patient is taking diuretics, a low fractional excretion of urea may suggest volume depletion as the likely cause. Fractional excretion of any substance is simply calculated as the ratio of the clearance of the analyte in question to the clearance of creatinine. However, a low fractional excretion of urea or sodium may have causes other than volume depletion. For example, because of the heterogeneous nature of nephron injury, contrast-induced injury, sepsis, or burns often result in a low fractional excretion of sodium despite intrinsic renal failure.

Intrinsic renal injury can be detected by examining the urine sediment. The classic manifestation of acute tubular necrosis (ATN) is the presence of dirty-brown granular casts. However, in severe AKI, there may be a large amount of amorphous granular material without cast formation (see Figs. 24.3 and 24.5). This occurs because severe AKI may result in failure to produce the Tamm-Horsfall protein that is now called uromodulin, leading to no formation of casts. In the absence of dirty-brown granular casts, a diagnosis of acute tubular injury can still be made based on the presence of dysmorphic epithelial cells in the urine. These epithelial cells, under hypoxic conditions, transform from the round, fried-egg appearance of the tubular cell to angular cells taking the shape of triangles or teardrops (see Fig. 24.3). A normal sediment, on the other hand, suggests minimal or no kidney injury.

The individual elements that can be seen in the urine and may be of diagnostic importance are as follows: dysmorphic RBCs, sterile pyuria manifested by white blood cells (WBCs) in the urine without bacteria, urinary tract infection characterized by both WBCs and bacteria in the urine, dysmorphic tubular cells suggesting ATN, intact renal tubular cells suggesting recovery from AKI, bubble cells, glitter cells, and oval fat bodies (see Figs. 24.2 and 24.3).

Budding yeast in a patient with diabetes may suggest the need to remove a long-standing indwelling catheter. Uric acid crystals in large amount suggest tumor lysis syndrome, calcium oxalate crystals may suggest ethylene glycol poisoning, and magnesium ammonium phosphate (triple phosphate) crystals may suggest infection with urease-positive organisms (see Fig. 24.4).

Casts can occur in various forms, such as RBC, WBC, epithelial cell, granular, hyaline, and dirty-brown granular casts. They can also occur

in various shapes, such as broad and narrow casts. Examples of these are demonstrated in Fig. 24.5.

Severity of Injury

The severity of injury needs to be assessed, as well as its relationship to the preexisting state of kidney health. Severe injury is required for AKI to be manifested when the kidney is otherwise healthy. Little damage is needed to produce a severe injury if CKD preexists. More important, however, is the response to injury. It remains unclear why certain individuals have low GFR and others with the same extent of injury do not. This likely reflects the protective nature of responses that can result in poor or better GFR.

Presence of Distant Organ Effects on Consequences

End-organ manifestations of AKI include pulmonary edema or acute respiratory distress syndrome, uremic encephalopathy as alteration of mental status or asterixis, and uremic pericarditis or pleuritis manifested as pericardial or pleural friction rub. Although pulmonary edema is still a common manifestation of uremia, uremic serositis and encephalopathy are now rare.

For a deeper discussion on this topic, see Chapter 106, “Approach to the Patient with Renal Disease,” in *Goldman-Cecil Medicine*, 26th Edition.

Fluid and Electrolyte Disorders

Biff F. Palmer

NORMAL VOLUME HOMEOSTASIS

In the average adult, the total body water is equal to 50% to 60% of body weight: 60% for men and 50% for women because of extra body fat, which is water free. Thus, in an average 70-kg male, total body water is 42 kg or 42 L, while in an average 70-kg female, total body water is 35 kg or L. Of the total body water, approximately two thirds is located intracellularly while one third is located extracellularly. Of the extracellular fluid (ECF) volume, only one fourth is located within the intravascular space. In a 70-kg man with a total body water of 42 L, 28 of these liters will be located intracellularly, while only 14 L are located in the ECF, and only 3.5 L are located in the extracellular intravascular compartment.

ECF volume is determined by the balance between sodium intake and excretion. Under normal circumstances, wide variations in salt intake lead to parallel changes in renal salt excretion, such that ECF volume and total body salt is maintained within narrow limits. This relative constancy of ECF volume is achieved by a series of afferent sensing systems, central integrative pathways, and both renal and extrarenal effector mechanisms acting in concert to modulate sodium excretion by the kidney (Table 25.1).

The concentration of sodium chloride (NaCl) in the plasma is regulated by renal water handling. The maintenance of plasma tonicity is achieved by sensing and effector mechanisms that differ from those that regulate volume. However, the systems that regulate volume and plasma tonicity do work in concert. For example, if the baroreceptors of the body detect that ECF volume is low, the kidney will respond by retaining NaCl. This will transiently lead to an increase in the tonicity of the ECF that will stimulate arginine vasopressin (AVP) release, causing renal water retention and expansion of the ECF volume.

Osmolality and Tonicity

Osmolality is defined as the number of particles per kilogram of solution. Plasma osmolality can be directly measured in an osmometer or can be calculated using the following equation:

$$\text{Calculated osmolality} = (\text{Na}^+ \times 2) + \text{glucose}/18 + \text{BUN}/2.8$$

where Na^+ is the sodium ion concentration and BUN is the blood urea nitrogen level.

The osmolar gap is the difference between the measured and calculated osmolality and is normally less than 10 mOsm/L. A higher value indicates the accumulation of an unmeasured substance such as ethanol, methanol, ethylene glycol, and acetone.

It is important to distinguish osmolality from tonicity. Whereas *osmolality* refers to all particles, *tonicity* describes whether the particles are effective or ineffective osmoles. Effective osmoles such as Na^+ , glucose, or mannitol cannot penetrate cell membranes and thus can

lead to changes in cell volume. Ineffective osmoles such as urea and alcohols are ineffective osmoles because they pass freely into and out of cells and are unable to effect changes in cell volume. As an example, chronic kidney disease patients with BUN levels greater than 100 mg/dL have no cellular shifts of fluid due to the urea. The plasma osmolality is high, but plasma tonicity is normal.

HYPONATREMIA

Hyponatremia is one of the most common electrolyte abnormalities encountered in clinical practice. Increasing age, medications, various disease states, and administration of hypotonic fluids are among the known risk factors for the disorder. Although hyponatremia is most commonly a marker of hypo-osmolality, there are three general causes of hyponatremia not associated with a hypo-osmolar state (Fig. 25.1). The first of these is pseudohyponatremia. This condition occurs in the setting of hyperglobulinemia or hypertriglyceridemia in which plasma water relative to plasma solids is decreased in blood leading to less Na^+ in a given volume of blood.

The second cause involves true hyponatremia but with elevations in the concentration of an effective osmole. Clinical examples include hyperglycemia as seen in uncontrolled diabetes or rarely hypertonic infusion of mannitol used in the treatment of cerebral edema. Increased plasma glucose concentration raises serum osmolality, which pulls water out of cells and dilutes the serum Na^+ . For every 100-mg/dL rise in glucose or mannitol the serum Na^+ will quickly fall by 1.6 mEq/L. The increased tonicity will also stimulate thirst and AVP secretion, both of which contribute to further water retention. As the plasma osmolality returns towards normal, the decline in serum Na^+ will be 2.8 mEq/L for every 100-mg/dL rise in glucose. The net result is a normal plasma osmolality but a low serum Na^+ .

The third cause of hyponatremia in the absence of a hypo-osmolar state is the addition of an isosmotic (or near isosmotic) non- Na^+ containing fluid to the extracellular space. This situation typically occurs during a transurethral resection of the prostate or during laparoscopic surgery when large amounts of a non-conducting flushing solution containing glycine or sorbitol are reabsorbed systemically.

The presence of hypotonic hyponatremia implies that water intake exceeds the ability of the kidney to excrete water. Because the normal kidney can excrete 20 to 30 L of water per day, the presence of hyponatremia with normal renal water excretion implies the patient is drinking at least those volumes of water. This condition is referred to as *primary polydipsia*. Urine osmolality will be less than 100 mOsm/L in this setting. Hyponatremia in association with a maximally dilute urine can also result from more moderate fluid intake combined with extremely limited solute intake, a condition often referred to as “beer potomania” syndrome.

TABLE 25.1 Sensors and Effectors That Determine Osmoregulation and Volume Regulation

Factor	Osmoregulation	Volume Regulation
What is sensed	Plasma osmolality	Effective arterial volume (EAV)
Sensors	Hypothalamic osmoreceptors	Low and high pressure baroreceptors
Effectors	Arginine vasopressin (AVP), Thirst	Aldosterone, Angiotensin II, Sympathetic nerves
What is effected	Urine osmolality, Thirst	Urine Na ⁺ excretion

In the absence of primary polydipsia, hypotonic hyponatremia results when water intake exceeds the renal capacity for water excretion due to an inappropriately concentrated urine (some value >100 mOsm/L). The effective arterial blood volume (EAV) must be defined in this setting. Decreased EAV causes baroreceptor stimulation of AVP secretion and leads to decreased distal delivery of filtrate to the tip of the loop of Henle, accounting for the inability to maximally dilute the urine. If EAV is low, ECF volume can be low in the volume-depleted patient (hypovolemic hyponatremia) or can be high in the edematous patient (hypervolemic hyponatremia). A normal EAV points to euvolemic causes of hyponatremia (isovolemic hyponatremia).

Approximately two thirds of diagnosed hyponatremia cases are acquired in the hospital, where the common practices of monitoring daily fluid intake, patient weight, and Na⁺ levels normally allow prompt diagnosis. Administration of hypotonic fluids in the postoperative period is a risk factor for acute iatrogenic hyponatremia, particularly because AVP levels remain increased several days after surgical procedures. Iatrogenic cases can be prevented by close monitoring of electrolytes and urine output and by fluid restriction and avoidance of solutions with low-Na⁺ content; this approach applies particularly to elderly patients.

In neurosurgical patients, the syndrome of inappropriate antidiuretic hormone secretion (SIADH) and cerebral salt wasting (CSW) are two potential causes of hyponatremia. Distinguishing between these two disorders can be challenging because there is considerable overlap in the clinical presentation. The primary distinction lies in the assessment of the EAV. SIADH is a volume-expanded state due to AVP-mediated renal water retention. CSW is characterized by a contracted EAV resulting from renal salt wasting. Making an accurate diagnosis is important because the therapy of each condition is quite divergent. Vigorous salt replacement is indicated in patients with CSW, and fluid restriction is the treatment of choice in patients with SIADH.

Common causes of hyponatremia outside the hospital setting include overhydration, diarrhea, vomiting, CNS infection, extreme exercise, liver failure, renal failure, congestive heart failure, drugs, SIADH, and combinations of these and other factors. Thiazide diuretics are the most common cause of drug-induced hyponatremia. Hyponatremia typically develops in the first 2 weeks of drug initiation and is most likely to occur in elderly women and during the summer months because of the increased ingestion of hypotonic fluids when it is hot. Concomitant use of nonsteroidal anti-inflammatory drugs (NSAIDs) and selective serotonin reuptake inhibitors (SSRIs) can further increase the risk of thiazide-induced hyponatremia.

Treatment of Hyponatremia

Symptoms of hyponatremia include nausea and malaise, which can be followed by headache, lethargy, muscle cramps, disorientation, restlessness, and obtundation. When treating a patient with hyponatremia,

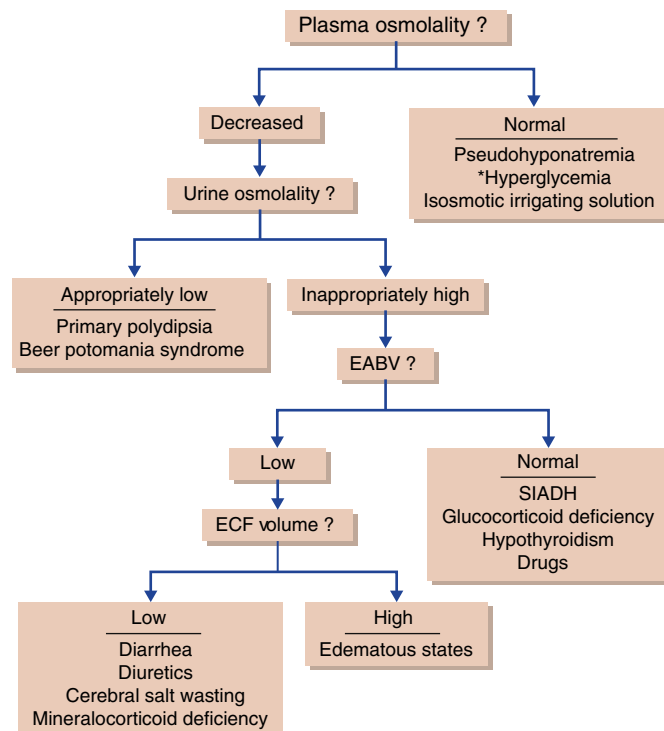

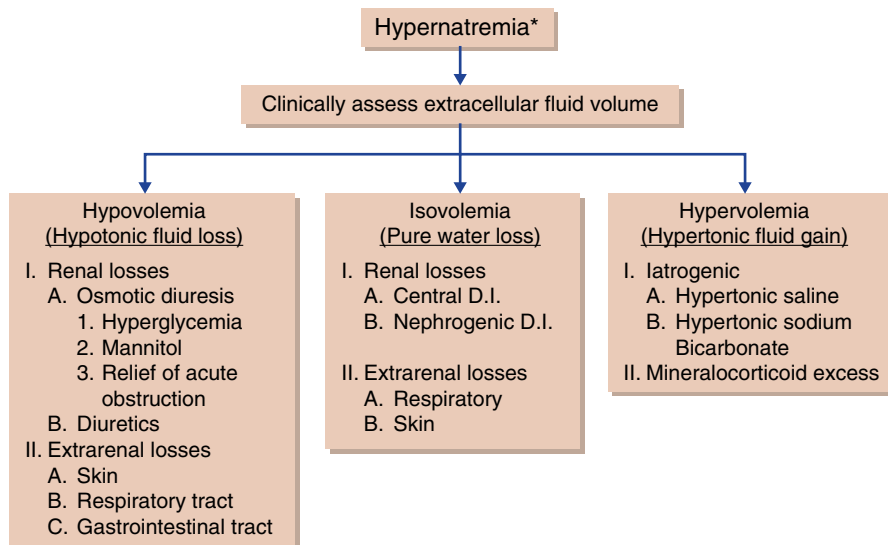

Fig. 25.1 Approach to the patient with hyponatremia. Assessment of effective arterial blood volume (EAV) is key to understanding the mechanism of renal NaCl retention and whether it is primary or in response to a low EAV. By definition, EAV is the arterial volume sensed by the kidney. Thus, if the kidney is working normally and it is retaining NaCl, EAV must be low, and if a normally functioning kidney is excreting large amounts of NaCl, the EAV is large. The physical examination is the most reliable way to assess EAV. The presence or absence of edema and orthostatic changes in blood pressure and pulse are particularly useful findings indicative of EAV. Laboratory tests are also useful in the assessment of EAV. Collection of a spot urinary sample for Na⁺, Cl⁻, and creatinine allows calculation of the fractional excretion of Na⁺ or fractional excretion of Cl⁻ using the following equations: $FE_{Na} (\%) = [(urine\ Na^+ \times plasma\ creatinine)/(plasma\ Na^+ \times urine\ creatinine)] \times 100$ $FE_{Cl} (\%) = [(urine\ Cl^- \times plasma\ creatinine)/(Plasma\ Cl^- \times urine\ creatinine)] \times 100$. If these parameters are low (<0.5 to 1%), a low EAV is indicated. Other findings suggestive of a low EAV include an increase in the blood urea nitrogen (BUN)/creatinine ratio (>20:1), increased serum uric acid concentration (due to increased proximal tubular reabsorption), and increased hematocrit and serum albumin concentration secondary to hemoconcentration. *Osmolality can be normal or increased with hyperglycemia.

the Na⁺ concentration should be raised at the rate at which it fell. In patients with chronic hyponatremia (>48 hours duration), the serum Na⁺ concentration has fallen slowly. Neurologic symptoms are generally minimal, brain size is normal, and the number of intracellular osmoles is decreased. Sudden return of ECF osmolality to normal values will lead to cell shrinkage and possibly precipitate osmotic demyelination. This complication can be avoided by limiting correction to less than 10 to 12 mEq/L in 24 hours and to less than 18 mEq/L in 48 hours. In a patient whose serum Na⁺ concentration has decreased rapidly (<48 hours), neurologic symptoms are frequently present, and there is cerebral edema. In this setting, there has not been enough time to remove osmoles from the brain, and rapid return to normal ECF osmolality merely returns brain size to normal.

In general, the development of hyponatremia in the outpatient setting is more commonly chronic in duration and should be corrected slowly. By contrast, hyponatremia of short duration is more likely to be

*All are associated with impairment of thirst or access to water

Fig. 25.2 Approach to the patient with hypernatremia.

encountered in hospitalized patients receiving intravenous free water. Use of “ecstasy,” exercise-induced hyponatremia, or patients with primary polydipsia can also lead to acute hyponatremia and if symptomatic may similarly require rapid correction.

HYPERNATREMIA

Hypernatremia is a relatively common problem, particularly among the elderly and critically ill. Hypernatremia always indicates hypertonicity and shrinkage of cells. It is an independent risk factor for mortality in the ICU setting.

The initial approach to any patient with hypernatremia is to determine why there has been inadequate intake of water (Fig. 25.2). Hypernatremia is rare in conscious patients who have free access to water because of the extreme sensitivity of the thirst mechanism. Usually there is inadequate water intake due to an alteration in the level of consciousness so that patients become unaware of thirst or cannot adequately communicate the need for water or there is restricted access to water. Only rarely is there a specific lesion of the thirst center. A reduced sensation of thirst occurs in otherwise normal individuals as a feature of increasing age.

The next step is to search for the presence of accelerated water loss or increased Na^+ gain, both of which will increase the likelihood of a patient developing hypernatremia. This can be accomplished by clinical assessment of EAV. Hypovolemic hypernatremia results from fluid losses in which the Na^+ concentration is less than the plasma concentration. Hypervolemic hypernatremia can be due to iatrogenic administration of hypertonic NaCl or hypertonic NaHCO_3 or from mineralocorticoid excess.

Pure water loss, whether from mucocutaneous routes or from the kidneys, causes isovolemic hypernatremia. Because two thirds of pure water loss is sustained from within cells, patients will not become clinically volume depleted unless the water deficit becomes substantial. Insensible losses from the respiratory tract or skin result in concentrated urine. Inappropriate water loss by the kidney, whether from central or nephrogenic diabetes insipidus, results in dilute urine. Although renal water loss can lead to hypernatremia in patients with impaired thirst or access to water, most patients with diabetes insipidus have neither of these defects and typically present with polyuria, polydipsia, and a normal serum sodium concentration.

Evaluation of Polyuria and Polydipsia

Polyuria can be the result of an osmotic diuresis or a water diuresis. In turn, a water diuresis may result from inappropriate water loss as in either central or nephrogenic diabetes insipidus or may represent appropriate water loss as in primary polydipsia. The clinical setting and urine osmolality help to differentiate between these processes (Fig. 25.3).

Osmotic diuresis causing polyuria is often evident from the clinical setting. Poorly controlled glucose levels in a patient with diabetes mellitus, administration of mannitol to a patient with increased intracranial pressure, and high-protein enteral feedings (urea diuresis) are all examples in which polyuria is the result of osmotic diuresis. Urine osmolality greater than 300 mOsm/L in the polyuric patient is suggestive of solute or osmotic diuresis.

After excluding the presence of osmotic diuresis, one must then discriminate between the causes of water diuresis. In patients with central diabetes insipidus, the onset of symptoms is characteristically abrupt in nature, whereas patients with nephrogenic diabetes insipidus typically have a more gradual onset of symptoms. Patients with primary polydipsia are more vague in dating the onset of their symptoms. Both nephrogenic and central diabetes insipidus are characterized by severe and frequent nocturia, a feature that is typically absent in patients with primary polydipsia. Patients with central diabetes insipidus seem to have a predilection for ice water, which is not typically described in the other two conditions. A serum Na^+ concentration less than 140 mEq/L is suggestive of primary polydipsia because these patients tend to be in mild positive water balance. By contrast, a value greater than 140 mEq/L is more suggestive of either central or nephrogenic diabetes insipidus because these patients tend to be in mild negative water balance. Finally, urine osmolality will increase in response to water deprivation in primary polydipsia but show no response in diabetes insipidus. Central and nephrogenic diabetes insipidus are distinguished by the change in urine osmolality following subcutaneous administration of AVP (increased in central with no change in nephrogenic).

Treatment of Hypernatremia

Signs and symptoms of hypernatremia include lethargy, weakness, fasciculations, seizures, and coma. Increased ECF osmolality initially causes cell shrinkage within the brain. In response, cells generate

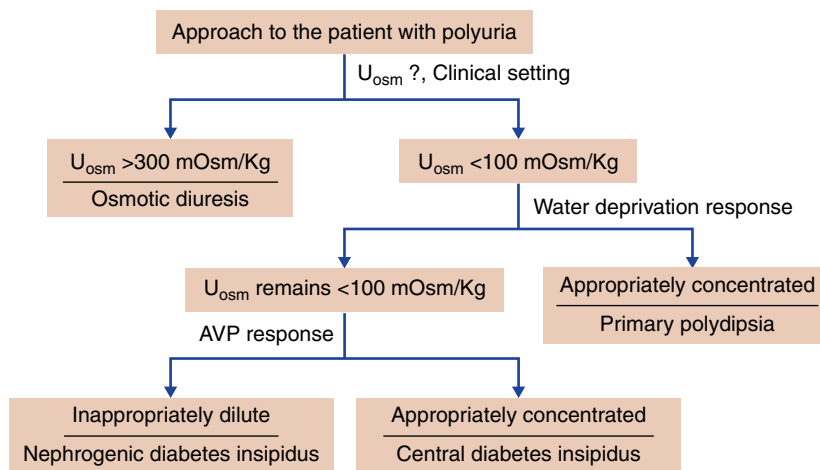

Fig. 25.3 Approach to the patient with polyuria. AVP, Arginine vasopressin; U, urine.

intracellular osmoles, which pull water back into the cells, returning brain size to normal. If extracellular osmolality is returned rapidly to normal, the extra intracellular osmoles will pull water into the brain cells, resulting in cerebral edema. Thus, in general, hypernatremia should be corrected slowly by water administration at a rate that leads to half correction in 24 hours. The water deficit can be estimated from the following formula:

$$\text{Water deficit} = \text{Current body water (0.6 in men and 0.5 in women} \times \text{body weight)} \times \left[\left(\frac{[\text{Na}^+]_{\text{plasma}}}{140} \right) - 1 \right]$$

Calculation of the amount of water to give must add insensible losses and any ongoing losses from the urinary and gastrointestinal tract. This formula also does not include the volume of isotonic saline required in those patients who may be concomitantly volume depleted. Careful monitoring of the serum Na^+ is required to ensure the rate of correction is appropriate.

HYPOKALEMIA

Hypokalemia is a common clinical disorder. Decreases in total body K^+ are usually due to gastrointestinal or renal losses whereas hypokalemia in the setting of normal total body K^+ is due to cell shift. In most cases, the cause can be determined by history, measurement of blood pressure, examination of acid-base balance, and measurement of urinary K^+ levels.

Cellular Shift With Normal Total Body Potassium

In the absence of physical and historical evidence of gastrointestinal or renal K^+ losses, either a redistribution of K^+ at the cellular level or laboratory error will account for a low serum K^+ . Spurious causes of hypokalemia can be seen in leukemia patients with leukocyte counts of 100 to 250,000 $\times 10^9/\text{L}$, in which still-viable leukocytes extract K^+ from the serum in the sample tube. Interestingly, some patients with acute myeloid leukemia develop kidney K^+ wasting due to increased urinary excretion of lysozyme. This protein increases the luminal electronegativity in the collecting duct, providing a greater driving force for K^+ secretion.

The regulation of K^+ distribution between the intracellular and extracellular space is referred to as internal K^+ balance. Although the kidney is ultimately responsible for maintenance of total body K^+ , factors that modulate internal balance are important in the disposal of acute K^+ loads. A large potassium meal could potentially double

extracellular K^+ were it not for the rapid shift of the K^+ load into cells. The kidney cannot excrete K^+ rapidly enough in this setting to prevent life-threatening hyperkalemia. Thus, it is important that this excess K^+ be rapidly shifted and stored in cells until the kidney has successfully excreted the K^+ load. The major regulators of K^+ shift into cells are insulin and catecholamines.

Insulin excess, whether given exogenously in a patient with diabetes mellitus or endogenous secretion as seen in a normal person given a high glucose load, will lower the serum K^+ . β -Adrenergic agonists used in the treatment of bronchospasm or in treating premature labor will cause similar K^+ shifts. In the setting of an acute myocardial infarction, hypokalemia may result as a sequela of high circulating epinephrine levels and might predispose to arrhythmias in this clinical setting. Other clinical disorders resulting in intracellular sequestration of K^+ are treatment of megaloblastic anemia with vitamin B_{12} , hypothermia, and barium poisoning. Hypokalemic periodic paralysis is inherited in an autosomal dominant pattern and is characterized by episodic hypokalemia resulting in muscle weakness. An acquired form of the disorder is seen in thyrotoxic patients, who are often of Japanese or Mexican descent.

Decreased Total Body Potassium

In the absence of cell shift, low serum K^+ can result from inadequate dietary intake, extrarenal losses through the gastrointestinal tract or skin, or renal losses. The urinary K^+ concentration serves as a useful guide in discerning between these possibilities. A urine K^+ concentration of less than 20 mEq/L is suggestive of extrarenal losses, whereas a urine concentration of greater than 40 mEq/L suggests renal K^+ losses. A limitation of a random value is the degree of urinary concentration. A urine K^+ concentration of 40 mEq/L may be an appropriate response in a hypokalemic patient with maximally concentrated urine due to decreased water intake. By the same token, a random urine value of less than 15 mEq/L may represent renal K^+ wasting if obtained in the setting of water diuresis.

The transtubular potassium gradient (TTKG) is a method designed to overcome the limitations of a random urine K^+ concentration in the evaluation of a dyskalemic patient:

$$\text{TTKG} = \frac{U_{\text{potassium}} \times \text{Serum}_{\text{osmolality}}}{\text{Serum}_{\text{potassium}} \times U_{\text{osmolality}}}$$

The formula estimates the ratio of K^+ in the lumen of the cortical collecting duct to that in the peritubular capillaries at a point where tubular fluid is isotonic relative to plasma. While still often used, the

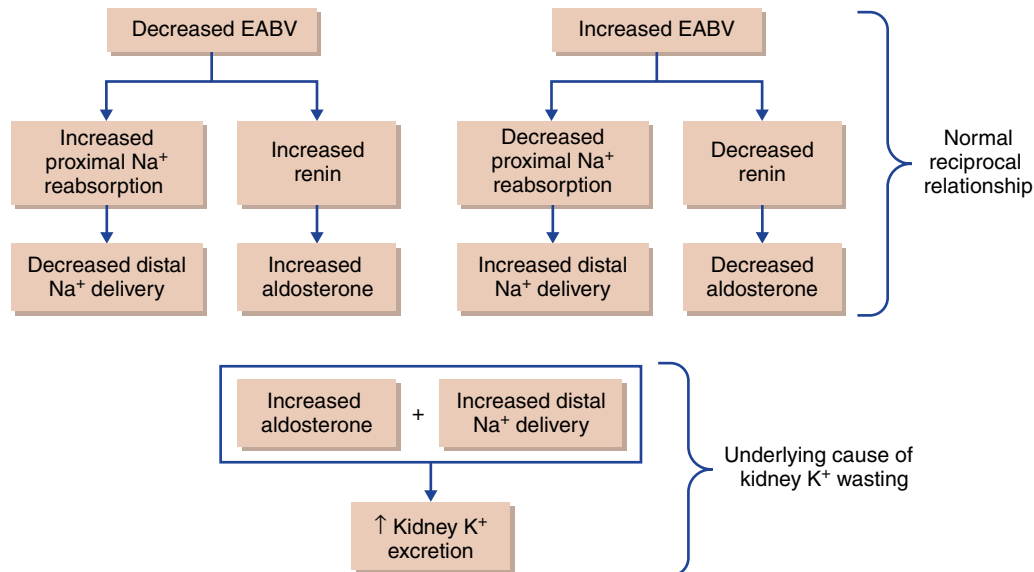

Fig. 25.4 The relationship between effective arterial volume and distal Na^+ delivery in determining renal K^+ excretion.

assumptions on which the formula is based have been called into question. For this reason, a urine K^+ to creatinine ratio is now the preferred way to assess renal K^+ handling. A ratio of less than 13 mEq K^+ /g creatinine or less than 2.5 mEq K^+ /mmol creatinine is considered an appropriate response to gastrointestinal potassium loss, remote use of diuretics, decreased dietary intake, and potassium shift into cells. Higher values suggest an inappropriate response of the kidney.

Inadequate dietary intake is an unusual cause of hypokalemia. Clinical situations associated with extreme K^+ -deficient diets include anorexia nervosa, crash diets, alcoholism, and intestinal malabsorption. Increased renal K^+ excretion owing to magnesium deficiency (which is often present in these clinical situations) may contribute to the observed hypokalemia.

Extrarenal Potassium Losses

Sweat, with its low concentration of K^+ , is an unusual cause of K^+ depletion. However, during physical training sweat losses can become substantial and K^+ depletion may result. Gastrointestinal syndromes are the most common clinical disorders of extrarenal K^+ losses. Diarrhea leads to fecal K^+ wastage and is associated with a normal anion gap acidosis. Acidosis will result in K^+ redistribution out of cells, leading to a degree of hypokalemia that is not as severe as the degree of total body K^+ depletion.

Renal Potassium Losses

Increased distal delivery of Na^+ and water and increased mineralocorticoid activity can each stimulate renal K^+ secretion. Under normal physiologic conditions, these two determinants are inversely regulated by EAV (Fig. 25.4). Decreases in EAV are associated with increased aldosterone secretion but lower distal delivery of Na^+ and water secondary to enhancement of reabsorption in the proximal nephron. It is for this reason that renal K^+ excretion is relatively independent of volume status. It is only under pathophysiologic conditions that distal Na^+ delivery and aldosterone become coupled. In this setting, renal K^+ wasting will occur. This coupling can be due to a primary increase in mineralocorticoid activity or a primary increase in distal Na^+ delivery. The term *primary* means that the changes are not secondary to changes in EAV. The causes of hypokalemia, grouped according to the physiologic determinants of renal K^+ excretion, are given in Fig. 25.5.

Primary Increase in Mineralocorticoid Activity

Increases in mineralocorticoid activity can be due to primary increases in renin secretion, primary increases in aldosterone secretion, or increases in a non-aldosterone mineralocorticoid or increased mineralocorticoid-like effect. In all of these conditions, ECF volume is expanded and hypertension is typically present. The differential diagnosis for the patient with hypertension, hypokalemia, and metabolic alkalosis rests on the measurement of plasma renin activity and plasma aldosterone levels.

Primary Increase in Distal Sodium Delivery

Conditions that give rise to primary increases in distal Na^+ delivery are characterized by normal or low ECF volume. Blood pressure is typically normal. Increases in distal Na^+ delivery are most frequently due to diuretics that act proximal to the cortical collecting duct. Increased delivery can also be the result of non-reabsorbed anions such as bicarbonate as with active vomiting or a type II proximal renal tubular acidosis. Ketoanions (β -hydroxybutyrate and acetoacetate) and the Na^+ salts of penicillins are other examples. The inability to reabsorb these anions in the proximal tubule results in increased delivery of Na^+ to the distal nephron. Because these anions also escape reabsorption in the distal nephron, a more lumen-negative voltage develops and the driving force for K^+ excretion into the tubular fluid is enhanced. Disorders of hypokalemia due to primary increases in distal Na^+ delivery can best be categorized by the presence of metabolic acidosis or metabolic alkalosis.

Clinical Presentation

The most important clinical manifestations of hypokalemia occur in the neuromuscular system. Low serum K^+ leads to cell hyperpolarization that impedes impulse conduction and muscle contraction. Typically, a flaccid paralysis develops in the hands and feet that moves proximally to eventually include the trunk and respiratory muscles. Death may occur from respiratory insufficiency. A myopathy may also occur that can evolve to rhabdomyolysis (muscle cell lysis) and acute kidney injury. Hypokalemia can also lead to smooth muscle dysfunction including paralytic ileus. Changes in electrocardiogram (ECG) include ST depression, T-wave flattening, and an increase in

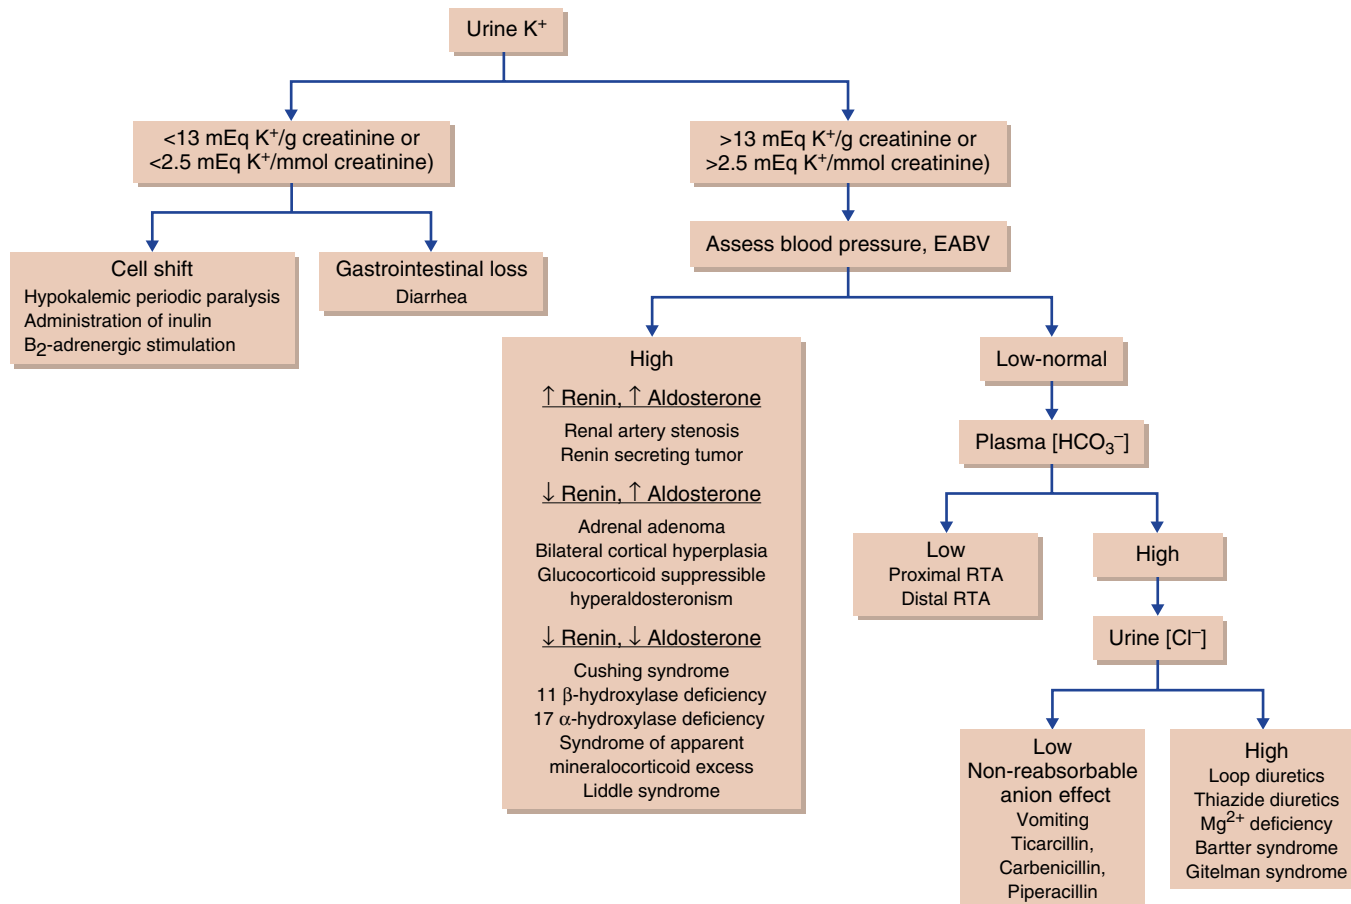

Fig. 25.5 Clinical approach to the hypokalemic patient.

the amplitude of the U wave. Patients treated with cardiac glycosides are at increased risk for premature ventricular contractions, and supra-ventricular and ventricular tachyarrhythmias, when hypokalemic.

Hypokalemia also causes a renal concentrating defect due both to a decrease in the medullary gradient and resistance of the cortical collecting tubule to AVP. This leads to polyuria and polydipsia. Prolonged hypokalemia can also lead to tubulointerstitial nephritis and renal failure (kaleopenic nephropathy). Because insulin release is regulated partially by serum K^+ , hypokalemia can lead to glucose intolerance.

Treatment of Hypokalemia

The serum K^+ levels can at times be misleading as to the degree of deficit because a normal or even increased K^+ level can occur with significant total body K^+ depletion. In the absence of significant K^+ shifts, a decline in the serum K^+ from 4 to 3 mEq/L generally is associated with a deficit of 300 to 400 mEq intracellular K^+ per 70 kg body weight. A serum K^+ concentration of 2 mEq/L reflects a deficit of roughly 600 mEq. Despite these guidelines, the serum K^+ level should be monitored frequently during replacement therapy.

K^+ can be given orally or intravenously as the potassium chloride (KCl) salt. Potassium bicarbonate or citrate can be given if there is concomitant metabolic acidosis. The safest way to administer KCl is orally. KCl can be given in doses of 100 to 150 mEq/day. Liquid KCl is bitter tasting and, like the tablet, can be irritating to the gastric mucosa. The microencapsulated or wax-matrix forms of KCl are better tolerated.

Intravenous administration of K^+ may be necessary if the patient cannot take oral medications or if the K^+ deficit is large and is resulting in cardiac arrhythmias, respiratory paralysis, or rhabdomyolysis.

Intravenous KCl should be given at a maximum rate of 20 mEq/hour and maximum concentration of 40 mEq/L. Higher concentrations will result in phlebitis. Replacement of KCl in dextrose-containing solutions can lower the serum K^+ further secondary to insulin release. Thus, saline solutions are preferred. Depending on the specific cause, additional therapy of chronic hypokalemia involves the use of K^+ -sparing diuretics such as amiloride, spironolactone or triamterene. These agents must be used cautiously in patients with renal insufficiency or in patients with other disorders that impair renal K^+ excretion.

HYPERKALEMIA

Like the hypokalemic disorders, a high serum K^+ can occur in the setting of normal or altered body stores of K^+ . The body has a marked ability to protect against hyperkalemia. This includes regulatory mechanisms that will excrete excess K^+ quickly and mechanisms that will redistribute excess K^+ into cells until it is excreted. All causes of hyperkalemia therefore involve abnormalities in these mechanisms.

Pseudohyperkalemia is an in vitro phenomenon due to the mechanical release of K^+ from cells during the phlebotomy procedure, specimen processing, or in the setting of marked leukocytosis and thrombocytosis. (As noted above, with certain leukemias with high WBC counts, extraction of K^+ from the serum by cells in the sample tube can result in spurious hypokalemia.)

Excessive Dietary Intake

In the presence of normal renal and adrenal function, it is difficult to ingest enough K^+ in the diet to produce hyperkalemia. Rather, dietary

intake of K^+ as a contributor to hyperkalemia is usually observed in the setting of impaired kidney function. Dietary sources particularly enriched with K^+ include melons, citrus juice, and commercial salt substitutes containing K^+ .

Cellular Redistribution

Cellular redistribution is a more important cause of hyperkalemia than of hypokalemia. Tissue damage is probably the most important cause of hyperkalemia due to redistribution of K^+ out of cells. This can be due to rhabdomyolysis, trauma, burns, massive intravascular coagulation, and tumor lysis (either spontaneous or following treatment). The effect of metabolic acidosis to cause K^+ exit from cells is dependent upon the type of acid present. Mineral acidosis (NH_4Cl or HCl) by virtue of the relative impermeability of the chloride anion results in the greatest efflux of K^+ from cells. By contrast, organic acidosis (lactic or β -hydroxybutyric) results in no significant efflux of K^+ . Increased osmolality as in uncontrolled diabetes causes K^+ to move out of cells. In fact, it is the hypertonic state as well as insulin deficiency that accounts for hyperkalemia often seen in patients with diabetic ketoacidosis who are total body K^+ depleted. β -Adrenergic blocking agents can interfere with the disposal of acute K^+ loads. Other drugs that can result in hyperkalemia include the depolarizing muscle relaxant succinylcholine and severe digitalis poisoning.

Decreased Renal Excretion of Potassium

Decreased renal excretion of K^+ can occur because of one or more of three abnormalities: a primary decrease in distal delivery of salt and water, abnormal cortical collecting duct function, and a primary decrease in mineralocorticoid levels.

Primary Decrease in Distal Delivery (Acute and Chronic Kidney Disease)

Acute decreases in glomerular filtration rate (GFR), as occur in acute kidney injury, lead to marked decreases in distal delivery of salt and water that may secondarily decrease distal K^+ secretion. When acute kidney injury is oliguric, distal delivery of $NaCl$ and volume are low and hyperkalemia is a frequent problem. When kidney injury is nonoliguric, however, distal delivery is usually sufficient and hyperkalemia is unusual. Decreased distal Na^+ delivery is a risk factor for hyperkalemia in patients with decompensated congestive heart failure. In chronic kidney disease patients, hyperkalemia is unusual until the GFR falls to less than 10-20 mL/min. The occurrence of hyperkalemia with a GFR of greater than 10 mL/min should raise the question of decreased aldosterone levels or a specific lesion of the cortical collecting duct.

Primary Decrease in Mineralocorticoid Activity

Decreased mineralocorticoid activity can result from disturbances that originate at any point along the renin-angiotensin-aldosterone system. Such disturbances can be the result of a disease state or be due to effects of various drugs. Hyperkalemia most commonly develops when one or more of these drugs are administered in a setting where the renin-angiotensin-aldosterone system is already impaired. One common example is the use of angiotensin-converting enzyme inhibitors (ACEI) or angiotensin-receptor blockers (ARB) in patients with diabetes mellitus with hyporeninemic hypoaldosteronism.

Distal Tubular Defects

Certain interstitial renal diseases can affect the distal nephron specifically and lead to hyperkalemia in the presence of only mild decreases in GFR and normal aldosterone levels. Amiloride and triamterene inhibit Na^+ transport, which makes the luminal potential more positive and secondarily inhibits K^+ secretion. A similar effect occurs with

trimethoprim and accounts for the development of hyperkalemia following the administration of the antibiotic trimethoprim-sulfamethoxazole. Spironolactone and eplerenone compete with aldosterone and thus block the mineralocorticoid effect.

Clinical Presentation

Hyperkalemia leads to depolarization of the resting membrane because the potential across cell membranes is in part determined by the ratio of intracellular to extracellular K^+ . The heart is particularly sensitive to this depolarizing effect. The progressive changes of hyperkalemia on the electrocardiogram are peaking of T waves, widening of the PR and QRS interval, development of a sine wave pattern, and eventually ventricular fibrillation and asystole. In general, ECG changes appear at a serum K^+ of 6 mEq/L with acute onset of hyperkalemia, whereas the ECG may remain normal up to a concentration of 8 to 9 mEq/L with chronic hyperkalemia. Hyperkalemia can also cause neuromuscular manifestations such as ascending paralysis and eventual flaccid quadriplegia. Hyperkalemia also decreases ammonia availability to act as a buffer for distal H^+ secretion. This effect impairs bicarbonate regeneration, leading to the development of a normal anion gap metabolic acidosis.

Treatment of Acute Hyperkalemia

The immediate treatment of life-threatening hyperkalemia is the administration of calcium, usually in the form of calcium gluconate or calcium chloride. ECG changes such as increasing PR interval or a widening QRS complex warrant treatment with calcium. Glucose and insulin therapy will shift K^+ into cells. Acute administration of glucose without insulin can potentially worsen hyperkalemia in patients with diabetes mellitus by raising extracellular osmolality and causing K^+ to shift into the extracellular space. $NaHCO_3$ administration through expansion of the ECF space results in dilution of the serum K^+ . Additionally, K^+ is shifted into cells whenever concomitant metabolic acidosis is corrected. Inhalation of β_2 -agonists such as albuterol or parenteral use of salbutamol can cause significant K^+ shifts into cells.

The effects of calcium, bicarbonate, glucose and insulin, and β_2 -agonist therapy will provide immediate relief of acute toxicity but will not decrease total body K^+ . Measures to reduce total body K^+ include the administration of K^+ binding drugs and dialysis.

Treatment of Chronic Hyperkalemia

After review of the patient's medication profile, drugs that can impair renal K^+ excretion should be discontinued if possible. Nonsteroidal anti-inflammatory drugs, either prescribed or those over-the-counter, are common offenders in this regard. Patients should be placed on a low K^+ diet with specific counseling against the use of K^+ -containing salt substitutes. Diuretics are particularly effective in minimizing hyperkalemia. In patients with an eGFR less than 30 mL/min, thiazide diuretics can be used, but loop diuretics are required with more severe renal insufficiency. In chronic kidney disease patients with metabolic acidosis (bicarbonate concentration < 22 mEq/L), $NaHCO_3$ should be given. K^+ -binding drugs can be utilized when hyperkalemia is refractory to the approaches outlined above. Sodium polystyrene sulfonate (Kayexalate) has been available for over 50 years but is poorly tolerated and has been linked to gastrointestinal toxicity. Patiromer and sodium zirconium cyclosilicate (ZS-9) are new K^+ -binding drugs that are well tolerated when used chronically and can maintain normokalemia in the setting of renin-angiotensin-aldosterone system inhibitors.

METABOLIC ACIDOSIS

Metabolic acidosis is diagnosed by a low pH, a reduced HCO_3^- concentration, and respiratory compensation resulting in a decrease in the

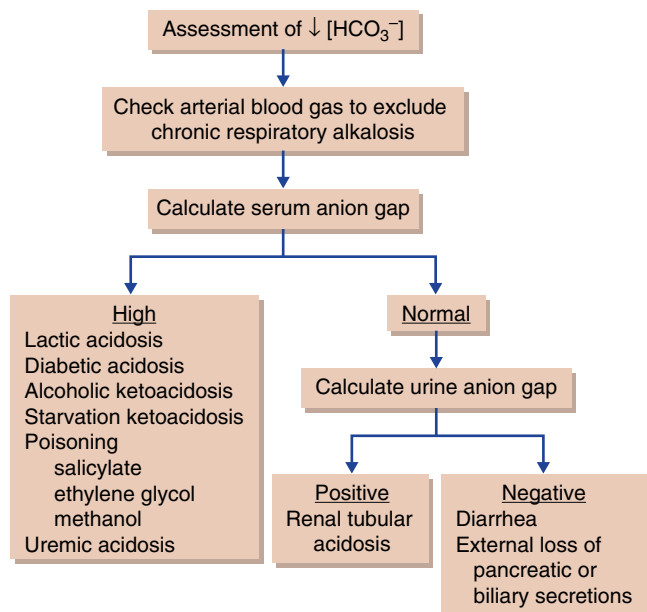

Fig. 25.6 Approach to the patient with a reduced serum HCO_3^- concentration.

partial pressure of carbon dioxide (PCO_2). A low HCO_3^- concentration alone is not diagnostic of metabolic acidosis because it also results from the renal compensation to chronic respiratory alkalosis. Measurement of the arterial pH differentiates between these two possibilities. The pH is low in hyperchloremic metabolic acidosis and high in chronic respiratory alkalosis. The clinical approach to a patient with a low serum HCO_3^- concentration is given in Fig. 25.6.

After confirming the presence of metabolic acidosis, calculation of the serum anion gap is a useful step in determining the differential diagnosis of the disorder. The anion gap is equal to the difference between the plasma concentrations of the major cation (Na^+) and the major measured anions ($\text{Cl}^- + \text{HCO}_3^-$).

$$\text{Anion gap} = (\text{Na}^+) - (\text{Cl}^-) - (\text{HCO}_3^-)$$

The normal value of the anion gap is approximately 12 ± 2 mEq/L. Most of the unmeasured anions consist of albumin; therefore, the normal anion gap changes in the setting of hypoalbuminemia (normal anion gap is approximately three times the serum albumin in g/dL). Because the total number of cations must equal the total number of anions, a fall in the serum HCO_3^- concentration must be offset by a rise in the concentration of other anions. If the anion accompanying excess H^+ is Cl^- , the fall in the serum HCO_3^- concentration is matched by an equal rise in the serum Cl^- concentration. The acidosis is classified as a normal gap or hyperchloremic metabolic acidosis. By contrast, if excess H^+ is accompanied by an anion other than Cl^- , the fall in HCO_3^- is balanced by a rise in the concentration of the unmeasured anion. The Cl^- concentration remains the same. In this setting, the acidosis is said to be a high anion gap metabolic acidosis.

A useful method for differentiating extrarenal from renal causes of metabolic acidosis is to measure urinary NH_4^+ excretion. Extrarenal causes of metabolic acidosis are associated with an appropriate increase in net acid excretion, primarily reflected by high levels of urinary NH_4^+ excretion. By contrast, net acid excretion and urinary NH_4^+ levels are low in metabolic acidosis of renal origin. Unfortunately, measurement of urinary NH_4^+ is not a test that is commonly available in clinical medicine. However, the amount of urinary NH_4^+ can be indirectly assessed by calculating the urinary anion gap (UAG).

$$\text{UAG} = (\text{UNa}^+ + \text{UK}^+) - \text{UCI}^-$$

Under normal circumstances, the UAG is positive, with values ranging from 30 to 50. Metabolic acidosis of extrarenal origin is associated with a marked increase in urinary NH_4^+ excretion and, therefore, a large negative value will be obtained for the UAG. If the acidosis is of renal origin, urinary NH_4^+ excretion will be minimal and the UAG will usually be positive.

The UAG can be misleading when other unmeasured ions are excreted. For example, increased urinary excretion of sodium keto acid salts in diabetic and alcoholic ketoacidosis and urinary excretion of sodium hippurate and sodium benzoate in toluene exposure can keep the UAG positive despite an appropriate increase in urinary ammonium excretion. Increased urinary excretion will also be missed when NH_4^+ is excreted with an anion other than Cl^- such as β -hydroxybutyrate or hippurate. In these settings, calculation of the urine osmolal gap is used as an indirect measure of ammonium excretion. The urine osmolal gap is the difference between the measured and the calculated urine osmolality:

$$\begin{aligned} \text{Urine osmolal gap} &= \text{calculated urine osmolality (mOsmol/kg)} \\ &= (2 \times [\text{Na}^+ + \text{K}^+]) + [\text{urea nitrogen in} \\ &\quad \text{mg/dL}] / 2.8 + [\text{glucose in mg/dL}] / 18 \end{aligned}$$

The urine osmolal gap normally ranges from approximately 10 to 100 mOsmol/kg. Because NH_4^+ salts are generally the only other major urinary solute that contribute significantly to the urine osmolality, values appreciably greater than 100 mOsmol/kg reflect increased excretion of NH_4^+ salts.

Urine pH cannot reliably differentiate acidosis of renal origin from that of extrarenal origin. For example, an acid urine pH does not necessarily indicate an appropriate increase in net acid excretion. With a significant reduction in the availability of NH_4^+ to serve as a buffer, only a small amount of distal H^+ secretion will lead to a maximal reduction in urine pH. In this setting, the pH of the urine is acid but the quantity of H^+ secretion is insufficient to meet daily acid production. By contrast, alkaline urine does not necessarily imply a renal acidification defect. In conditions where availability of NH_4^+ is not limiting, distal H^+ secretion can be massive and yet the urine remains relatively alkaline because of the buffering effects of NH_4^+ .

Hyperchloremic or Normal Anion Gap Metabolic Acidosis

Hyperchloremic (normal anion gap metabolic) acidosis can be of renal or extrarenal origin. Metabolic acidosis of renal origin is the result of abnormalities in tubular H^+ transport. Metabolic acidosis of extrarenal origin is most commonly caused by gastrointestinal losses of HCO_3^- . Other causes include the external loss of biliary and pancreatic secretions and ureteral diversion procedures. Fig. 25.7 provides a clinical approach to metabolic acidosis of renal origin.

Renal Origin

Proximal renal tubular acidosis (type II). The diagnosis of proximal RTA is suspected in a patient with a normal anion gap acidosis, hypokalemia, and an intact ability to acidify the urine to a pH of less than 5.5 while in a steady state. In the steady state, the serum HCO_3^- concentration is usually in the range of 16 to 18 mmol/L. Proximal RTA can be an isolated finding but most commonly is accompanied by generalized dysfunction of the proximal tubule (Fanconi syndrome). The urine anion gap is positive because proximal tubular dysfunction also impairs ammoniogenesis.

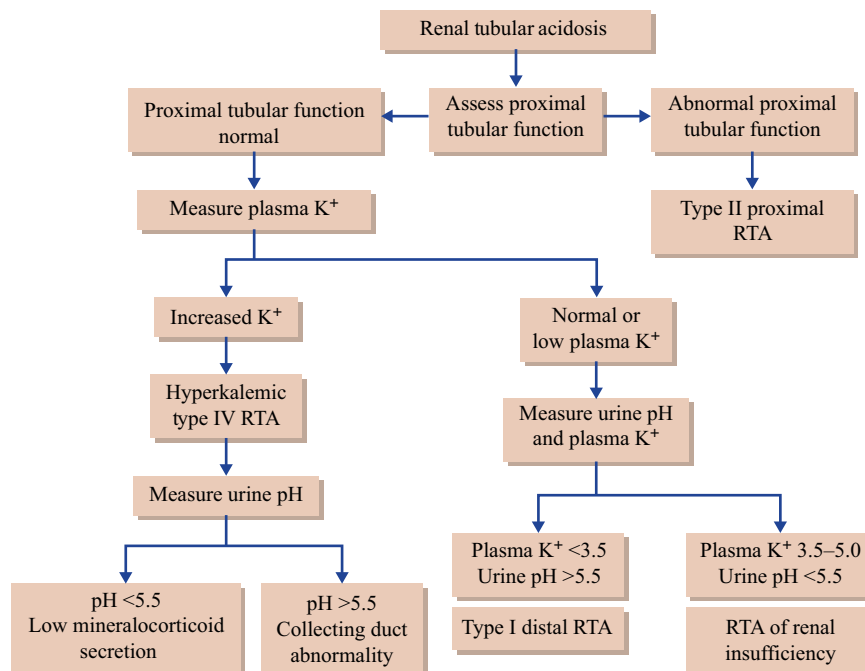

Fig. 25.7 Approach to the patient with acidosis of renal origin.

Proximal RTA is not associated with nephrolithiasis or nephrocalcinosis. However, osteomalacia can develop because of chronic hypophosphatemia and/or deficiency in the active form of vitamin D. Osteopenia may also be present because of acidosis-induced demineralization of bone. The treatment of patients with proximal RTA is difficult. Correction of the acidosis is often not possible even with large amounts of HCO_3^- (3 to 5 mmol/kg daily) because exogenous alkali is rapidly excreted in the urine. In addition, such therapy leads to accelerated renal K^+ losses. Use of a thiazide diuretic to induce enough volume depletion to lower the GFR and thus decrease the filtered load of HCO_3^- may increase the effectiveness of alkali therapy. Potassium-sparing diuretics may limit the degree of renal K^+ wasting. Once therapy is initiated, close monitoring is required to guard against severe electrolyte derangements. Acetazolamide and topiramate can cause metabolic acidosis due to inhibitory effects on carbonic anhydrase.

Hypokalemic distal renal tubular acidosis (type I). The diagnosis of distal RTA should be considered in a patient with hyperchloremic normal gap acidosis, hypokalemia, and an inability to lower the urine pH maximally. A urine pH greater than 5.5 in the setting of systemic acidosis is consistent with distal RTA. The urinary anion gap is positive. The systemic acidosis tends to be more severe than in patients with a proximal RTA with serum HCO_3^- concentrations as low as 10 mmol/L. Hypokalemia can also be severe and cause musculoskeletal weakness and symptoms of nephrogenic diabetes insipidus. Patients frequently manifest nephrolithiasis and nephrocalcinosis. This predisposition to renal calcification results from the combined effects of increased urinary Ca^{2+} excretion due to acidosis-induced bone mineral dissolution, a persistently alkaline urine pH, and low urinary citrate excretion.

Correction of the metabolic acidosis in distal RTA can be achieved by administration of alkali in an amount equal to daily acid production (usually 1 to 2 mmol/kg per day). In patients with severe K^+ deficits, correction of the acidosis with HCO_3^- can transiently cause further lowering of the extracellular K^+ concentration and result in symptomatic hypokalemia. In this setting, the K^+ deficit should be corrected prior to correcting the acidosis. Potassium citrate is the preferred form of alkali for those patients with persistent hypokalemia or with calcium stone disease.

Hyperkalemic distal renal tubular acidosis (type IV). A type IV RTA should be suspected in a patient with a hyperchloremic normal gap metabolic acidosis associated with hyperkalemia. The urinary anion gap is slightly positive, indicating little to no NH_4^+ excretion in the urine. Patients in which the disorder is caused by a defect in mineralocorticoid activity typically have a urine pH of less than 5.5, reflecting a more severe defect in NH_3 availability than in H^+ secretion. In patients with structural damage to the collecting duct, the urine pH may be alkaline, reflecting both impaired H^+ secretion and decreased urinary NH_4^+ excretion. The syndrome occurs most often in association with mild-to-moderate renal insufficiency; however, the magnitude of hyperkalemia and acidosis are disproportionately severe for the observed degree of renal insufficiency (Table 25.2). The primary goal of therapy is to correct the hyperkalemia. In many instances, lowering the serum K^+ will simultaneously correct the acidosis by restoring renal NH_4^+ production, thereby increasing the buffer supply for distal acidification.

Renal tubular acidosis of renal insufficiency. Patients with chronic kidney disease initially develop a hyperchloremic normal gap metabolic acidosis associated with normokalemia as the GFR falls below 30 mL/min. With more advanced chronic kidney disease (GFR < 15 mL/min), the acidosis changes to predominately an anion gap metabolic acidosis reflecting a progressive inability to excrete phosphate, sulfate, and the Na^+ salts of various organic acids. At this stage, the acidosis is commonly referred to as *uremic acidosis*.

Correction of the metabolic acidosis in patients with chronic kidney disease is achieved by treatment with NaHCO_3 0.5 to 1.5 mmol/kg/day beginning when the HCO_3^- level is less than 22 mmol/L. Metabolic acidosis needs to be aggressively treated because it can contribute to metabolic bone disease, increase catabolism, and contribute to the progressive loss of kidney function.

Extrarenal Origin of Metabolic Acidosis

Diarrhea. Loss of HCO_3^- in intestinal secretions beyond the stomach leads to the development of metabolic acidosis. Volume loss signals the kidney to increase the reabsorption of salt. Renal retention of NaCl

combined with the intestinal loss of NaHCO_3 generates a hyperchloremic normal gap metabolic acidosis. Net acid excretion markedly increases due to increases in urinary excretion of NH_4^+ . Hypokalemia due to gastrointestinal losses and the low serum pH both stimulate the synthesis of NH_3 in the proximal tubule. The increase in availability of NH_3 to act as a urinary buffer allows for a maximal increase in H^+ secretion by the distal nephron. Urine pH during chronic diarrheal states may be persistently greater than 6.0 due to the large increase in buffer capacity.

A patient who presents with hypokalemic hyperchloremic metabolic acidosis with a urine pH greater than 5.5 could have either a diarrheal state or a hypokalemic (type I) distal RTA. Although the clinical history would be the easiest way to distinguish between these two possibilities, in a patient with surreptitious laxative abuse this may not be helpful. Determination of the urinary anion gap is the best way to distinguish between them. In diarrhea, urine pH is high because of the large amount of NH_4^+ in the urine. This would be reflected by a negative urinary anion gap because most of the NH_4^+ is excreted in the urine as NH_4Cl . In hypokalemic distal RTA the urine pH is high because of the inability to secrete H^+ in the distal nephron. Urinary excretion of NH_3 is very low and the urinary anion gap is positive.

Ileal conduits. Surgical diversion of the ureter into the intestine may lead to the development of a hyperchloremic normal gap metabolic acidosis due to systemic reabsorption of NH_4^+ and Cl^- from the urinary fluid and exchange of Cl^- for HCO_3^- through activation of the $\text{Cl}^-/\text{HCO}_3^-$ exchanger on the intestinal lumen. The main determinants for this complication are the length of time the urine is in contact with the bowel and the total surface area of bowel exposed to urine.

Anion Gap Metabolic Acidosis

Lactic Acidosis

Lactic acidosis is generated whenever an imbalance develops between the production and utilization of lactic acid. The accumulation of a

nonchloride anion accounts for the increase in anion gap. Severe exercise and grand mal seizures are examples in which lactic acidosis can develop because of increased production. The short-lived nature of the acidosis in these conditions suggests that a concomitant defect in lactic acid utilization is present in most conditions of sustained and severe lactic acidosis. Type A lactic acidosis is characterized by disorders in which there is underperfusion of tissue or acute hypoxia. Such disorders include patients with cardiopulmonary failure, severe anemia, hemorrhage, hypotension, sepsis, and carbon monoxide poisoning. Type B lactic acidosis occurs in patients with a variety of disorders that have in common the development of lactic acidosis in the absence of overt hypoperfusion or hypoxia (Table 25.3).

D-Lactic Acidosis

D-Lactic acidosis is a unique form of metabolic acidosis that can occur in the setting of small bowel resections or in patients with a jejunoileal bypass. These short bowel syndromes create a situation in which carbohydrates that are normally reabsorbed in the small intestine are delivered in large amounts to the colon. In the presence of colonic bacterial overgrowth, these substrates are metabolized into D-lactate and absorbed into the systemic circulation. Accumulation of D-lactate produces an anion gap metabolic acidosis in which the serum lactate is normal because the standard test for lactate is specific for L-lactate. These patients typically present after ingestion of a large carbohydrate meal with neurologic abnormalities consisting of confusion, slurred speech, and ataxia. Ingestion of low-carbohydrate meals and antimicrobial agents to decrease the degree of bacterial overgrowth are the principal treatments.

Diabetic Ketoacidosis

Diabetic ketoacidosis is a metabolic condition characterized by the accumulation of acetoacetic acid and β -hydroxybutyric acid resulting from insulin deficiency and a relative or absolute increase in glucagon concentration. The degree to which the anion gap is elevated will depend on the rapidity, severity, and duration of the ketoacidosis as well as the status of the ECF volume. Although an anion gap acidosis is the dominant disturbance in diabetic ketoacidosis, a hyperchloremic normal gap acidosis is often present in the earliest stages of ketoacidosis when extracellular volume is near normal.

Confirmation of the presence of ketoacids can be achieved with use of nitroprusside tablets or reagent strips. However, this test can be misleading in assessing the severity of ketoacidosis because it only detects the presence of acetone and acetoacetate and does not permit reaction with β -hydroxybutyrate. Treatment of diabetic ketoacidosis involves the use of insulin and intravenous fluids to correct volume depletion. Deficiencies in K^+ , Mg^{2+} , and phosphate are common and, therefore, these electrolytes are typically added to intravenous solutions.

Alcoholic Ketoacidosis

Ketoacidosis develops in patients with a history of chronic ethanol abuse, decreased food intake, and often a history of nausea and vomiting. The presence of alcohol withdrawal, volume depletion, and starvation markedly increases the levels of circulating catecholamines and results in the peripheral mobilization of fatty acids that is much larger in magnitude than that typically found with starvation alone. The metabolism of alcohol leads to an increase in the $NADH:NAD^+$ ratio causing a higher β -hydroxybutyrate to acetoacetate ratio. The nitroprusside reaction may be diminished by this redox shift despite the presence of severe ketoacidosis. Glucose administration leads to the rapid resolution of the acidosis because stimulation of insulin release leads to diminished fatty acid mobilization from adipose tissue as well as decreased hepatic output of ketoacids.

Ethylene Glycol and Methanol Poisoning

Ethylene glycol and methanol poisoning are characteristically associated with the development of a severe anion gap metabolic acidosis. Together with the appearance of the anion gap, an osmolar gap also becomes manifest and is an important clue to the diagnosis of ethylene glycol and methanol poisoning. Metabolism of ethylene glycol by alcohol dehydrogenase generates various acids, including glycolic, oxalic, and formic acids. Ethylene glycol is a component of antifreeze and solvents and is ingested by accident or as a suicide attempt. The initial effects of intoxication are neurologic and begin with drunkenness but can quickly progress to seizures and coma. If left untreated, cardiopulmonary symptoms such as tachypnea, noncardiogenic pulmonary edema, and cardiovascular collapse may appear. Twenty-four to 48 hours after ingestion, patients may develop flank pain and acute kidney injury, which are often accompanied by abundant calcium oxalate crystals in the urine.

Methanol is also metabolized by alcohol dehydrogenase and forms formaldehyde, which is then converted to formic acid. Methanol is found in a variety of commercial preparations such as shellac, varnish, and de-icing solutions. As with ethylene glycol ingestion, methanol is ingested by accident or as a suicide attempt. Clinically, methanol ingestion is associated with an acute inebriation followed by an asymptomatic period lasting 24 to 36 hours. At this point, abdominal pain caused by pancreatitis, seizures, blindness, and coma may develop. The blindness is due to direct toxicity of formic acid on the retina. Methanol intoxication is also associated with hemorrhage in the white matter and putamen that can lead to the delayed onset of a Parkinson-like syndrome. Lactic acidosis is also a feature of methanol and ethylene glycol poisoning and contributes to the elevated anion gap.

In addition to supportive measures, the therapy for ethylene glycol and methanol poisoning is centered on reducing the metabolism of the parent compound and accelerating the removal of the alcohol from the body. Fomepizole (4-methylpyrazole) is now the agent of choice to inhibit the enzyme alcohol dehydrogenase and prevent formation of toxic metabolites.

Salicylate Poisoning

Aspirin (acetylsalicylic acid) poisoning leads to increased lactic acid production. The accumulation of lactic, salicylic, keto, and other organic acids account for the development of an anion gap metabolic

acidosis. At the same time, salicylate has a direct stimulatory effect on the respiratory center. Increased ventilation lowers the PCO_2 , contributing to the development of a respiratory alkalosis. Children primarily manifest an anion gap metabolic acidosis with toxic salicylate levels, whereas a respiratory alkalosis is most evident in adults.

In addition to conservative management, the initial goal of therapy is to correct systemic acidemia and to increase the urine pH. By increasing systemic pH, the ionized fraction of salicylic acid will increase and as a result, there will be less accumulation of the drug in the central nervous system. Similarly, an alkaline urine pH will favor increased urinary excretion because the ionized fraction of the drug is poorly reabsorbed by the tubule. At serum concentrations of greater than 80 mg/dL or in the setting of severe clinical toxicity, hemodialysis can be used to accelerate the removal of the drug from the body.

Pyroglutamic Acidosis

Pyroglutamic acidosis is a cause of anion gap metabolic acidosis accompanied by alterations in mental status ranging from confusion to coma. Reported cases occur in critically ill patients receiving therapeutic doses of acetaminophen, a setting in which glutathione levels are reduced because of acetaminophen metabolism and oxidative stress associated with critical illness. The diagnosis of pyroglutamic acidosis should be considered in patients with unexplained anion gap metabolic acidosis and recent acetaminophen ingestion.

METABOLIC ALKALOSIS

The pathogenesis of metabolic alkalosis involves both the generation and maintenance of this disorder. The generation of metabolic alkalosis refers to the addition of new HCO_3^- to the blood because of either loss of acid or gain of alkali. New HCO_3^- may be generated by either renal or extrarenal mechanisms. Because the kidneys have an enormous capacity to excrete HCO_3^- , even vigorous HCO_3^- generation may not be enough to produce sustained metabolic alkalosis. To maintain a metabolic alkalosis, the capacity of the kidney to correct the alkalosis must be impaired or the capacity to reclaim HCO_3^- must be enhanced.

Clinical Consequences of Metabolic Alkalosis

Metabolic alkalosis is generally considered a benign condition; however, a high blood pH can result in a number of effects that decrease tissue perfusion. Increases in blood pH (alkalemia) cause respiratory depression and decrease tissue oxygen delivery through the Bohr effect and vasoconstriction. Alkalosis should be aggressively corrected in critically ill patients in whom perfusion of the heart and brain is essential.

Approach and Treatment of Metabolic Alkalosis

Metabolic alkalosis is best approached according to the mechanism of maintenance because correction of the maintenance mechanism leads to correction of the metabolic alkalosis. If EAV can be restored with saline, the metabolic alkalosis is easily corrected. Several conditions are poorly responsive to the administration of NaCl. Metabolic alkalosis in these conditions is generally maintained by a combination of increased mineralocorticoid levels along with high distal Na^+ delivery and hypokalemia. The distinction between these entities relies on assessment of EAV (Table 25.4).

Decreased EAV: Saline Responsive

Gastrointestinal acid loss. Loss of acid, as occurs with vomiting or nasogastric suction, is a common cause of metabolic alkalosis maintained by volume contraction. The loss of gastric acid generates a metabolic alkalosis, while the loss of NaCl in the gastric fluid leads

TABLE 25.4 Classification of Metabolic Alkalosis According to Mechanism, Cause, and Response to Administration of Saline

Effective Arterial Volume (EAV)	Low	Low	High
Urine Cl ⁻ concentration (mEq/L)	<15	>15	>15
Response to saline	Corrects (saline responsive)	No correction (saline resistant)	No correction (saline resistant)
Maintenance	Low EAV	Low EAV + high distal Na ⁺ delivery and mineralocorticoid effect	High distal Na ⁺ delivery and mineralocorticoid effect
Etiology	Gastrointestinal acid loss Vomiting/nasogastric suction Congenital chloridorrhea Villous adenoma Post-hypercapneic alkalosis Diuretics Non-reabsorbable anions	Primary increase in distal delivery of Na ⁺ Active diuretic use (loop and thiazide) Mg ²⁺ deficiency Bartter syndrome Gitelman syndrome	Primary increase in mineralocorticoid or mineralocorticoid like effect Conn's syndrome Liddle syndrome Glucocorticoid-suppressible hyperaldosteronism

TABLE 25.5 Treatment of Various Saline-Resistant Causes of Metabolic Alkalosis

DECREASED EAV		INCREASED EAV	
Cause	Treatment	Cause	Treatment
Thiazide and loop diuretics	Discontinue drug, replete EAV	Renin secreting tumor	Remove tumor
Mg ²⁺ deficiency	Replete Mg ²⁺ deficit	Primary hyperaldosteronism	Remove tumor, spironolactone for BAH
Gitelman syndrome	Amiloride, triamterene, or spironolactone, K ⁺ supplements, Mg ²⁺ supplements	Glucocorticoid suppressible hyperaldosteronism	Dexamethasone
Bartter syndrome	Amiloride, triamterene, or spironolactone, K ⁺ supplements, Mg ²⁺ supplements in some	Liddle syndrome	Amiloride or triamterene

BAH, Bilateral adrenal hyperplasia; EAV, effective arterial blood volume.

to volume contraction. During active vomiting, the plasma HCO₃⁻ concentration tends to be higher than the threshold for reabsorption in the proximal nephron. The resultant bicarbonaturia leads to increased excretion of NaHCO₃ and KHCO₃, resulting in further total body Na⁺ depletion and development of K⁺ depletion. During this active phase, urine Cl⁻ is less than 15 mEq/L, in the presence of high urine Na⁺, high urine K⁺, and a urine pH of 7 to 8. When the patient stops vomiting, equilibrium is established such that bicarbonaturia stops but a metabolic alkalosis is maintained by the volume contraction, K⁺ depletion, and reduction in GFR. Of these factors, decreased EAV is clearly the main factor in maintenance of metabolic alkalosis. At this time, urine Na⁺ and Cl⁻ are both low. Administration of NaCl results in bicarbonaturia and the metabolic alkalosis is corrected.

Diuretics. Thiazide and loop diuretics are another common cause of metabolic alkalosis. These diuretics lead to metabolic alkalosis generated in the distal nephron by the combination of high aldosterone levels and enhanced distal delivery of Na⁺. If diuretics are stopped and the patient is maintained on a low-salt diet, the alkalosis will be maintained despite the fact that distal delivery is no longer increased. In this setting, patients tend to be volume contracted and K⁺ deficient. Once again, the contraction of EAV is the major factor leading to the maintenance of metabolic alkalosis. Saline infusion in this setting corrects the metabolic alkalosis.

Decreased EAV: Saline Resistant

In some forms of metabolic alkalosis, the alkalosis is maintained by decreased EAV, but because other maintenance factors are also present, the alkalosis is not completely saline responsive. In these patients,

saline infusions may improve the metabolic alkalosis but will not completely correct it. In general, these patients may have a low EAV but typically do not have a low urine Cl⁻. Continued use of thiazide or loop diuretics, magnesium deficiency, Gitelman syndrome, and Bartter syndrome are examples of this condition. The treatment of various causes of metabolic alkalosis is summarized in Table 25.5.

Increased EAV: Saline Resistant

The last type of metabolic alkalosis is not maintained by decreased EAV, but rather is maintained by high mineralocorticoid levels (in the presence of maintained distal delivery of Na⁺) and K⁺ deficiency. The most common cause of this saline-resistant alkalosis is a primary increase in mineralocorticoid levels not related to volume contraction. The mechanism of the generation of the alkalosis described above, enhanced Na⁺ delivery with high mineralocorticoid activity, is also responsible for maintenance of the metabolic alkalosis in this setting. In addition, K⁺ deficiency, which also occurs in this setting, exacerbates the tendency to alkalosis.

The preferred treatment of metabolic alkalosis in patients with volume expansion and primary mineralocorticoid excess is to remove the underlying cause of the persistent mineralocorticoid activity. When this is not possible, therapy is directed at blocking the actions of the mineralocorticoid at the level of the kidney.

RESPIRATORY ALKALOSIS

Primary respiratory alkalosis results from hypocapnia and is defined by an arterial partial pressure of carbon dioxide (Paco₂) of less than 35

TABLE 25.6 Compensation in Acid-Base Disorders

Disorder	Compensatory Changes
Acute respiratory acidosis	For every 10 mm Hg rise in P_{CO_2} the HCO_3^- increases by 1 mEq/L
Chronic respiratory acidosis	For every 10 mm Hg rise in P_{CO_2} the HCO_3^- increases by 3.5 mEq/L
Acute respiratory alkalosis	For every 10 mm Hg fall in P_{CO_2} the HCO_3^- decreases by 2 mEq/L
Chronic respiratory alkalosis	For every 10 mm Hg decrease in P_{CO_2} the HCO_3^- decreases by 5 mEq/L
Metabolic acidosis	1.2 mm Hg decrease in P_{CO_2} for each 1 mEq/L fall in HCO_3^- $P_{CO_2} = HCO_3^- + 15$ $P_{CO_2} = \text{last digits of pH}$
Metabolic alkalosis	P_{CO_2} increases by 0.7 for each mEq/L HCO_3^-

mm Hg in the setting of alkalemia. Primary respiratory alkalosis must be differentiated from secondary hypocapnia, which is a compensatory mechanism in the setting of primary metabolic acidosis.

Etiology

Respiratory alkalosis is the most frequent acid-base disturbance encountered. It is particularly common in hospitalized patients, where it can be the initial clue to the presence of gram-negative sepsis. Hepatic failure is a common and important cause of primary hypocapnia. The severity of hypocapnia correlates with the level of blood ammonia and has prognostic significance. The presence of respiratory alkalosis can be an important clue to the presence of salicylate intoxication. High progesterone levels (pregnancy) can also cause respiratory alkalosis.

Clinical Manifestation of Respiratory Alkalosis

Mild respiratory alkalosis causes lightheadedness, palpitations, and paresthesias of the extremities and the circumoral area. Acute hypocapnia decreases cerebral blood flow and causes binding of free calcium to albumin in the blood. Thus, patients with acute respiratory alkalosis might present clinically in a similar way to patients with hypocalcemia, manifesting positive Chvostek and Trousseau signs. Patients with ischemic heart disease might occasionally develop cardiac arrhythmias, ischemic electrocardiographic changes, and even angina pectoris during acute hypocapnia.

Diagnosis

The diagnosis of respiratory alkalosis is made by evaluating the patient's history, performing a physical exam, and obtaining laboratory data including a blood gas analysis. Tachypnea or Kussmaul breathing can be detected on physical exam and may be the first clue to the presence of a primary respiratory alkalosis or a compensatory respiratory mechanism in the setting of a primary metabolic acidosis. Changes in serum electrolytes can aid in the diagnosis of respiratory alkalosis. An acute fall in P_{CO_2} causes a HCO_3^- - Cl^- shift in red blood cells and accounts for the small initial compensatory response in acute respiratory alkalosis in which the HCO_3^- concentration falls by 2 mEq/L for every 10 mm Hg decrease in P_{CO_2} . Table 25.6 provides the expected compensatory responses for acid-base disorders.

In chronic respiratory alkalosis, the renal HCO_3^- reabsorptive capacity decreases and there is a transient HCO_3^- diuresis. This process takes 2 to 3 days to become fully manifest. Once a new steady state is achieved, the HCO_3^- concentration will have decreased by 5 mEq/L

for each 10 mm Hg fall in P_{CO_2} . A higher or lower value for the plasma HCO_3^- concentration suggests the presence of an additional metabolic disorder.

To defend ECF volume in the setting of increased urinary loss of $NaHCO_3$, the kidney retains $NaCl$. These changes are reflected in the serum electrolytes of patients with chronic respiratory alkalosis in which the Cl^- is typically increased with respect to the serum Na^+ concentration. Another characteristic finding is an increase of 3 to 5 mEq/L in the serum anion gap. The increased gap is due to the greater fixed negative charge on serum albumin as well as an increase in serum lactate concentration. Lactate production is increased due to a stimulatory effect of high pH on phosphofructokinase, the rate-limiting step in the glycolytic pathway.

Treatment

Primary respiratory alkalosis is treated by correcting the underlying cause. A patient with anxiety-hyperventilation syndrome should be treated by providing reassurance. Rebreathing into a paper bag or any other closed system will cause the P_{CO_2} to increase with each breath taken and lead to a partial correction of hypocapnia and improvement of symptoms. In the rare case where there is no response to conservative management, sedatives can be used. In mechanically ventilated patients, the P_{CO_2} can be increased by either raising the inspired CO_2 tension or by increasing the dead space of the ventilator circuit. Correction of respiratory alkalosis may prove helpful in correcting arrhythmias in patients with underlying coronary disease. In contrast, caution is warranted in raising the P_{CO_2} in patients with brain injury because cerebral perfusion may increase and cause further worsening of intracranial pressure. Respiratory alkalosis frequently develops as a complication of hypoxia. Administration of oxygen or return to lower altitudes can reverse the respiratory alkalosis that develops in this setting.

RESPIRATORY ACIDOSIS

Respiratory acidosis develops because of ineffective alveolar ventilation. This acid-base disorder, which is also called primary hypercapnia, needs to be differentiated from secondary hypercapnia, which develops as a compensatory mechanism in the setting of primary metabolic alkalosis. Primary hypercapnia is clinically recognized by the presence of P_{aCO_2} levels of greater than 45 mm Hg on arterial blood gas analysis. However, P_{aCO_2} levels of less than 45 mm Hg might still be indicative of respiratory acidosis if a primary metabolic acidosis is not adequately compensated by alveolar ventilation.

Etiology of Respiratory Acidosis

The development of respiratory acidosis is usually multifactorial. Major causes of CO_2 retention include diseases or malfunction within any element of the respiratory system, including the central and peripheral nervous systems, the respiratory muscles, the thoracic cage, the pleural space, the airways, and the lung parenchyma. The following six factors should be considered in the differential diagnosis of acute and chronic respiratory acidosis: inhibition of the medullary respiratory center, disorders of the chest wall and the respiratory muscles, airway obstruction, disorders affecting gas exchange across the pulmonary capillary, increased CO_2 production, and mechanical ventilation.

Clinical Manifestations of Respiratory Acidosis

Hypercapnic encephalopathy is a clinical syndrome that usually starts with irritability, headache, mental cloudiness, apathy, confusion, anxiety, restlessness, and can progress to asterixis, transient psychosis, delirium, somnolence, and coma. Papilledema and other manifestations of

increased intracranial pressure that are collectively named *pseudotumor cerebri* are occasionally observed in patients with either acute or chronic hypercapnia. The increase in intracranial pressure is in part due to cerebral vasodilation resulting from acidemia. Acute respiratory acidosis is typically more symptomatic than acute metabolic acidosis because CO_2 diffuses and equilibrates across the blood-brain barrier much more rapidly than does HCO_3^- , resulting in a more rapid fall in cerebral spinal fluid and cerebral interstitial pH. Severe hypercapnia can also lead to decreased myocardial contractility, arrhythmias, and peripheral vasodilation, particularly when the blood pH falls to less than 7.1.

Diagnosis

The diagnosis of primary respiratory acidosis is made by the presence of acidemia and hypercapnia on arterial blood gas analysis. Changes in the serum chemistries can aid in the diagnosis of respiratory acidosis. Acute hypercapnia is associated with a shift of HCO_3^- out of red blood cells in exchange for Cl^- ; a process termed the *red cell HCO_3^- - Cl^- shift*. Acutely, the plasma HCO_3^- concentration increases by 1 mmol/L for each 10 mm Hg elevation in Paco_2 . After 24 to 48 hours of hypercapnia proximal tubular cells increase H^+ secretion, resulting in accelerated HCO_3^- reabsorption. The retention of NaHCO_3 leads to slight expansion of the ECF compartment and causes increased renal excretion of NaCl to return volume back to normal. The net effect is increased serum HCO_3^- and decreased Cl^- concentration. In chronic respiratory acidosis, there is a 3.5 mEq/L increase in HCO_3^- for each 10 mm Hg elevation in Paco_2 . Higher or lower plasma HCO_3^- concentrations suggest the presence of mixed respiratory and metabolic acid-base disorders.

Treatment of Respiratory Acidosis

The mainstay of treatment in respiratory acidosis is to recognize and treat the underlying cause whenever possible. Patients with acute respiratory acidosis are primarily at risk of hypoxemia rather than hypercapnia or acidemia. Thus, immediate therapeutic efforts should focus on establishing and securing a patent airway to provide adequate oxygenation. In patients with status asthmaticus, a lower ventilatory rate and peak inspiratory pressure may be required to minimize barotrauma to the lung but at the expense of a persistently higher Pco_2 . Small amounts of NaHCO_3 can help prevent excessive falls in blood pH in this setting. The downside of such therapy is that infusion of NaHCO_3 can result in increased CO_2 production, causing a further increase in Pco_2 when ventilation cannot be increased.

Excessive oxygen should be avoided in patients with chronic respiratory acidosis because it may lead to worsening hypoventilation. When mechanical ventilation is required, care should be taken to lower the Paco_2 carefully and slowly because there is the risk of overshoot alkalemia due to the presence of a high HCO_3^- (post-hypercapnic metabolic alkalosis). The kidneys must excrete the HCO_3^- in order to normalize the acid-base status. This excretion will not occur when EAV is reduced either because of salt depletion owing to restricted intake or diuretic therapy or a salt retentive state such as heart failure and cirrhosis. Correction of the superimposed metabolic alkalosis can usually be achieved with saline and discontinuation of loop diuretics if they are being utilized. In edematous patients with heart failure, this may not be possible, and acetazolamide may be needed to correct the alkalosis.

Glomerular Diseases

Sanjeev Sethi, An S. De Vriese, Fernando C. Fervenza

INTRODUCTION

Glomerular injury or disease can manifest as hematuria, proteinuria, hypertension, fluid retention, and a reduction in the glomerular filtration rate. Traditionally, glomerular diseases have been grouped according to clinical presentation, including asymptomatic microscopic hematuria, the nephritic syndrome, the nephrotic syndrome, rapidly progressive glomerulonephritis (RPGN), and chronic glomerulonephritis. An alternative classification of glomerular diseases is according to the histologic pattern on kidney biopsy, such as minimal change disease (MCD), membranoproliferative glomerulonephritis (MPGN), membranous nephropathy, and focal segmental glomerulosclerosis (FSGS). However, many glomerular diseases can manifest with more than one constellation of signs and symptoms and show more than one histologic pattern on renal biopsy. In addition, a particular clinical presentation or histologic pattern can be caused by different underlying disease processes. Great progress has been made in unraveling the molecular causes of glomerular diseases. For instance, autoantibodies against the phospholipase A₂ receptor or thrombospondin-7A receptor have been associated with membranous nephropathy. In the future, the etiologic approach to the classification of glomerular diseases will undoubtedly be expanded. As such, a condition can be more accurately described by combining the different approaches (e.g., antiphospholipase A₂ receptor antibody-associated membranous nephropathy presenting with nephrotic syndrome).

CLINICAL PRESENTATION

A detailed history and careful physical examination, with particular attention to the time of symptom onset, help to clarify the differential diagnosis of suspected glomerular disease. Blood pressure and fluid status should be recorded. Urine microscopy is a critical element of this assessment, and it may reveal hematuria, typically with dysmorphic red blood cells and casts. Hematuria due to glomerular disease is painless and the urine is often brown or cola-colored rather than bright red; clots are rare. The differential diagnosis should be made with other causes of brown urine, including hemoglobinuria, myoglobinuria, and specific foods or drug dyes (e.g., beetroot). Normal red blood cell excretion is 3 or fewer red blood cells per high power field or less than 8000 red blood cells per milliliter of uncentrifuged urine. To distinguish glomerular from nonglomerular hematuria, a freshly voided urinary sediment can be examined microscopically. With nonglomerular hematuria, the erythrocytes are normocytic, have a biconcave appearance, and a regular shape. In glomerular hematuria, the erythrocytes are microcytic, lack a biconcave disc appearance, and are irregularly shaped (dysmorphic). Usually 50% or more of the erythrocytes are dysmorphic and red blood cell casts may also be seen (active urinary sediment). Glomerular hematuria is generally seen throughout

the voiding process and can be increased by vigorous exercise or fever. Terminal hematuria (hematuria confined to the last few milliliters of a void) is a feature of bladder disease.

Quantitative evaluation of the degree of urinary protein excretion is essential. In adults, urinary total protein excretion is less than 150 mg/24 h, and urinary albumin excretion is less than 20 mg/24 h. Persistent albumin excretion of 30 to 300 mg/24 h is termed microalbuminuria. Albumin excretion above 300 mg/24 h, the level at which the standard dipstick becomes positive, reflects overt proteinuria. Levels above 3.5 g/24 h are considered to be nephrotic-range proteinuria. It should be recognized that nephrotic-range proteinuria (>3.5 g/24 h) and nephrotic syndrome (>3.5 g/24 h and serum albumin <3.5 g/dL by bromocresol green method or <3.0 g/dL by bromocresol purple method) are not synonymous. This distinction is particularly important when the kidney biopsy reveals FSGS. Patients with full-blown nephrotic syndrome most likely have primary FSGS, whereas patients with nephrotic-range proteinuria often have FSGS due to a secondary process.

A 24-hour urine collection remains the gold standard, but it is cumbersome to perform, is often collected incorrectly, and does not provide a rapid result. The accuracy of the urine collection should be assessed by simultaneously quantifying urinary total protein and creatinine excretion. If urinary creatinine excretion is within 15% of the expected value (expected creatinine excretion in 24 hours = [140 – age in years] × weight in kg × 0.2 [× 0.85 if female]), the collection can generally be regarded as accurate. A protein-to-creatinine ratio measured on a 24-hour urine collection is a useful alternative. Using the protein and creatinine concentration available from the readings on the 24-hour urine collection, calculate the urine protein to creatinine ratio (UPCR). Then, multiply the calculated UPCR by the expected 24-hour urine creatinine excretion (as per the above-mentioned formula) to estimate the magnitude of protein in the collection.

The above-mentioned approach assumes that the patient's 24-hour urine creatinine excretion is appropriate for their body size. If this relationship is altered by malnutrition, muscle wasting, limb-loss, body-building or unusual habits, then as carefully as possible a complete and accurate 24-hour urine collection must be obtained. For vegetarians, the expected 24-hour urine creatinine excretion should be reduced by about one third. Random "spot" or first morning UPCR should not be used to estimate proteinuria. Such values are inherently highly variable due to variation in protein excretion during the day and differences in urinary creatinine excretion based on age, gender, and lean body (muscle) mass.

Glomerular proteinuria can be classified as transient or hemodynamic (functional) (e.g., fever, exercise induced, orthostatic) or as persistent (fixed). Although functional proteinuria is benign, fixed nephrotic-range proteinuria usually results from glomerular diseases. Total proteinuria greater than 1 g/24 h in a patient with a negative

urine dipstick (which detects only albumin) suggests that the proteinuria is caused by light chains or low-molecular-weight proteins (e.g., retinol-binding protein, α_1 -microglobulin).

CLINICAL SYNDROMES

Asymptomatic Microscopic Hematuria

Glomerular hematuria can occur with or without subnephrotic range proteinuria. Renal function parameters and blood pressure are typically normal.

Glomerular diseases commonly presenting with asymptomatic hematuria include IgA nephropathy, Alport syndrome, and thin glomerular basement disease.

Nephrotic Syndrome

Nephrotic syndrome is defined as persistent urinary total protein excretion greater than 3.5 g/24 h, accompanied by a serum albumin concentration less than 3.5 g/dL. Edema, hyperlipidemia, and lipiduria (i.e., doubly refractile fat bodies) are common but are not required for the diagnosis.

Complications of the nephrotic syndrome include hypogammaglobulinemia, vitamin D deficiency due to loss of vitamin D-binding protein, and iron deficiency anemia due to hypotransferrinemia. Thrombotic complications from loss of antithrombin III such as renal vein thrombosis may occur, especially in patients with greater protein loss (>10 g/24 h) and serum albumin levels less than 2 g/dL. Patients with severe nephrotic syndrome are particularly susceptible for acute renal failure when there is superimposed volume depletion, sepsis or use of nephrotoxic agents such as nonsteroidal anti-inflammatory drugs (NSAIDs).

Management of patients with nephrotic syndrome includes diuretics to control edema, regulation of blood pressure (angiotensin-converting enzyme inhibitors [ACEIs] and angiotensin-receptor blockers [ARBs] are preferred), limitation of the intake of protein to between 0.8 and 1 g/kg/day and sodium to less than 4 g/day, and control of lipid levels. Anticoagulation should be considered for patients at increased risk, especially if the nephrotic syndrome is caused by membranous nephropathy or amyloidosis.

Glomerular diseases commonly presenting with nephrotic syndrome include MCD, FSGS, membranous nephropathy, HIV-associated nephropathy, amyloidosis and diabetic nephropathy.

Nephritic Syndrome

The nephritic syndrome is defined by oliguria, edema, hypertension, proteinuria (usually <3.5 g/24 hr), and abnormal urinalysis with dysmorphic red blood cells or red blood cell casts. Glomerular diseases commonly presenting with nephritic syndrome include infection-related glomerulonephritis, IgA nephropathy, and C3 glomerulopathy.

Rapidly Progressive Glomerulonephritis

RPGN is a clinical syndrome characterized by progressive loss of kidney function with a time course of days to months in a patient with active urinary sediment (see Chapter 24 and E-Fig. 29.1 and Table 29.3). Patients may have oliguria. Most of the pulmonary-renal syndromes manifest in this fashion, and the pathologic corollary is often a focal, necrotizing, crescentic glomerulonephritis. When RPGN is suspected, renal biopsy with immunofluorescence studies is extremely helpful.

Linear deposition of immunoglobulin G (IgG) points to Goodpasture disease or anti-glomerular basement membrane (anti-GBM)-mediated glomerulonephritis. Immunoglobulins and complement suggest systemic lupus erythematosus (SLE), cryoglobulinemia, immunoglobulin A (IgA) nephropathy, or postinfectious glomerulonephritis. Negative or weak immunofluorescence (pauci-immune) findings usually indicate an antineutrophil cytoplasmic autoantibody (ANCA) vasculitis (Fig. 26.1).

Chronic Glomerulonephritis

Patients can be presumed to have chronic glomerulonephritis in the setting of a slowly progressive loss of renal function over the course of months or years, accompanied by persistent glomerular hematuria. Proteinuria is usually in the subnephrotic range. Hypertension is nearly always present. Renal ultrasound usually shows small kidneys with increased echogenicity.

Glomerular diseases often presenting as chronic glomerulonephritis include IgA nephropathy, C3 glomerulopathy, and Alport syndrome.

PRIMARY PODOCYTOPATHIES

Minimal Change Disease

MCD is defined by a renal biopsy with no significant glomerular abnormalities on light microscopy, negative immunoglobulin and complement deposition on immunofluorescence, and widespread foot

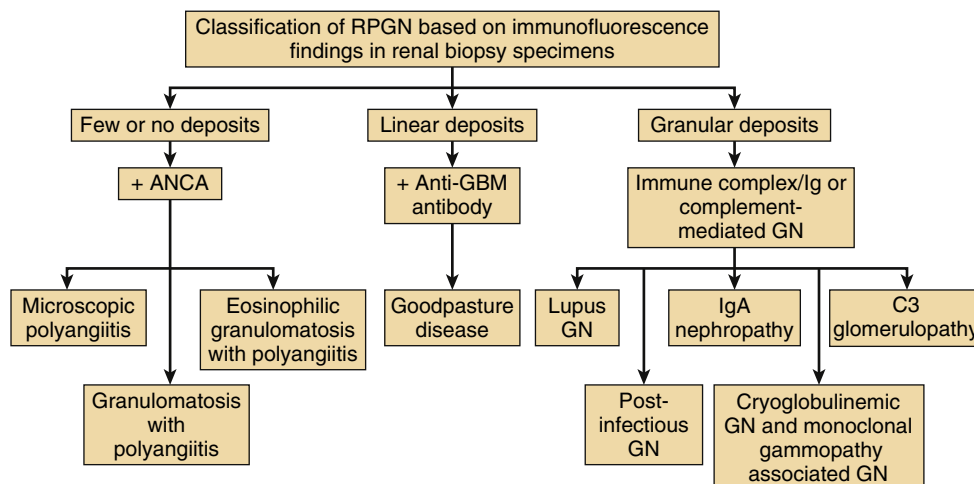

Fig. 26.1 Rapidly progressive glomerulonephritis (RPGN) is classified according to immunofluorescence microscopy findings in renal biopsy specimens. ANCA, Antineutrophil cytoplasmic autoantibody; GBM, glomerular basement membrane; GN, glomerulonephritis; IgA, immunoglobulin A.

process effacement on electron microscopy (Fig. 26.2). MCD is the most common cause of nephrotic syndrome in children and accounts for up to 20% of adults with primary nephrotic syndrome.

The pathogenesis of MCD is unknown. The association with Hodgkin lymphoma suggests that MCD may be a consequence of T-lymphocyte abnormalities, with T cells producing a lymphokine that is toxic to glomerular epithelial cells. Most cases of MCD are idiopathic, although drugs (e.g., NSAIDs), hematologic malignancies (mainly Hodgkin lymphoma), and thymoma are well-recognized causes of secondary MCD. Concomitant interstitial nephritis suggests drugs (e.g., NSAIDs) as the likely cause of MCD.

In children, MCD usually manifests with nephrotic syndrome of acute onset. Hematuria, hypertension, or impaired renal function is unusual and suggests another diagnosis. When nephrotic syndrome occurs in a child with normal urinalysis results, the diagnosis is MCD until proven otherwise, and treatment with high-dose corticosteroid therapy can be started, often without the need of a renal biopsy.

More than 90% of children achieve complete remission after 4 to 8 weeks of treatment. Children who do not respond to corticosteroid therapy should undergo a renal biopsy. Adolescents and adults also respond to high-dose corticosteroids (>80%), but the response is slower, and treatment for 16 weeks or more may be required to achieve remission. Therapy usually is continued for 4 to 8 weeks after remission.

Among patients who have a response to corticosteroids, about 25% have a long-term remission. However, up to 25% of the patients have frequent relapses, and up to 30% become steroid dependent. For these patients, alternative therapies aiming to minimize corticosteroid

toxicity include alkylating agents, antimetabolites, calcineurin inhibitors (cyclosporine or tacrolimus), and rituximab (a chimeric human-murine monoclonal antibody that targets the CD20 antigen expressed on B cells). Although these agents may allow a lower corticosteroid dose, some patients respond poorly or not at all, and their use may be complicated by significant side effects. Noncompliance is always a concern, especially in young patients.

Focal Segmental Glomerulosclerosis

FSGS is not a specific disease entity, but a lesion, caused by a wide variety of conditions. The common pathophysiologic element is podocyte injury and depletion leading to glomerular scarring (Fig. 26.3). FSGS accounts for less than 15% of cases of idiopathic nephrotic syndrome in children and up to 25% in adults. In African Americans, FSGS is often associated with the presence of the G1 and G2 polymorphisms in the *APOL1* gene. Hypertension is found in 30% to 50% of patients with FSGS, and microscopic hematuria occurs in 25% to 75% of cases. Up to 30% of those with FSGS have impaired renal function.

The pathogenesis of idiopathic or primary FSGS is unknown. A circulating permeability factor has been demonstrated in some patients. The soluble urokinase-type plasminogen activator receptor (suPAR) has been identified as a potential marker because levels are elevated in two thirds of cases of primary FSGS and levels are higher in renal transplant recipients with recurrent FSGS. However, suPAR levels do not distinguish primary from secondary FSGS, and serum levels increase with reductions in the glomerular filtration rate. Further research is needed to define the role of serum suPAR in primary FSGS.

Fig. 26.2 Minimal change disease. (A) Light microscopy shows a normal-appearing glomerulus (periodic acid–Schiff, $\times 40$). (B and C) Electron microscopy shows diffuse foot process effacement (arrows) (B, $\times 2500$; C, $\times 4200$). Immunofluorescence studies were negative for immune deposits.

Fig. 26.3 Focal segmental glomerulosclerosis. (A) Light microscopy shows segmental sclerosis (arrow) with segmental consolidation of the glomerular capillary tufts and visceral epithelial cell hypertrophy over the segmentally sclerosed tufts (silver methenamine, $\times 40$). (B) Electron microscopy shows diffuse foot process effacement (arrows) of the visceral epithelial cells ($\times 1850$). Immunofluorescence studies were negative for immune deposits.

Secondary causes of FSGS include genetic mutations in podocyte genes, human immunodeficiency virus (HIV) infection, drugs, sickle cell disease, vesicoureteral reflux, obesity, unilateral renal agenesis, remnant kidneys, and aging (Table 26.1). Five histologic variants of FSGS have been described according to the Columbia classification: classic (or Not Otherwise Specified), perihilar, cellular, tip, and collapsing. However, this classification is based on LM examination only and does not take into account the degree of foot process effacement on EM. This classification has potential prognostic significance, but it should not be used as a tool to differentiate the different pathophysiologic forms of FSGS. The collapsing variant, which has the worst prognosis, is more common in African Americans and patients with HIV infection.

Spontaneous remission of proteinuria is uncommon (<5% of cases). Treatment of the primary forms consists of prolonged (>4 months) high-dose corticosteroid therapy (prednisone, 1 mg/kg/day), but there is no study comparing this approach with other forms of therapy. However, if patients are going to respond to corticosteroids, proteinuria starts to decrease soon after the start of treatment, and those who show no significant reduction (>30%) in proteinuria after 2 to 3 months of prednisone at 1 mg/kg/day (maximum 80 mg/day) are unlikely to respond, and corticosteroid therapy should be tapered and discontinued. For patients who respond to corticosteroids but undergo relapse, alternative therapy includes the use of cytotoxic drugs alone or in combination with corticosteroids, calcineurin inhibitors, and possibly rituximab. Patients with limiting side effects or contraindications to corticosteroids (e.g., obesity) can be treated with a calcineurin

inhibitor as first-line therapy. Similarly to treatment with corticosteroids, if patients are going to respond to a calcineurin inhibitor, proteinuria starts to decrease soon after the start of treatment. For patients with secondary forms of FSGS, treatment should target the cause.

In all patients, treatment with an ACEI or ARB, alone or in combination, may substantially reduce proteinuria and prolong renal survival. Patients who have a non-nephrotic-range proteinuria have the best renal survival (>80% at 10 years). In patients who continue to have a high degree of proteinuria (>10 g/day), end-stage renal disease (ESRD) typically develops over 5 to 20 years. Idiopathic FSGS may recur in a transplanted kidney.

Membranous Nephropathy

Membranous nephropathy is the leading cause of nephrotic syndrome in white individuals. It occurs in persons of all ages and races but is most often diagnosed in middle age, with the incidence peaking during the fourth and fifth decades of life. The male-to-female ratio is about 2:1. Most patients have nephrotic syndrome, normal renal function, and no hypertension. Microscopic hematuria may be detected in about one third of patients.

Autoantibodies against the phospholipase A₂ receptor (PLA₂R) and thrombospondin-7A in podocytes are found in about 70% and less than 5% of patients with the primary form of the disease, respectively. Recently, three new antigens have been discovered in primary membranous nephropathy. These include neural epidermal growth factor-like 1 protein (NELL-1), semaphorin 3B (Sema3B), and protocadherin 7 (PCDH7). Secondary membranous nephropathy is caused by autoimmune diseases (e.g., SLE, autoimmune thyroiditis), infection (e.g., hepatitis B virus [HBV], hepatitis C virus [HCV]), drugs (e.g., penicillamine, NSAIDs), and solid malignancies (e.g., colon cancer, lung cancer). A subset of patients with membranous nephropathy is associated with accumulation of exostosin 1 (EXT1) and exostosin 2 (EXT2) in the glomerular basement membrane. Autoimmune disease is common in this group of patients, and EXT1/EXT2 may represent the target antigen in secondary (autoimmune) membranous nephropathy.

On light microscopy, capillary walls may appear thickened, and methenamine silver stain shows subepithelial projections (“spikes”) along the capillary walls. Immunofluorescence microscopy shows marked granular deposition of IgG and C3 along the capillary walls, and subepithelial deposits are seen on electron microscopy (Fig. 26.4). Staining for IgG subclasses may help to differentiate primary from secondary membranous nephropathy. IgG1, IgG2 and IgG3 tend to be highly expressed in lupus membranous nephropathy (class V lupus nephritis), whereas IgG1 and IgG4 tend to be highly expressed in primary membranous nephropathy. IgG4 staining tends to be absent in the immune deposits of membranous nephropathy secondary to malignancy.

Up to one third of the patients with membranous nephropathy undergo spontaneous remission, and another one third of patients

TABLE 26.1 Causes of Focal Segmental Glomerulosclerosis

Primary (Idiopathic) FSGS

- Attributed to a circulating permeability factor

Secondary FSGS

- Genetic mutations in podocyte genes
- Viral: HIV-associated nephropathy, parvovirus B19, simian virus 40, cytomegalovirus
- Drug induced: heroin, interferon (α , β , γ), pamidronate, sirolimus, calcineurin inhibitors
- Adaptive: reduced nephron mass or glomerular adaptation, unilateral renal agenesis, obesity-related glomerulopathy, basement membrane defects healing phase of focal proliferative glomerulonephritis, body building, sickle cell anemia, hypertensive nephrosclerosis, thrombotic microangiopathy, aging kidney
- Other causes: hemophagocytic syndrome

FSGS, Focal segmental glomerulosclerosis; HIV, human immunodeficiency virus.

Fig. 26.4 Membranous nephropathy. (A) Light microscopy shows thickened glomerular basement membranes (x60). (B) Immunofluorescence study shows granular immunoglobulin G deposition along the capillary walls (x20). (C) Electron microscopy shows subepithelial electron-dense deposits (arrows) (x15,000).

undergo partial remission. Initial therapy should include angiotensin II receptor blockade, a low-salt diet (<4 g/day), a low-protein diet (0.8 to 1 g/kg/day), and lipid control. If spontaneous remission occurs, it usually does so within the first 12 to 24 months.

Early treatment should be given to patients with severe nephrotic syndrome (e.g., proteinuria >10 g/24 h) and high or increasing anti-PLA₂R antibody titers, while conservative therapy is continued in asymptomatic patients, who maintain proteinuria at less than 4 g/24 h and have low or decreasing anti-PLA₂R antibody titers.

Rituximab has recently garnered attention as a potential breakthrough in the treatment of membranous nephropathy. A recent multicenter randomized controlled trial of rituximab versus cyclosporine in patients with severe membranous nephropathy (MENTOR) revealed that rituximab is not inferior to cyclosporine in inducing complete or partial remission of proteinuria but is superior in maintaining long-term remission of proteinuria and will likely become the first-line therapy for the treatment of membranous nephropathy.

The probability of renal survival is more than 80% at 5 years and about 60% at 15 years. Patients with an accelerated course should be evaluated for superimposed anti-GBM disease, acute interstitial nephritis, or renal vein thrombosis.

IMMUNE-COMPLEX GLOMERULONEPHRITIS

Infection-Related Glomerulonephritis

Poststreptococcal glomerulonephritis (PSGN) is a classic form of acute glomerulonephritis that develops 1 to 4 weeks after a pharyngitis or skin infection with specific (nephritogenic) strains of group A β -hemolytic streptococci. It typically occurs in children and usually has a benign course. More recently, however, infection-related glomerulonephritis has been recognized to have a broader spectrum, affecting elderly and immunocompromised patients and associated with different bacteria, particularly staphylococci. Unlike classic PSGN, the variant occurs when the infection is still active and has an unfavorable prognosis. The term *infection-related GN* is often used to include both PSGN and GN occurring in the setting of a concurrent infection.

Infection-related glomerulonephritis manifests clinically with the abrupt onset of nephritic syndrome. In patients with PSGN, cultures are usually negative, but elevated titers of antistreptolysin O (ASO), antistreptokinase, antihyaluronidase, and anti-deoxyribonuclease (anti-DNAse B) antibodies may provide evidence of recent streptococcal infection. Activation of the alternative complement pathway is reflected by low C3 complement levels. C4 levels are usually normal or mildly decreased. Other nephrologic conditions associated with low complement are C3 glomerulopathy, lupus nephritis, cryoglobulinemic glomerulonephritis, fibrillary glomerulonephritis, IgG4-mediated renal disease, and cholesterol emboli (Table 26.2).

Renal biopsy typically shows diffuse glomerular hypercellularity and infiltration of polymorphonuclear leukocytes, monocytes, or macrophages on light microscopy. Immunofluorescence shows granular deposition of IgG, C3, and occasionally immunoglobulin M (IgM). On

electron microscopy, characteristic dome-shaped subepithelial deposits (“humps”) can be seen along the GBM (Fig. 26.5).

Treatment is supportive and aims to minimize fluid overload, optimize blood pressure control, and eradicate ongoing infection. For children, the prognosis is excellent, with most patients recovering renal function in 1 to 2 months. Some patients have persistent microscopic hematuria, proteinuria, hypertension, and renal dysfunction and are said to have *atypical, persistent, or resolving* PSGN. Some of these patients have mutations or autoantibodies to proteins in the alternative complement cascade and as such represent patients with C3 glomerulopathy.

Immunoglobulin A (IgA) Nephropathy

IgA nephropathy (formerly called Berger disease) is the most common form of primary glomerulopathy. On light microscopy, mesangial proliferation is seen, along with mesangial deposition of IgA on immunofluorescence and electron-dense deposits in the mesangium on electron microscopy (Fig. 26.6).

Patients may have episodes of macroscopic hematuria accompanying an intercurrent upper respiratory tract infection (synpharyngitic) or have asymptomatic hematuria, with or without proteinuria, detected on routine urinalysis. Proteinuria is common, but nephrotic syndrome occurs in less than 10% of cases and raises the possibility of a primary podocytopathy (e.g., MCD) superimposed on the IgA nephropathy.

The pathogenesis of IgA nephropathy has been linked to galactose-deficient IgA1 (GD-IgA1) molecules and increased formation of anti-GD-IgA1 autoantibodies, with deposition of IgG or IgA anti-GD-IgA1 immune complexes in the mesangium, resulting in activation of complement and cytokine cascades. Secondary causes of IgA nephropathy include chronic liver disease, celiac disease, dermatitis herpetiformis, and ankylosing spondylitis.

In up to 60% of the patients, IgA nephropathy has a benign clinical course, and patients maintain proteinuria of less than 500 mg/24 h and preserved renal function. However, progression to ESRD occurs in up to 40% of patients over 10 to 25 years. Clinical predictors of progression include proteinuria greater than 1 g/24 h, hypertension, presence of crescents on renal biopsy, and impaired renal function at diagnosis. Any degree of proteinuria carries a worse prognosis for a patient with IgA nephropathy. IgA nephropathy frequently recurs after renal transplantation, but loss of the allograft from recurrent disease is uncommon.

The use of angiotensin II system blockade and high-dose corticosteroids has been beneficial in slowing or halting progression of renal disease. Henoch-Schönlein purpura is the systemic form of IgA nephropathy. The prognosis is generally good for children but varies in adults.

In patients with normal renal function, treatment is supportive only. Patients with persistent proteinuria greater than 1 g/24 h and/or progressive renal failure should be considered for treatment with high-dose corticosteroids with or without cytotoxic medication.

Membranoproliferative Glomerulonephritis

MPGN is not a specific disease entity but a pattern of glomerular injury resulting from predominantly subendothelial and mesangial deposition of immune complexes or complement factors and their products. On light microscopy, mesangial hypercellularity, endocapillary proliferation, and capillary wall remodeling with double-contour formation are characteristic, and they result in a lobular accentuation of the glomerular tufts. Immunofluorescence microscopy shows immunoglobulins or complement factors, depending on the underlying cause of MPGN. Electron microscopy typically shows mesangial and subendothelial deposits, and, less commonly, intramembranous and subepithelial deposits (Fig. 26.7).

Based on a recent proposal, MPGN can be classified as immune complex mediated or complement mediated. Immune complex-mediated MPGN shows immunoglobulin and complement factors on immunofluorescence

TABLE 26.2 Glomerular Diseases Associated With Hypocomplementemia

Acute lupus nephritis
C3 glomerulopathy (C3 glomerulonephritis and dense deposit disease)
Cholesterol emboli
Cryoglobulinemic glomerulonephritis
Postinfectious glomerulonephritis
IgG4-related nephropathy
Fibrillary glomerulonephritis

Fig. 26.5 Postinfectious glomerulonephritis. (A and B) Light microscopy shows diffuse endocapillary proliferative glomerulonephritis. Notice the prominent neutrophil infiltration in the glomerular capillaries (A, hematoxylin and eosin; B, silver methenamine; both $\times 40$). (C and D) Immunofluorescence studies show granular immunoglobulin G and C3 deposition along the capillary walls (both $\times 20$). (E and F) Electron microscopy shows subendothelial deposits (*white arrows*) and subepithelial humplike deposits (*black arrows*). The subendothelial deposits likely result from circulating immune complexes that are deposited along the glomerular capillary walls and drive the inflammatory response (E, $\times 5800$). The subepithelial deposits likely represent in situ immune complex formation (F, $\times 2850$).

Fig. 26.6 Immunoglobulin A (IgA) nephropathy. (A) Light microscopy shows mesangial hypercellularity (*black arrow*) (silver methenamine, $\times 40$). (B) Immunofluorescence microscopy shows bright mesangial IgA staining. (C) Electron microscopy shows large mesangial electron-dense deposits (*arrow*) ($\times 7860$).

microscopy. Complement-mediated MPGN shows complement factors and a lack of significant immunoglobulin on immunofluorescence microscopy (Fig. 26.8). Immune complex/Ig-mediated MPGN results from chronic infections, autoimmune diseases, and monoclonal gammopathies. Complement-mediated MPGN is caused by genetic or acquired dysregulation of the alternative pathway of complement (C3 glomerulopathy) and can be further subclassified as C3 glomerulonephritis and dense deposit disease (DDD) based on electron microscopy examination.

Immune complex-mediated MPGN precipitated by an infection is most commonly caused by HCV (i.e., cryoglobulinemic glomerulonephritis). The clinical presentation varies and can include nephrotic and nephritic features. In patients with cryoglobulinemic MPGN, the levels of C3, C4, and CH50 are persistently low, reflecting activation of classical complement pathway. Patients with C3 glomerulonephritis or DDD may have a persistently low level of C3 but a normal level of C4. A C3 nephritic factor is found in many cases. C3 nephritic factor

is an autoantibody to alternative pathway C3 convertase, resulting in persistent breakdown of C3.

The absence of well-designed studies based on the current insights in the pathogenesis of MPGN make it impossible to give strong treatment recommendations. From a practical point of view, patients with MPGN due to chronic infections (e.g., HCV, endocarditis), autoimmune disease, and plasma cell dyscrasias (monoclonal gammopathy) should undergo treatment of the underlying disease. Patients with normal kidney function, no active urinary sediment, and non-nephrotic-range proteinuria can be treated conservatively with angiotensin II blockade to control blood pressure and reduce proteinuria, because the long-term outcome is relatively benign in this setting. Follow-up is required to detect early deterioration in kidney function. Patients with C3 glomerulonephritis or DDD with proteinuria greater than 1000 mg/24 h and/or abnormal kidney function but not rapidly progressive disease, and who do not have a genetic mutation leading to factor H deficiency, can be considered for additional treatment

Fig. 26.7 Immune complex–mediated membranoproliferative glomerulonephritis due to hepatitis C virus infection. (A) Light microscopy shows a membranoproliferative pattern of injury with mesangial expansion, endocapillary proliferation, double-contour formation along the capillary walls, and lobular accentuation of the glomerular tufts (silver methenamine, $\times 40$). (B and C) Immunofluorescence microscopy shows bright capillary wall staining for immunoglobulin M (B, $\times 40$) and for C3 (C, $\times 40$). (D) Electron microscopy shows capillary wall thickening and a double-contour formation due to accumulation of subendothelial electron-dense deposits (*black arrows*), cellular elements, and new basement membrane formation (i.e., duplication) (*yellow arrow*) that produces the double contour. The *thick white arrow* indicates the old basement membrane, and fibrin tactoids (*white arrows*) in glomerular capillary loops indicate a prothrombotic state ($\times 1350$).

Fig. 26.8 C3 glomerulonephritis. Light microscopy shows features of mesangial proliferative glomerulonephritis (A, periodic acid–Schiff, $\times 40$) and membranoproliferative glomerulonephritis (B, silver methenamine stain, $\times 40$) in the same biopsy. Immunofluorescence microscopy shows bright granular mesangial and capillary wall staining for C3 (C) and negative staining for immunoglobulin G (D). (E) Electron microscopy shows a large accumulation of smudgy mesangial deposits (*arrow*) ($\times 10,000$). (F) Electron microscopy shows subendothelial deposits (*black arrow*) and subepithelial humplike deposits (*white arrows*) ($\times 150,000$). The subepithelial deposits sometimes make it difficult to distinguish C3 glomerulonephritis from postinfectious glomerulonephritis. However, C3 glomerulonephritis may not show Ig (as in this case), and the term *atypical postinfectious glomerulonephritis* sometimes is applied in cases of C3 glomerulonephritis with subepithelial humplike deposits.

with mycophenolate mofetil plus oral corticosteroids. Patients who have advanced renal insufficiency and severe tubulointerstitial fibrosis of renal biopsy are unlikely to benefit from immunosuppressive therapy.

Lupus Nephritis

Lupus nephritis occurs in up to 50% to 70% of patients with SLE and is associated with a poor prognosis. Proteinuria is the most common

TABLE 26.3 Abbreviated International Society of Nephrology/Renal Pathology Society 2003 Classification of Lupus Nephritis

Type	Morphologic Class	Renal Manifestation
I	Minimal mesangial lupus nephritis	Normal urinary sediment
II	Mesangial proliferative lupus nephritis	Low-grade hematuria and/or proteinuria Normal renal function
III	Focal lupus nephritis	Active sediment, proteinuria <3 g/1.73 m ² /day
IV	Diffuse lupus nephritis	Nephritic and nephrotic syndromes Hypertension; progressive renal failure
V	Membranous lupus nephritis	Nephrotic syndrome
VI	Advanced sclerosing lupus nephritis	Inactive urinary sediment Chronic renal failure

Modified from Weening JJ, D'Agati VD, Schwartz MM, et al: The classification of glomerulonephritis in systemic lupus erythematosus revisited, *J Am Soc Nephrol* 15:241-250, 2004.

initial manifestation, and it is often in the nephrotic range and accompanied by a decline in renal function. Urinalysis does not always reflect the severity of the glomerular lesion, and kidney biopsy is indicated in those with proteinuria or active urinary sediment, or both, because the type of renal lesion influences the therapeutic decisions. The International Society of Nephrology/Renal Pathology Society (ISN/RPS) classification of lupus nephritis recognizes six morphologic classes of renal involvement (Table 26.3). However, patients may migrate from one class to another spontaneously or after treatment.

Immunofluorescence typically shows glomerular deposition of IgG, IgM, IgA, C1q, and C3 (i.e., full-house pattern). On electron microscopy, tubuloreticular inclusions are common within glomerular and vascular endothelial cells. Electron-dense deposits sometimes show fingerprint-like substructures (Fig 26.9). Histologic lesions correlate with the prognosis; classes III and IV have the worst prognosis (see Fig 26.9). Other manifestations of SLE include acute and chronic tubulointerstitial nephritis and glomerular capillary thrombi in patients with antiphospholipid antibodies.

Three guidelines for the management of lupus nephritis have been published recently by the American College of Rheumatology, the Kidney Disease-Improving Global Outcomes (KDIGO) working group, and the Joint European League Against Rheumatism and European Renal Association–European Dialysis and Transplant Association (EULAR/ERA-EDTA). For class I lupus nephritis, the prognosis is excellent, and no immunosuppression is required. Patients with class II lupus nephritis and proteinuria less than 1 g/24 h should be treated as dictated by the extrarenal clinical manifestations of lupus. Patients with class II lupus nephritis and proteinuria greater than 3 g/24 h should be treated with corticosteroids or calcineurin inhibitors.

Fig. 26.9 Light microscopy (A to C) and electron microscopy (D) are used to identify lupus nephritis. (A) Mild mesangial proliferative glomerulonephritis (International Society of Nephrology/Renal Pathology Society [ISN/RPS] class II) has mesangial hypercellularity (arrows) (periodic acid–Schiff, $\times 40$). (B) Diffuse endocapillary proliferation with cryoglobulins in the glomerular capillaries, identified as pale, silver-negative material (arrow) (silver methenamine, $\times 20$). (C) In diffuse proliferative glomerulonephritis (ISN/RPS class IV), the glomerulus on top shows a large cellular crescent (black arrows), and the glomerulus at the bottom shows diffuse endocapillary proliferation (white arrows) (silver methenamine, $\times 20$). (D) Electron-dense deposits have fingerprint substructures (arrow) ($\times 46,000$).

TABLE 26.4 Cryoglobulins and Associated Diseases

Cryoglobulinemia Type	Immunoglobulin Class	Associated Diseases
I. Monoclonal immunoglobulins	M > G > A > BJP	Myeloma, Waldenström macroglobulinemia
II. Mixed cryoglobulins with monoclonal immunoglobulins	M/G ≫ G/G	Sjögren syndrome, Waldenström macroglobulinemia, lymphoma, essential cryoglobulinemia
III. Mixed polyclonal immunoglobulins	M/G	Infection, SLE, vasculitis, neoplasia, essential cryoglobulinemia

A, IgA; BJP, Bence Jones protein (κ light chain); G, IgG; M, IgM; SLE, systemic lupus erythematosus.

Patients with class III or IV lupus nephritis should undergo induction therapy with corticosteroids plus cyclophosphamide or mycophenolate mofetil because both are considered equivalent. Pure class V (membranous) lupus nephritis usually has a benign prognosis, and initial therapy should be supportive. However, patients with progressive or persistent nephrotic-range proteinuria should be treated with corticosteroids plus an additional immunosuppressive agent (e.g., cyclosporine, tacrolimus, mycophenolate mofetil or rituximab). Patients with ESRD should be considered for renal transplantation because there is a low rate of recurrence in the transplanted kidney.

Cryoglobulinemic Glomerulonephritis

Cryoglobulins are immunoglobulins that precipitate at low temperatures and redissolve on rewarming. Cryoglobulinemia usually leads to a systemic inflammatory syndrome with weakness, arthralgias or arthritis, palpable purpura, peripheral neuropathy, and glomerulonephritis. Serum levels of C4 are typically low due to activation of complement by the classical pathway. The disease mainly involves small to medium-sized blood vessels and causes vasculitis due to cryoglobulin-containing immune complexes.

Cryoglobulinemia is classified as type I, II, or III on the basis of immunoglobulin composition. It can be idiopathic or occur in association with autoimmune diseases (see Fig. 26.11B), malignancy, or infection (Table 26.4). HCV infection is the most common cause of cryoglobulinemia.

Renal disease occurs in 20% to 60% of patients with cryoglobulinemia and manifests as proteinuria, microscopic hematuria, nephrotic syndrome, or renal impairment. Hypertension is common and may be severe, particularly in the setting of acute nephritic syndrome. The cryocrit values correlate poorly with disease activity. On light microscopy, renal biopsy specimens show an immune complex-mediated membranoproliferative pattern of injury, and on electron microscopy, diffuse, dense subendothelial deposits with a microtubular or crystalline appearance may be seen occluding the capillary loops.

Treatment targets the underlying pathologic process to minimize or eliminate the associated cryoglobulinemia. Patients with active HCV infection, for example, should receive antiviral therapy when possible, and those with a monoclonal gammopathy should receive appropriate antimyeloma therapy. Immunosuppressive therapy (including the use of rituximab) with or without plasmapheresis should be considered for patients with a rapidly progressive, organ- or life-threatening course, regardless of the cause of the mixed cryoglobulinemia. Overall, the renal prognosis is usually good, with few patients progressing to ESRD. The long-term outcome reflects the underlying process.

Fibrillary Glomerulonephritis and Immunotactoid Glomerulopathy

Fibrillary glomerulonephritis and immunotactoid glomerulopathy are uncommon disorders, being present in 0.5 to 1% of native kidney biopsies. Fibrillary glomerulonephritis is by far more common, accounting for approximately 85% to 90% of cases. The identification of the protein DnaJ heat shock protein family (Hsp40) member B9 (DNAJB9) in the glomeruli of patients with fibrillary glomerulonephritis but not in those with immunotactoid glomerulopathy has established that the two are distinct, pathogenically unrelated disease entities (Fig. 26.10). In approximately one third of patients with fibrillary glomerulonephritis a history of malignancy, monoclonal gammopathy or autoimmune disease can be documented. By contrast, immunotactoid glomerulopathy is more frequently associated with chronic lymphocytic leukemia and related B-cell lymphomas or multiple myeloma.

In fibrillary glomerulonephritis, light microscopic findings are nondiagnostic and variable, showing patterns that may be seen in other glomerulonephritides. Immunofluorescence microscopy is positive for IgG, C3, and usually both kappa and lambda (i.e., polyclonal) light chains. Electron microscopy shows random fibrillar deposits in the mesangium and glomerular capillary walls that are clearly distinct from those seen in amyloidosis. The fibrils are larger than those in amyloidosis (16 to 24 nm in fibrillary glomerulonephritis and 30 to 50 nm in immunotactoid glomerulopathy (with microtubular formation) versus 10 nm in diameter in amyloidosis).

The presenting clinical features of fibrillary glomerulonephritis and immunotactoid glomerulopathy are similar to those in other forms of glomerular disease, including hypertension, hematuria, proteinuria, and abnormal renal function.

No therapies have been clearly shown to be beneficial for either fibrillary glomerulonephritis or immunotactoid glomerulopathy. Patients with an associated malignancy, monoclonal gammopathy or autoimmune disease, may benefit from treatment of the underlying disorder.

Pauci-Immune Glomerulonephritis: Antineutrophil Cytoplasmic Antibody–Associated Vasculitides

The ANCA-associated vasculitides (AAVs) are a group of three heterogeneous syndromes: granulomatosis with polyangiitis (GPA, formerly Wegener's granulomatosis), microscopic polyangiitis (MPA), and eosinophilic granulomatosis with polyangiitis (EGPA, formerly Churg-Strauss syndrome). The unifying feature is a necrotizing small vessel vasculitis with a predilection for the kidneys, lungs, and peripheral nervous system that occurs in association with autoantibodies against antigens in the cytoplasm of neutrophils (i.e., myeloperoxidase [MPO] and proteinase 3 [PR3]).

Approximately 75% of the patients with GPA are PR3-ANCA positive, and 20% are MPO-ANCA positive, whereas about 50% of patients with MPA are MPO-ANCA positive and about 40% are PR3-ANCA positive. Necrotizing granulomatous inflammation, which affects the upper and lower respiratory tract and frequently precedes other disease manifestations, is characteristic of GPA but not MPA. EGPA is characterized by asthma and eosinophilia in addition to features of small vessel vasculitis such as mononeuritis multiplex. AAV is the most common cause of a RPGN in patients older than 60 years. AAV is associated with signs and symptoms ranging from limited renal disease to RPGN and pulmonary-renal syndrome (Table 26.5). Renal biopsy is characterized by a focal, necrotizing, and crescentic glomerulonephritis with pauci-immune immunofluorescence (Fig. 26.11).

Patients with newly diagnosed severe AAV vasculitis can be treated with a combination of high-dose corticosteroids and cyclophosphamide or high-dose corticosteroids and rituximab. The PEXIVAS trial

Fig. 26.10 Fibrillary glomerulonephritis. (A–B) Light microscopy showing mesangial expansion with increase in cellularity (*white arrow*) and thickened capillary walls (*black arrow*) (A, hematoxylin and eosin $\times 40$; B, periodic acid–Schiff stain $\times 40$). (C) Congo red stain is negative ($\times 40$). (D) Immunohistochemistry for DNAJB9 is positive. (E) Immunofluorescence studies show IgG staining in the mesangium and along capillary walls, and (F) electron microscopy shows fibrillary deposits (*thick arrows*) along the capillary walls ($\times 30000$).

TABLE 26.5 Signs and Symptoms of Antineutrophil Cytoplasmic Autoantibody Vasculitis

Abdominal pain and gastrointestinal bleeding
Cutaneous purpura, petechiae, nodules, ulcerations, and necrosis
Facial pain, necrotizing (hemorrhagic) sinusitis, and septal perforation
Hematuria, proteinuria, and renal failure
Hemoptysis and pulmonary infiltrates or nodules
Muscle and pancreatic enzymes in blood
Myalgias and arthralgias
Peripheral neuropathy (mononeuritis multiplex)

showed that addition of plasma exchange in patients with pulmonary hemorrhage, respiratory compromise, or severe renal failure (i.e., serum creatinine >5.5 mg/dL) is of no benefit. The prognosis for AAV varies. Those with severe renal failure have the worst prognosis, and even after successful therapy AAVs have a relapse rate of 30% to 50% in the first 5 years. In patients with renal involvement, rising ANCA titers are predictors of relapse. Patients with GPA or who are PR3-ANCA positive or presenting with relapsing disease are at higher risk for future relapses.

Anti–Glomerular Basement Membrane Antibody–Mediated Glomerulonephritis

Anti-GBM antibody–mediated glomerulonephritis (anti-GBM GN, formerly called Goodpasture disease) is a pulmonary–renal syndrome caused by circulating anti-GBM antibodies. On immunofluorescence staining of biopsy specimens, a linear pattern of IgG staining is seen along the GBM and alveolar basement membrane (Fig. 26.12) using antibodies directed against the $\alpha 3$ chain of type IV collagen (COL4A3

protein). Patients usually have RPGN and various degrees of pulmonary hemorrhage.

The treatment of anti-GBM GN is based on high-dose pulse methylprednisolone (1 g/day for 1 to 3 days) followed by corticosteroids (prednisone, 1 mg/kg/day up to 80 mg daily) in combination with oral cyclophosphamide (2 to 3 mg/kg/day up to 200 mg daily, adjusted for age and creatinine level) and plasma exchange. The prognosis is predicted in part by the percentage of circumferential crescents on the renal biopsy specimen, oliguria, and the need for dialysis. Those with an initial serum creatinine level less than 5.0 mg/dL have a 90% probability of renal survival at 5 years; but those with 100% circumferential crescents and on dialysis do not recover renal function, and immunosuppressive regimens should be avoided except in the case of pulmonary hemorrhage.

Anti-GBM GN rarely recurs. Patients with ESRD are candidates for renal transplantation after the antibody has disappeared (6 to 12 months).

GLOMERULAR DISEASES CAUSED BY PLASMA CELL DYSCRASIAS

Amyloidosis

Amyloidosis is characterized by systemic extracellular deposition of randomly arranged fibrils 8 to 12 nm in diameter that stain positive with Congo red (i.e., orange–green birefringence with polarized light) or thioflavin T. Several processes, including malignancy, genetic mutations, and aging, can produce at least 24 amyloidogenic proteins. With renal deposition, amyloid in biopsy specimens appears as pale, amorphous, extracellular deposits that are periodic acid–Schiff (PAS) and methenamine silver stain negative (Fig. 26.13).

The affinity for kidney compared with other target organs varies according to the type of amyloid protein. Renal manifestations include proteinuria, nephrotic syndrome, and renal failure. Affected patients typically have large kidneys on ultrasound, but the diagnosis depends

Fig. 26.11 Crescentic glomerulonephritis in a patient with MPO-ANCA associated vasculitis. (A and B) Light microscopy and silver methenamine staining show a large cellular crescent (*black arrow*) with fibrinoid necrosis (*blue arrow*), hemorrhage into the Bowman capsule (*yellow arrow*), and collapse of capillary tufts (A, $\times 20$; B, $\times 40$). (C and D) Electron microscopy shows fibrinoid necrosis (i.e., necrotizing lesion) in the Bowman space (*white arrow*) and capillary loops (*short white arrow*) (both, $\times 11100$).

Fig. 26.12 Anti-glomerular basement membrane-mediated disease. (A) Light microscopy shows a large, circumferential crescent (*arrow*), with collapse of the glomerular capillary tufts and many infiltrating neutrophils in the crescent (periodic acid-Schiff, $\times 20$). Immunofluorescence microscopy shows linear staining for anti-immunoglobulin G antibody (B) along the glomerular capillary walls and bright staining for fibrinogen in the Bowman tuft (C), indicating crescent formation and fibrinoid necrosis (both, $\times 40$).

on demonstration of amyloid deposits. After amyloid is detected, typing should be performed when possible because treatments vary according to the protein involved. The most common approach to amyloid typing involves immunofluorescence or immunohistochemistry, but genetic testing and liquid chromatography mass spectrometry are also helpful for high-resolution amyloid typing.

Treatment of amyloidosis depends on the origin of the amyloidogenic protein. In patients with amyloid light chain (AL) amyloidosis, antimyeloma therapy can be beneficial. In selected cases, bone marrow transplantation has led to resolution of the disease. Secondary amyloid A (AA) amyloidosis is most common in patients with rheumatoid arthritis, inflammatory bowel disease, chronic infection, or familial Mediterranean fever. Treatment of AA amyloidosis is directed at the underlying inflammatory process with antimicrobials or anti-inflammatory medications.

Light Chain Deposition Disease

Light chain deposition disease is a paraprotein-associated disorder. The peak incidence is in the sixth decade of life, and men are affected more commonly than women. Approximately 30% to 50% of patients with light chain deposition disease have multiple myeloma. Most have a detectable monoclonal protein (usually κ light chain) in the serum or urine, but no hematologic abnormality is identified in about 10% of cases. The clinical presentation is very heterogeneous and can vary from mild renal dysfunction, proteinuria without nephrotic syndrome, to clinically overt acute renal failure. Fanconi syndrome, characterized by normoglycemic glycosuria, aminoaciduria, and phosphaturia, is the classic presentation. Immunoglobulin deposits in other organs may result in myriad of associated clinical symptoms.

Renal biopsy specimens show acellular, eosinophilic mesangial nodules that stain strongly positive with PAS, often mimicking diabetes

Fig. 26.13 Amyloidosis. (A) Light microscopy shows amyloid deposits characterized by mesangial expansion (*small arrows*) with material negative for staining. The material is also seen in vessel walls, where the *arrow* points to vascular deposits (periodic acid–Schiff stain, $\times 20$). (B) Congo red staining is positive for amyloid and shows reddish-brown material in the glomeruli, interstitium, and vessel walls ($\times 10$). (C) Amyloid deposits show apple green to orange-yellow birefringence under polarized light ($\times 20$). (D) Electron microscopy shows randomly oriented amyloid fibrils. The fibrils measured 9 nm thick ($\times 49,000$).

mellitus. The deposited monoclonal proteins do not form fibrils and are Congo red negative. Immunofluorescence microscopic findings are diagnostic, with diffuse linear immunoglobulin light chain deposition (κ in 80% of cases) along the GBM and tubular basement membranes. On electron microscopy punctate powdery granular electron dense deposits are seen along the GBM and TBM (Fig. 26.14).

Encouraging results have emerged with the use of anti-plasma cells targeted therapy and autologous stem cell transplantation. Unless remission is achieved after chemotherapy, the disease will recur in the kidney allograft.

FIBRILLARY GLOMERULONEPHRITIS AND IMMUNOTACTOID GLOMERULOPATHY

See section on immune-complex glomerulonephritis.

GLOMERULONEPHRITIS ASSOCIATED WITH VIRAL INFECTIONS

Hepatitis B

HBV-mediated glomerular disease usually manifests as membranous nephropathy, especially in children. The diagnosis of HBV-mediated glomerular disease requires detection of the virus in the blood and the exclusion of other causes of glomerular diseases.

HBV-mediated glomerular disease usually has a favorable prognosis, with a high spontaneous remission rate in children, but it is often progressive in adults. Patients with HBV infection and glomerulonephritis should receive antiviral therapy (e.g., entecavir) as recommended by standard clinical practice guidelines for management of HBV infection. Those with severe vasculitis or RPGN may be candidates for immunosuppressive therapy in combination with antiviral

therapy. Rituximab treatment of patients who are positive for HBV has been associated with fatal acute hepatitis. Rituximab is therefore contraindicated in patients with chronic HBV unless antiviral therapy is also given and in patients with an active hepatitis flare.

Hepatitis C

See the section on cryoglobulinemic glomerulonephritis.

HIV-Associated Nephropathy

Patients with HIV infection can have many forms of kidney injury due to sepsis, co-infection with HBV or HCV, nephrotoxic drugs, and use of antiretroviral agents. HIV-associated nephropathy (HIVAN) is a clinicopathologic entity characterized by nephrotic-range proteinuria and a collapsing form of FSGS, often with microcystic tubular dilation. On electron microscopy, tubuloreticular inclusions (i.e., interferon fingerprints) may be seen within the glomerular and vascular endothelial cells.

HIVAN occurs almost exclusively in patients of African descent when CD4 levels are low. It is thought to be caused by infection and subsequent expression of HIV viral genes in podocytes. The onset of proteinuria is typically acute. Proteinuria can be greater than 10 g/day, and renal insufficiency can progress rapidly.

THROMBOTIC MICROANGIOPATHIES

Thrombotic microangiopathy is characterized by thrombocytopenia, microangiopathic hemolytic anemia, and microvascular occlusion, resulting in various degrees of organ dysfunction. Markers of hemolysis include low haptoglobin levels, increased levels of lactate dehydrogenase and unconjugated bilirubin, and a high reticulocyte count. Schistocytes are seen in peripheral blood smears.

Fig. 26.14 Light chain deposition disease. (A) Light microscopy shows glomeruli with silver-positive mesangial nodules (*arrow*) and thickened tubular basement membranes (silver methenamine, $\times 10$). (B) Periodic acid-Schiff staining shows thickened, wavy tubular basement membranes (*arrow*) ($\times 10$). Immunofluorescence studies found negative staining for λ light chains (C) and bright staining for κ light chains (D) along the tubular basement membranes (both $\times 10$). (E) Electron microscopy shows granular, punctate, electron-dense deposits (*arrows*) along the tubular basement membranes ($\times 5800$).

The quintessential forms of thrombotic microangiopathy include hemolytic uremic syndrome (HUS) and thrombotic thrombocytopenic purpura (TTP). Although previously thought to represent different manifestations of the same disease, these disorders are distinct clinically and mechanistically. In adults, predominant neurologic involvement suggests a diagnosis of TTP, and predominant renal involvement points to HUS. In most cases, the clinical presentations are very similar, making it difficult to distinguish between HUS and TTP on clinical grounds alone. Other causes of thrombotic microangiopathy include malignant hypertension, drugs (e.g., cocaine, quinidine, ticlopidine), autoimmune diseases (e.g., SLE, scleroderma, antiphospholipid antibody syndrome), malignancy, HIV infection, and antibody-mediated rejection.

Kidney biopsy in HUS and TTP reveals microthrombi in glomerular capillaries and arterioles, and mesangial expansion with loose granular material, called *mesangiolytic*, may be seen in HUS and TTP and in malignant hypertension or autoimmune diseases (Fig. 26.15). Malignant hypertension and autoimmune diseases may also show thickening and intimal fibrosis of arteries and onion-skinning (i.e., laminated deposition of basement membrane-type material) of the vessel walls. Thrombi are common and may occlude the vascular lumen.

Hemolytic Uremic Syndrome

Two subtypes of HUS are recognized: a sporadic or diarrhea-associated form (D+ HUS) and an atypical or non-diarrhea-associated form (D- HUS). D+ HUS is the most frequently encountered form, and it is linked strongly to ingestion of meat contaminated with enterohemorrhagic *Escherichia coli* or other infectious agents. The bacterium produces a Shiga-like toxin that binds to a glycolipid receptor on renal endothelial cells and triggers activation of the alternative complement cascade, leading to endothelial damage. Therapy for D+ HUS is supportive. Children with D+ HUS have a good prognosis (90% recover renal function), but older patients have increased mortality rates and unfavorable long-term renal survival.

Atypical or D- HUS represents 10% to 15% of the cases of HUS and is more common in adults. The disease results from genetic mutations or autoantibodies against complement factors or complement factors regulating proteins (i.e., C3, factor B, factor H, factor I, MCP, CFHR1, and CFHR3) that control the activity of C3 convertase of the alternative complement pathway. The resulting defective control of C3 convertase leads to widespread activation of the complement cascade.

The complement inhibitor eculizumab has been approved for the treatment of patients with atypical HUS. Eculizumab and plasma infusion may also be considered in the treatment of children with D+ HUS and severe central nervous system involvement such as seizures, stroke, or coma.

Fig. 26.15 Thrombotic microangiopathy. (A) Light microscopy shows multiple, small thrombi (*arrows*) in glomerular capillaries in the setting of hemolytic uremic syndrome (Masson trichrome, $\times 40$). (B) Light microscopy shows a thrombus (*arrow*) in a small artery in the setting of scleroderma (silver methenamine, $\times 20$).

Fig. 26.16 Alport syndrome. (A) Light microscopy shows focal segmental glomerulosclerosis (*arrow*) (periodic acid–Schiff, $\times 40$). (B) Light microscopy shows numerous foam cells (*arrow*) in the interstitium (silver methenamine, $\times 40$). (C) Electron microscopy shows thickening of the glomerular capillary walls with multiple lamellations of basement membrane material (*arrow*) and formation of the classic basket-weave appearance ($\times 212,000$).

Thrombotic Thrombocytopenic Purpura

TTP results from mutations in the von Willebrand factor (VWF)–cleaving protease (ADAMTS13) or development of an autoantibody against ADAMTS13. ADAMTS13 cleaves large multimers of VWF, and abnormalities or deficiency of ADAMTS13 activity affects VWF function. Patients can have acute or chronic (i.e., relapsing) TTP. Microthrombi rich in large VWF multimers develop in the arterioles and capillaries of the brain and other organs.

Genetic or acquired forms of ADAMTS13 deficiency can be treated by plasma infusion or exchange to supply functional protease. Plasma exchange should be initiated promptly, based on findings of microangiopathic hemolytic anemia and thrombocytopenia without evidence of other causes of thrombotic microangiopathy (e.g., scleroderma, malignancy, antiphospholipid syndrome). Treatment should not await test results for the levels or activity of ADAMTS13.

DISEASES WITH GLOMERULAR BASEMENT MEMBRANE ABNORMALITIES

Alport Syndrome

Alport syndrome is an inherited disorder of basement membranes. In more than one half of patients, the disease results from a mutation in the *COL4A5* gene that codes for the $\alpha 5$ chain of type IV collagen ($\alpha 5[IV]$). The mutation in *COL4A5* disables a developmental switch in the GBM collagen that retains its embryonic phenotype and results in a friable GBM.

Alport syndrome is frequently associated with sensorineural hearing loss and ocular abnormalities (e.g., lenticonus of the anterior

lens capsule). Patients characteristically have persistent or intermittent hematuria and usually have mild proteinuria, which progresses with age and may reach nephrotic range in up to 30%. The disease is X-linked in approximately 85% of patients, but autosomal recessive and autosomal dominant patterns of inheritance have been described.

In virtually all male patients, the syndrome progresses to ESRD, often before the age of 30 years. The disease is usually mild in heterozygous women, but some develop ESRD, usually after the age of 50 years. The rate of progression to ESRD is fairly constant among affected men within individual families, but it varies markedly from family to family. The degree of deafness correlates with the rate of progression to ESRD.

On light microscopy, the glomerular changes are nonspecific. Diagnostic features are usually seen on electron microscopy. At an early stage, thinning of the GBM may be the only visible abnormality and may suggest thin basement membrane disease. With time, the GBM thickens, and the lamina densa splits into several irregular layers that may branch and rejoin, producing a characteristic basket-weave appearance (Fig. 26.16).

Immunohistochemical studies of type IV collagen show the absence of $\alpha 3(IV)$, $\alpha 4(IV)$, and $\alpha 5(IV)$ chains from the GBM and distal tubular basement membrane. This abnormality occurs only in patients with Alport syndrome and is diagnostic. In families with an unquestionable diagnosis, evaluation of patients with newly diagnosed hematuria can be limited to kidney ultrasound and urinary tract examination in most cases. If a defined mutation has been previously identified, molecular diagnosis of affected men or gene-carrying women is possible. In other cases, confirmation of the diagnosis can be obtained by examination of skin biopsy by immunofluorescence for the expression of the $\alpha 5(IV)$

Fig. 26.17 (A) In thin glomerular basement membrane nephropathy, electron microscopy shows glomerular basement membranes (arrows) that are 198 nm thick ($\times 5800$). (B) Alport syndrome. Electron microscopy showing thickened glomerular capillary walls with lamellations and disorganization of the glomerular basement membranes ($\times 30000$). Arrows point to thin glomerular basement membranes in A and to the lamellations in B.

chain. Absence of the $\alpha 5(\text{IV})$ chain from epidermal basement membrane is diagnostic of X-linked Alport syndrome and may avoid a renal biopsy. Direct sequencing of the *COL4A5* gene can help to diagnose patients in whom a clear diagnosis cannot be made based on clinical findings and histologic methods or to identify the carrier state in asymptomatic female members of X-linked Alport syndrome families.

No specific treatment is available for Alport syndrome. Tight control of blood pressure and moderate protein restriction are recommended to retard the progression of renal disease, but the benefit is unproven. Patients with Alport syndrome are phenotypic knockouts for the $\alpha 3(\text{IV})$ chain. Consequently, kidney transplantation carries a 5% to 10% risk of subsequent anti-GBM GN due to the introduction of an intact $\alpha 3(\text{IV})$ chain with the transplanted kidney and subsequent generation of auto-antibodies to the antigen present in the intact $\alpha 3(\text{IV})$ chain of the transplanted kidney.

Thin Glomerular Basement Membrane Nephropathy

Thin glomerular basement membrane nephropathy, also known as benign familial hematuria, is a relatively common condition characterized by isolated glomerular hematuria and associated with the renal biopsy finding of an excessively thin GBM. It is usually transmitted as an autosomal dominant disease. Heterozygous mutations in the *COL4A3* or *COL4A4* genes have been described in numerous patients with thin glomerular basement membrane nephropathy, indicating a genetically heterogeneous condition.

The usual clinical presentation is isolated, persistent hematuria that is first detected in childhood. In some patients, hematuria is intermittent and may not manifest until adulthood. On light microscopy, glomeruli appear normal, and immunofluorescence microscopy shows no immunoglobulin or complement deposition. Electron microscopy shows diffuse thinning of the GBM (Fig. 26.17). In adults, a GBM thickness less than 250 nm strongly suggests thin GBM disease.

The condition is usually benign and requires no specific treatment. However, a few patients have progressive renal disease that leads to ESRD.

FABRY'S DISEASE

Fabry's disease is an X-linked recessive inborn error of glycosphingolipid metabolism caused by deficient activity of the lysosomal enzyme α -galactosidase A, which results in the progressive accumulation of neutral glycosphingolipids (predominately globotriaosylceramide, particularly in the vascular endothelial cells of the kidney and heart.

Early manifestations of the disease include angiokeratoma, episodic pain crises, and hypohidrosis. With time, progressive

Fig. 26.18 Fabry's disease. Electron microscopy shows visceral epithelial cells (i.e., podocytes) with numerous multilamellated structures called myelin bodies or zebra bodies (arrows) that are made of glycosphingolipids ($\times 4800$).

globotriaosylceramide accumulation in the microvasculature in the kidney, heart, and brain leads to clinical manifestations such as proteinuria, renal failure, cardiac arrhythmias, and strokes, resulting in early death during the fourth and fifth decades of life of affected men.

Light microscopy reveals vacuolated glomerular cells, especially podocytes. Electron microscopy shows enlarged podocyte lysosomes filled with osmiophilic, granular to lamellated membrane structures (i.e., zebra bodies) (Fig. 26.18). Enzyme replacement therapy can lead to significant improvement of neuropathic pain, but the beneficial effects on the severity or progression of other disease manifestations are less clear.

DIABETIC NEPHROPATHY

Diabetic nephropathy accounts for more than 50% of patients on dialysis in the United States. In type 1 diabetes mellitus, nephropathy usually manifests 10 to 15 years after the initial diagnosis; and a similar natural history is likely for patients with type 2 diabetes mellitus. The main risk factors include a positive family history of diabetic nephropathy, hypertension, and poor glycemic control. The risk may be greater in some racial groups (e.g., Pima Indians, African Americans).

The pathogenesis is complex. Increased glycosylation of proteins with accumulation of advanced glycosylation end products that

Fig. 26.19 Light microscopy shows diabetic glomerulosclerosis. (A and B) Early diabetic nodule formation (arrows). (C and D) Well-formed Kimmelstiel-Wilson lesions result from mesangial expansion (thin black arrows). The nodules are periodic acid–Schiff and silver methenamine positive. The glomerular capillary lumen is distended by formation of small microaneurysms (thick black arrows). The glomerular basement membrane and Bowman capsule (white arrows) are thickened (A and C, periodic acid–Schiff; B and D, silver methenamine; all $\times 40$).

cross-link with collagen and glomerular hyperfiltration with hypertension are important. Microalbuminuria (i.e., urinary albumin excretion >30 but <300 mg/24 h) is the initial manifestation of diabetic nephropathy. With time, microalbuminuria may evolve into overt proteinuria (>300 mg/24 h), with the degree of proteinuria correlating roughly with the renal prognosis.

After overt proteinuria develops, progression to ESRD is relentless, although rates of decline vary among patients. For patients with type 1 diabetes, there is a strong correlation (95%) between the development of nephropathy and other signs of diabetic microvascular compromise (e.g., diabetic retinopathy), but the correlation is weaker for patients with type 2 diabetes. Hypertension is almost universal among patients with proteinuria. It is difficult to control and usually requires at least three antihypertensive agents.

On renal biopsy, early signs of diabetic nephropathy include glomerular hypertrophy and thickening of the GBM. As the disease progresses, arteriolar hyalinosis, arteriosclerosis, and progressive mesangial expansion (i.e., diffuse diabetic glomerulosclerosis) and nodular formations (i.e., Kimmelstiel-Wilson nodules) develop (Fig. 26.19). For patients with a history of diabetes longer than 10 years and retinopathy, a renal biopsy may not be necessary. However, renal biopsy is indicated for patients with an atypical course of the disease (e.g., nephrotic syndrome), those with less than 10 years of type 1 diabetes, or patients with rapid loss of renal function.

Treatment with ACEIs or ARBs slows progression of diabetic nephropathy and should be used in all patients with albuminuria, even if normotensive. Tight glycemic control (i.e., glycated hemoglobin

$<7.0\%$) may also retard progression of diabetic nephropathy. Target systolic blood pressure should be less than 125 mm Hg, but this may be difficult to achieve and may require multiple medications and a strict low-salt diet.

Major Nonglomerular Disorders of the Kidney

Nilum Rajora, Shani Shastri, Pooja Koolwal, Ramesh Saxena

INTRODUCTION

Nonglomerular structures of the kidney include blood vessels, tubules, and interstitium. The tubulointerstitial compartment comprises 80% of kidney parenchyma, with most of the volume accounted for by tubules, interstitial cells, extracellular matrix, and interstitial fluid. Although primary glomerular and vascular diseases are associated with significant tubulointerstitial changes, the clinical presentations are dominated by injury of the glomeruli and the vasculature, and are discussed in [Chapters 26 and 28](#).

Primary tubulointerstitial disorders are characterized by structural and functional abnormalities predominantly involving kidney tubules and the interstitium and are associated with a myriad of clinical presentations based on the principal structure involved: acute tubulointerstitial nephritis, characterized by sudden onset and a rapid decline in kidney function; chronic tubulointerstitial nephropathy, characterized by a more protracted clinical course; cystic diseases with kidney cysts and kidney failure; nephrolithiasis with pain, hematuria, and sometimes acute kidney injury (AKI). This chapter will cover primary tubulointerstitial disorders of the kidney.

ACUTE INTERSTITIAL NEPHRITIS

Definition, Epidemiology, and Pathology

Acute interstitial nephritis (AIN), also called *tubulointerstitial nephritis*, is characterized by inflammation and edema of the kidney interstitium; glomeruli and vessels are distinctly normal. AIN is associated with an acute, rapid decline in kidney function and is a common cause of AKI. AIN is seen in 1% to 3% of kidney biopsies, but if biopsy is done in the setting of AKI with clinical suspicion for AIN, 15% to 27% of biopsies show AIN.

On gross examination, the kidneys are pale and swollen. Histologically, the hallmarks of AIN include interstitial edema and infiltration of the interstitium with inflammatory cells comprising lymphocytes, monocytes, plasma cells, eosinophils, and macrophages (E-Figs. 27.1 and 27.2). This inflammation can progress to fibrotic changes in 7 to 10 days. Immunofluorescence studies typically are unrevealing. Tubular basement membrane immune deposits can be seen in cases of AIN associated with some drug-induced tubulointerstitial nephritis, immunoglobulin G4 (IgG4)-associated nephritis, membranous nephropathy, membranoproliferative glomerulonephritis, lupus nephritis, Sjögren syndrome, and other autoimmune diseases.

Any drug can cause AIN but frequently used therapeutic drugs merit particular emphasis. Common causes of AIN are shown in [Table 27.1](#). They include antibiotics, allopurinol, mesalamine, nonsteroidal anti-inflammatory drugs (NSAIDs), proton pump inhibitors, and chemotherapeutic agents. Other causes of AIN include infections, autoimmune disorders, tubulointerstitial nephritis and uveitis

syndrome, snakebite, and herbal supplements. Nephrotoxicity of novel biologic agents used in cancer therapy is increasingly being recognized (see [Table 27.1](#)). Several of these drugs are associated with AIN. In many such cases, autoimmunity rather than drug sensitivity is the basis of tubulointerstitial inflammation.

Clinical Presentation

In most cases, AIN begins abruptly with a decrease in kidney function within days of exposure to the offending agent. However, AIN may ensue after several weeks of the exposure in some cases. Characteristic clinical manifestations include rash, fever, and eosinophilia. Modest proteinuria (usually <1 g/day) or hematuria may be observed, and oliguria is uncommon. A high index of suspicion is required for diagnosis because these features may be absent.

Diagnosis and Differential Diagnosis

When evaluating a patient with a recent decline in kidney function, the diagnosis of AIN is suggested by a history of exposure to the known offending agents coupled with typical clinical features. In addition to identifying elevated serum creatinine levels, a urinalysis can detect the characteristic findings of white blood cells, red blood cells, and white blood cell casts in urine. Identification of eosinophils in urine with Hansel or Wright stains is highly suggestive, but their absence does not rule out AIN. Moreover, eosinophils in urine can be observed in other diseases, including cholesterol embolism, urinary tract infections, parasitic disorders, and glomerulonephritis.

Unfortunately, there is currently no noninvasive test that reliably diagnoses drug-induced AIN. Kidney biopsy should be considered when the diagnosis is not obvious. Besides tubular injury, other histologic features may suggest the underlying disease that is associated with AIN. IgG4-related AIN has presence of tubular basement membrane immune complex deposits and an increase in IgG4-positive plasma cells in the interstitium. Sarcoidosis associated AIN may also have granulomas on biopsy, and AIN related to systemic lupus erythematosus (SLE) may also show diffused immune complex deposits on immunofluorescence. A definitive diagnosis of AIN requires a kidney biopsy, although most times it is not necessary for management when clinical features are highly suggestive.

Treatment and Prognosis

Treatment of patients with AIN consists of removal of the offending drug and management of the underlying infection or autoimmune process. The role of corticosteroids in limiting the inflammatory process is controversial, but early use (within 7 to 14 days) may decrease the duration of AIN and protect kidney function. When indicated, the usual approach includes high-dose intravenous methylprednisolone (250 mg consecutively for 3 days), followed by oral prednisone (1 mg/kg) tapering over 4 to 6 weeks. Patients who are intolerant or resistant

TABLE 27.1 Causes of Acute Interstitial Nephritis

Cause	Examples
Antibiotics	Penicillin Cephalosporin Sulfa drugs Ciprofloxacin Rifampin
Nonsteroidal anti-inflammatory drugs	Naproxen Ibuprofen Diclofenac Celecoxib
Diuretics	Thiazides Furosemide Triamterene
Other drugs	Cimetidine Proton pump inhibitors Phenytoin Allopurinol
Chemotherapeutic agents	Ifosfamide Interferon Sorafenib Sunitinib Adriamycin Ipilimumab Carboplatin Bevacizumab
Systemic infections	Legionnaires disease Leptospirosis Streptococcal infection Cytomegalovirus infection
Primary kidney infections	Acute bacterial pyelonephritis
Autoimmune disorders	Sarcoidosis Sjögren syndrome

to steroids may benefit from mycophenolate mofetil (500 to 1000 mg twice daily).

Most cases of drug-related AIN resolve after removal of the offending drug. In tubulointerstitial nephritis and uveitis syndrome, both the ocular and kidney changes respond to a brief course of corticosteroids, but the disease can relapse. The overall prognosis depends on the duration of the AIN; a longer interval between onset of AIN and drug withdrawal can lead to irreversible kidney damage. Because of the rapid transformation of interstitial cellular infiltrates into fibrosis, up to 40% of patients may not fully recover baseline kidney function, and about 10% of the patients may become dialysis dependent.

CHRONIC INTERSTITIAL NEPHRITIS

Chronic interstitial nephritis (CIN) is a clinicopathologic diagnosis. Prolonged exposure to a causative agent initiates an indolent inflammatory process, and CIN can lead to permanent kidney damage over months to years before it manifests clinically. Patients usually have a gradual decline in kidney function. CIN is common and accounts for 15% to 30% of all cases of end-stage renal disease (ESRD).

Pathology

Histologically, CIN shows tubular atrophy, flattened epithelial cells, tubule dilation, interstitial fibrosis, and areas of mononuclear cell

TABLE 27.2 Clinical Findings That Suggest Chronic Interstitial Nephritis

Hyperchloremic metabolic acidosis (out of proportion to the degree of kidney injury)
Hyperkalemia (out of proportion to the degree of kidney injury)
Reduced maximal urinary concentrating ability (e.g., polyuria, nocturia)
Partial or complete Fanconi syndrome (e.g., phosphaturia, bicarbonaturia, aminoaciduria, uricosuria, glycosuria)
Modest proteinuria (<2 g/day)
Anemia
Hypertension

infiltration within the interstitial compartment (E-Fig. 27.3). The infiltrates are typically less conspicuous compared with AIN, and there is more interstitial fibrosis. In earlier stages of CIN, glomeruli are usually spared, but with progression, glomerular abnormalities such as segmental and global sclerosis can develop.

Clinical Presentation and Laboratory Findings

Patients with CIN are usually asymptomatic until they develop overt chronic kidney disease (CKD). The features are nonspecific and include fatigue, lack of appetite, nausea, vomiting, hypertension, and sleep disturbances, and other laboratory and clinical findings may develop, as listed in Table 27.2. CIN can also cause proximal or distal tubular dysfunction, which can lead to defects in acidification of the urine, partial or complete Fanconi syndrome and decreased concentrating ability. Laboratory data for these patients may show elevated levels of creatinine, proteinuria, hematuria, glycosuria, and pyuria. Due to the destruction of erythropoietin-producing interstitial cells, anemia, associated fatigue, and decreased exercise tolerance are common as CIN progresses.

Diagnosis and Differential Diagnosis

The histologic findings of CIN are nonspecific, and the differential diagnosis can be extensive, as shown in Table 27.3. Repeated injuries from drugs, toxins, radiation nephritis, and reflux nephropathy can result in a similar histologic picture. The most common cause of CIN is chronic NSAID use. Other causes include infections, immune-mediated disorders, drug reactions, hematologic disorders, chronic urinary tract obstruction, and urinary reflux. Some metabolic disorders and exposure to heavy metals can also lead to CIN. The clinical importance, distinguishing features, causes, and management of several forms of CIN are discussed in the following sections.

Analgesic Nephropathy

Analgesic nephropathy is the prototype CIN, and it occurs commonly worldwide. This disorder is caused by long-term ingestion of aspirin in various combinations with phenacetin, caffeine, or acetaminophen. In its most severe form, analgesic nephropathy is associated with papillary necrosis.

The cumulative amount of phenacetin-acetaminophen combination required to cause CIN is estimated to be at least 2 to 3 kg. Although initially thought to be exclusively associated with phenacetin-containing combinations, all analgesics, including acetaminophen, aspirin, and NSAIDs, are capable of inducing CIN.

Analgesic nephropathy is most commonly detected in women in the sixth and seventh decades of life. Patients with analgesic nephropathy may have elevated serum creatinine, modest proteinuria, sterile pyuria, and anemia. Occasionally, patients develop flank pain and gross hematuria, suggesting papillary necrosis. Diagnosis is supported

E-Fig. 27.3 Chronic interstitial nephritis. Interstitial chronic inflammatory cell infiltrate (*arrows*) with tubular atrophy (*double arrows*) (periodic acid-Schiff, $\times 200$).

TABLE 27.3 Conditions Associated With Chronic Interstitial Nephritis

Associated Conditions	Examples
Hereditary diseases	Karyomegalic interstitial nephritis
Metabolic disturbances	Hypercalcemia, nephrocalcinosis Hyperuricemia Hyperoxaluria Hypokalemia Cystinosis
Drugs and toxins	Analgesics, nonsteroidal anti-inflammatory drugs Lead Nitrosoureas Cisplatin Calcineurin inhibitors Lithium Chinese herbs Olanzapine
Immune-mediated diseases	Granulomatosis with polyangiitis (Wegener's granulomatosis) Sjögren syndrome Systemic lupus erythematosus Vasculitis Sarcoidosis Crohn's disease
Hematologic disease or malignancy	Multiple myeloma Sickle cell disease Lymphoma
Infection	Chronic pyelonephritis Xanthogranulomatous pyelonephritis Hepatitis Epstein-Barr virus HIV
Obstruction	Tumors Stones Bladder outlet obstruction Vesicoureteral reflux
Miscellaneous disorders	Mesoamerican nephropathy Radiation nephritis Hypertensive arterionephrosclerosis Renal ischemic disease

by a history of heavy analgesic use, and computed tomography (CT) may reveal microcalcifications at the papillary tips.

Treatment of analgesic nephropathy is supportive and includes discontinuation of analgesic use. Long-term follow-up studies are characterized by progression to ESRD requiring renal replacement therapies. A high incidence of uroepithelial cancers is also observed in patients with long-term analgesic use.

Chinese Herb Nephropathy and Balkan Endemic Nephropathy

Chinese herb nephropathy (CHN) and Balkan endemic nephropathy (BEN), also called *aristolochic acid nephropathy* (AAN), are chronic tubulointerstitial kidney diseases associated with urothelial carcinoma. The clinical expression and pathologic lesions observed at different stages of CHN and BEN are strikingly similar except for the higher prevalence of CHN among women and familial clustering of BEN. Both have been linked to exposure to the nephrotoxin and carcinogen aristolochic acid. It has been suggested that the terms *CHN* and *BEN* should be abandoned and replaced by the term *AAN*.

Aristolochic acid is a major component of *Aristolochia*-containing herbal remedies and is commonly prescribed in China and other Asian countries. AAN was first reported in 1993 in Belgium in young women taking aristolochic acid-containing Chinese herbs for weight reduction, and the finding has been confirmed by many others. BEN was described 50 years ago in farming villages in the Balkan area, where there is dietary exposure to aristolochic acid through the contamination of flour prepared from locally grown wheat.

Unique features of AAN include clustering of the cases among adults in endemic areas and close association with upper urinary tract carcinomas. About 50% of the affected patients develop transitional cell carcinomas; aristolochic acid induces DNA damage with a distinct molecular signature. Unfortunately, no effective specific treatment for AAN is available. Management is supportive with regular monitoring for urothelial malignancy.

Heavy Metals

Heavy metals such as cadmium, lead, and chromium can cause CIN, and exposure usually represents an environmental toxin. Cadmium exposure occurs with tobacco smoke and contaminated water and food. Lead exposure occurs from contact with lead-based paint and lead-contaminated dust and soil. Chromium is used to increase the hardness and corrosion resistance of alloy steel, and chromium exposure can occur when industrial plant employees work with alloy steels, dyes, paints, inks, and plastics. Proximal tubules are the principal site of accumulation and injury, but other nephron segments also can be injured.

Heavy metal nephrotoxicity ranges from mild tubular dysfunction to advanced CKD. The extent of kidney damage depends on the nature, dose, route, and duration of exposure. With chronic exposure, changes consistent with CIN are observed on kidney biopsy. The best-characterized clinical feature of heavy metal kidney toxicity is the Fanconi syndrome, which results from proximal tubule damage. These patients have low-molecular-weight proteinuria, aminoaciduria, bicarbonaturia, glycosuria, and phosphaturia. Other clinical findings of lead toxicity include gout from decreased urate excretion in proximal tubules, hemolytic anemia, encephalopathy, and neuropathy.

Other than supportive care, no specific treatment is available for heavy metal-associated kidney disease. Chelating agents may be used in acute poisoning, but no randomized clinical trials have proved the efficacy of chelation on clinical outcomes.

Sarcoidosis

Sarcoidosis is a chronic, multisystem, inflammatory disease of unknown origin. It is characterized by noncaseating, epithelioid granulomas in affected organs, leading to organ dysfunction. The severity and diversity of the clinical manifestations related to sarcoidosis depend on the extent of the infiltrating granulomatous lesions. Granulomatous tubulointerstitial nephritis is observed in approximately 20% of patients with sarcoidosis and responds well to steroid therapy. Sarcoidosis is described in details elsewhere.

Corticosteroid therapy is effective in the acute setting and in advanced tubulointerstitial nephritis. Treatment includes prednisone (1 mg/kg/day) for 6 to 12 weeks followed by taper. Some patients with granulomatous tubulointerstitial nephritis may require long-term treatment with steroids to preserve kidney function, although the side effects of steroids limit their use in advanced kidney disease. The efficacy of corticosteroid-sparing agents such as mycophenolate mofetil or azathioprine for sarcoid-related interstitial nephritis requires further investigation.

Radiation Nephritis

Radiation exposure is a significant cause of CKD, and radiation nephritis develops in most patients if they are exposed to more than

23 Gy. Ionizing radiation directly damages all molecules, including DNA, and initiates cellular synthesis of reactive oxygen species, which cause secondary tissue damage. Hydroxyl radicals are generated within milliseconds of tissue exposure. Oxidative stress and other factors may play additional roles over time, and patients may develop severe kidney injury and impaired function 6 to 12 months (or longer) after exposure. Histopathologically, early and late changes can be seen that include cell swelling, mesangiolytic, variable tubular injury, tubular atrophy, glomerular scarring, and increased mesangial matrix.

The diagnosis is usually based on a history of radiation exposure and the clinical findings of kidney injury. Treatment is supportive.

Sickle Cell Disease

CKD is relatively common in patients with sickle cell disease, an inherited hematologic disorder characterized by hemolytic anemia and vascular occlusion by sickled red cells. Under normal conditions, the renal medullary zone is characterized by low oxygen tension, acidic pH, and high osmolality, which can predispose to increased blood viscosity and red blood cell sickling. This increases the likelihood of local ischemia and infarction of the kidney microcirculation. In the vasa recta, vascular occlusion can interfere with the countercurrent exchange system in the inner medulla, resulting in a defect in the urine-concentrating mechanism.

Patients may have nocturia or polyuria and can develop gross hematuria due to papillary necrosis resulting from medullary ischemia and infarction. The sloughed papillae can obstruct urinary tract outflow, leading to obstructive nephropathy and kidney failure. Another abnormality associated with sickle cell disease is proteinuria, a consequence of glomerular hyperfiltration that results from reduction in nephron mass.

The treatment of sickle cell nephropathy focuses on primary management of the hematologic disorder. Tubular dysfunction may require potassium and bicarbonate supplementation to treat hypokalemia and acidosis, and those with ESRD are treated with dialysis and renal transplantation.

Lithium

Lithium is a monovalent cation, which is freely filtered through the glomeruli. Up to 80% of filtered lithium is reabsorbed in the proximal tubule, and a small fraction is reabsorbed in the distal nephron through the epithelial sodium channel ($E_{Na}C$). Lithium causes dysregulation of the aquaporin water channel and $E_{Na}C$ expression in the cortical collecting duct. The most common manifestation of kidney disease associated with lithium is CIN manifesting as a chronic, insidious decline in kidney function. The course of kidney disease after discontinuation of lithium is highly unpredictable, with no reliable clinical clues to identify those destined for recovery or progression.

Lithium also is associated with nephrogenic diabetes insipidus, which can occur in up to 40% of patients as early as 8 weeks after lithium initiation. Other tubular dysfunctions associated with lithium include water diuresis, natriuresis, and metabolic acidosis. Lithium-associated nephrogenic diabetes insipidus can be treated with $E_{Na}C$ blockade by amiloride.

Mesoamerican Nephropathy

Mesoamerican nephropathy, now formally designated as CKD of non-traditional causes, is an emerging form of progressive CKD identified in the last two decades. It is primarily seen in agricultural workers (usually in sugarcane or cotton plantations) in Central America. A similar nonproteinuric CKD has been described in South Asia and Sri Lanka as well. The most significant risk factor is prolonged, strenuous physical labor in hot and humid climates. Other risk factors include

male gender, low body mass, consumption of high-fructose beverages, exposure to heavy metals from soil, nephrotoxins or NSAIDs and infectious diseases such as leptospirosis and hantavirus infections. Pesticide exposure alone does not appear to increase risk. Pathogenesis is not yet clearly understood; however, current hypothesis suggests that repeat episodes of heat stress and dehydration lead to activation of renin-angiotensin-aldosterone system, vasopressin and polyol-fructokinase pathway causing increased oxidative stress and recurrent AKI, eventually leading to tubulointerstitial nephritis. Moreover, heat exposure and consequent dehydration can enhance tubular reabsorption of toxins and potentially enhance toxin-mediated kidney injury. Furthermore, heat exposure can result in heat stroke or low grade rhabdomyolysis that can exacerbate kidney injury.

Patients are usually young or middle-aged men, normotensive, have minimal edema, and may describe symptoms of dysuria or nocturia. Laboratory data are notable for elevated creatinine, hypokalemia, hypomagnesemia, hyperuricemia, and urinalysis is often unremarkable with no hematuria and minimal (if any) proteinuria. Abdominal ultrasound shows small kidneys with cortical thinning. Diagnosis requires appropriate clinical context and kidney biopsy. Histologic features show tubulointerstitial damage, glomerulosclerosis, and chronic glomerular ischemia. Treatment is supportive and further efforts should be directed to preventing disease progression.

Urinary Tract Obstruction

Urinary tract obstruction is a common cause of AKI and CKD. When kidney function is normal at baseline, unilateral or partial obstruction anywhere along the urinary tract may be asymptomatic, with no discernible change in kidney function or urine output. Bilateral urinary tract obstruction, however, can lead to acute and chronic kidney injury and ESRD. It is important to address this possibility early in the clinical course of unexplained kidney injury or uremia.

Obstruction to urine flow causes an increase in ureteral intraluminal pressure. Over time, nephron tubules are injured, and the resulting changes in thromboxane A_2 and angiotensin levels decrease renal blood flow. Tubular damage leads to urinary concentrating defects, renal tubular acidosis (RTA), and hyperkalemia. If complete obstruction is not relieved, ischemia and nephron loss decrease the glomerular filtration rate.

Common causes of obstructive nephropathy are shown in [Table 27.4](#). Among elderly men, benign prostatic hypertrophy is of particular concern. Overall, the clinical presentation depends on the cause, site, and time course of obstruction. Patients with obstructive nephropathy may present with decreased urine output associated with suprapubic pain (i.e., bladder distention from ureteral obstruction), renal colic (i.e., nephrolithiasis), urinary tract infections, fever, AKI, hypertension, and hematuria. Pain resulting from stretching of the urinary collecting system is the most common presenting symptom. Acute ureteral obstruction usually results in severe flank pain that typically radiates to the groin and is referred to as *renal colic*. Patients with complete bladder outlet obstruction develop AKI and anuria. Patients with incomplete or intermittent bladder outlet obstruction have urinary hesitancy, dribbling, urgency, decreased urine stream, nocturia, and polyuria. These patients are usually pain free. Tubular injury from obstruction causes decreased urinary concentrating capability leading to polyuria.

The physical examination should include palpation of the kidney and bladder, as well as a rectal, pelvic, and prostate assessment. The patient may have an enlarged and palpable bladder, enlarged prostate, costovertebral tenderness, groin pain, hypertension, or gross hematuria. The mainstays of the initial evaluation include measurement of the postvoid residual volume of the bladder (>125 mL is considered

TABLE 27.4 Causes of Urinary Obstruction

Cause	Examples
Congenital urinary tract malformation	Meatal stenosis Ureterocele Posterior urethral valves Urethral atresia Phimosis Megaureter–prune belly syndrome
Intraluminal obstruction (urethra and bladder outlet)	Phimosis Urethral strictures Benign prostatic hyperplasia Pelvic tumor Anticholinergic drugs Neurogenic bladder Tuberculosis Radiation Trauma Calculi Blood clots Papillary necrosis (sickle cell disease, diabetes mellitus)
Extrinsic compression	Pelvic tumors Prostatic hypertrophy Retroperitoneal fibrosis or tumors
Acquired anomalies	Urethral strictures Neurogenic bladder Intratubular precipitates Bladder mass or stones

significant and may indicate obstruction) and ultrasound or CT scan of kidneys and urinary tract to evaluate the kidneys, ureters, and bladder for distention or other abnormalities.

The initial goals of therapy are to manage volume status, electrolyte abnormalities, infection, and other complications of obstructive nephropathy and to relieve the obstruction as soon as possible to prevent further damage to the kidney parenchyma. If urinary obstruction is suspected, a catheter should be placed in the bladder to address possible bladder outlet obstruction. If a large postvoid residual volume (>125 mL) is detected, the urinary catheter should remain in place while the cause is ascertained. Occasionally, relief of obstruction is associated with a large postobstructive diuresis that may be sufficient in degree to cause volume depletion and hypotension.

If the obstruction is acute, complete recovery of kidney function can be expected. If the anatomic site of the urinary tract obstruction is above the bladder, more sophisticated approaches to drainage (e.g., percutaneous nephrostomy tube placement) may be required to relieve obstruction.

CYSTIC KIDNEY DISEASES

Kidney cysts are fluid-filled tubular structures lined by a polarized epithelium. They result from defects in the structure and function of renal tubular epithelial cells. Kidney cysts can be solitary or multiple, simple or complex. Cystic kidney disease can be developmental, hereditary or acquired that develops in patients with CKD. Cystic diseases can be localized to kidneys or have systemic manifestations. Depending on the underlying cause of cysts, age of presentation can vary from prenatal to later in life. Cystic kidney diseases are also important causes of ESRD.

Several cellular and molecular mechanisms involved in cystogenesis have been uncovered in recent years. An algorithm for evaluation of kidney cysts is outlined in E-Fig. 27.4.

Simple Cysts

Simple cysts are most common. Widespread use of ultrasonography and CT has resulted in frequent detection of kidney cysts. They are usually unilateral, solitary, well-defined structures, but they can be multiple and bilateral. They tend to be more common among older adults and are often benign, incidental findings on radiographic imaging. Sonography reveals a thin-walled, fluid-filled cavity with no septations or calcifications. The diameter varies between 0.5 and 1.0 cm, but a few may be as large as 3 to 4 cm in diameter.

Diagnosis: Simple cysts are usually asymptomatic but occasionally may result in a palpable abdominal mass, infection, back pain, or hematuria. Differentiation of simple cysts from cysts associated with genetic disorders is based on the cystic pattern, age at detection, and family history.

Treatment: In the absence of symptoms, no treatment is required for simple cysts. If the kidney cyst becomes infected, causes pain, or leads to renin-mediated hypertension, percutaneous drainage is often the first step in further evaluation and management.

Complex Cysts

Differentiation of simple from complex cysts is usually made radiographically. When in doubt, histologic examination is required to exclude malignancy, but imaging is sensitive and specific, and it suffices in most cases. The distinction between complex and simple cysts is important in monitoring the need for intervention because simple cysts are usually benign, whereas complex cysts have a higher risk of malignancy and other complications. In a simple cyst, complications such as hemorrhage or infection can result in the development of features of more complex cysts, including calcification, septa, irregular borders, and multilobularity.

Initial evaluation of kidney cyst includes ultrasonography and, if ultrasound is equivocal, triphasic CT is done to characterize the cyst. If the characteristics of a cyst in terms of size, nodularity, mural enhancement, or septations change over time, the likelihood of malignancy increases.

To help with diagnosis and management, the Bosniak classification of kidney cysts was introduced in 1986 and has been revised since then. This classification, which includes four categories with several important subcategories, based on triphasic CT findings, is described in Table 27.5. Category I and category II cysts are benign. Category II F cysts have a range of reported malignancy rates of 0 to 38% so requires follow-up. The risk increases to almost 50% for category III cysts. Category III and IV renal cysts are considered to be renal carcinoma unless proven otherwise, and they are usually surgically resected. While the current Bosniak classification of kidney cysts predicts likelihood of cancer, it does not assess the aggressiveness of the tumor. With the technological innovations and advancement of knowledge, new proposal for further revision of Bosniak classification was made in 2019.

Acquired Cystic Kidney Disease in CKD

Acquired cystic kidney disease (ACKD) is a disease consequent from long-term CKD. It is defined by three or more cysts per kidney in a patient with CKD or ESRD. The prevalence of ACKD increases with the duration of dialysis, reaching 87% after 10 years of dialysis. Patients of male gender, older age, with history of heart disease, larger kidneys, and kidney calcifications are more likely to develop ACKD.

TABLE 27.5 Bosniak Renal Cyst Classification Scheme

Category	Description
I. Simple cyst	A benign simple cyst with a thin wall and no septa, calcifications, or solid components.
II. Minimally complicated	A benign cystic lesion with a few thin septa. The wall or septa may contain fine calcifications or short segment of a slightly thickened calcification. (This category also includes uniformly high-attenuating lesions that are less than 3 cm in diameter, well marginated, and nonenhancing.)
III. Indeterminate	Well-marginated cysts but more complicated than category II. They have multiple thin septa or minimal smooth thickening of the septa or wall and may contain calcifications that may be thick and nodular. (This category also includes totally intrarenal, nonenhancing high-attenuating lesions that are more than 3 cm in diameter.)
IV. Malignancy	Indeterminate cystic masses that have thickened, irregular, or smooth walls or septa. These lesions are enhancing on computed tomography. Between 40% and 60% of lesions are malignant (e.g., cystic renal cell carcinoma, multiloculated cystic renal cell carcinoma). The remaining lesions are hemorrhagic, chronic, infected cysts or multiloculated cystic nephroma and are benign.
	On computed tomography, they have characteristics of category III cysts and contain enhancing soft tissue components that are adjacent to and independent of the wall or septum on the cyst. Between 85% and 100% of lesions are malignant; evaluation and surgical excision are recommended.

Neither the cause of the underlying ESRD nor the mode of dialysis influences the progression of ACKD. It has been postulated that damage to the kidney parenchyma in CKD increases local growth factors levels that promote hypertrophy and cyst generation in the remaining nephrons. In some cases, increased levels of growth factors and mutated genes (e.g., *ERBB2*) may cause the malignant transformation of cysts, the primary clinical concern in 3% to 7% of ACKD patients.

ACKD-related cyst formation is limited to the kidneys and is an incidental finding on radiographic imaging. Patients with ACKD are usually asymptomatic but may develop infectious or bleeding complications. ACKD can be differentiated from hereditary causes of cystic renal disease by presence of CKD or ESRD and the absence of any other clinical findings.

Patients with ACKD do not require specific treatment. Cysts are managed based on the Bosniak category as discussed in the section on renal cell carcinoma (RCC). Routine screening for ACKD among dialysis patients is contentious but is recommended for patients during their pretransplantation evaluation. Kidney transplant recipients with ACKD should get yearly kidney ultrasound because of higher risk of malignancy due to exposure to immunosuppression and longer life expectancy.

Hereditary Cystic Kidney Diseases

The most common inherited cystic kidney diseases are the polycystic kidney diseases (PKDs), including autosomal dominant and autosomal recessive forms of PKD. Other hereditary cystic renal diseases include autosomal dominant tubulointerstitial kidney disease, Von Hippel–Lindau disease (VHL), and tuberous sclerosis. In the inherited disorders, several mutations have been associated with cyst formation. In PKD, the cysts are not connected to the urinary drainage system, and cellular secretion results in cyst enlargement. Mutation of any of the tubular epithelial–related genes such as *PKD1*, *PKD2*, and mucin-1 (*MUC1*) can result in disruption of normal ciliary function, resulting in cyst formation from over-proliferation of tubular epithelium and increased fluid secretion.

Polycystic Kidney Disease

PKD consists of two main form of monogenetic cystic kidney disease: autosomal dominant polycystic kidney disease (ADPKD) and autosomal recessive polycystic kidney disease (ARPKD). Patients with PKD develop multiple fluid-filled cysts in both kidneys and sometimes in other organs as well. Cysts usually form in the distal segment of the nephron and collecting ducts from outgrowths of kidney epithelial cells, abnormal fluid secretion, and altered cell-matrix interaction. Once the cysts are formed, they detach from the tubules and

TABLE 27.6 Extrarenal Manifestations of ADPKD

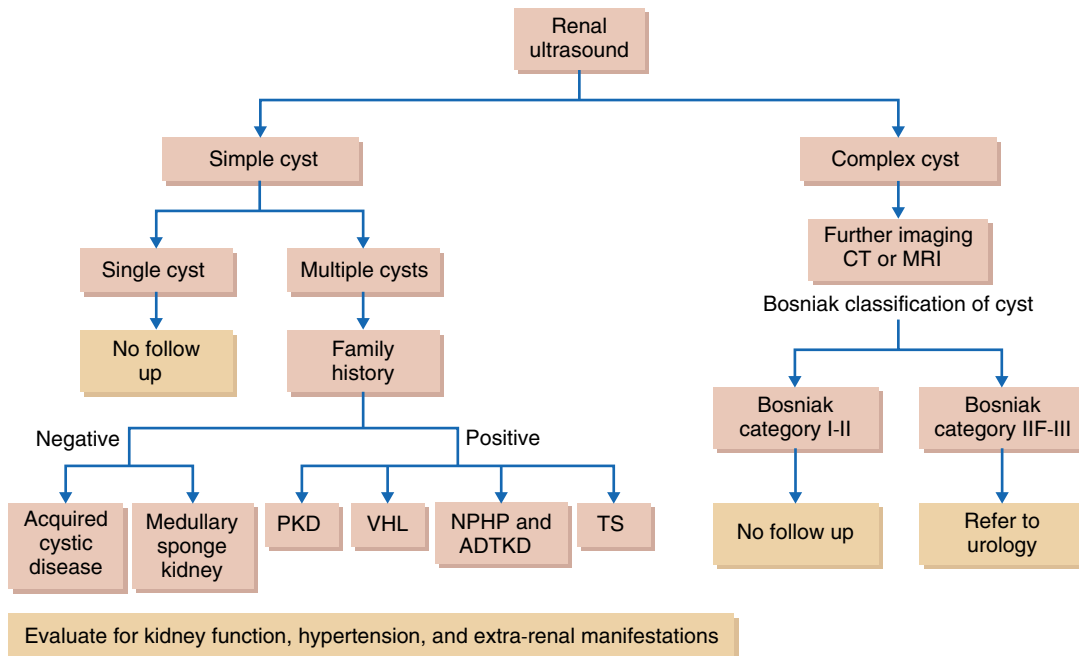

Organ Involved	Manifestations
Liver	Polycystic liver disease
Brain	Intracranial aneurysms
Vascular	Thoracic aortic dissection Coronary artery aneurysm
Cardiac	Valvular heart disease Mitral valve prolapse and regurgitation Tricuspid valve prolapse and regurgitation
Other	Pancreatic cyst Seminal vesicle cyst Colonic and duodenal diverticula

progressively increase in size, compressing nearby nephrons, interstitium, and vessels. Injury to adjacent kidney structures leads to inflammation and fibrosis.

Autosomal Dominant Polycystic Kidney Disease

Definition and epidemiology. ADPKD is the most common cause of cystic renal disease and an important cause of ESRD. The monogenetic, progressive disorder is characterized by multiple cysts in kidneys and other organs, including the liver and pancreas. The incidence of ADPKD is 1 case in 400 to 1000 live births, and between 300,000 and 600,000 Americans are affected by the disease.

Pathology and pathogenesis. Mutations in the *PKD1* and *PKD2* genes are responsible for about 85% and 15% of ADPKD cases, respectively, and there is evidence for important modifier genes. *PKD1* is located on chromosome 14 and encodes the protein polycystin 1 (PC1), which functions as a membrane receptor. *PKD2* is located on chromosome 4 and encodes polycystin 2 (PC2), which functions as a calcium-permeable cation channel (E-Fig. 27.5). PC1 and PC2 regulate intracellular calcium homeostasis and signaling pathways involved in tubular morphogenesis and cell-cell interactions. PC1 and PC2 also are integral membrane proteins of cilia, including the primary cilia of renal tubular cells. ADPKD is now classified under the new class of diseases called *ciliopathies*. In addition to renal tubules, PC1 and PC2 proteins are found in diverse cell types, including bile ducts, endothelial cells, and neurons. Consequently, ADPKD patients with mutated PC1 or PC2 proteins often have extrarenal manifestations (Table 27.6).

E-Fig. 27.4 Algorithm for management of renal cyst. *ADTKD*, Autosomal tubulointerstitial kidney disease; *CT*, computed tomography; *MRI*, magnetic resonance imaging; *NPHP*, nephronophthisis; *PKD*, polycystic kidney disease; *TS*, tuberous sclerosis; *VHL*, Von Hippel-Lindau.

E-Fig. 27.5 Structure of polycystic kidney disease proteins. (Modified from Igarashi P, Somlo S: Genetics and pathogenesis of polycystic kidney disease, *J Am Soc Nephrol* 13:2384-2398, 2002.)

TABLE 27.7 Ultrasonography Criteria of ADPKD

Age	Number of Cysts
<i>Positive family history</i>	≥2 unilateral or bilateral
<30 years	≥3 cysts unilateral or bilateral
30-39 years	≥2 cysts in each kidney
40-59 years	≥4 cysts in each kidney
>60 years	
<i>No family history</i>	>10 cysts in each kidney
16-40 years	

In the kidney, increase in cyst size and number over time damages adjacent renal architecture and causes CKD and renin-mediated hypertension. Total kidney volume increases continuously and is associated with progressive decline of kidney function. Higher rates of kidney enlargement are associated with a more rapid decrease in kidney function.

Clinical presentation. ADPKD is a multisystem disease. The clinical presentation may range from no symptoms to an array of systemic manifestations, including polycystic liver disease, which is detected in about 80% of adults. Cardiac valvular abnormalities and cerebral aneurysms are key noncystic features of ADPKD, and familial clustering of cases occurs. Cerebral aneurysms are observed in about 8% of patients with ADPKD, but the incidence increases to 20% among those with a positive family history of cerebral aneurysm or subarachnoid hemorrhage. ADPKD patients, with positive family history of cerebral aneurysm or sudden death of unknown cause, should be screened for cerebral aneurysm.

Most patients with ADPKD develop cysts before the age of 30, but CKD can be delayed to beyond the fourth decade. Patients with the *PKD2* mutation have later onset and slower progression of the disease than patients with the *PKD1* mutation. Kidney survival associated with *PKD2* mutations is about 20 years longer than that associated with *PKD1* mutations. Besides the cysts, other kidney manifestations of APKD include urinary concentrating defects, hypertension, and nephrolithiasis. Twenty percent of patients with ADPKD can develop uric acid and calcium oxalate nephrolithiasis and may have renal colic, obstructive nephropathy, or urinary tract infection.

Diagnosis. ADPKD is usually diagnosed by imaging of the kidneys. The finding of three or more cysts (unilateral or bilateral) in those younger than age 30, two or more cysts in each kidney in those between 40 and 59 years of age, and four or more cysts in each kidney in patients older than 60 years is sufficient to make diagnosis of ADPKD (Table 27.7). Absence of more than two cysts in individuals older than 40 years of age makes ADPKD very unlikely. Genetic testing is usually not required for an individual with a positive family history if other diagnostic criteria for ADPKD are met, but other family members should be screened with ultrasound of kidneys.

Treatment. Total kidney volume correlates with disease manifestation of PKD. No specific treatment is available to prevent the growth of kidney or liver cysts. Tolvaptan, a vasopressin receptor 2 inhibitor, has been recently approved to slow progression of kidney disease in PKD. Given the high cost and side effect profile of the drug, it should only be given to select patients with ADPKD who will likely benefit most from it. Due to hepatotoxicity, use of tolvaptan requires close monitoring of liver enzymes. Other interventions include enhanced hydration; maintenance of healthy weight; decrease in sodium, protein, and caffeine intake; and treatment of hypertension and dyslipidemia, which may delay the progression of renal disease. Renin-mediated hypertension is a common complication of ADPKD, and it contributes

to an increased incidence of cardiovascular mortality and faster progression to ESRD. The main and most effective therapy remains control of hypertension by angiotensin-converting enzyme inhibitors or angiotensin-receptor blockers to achieve a target blood pressure of less than 125/75 mm Hg. Dual blockade with angiotensin-converting enzyme inhibitors and angiotensin-receptor blockers does not provide any additional benefit and increases risk of hyperkalemia.

Renal cyst enlargement can cause pain, and cysts can be complicated by infection or bleeding that warrants specific intervention. Surgical decompression is usually reserved for patients who fail conservative management. If ESRD occurs, patients are treated with renal replacement therapy, including dialysis and kidney transplantation. Preemptive management of intracranial aneurysms is important but controversial.

Prognosis. The time of onset and rate of progression of ADPKD varies from patient to patient, even within the same family. Risk factors for progressive CKD include increases in kidney cyst volume, a *PKD1* gene mutation, and uncontrolled hypertension. Other risk factors include male gender, diagnosis of ADPKD before 30 years of age, hypertension before 35 years of age, concurrent diabetes mellitus, and hematuria. About 45% of the patients with ADPKD develop ESRD by 60 years of age, but they have a better prognosis than patients with ESRD from other causes.

Autosomal Recessive Polycystic Kidney

Definition and epidemiology. ARPKD also is classified under the ciliopathies. ARPKD is characterized by diffuse dilation of the collecting ducts and congenital hepatic fibrosis. The estimated incidence of ARPKD is 1 case in 20,000 live births.

Pathogenesis. Mutations in *HNF1B* and the polycystic kidney and hepatic disease 1 gene (*PKHD1*) are responsible for ARPKD. *PKHD1* is a large gene located on chromosome 6. More than 300 mutations have been identified at different loci of the *PKHD1* gene. Fibrocystin (i.e., polyductin) is the product of *PKHD1* and is expressed in the primary cilia of the thick ascending limb, in cortical and medullary ducts in the kidney, and in hepatic bile ducts. It has an important role in the terminal differentiation of kidney and biliary ductules.

Clinical presentation. ARPKD, phenotypically, is highly variable. Patients with ARPKD may be diagnosed at different ages, but those with a more severe phenotype present in utero or at birth because they develop enlarged kidneys, oligohydramnios, pulmonary hypoplasia, Potter facies (flattened nose, recessed chin, epicanthal folds, and low-set ears), and deformities of the spine and limb. Neonates usually have kidney enlargement and kidney failure, and older patients have liver disease, including portal hypertension, hepatosplenomegaly, variceal bleeding, and hepatic fibrosis.

Differential diagnosis. The initial diagnosis is usually suspected on the basis of kidney imaging with antenatal or infantile ultrasound. Abdominal ultrasound shows bilateral enlarged kidneys with multiple cysts. Fetal imaging shows oligohydramnios, pulmonary hypoplasia, and Potter syndrome. Although molecular diagnostic analysis is the gold standard for diagnosing ARPKD, it is difficult to perform due to the high level of heterogeneity of the *PKHD1* gene.

Treatment and prognosis. No treatment is available for ARPKD, and genetic testing is usually not performed outside of research scenarios. Most deaths occur in utero or at the time of birth, and of those with ARPKD who survive birth, 20% to 30% die within the first year of life. Neonates have more kidney manifestations, and older patients have more liver disease manifesting as portal hypertension, hepatosplenomegaly, and bleeding esophageal or gastric varices. The likelihood of patients being alive without ESRD increases with older age at presentation due to their more benign phenotypes. Due to autosomal recessive inheritance, recurrence risk of ARPKD in subsequent pregnancies of parents of an ARPKD child is 25%.

Juvenile Nephronophthisis and Autosomal Dominant Tubulointerstitial Kidney Disease

Definition and epidemiology. Nephronophthisis (NPHP) and autosomal dominant tubulointerstitial kidney disease (ADTKD) are hereditary forms of cystic kidney disease. Both produce bilateral cysts at the corticomedullary junction of the kidney and are associated with progressive CKD and ESRD. They are clinically and pathologically indistinguishable, and they are separated only by the age of onset and mode of inheritance.

NPHP is an autosomal recessive cystic kidney disease, and the median age of onset of renal disease is 11.5 years. ADTKD has an autosomal dominant pattern of inheritance, and the median age of onset of renal disease is 28.5 years. NPHP is more common than ADTKD and is the most common cause of ESRD in the first 3 decades of life.

Pathogenesis. Several genes are associated with the NPHP and ADTKD phenotypes. Functional defects of any of the proteins associated with these genes can lead to ciliary dysfunction and development of multiple cysts. Mutations in at least three genes—*MUC1*, *REN*, and *UMOD* encoding mucin-1, renin, and uromodulin, respectively—can lead to ADTKD. *UMOD* gene mutation is the most common mutation and patients with this mutation develop gout at an early age along with CKD. NPHP is caused by mutations in at least 20 genes encoding proteins that are associated with cilia, basal bodies, and centromeres. Mutation of *NPHP1* is the most common mutation, reported in approximately 20% of the patients, whereas other mutations contribute to less than 3% each.

Clinical presentation. The three clinical forms of NPHP are based on the onset of ESRD: an infantile form with a median onset at 1 year of age, a juvenile form with a median onset at 13 years of age, and an adolescent form with a median onset at 19 years of age. Some children may present with extrarenal symptoms: retinitis pigmentosa (Senior-Løken syndrome), mental retardation, cerebellar ataxia, bone anomalies, or liver fibrosis. Situs inversus and ventricular cardiac septal defect can also be present in the infantile form of NPHP. In patients with ADTKD, symptoms usually develop in the fourth or fifth decade of life and include hematuria, infection or nephrolithiasis. ESRD develops between the ages of 50 and 70 years.

Differential diagnosis. The diagnosis of NPHP or ADTKD is based mainly on clinical features. Medullary cysts, a low urinary specific gravity, and absence of significant proteinuria may suggest either disease. Genetic testing is available for several gene mutations and can be applied based on the age at presentation. Siblings can be screened by kidney ultrasound and urine concentration test results. Kidney biopsy is usually not indicated because the findings of interstitial fibrosis and tubular atrophy are nonspecific.

Treatment and prognosis. No specific treatment is available for NPHP or ADTKD, and treatment is mainly supportive. The time of onset of ESRD varies between 30 and 60 years, depending on the type of mutation. Sodium supplementation for salt wasting, allopurinol for gout, and dialysis or renal transplantation for ESRD are part of supportive care. NPHP and ADTKD do not recur after renal transplantation.

Medullary Sponge Kidney

Medullary sponge kidney (MSK), also known as Lenarduzzi-Cacchi-Ricci disease, is a relatively uncommon cystic disorder. It usually occurs sporadically, but familial cases have been reported. MSK is characterized by ectasia and cystic dilation of medullary and papillary collecting ducts, resulting in a spongy appearance of the kidney on imaging. MSK is associated with urinary acidification and concentration defects, a high risk of nephrocalcinosis and kidney stones, and a

moderate risk of urinary infections and CKD. The prevalence of MSK is 1 case in 5000 persons in the general population, and 15% to 20% of patients with nephrolithiasis have MSK.

No clear genetic basis for MSK has been established. MSK is usually detected between the ages of 30 and 50 years. Most patients with MSK are asymptomatic and may have incidental findings on imaging. The clinical course is benign and is usually not associated with ESRD.

When suspected, CT urography has replaced intravenous urography as the imaging study of choice for the diagnosis of MSK. There is retention of contrast media in renal pyramids and cystic collecting ducts, giving the appearance of blush or diffused linear striations. Nephrocalcinosis is common in patients with MSK but is not required to make the diagnosis of MSK. CT imaging may help in excluding papillary necrosis, ADPKD, obstruction, or pyelonephritis.

TUBEROUS SCLEROSIS

Definition and Epidemiology

Tuberous sclerosis complex (TSC) (i.e., Bourneville disease) is an autosomal dominant genetic disorder that affects adults and children. TSC causes benign tumors to form in multiple organ systems, including the skin, brain, and kidneys. TSC is often characterized by related neurologic disorders such as epilepsy and mental retardation.

The prevalence of TSC in the general population is approximately 1 in 10,000 and 50% to 65% of cases are sporadic. Because TSC has an autosomal dominant pattern of inheritance, there is a 50% risk of siblings being affected. Genetic counseling is important for affected families. The overall diagnosis and management of TSC is discussed in [Chapter 115](#).

Pathology

TSC is caused by inactivating mutations in the *TSC1* or *TSC2* genes, located on chromosome 9, and chromosome 16, adjacent to the *PKD1* gene, respectively. They, respectively, encode the hamartin and tuberin proteins, which together form a complex that regulates specific cellular growth, motility, and migration of cells. Inactivating mutations of the *TSC1* or *TSC2* genes result in disruption of these processes and may cause unrestricted growth of cells and tumorigenesis.

TSC conveys a lifetime risk of 2% to 3% for RCC. Kidney tumors are usually bilateral and occur at an early age. More commonly, the tumors are benign angiomyolipomas, composed of abnormal, thick-walled vessels, smooth muscle cells, and adipose tissue, seen in about 80% of patients with TSC by the age of 10 years. These benign kidney tumors often require no treatment. However, they can grow, become locally invasive, and cause bleeding, pain, and hypertension.

Conclusive guidelines for surveillance are unavailable, but annual magnetic resonance imaging of kidney and brain lesions is suggested until the age of 21 years and then every 2 to 3 years to monitor their growth. Patients with progressive lesions should have yearly imaging. If the angiomyolipomas become locally invasive or cause bleeding, surgical intervention is needed.

Mutations in the *TSC1* or *TSC2* gene cause constitutive activation of mTOR. Everolimus, an inhibitor of mTOR, has been approved for the treatment of patients with TSC-associated subependymal giant cell astrocytomas, who are not surgical candidates.

VON HIPPEL–LINDAU DISEASE

VHL is an autosomal dominant disease that affects multiple organ systems. It is caused by germline mutations in *VHL*, a tumor suppressor gene located on chromosome 3. This mutation predisposes to RCC and to tumor formation in other organs, including the eyes, cerebellum, spinal cord, adrenal glands, epididymis, and pancreas. VHL

TABLE 27.8 TNM Staging System of Renal Cell Carcinoma

Primary Tumor (T)			
TX	Primary tumor cannot be assessed		
T0	No evidence of primary tumor		
T1	Tumor <7 cm and limited to the kidney		
T1a	Tumor <4 cm and limited to the kidney		
T1b	Tumor >4 cm but <7 cm and limited to the kidney		
T2	Tumor >7 cm and limited to the kidney		
T2a	Tumor >7 cm but <10 cm and limited to the kidney		
T2b	Tumor >10 cm and limited to the kidney		
T3	Tumor extends into major veins or perinephric tissues but not into the ipsilateral adrenal gland and not beyond Gerota fascia		
T3a	Tumor grossly extends into the renal vein or its segmental branches, or tumor invades perirenal and/or renal sinus fat but not beyond Gerota fascia		
T3b	Tumor grossly extends into the vena cava below the diaphragm		
T3c	Tumor grossly extends into the vena cava above the diaphragm or invades the wall of the vena cava		
T4	Tumor invades beyond Gerota fascia, including contiguous extension into the ipsilateral adrenal gland		
Regional Lymph Nodes (N)			
NX	Regional lymph nodes cannot be assessed		
N0	No regional lymph node metastasis		
N1	Metastasis in regional lymph node(s)		
Distant Metastasis (M)			
M0	No distant metastasis		
M1	Distant Metastasis		
Anatomic Stage/Prognosis Groups			
Stage I	T1	N0	M0
Stage II	T2	N0	M0
Stage III	T1 or T2	N1	M0
	T3	N0 or N1	M0
Stage IV	T4	Any N	M0
	Any T	Any N	M1

affects approximately 1 in 40,000 births, and about 7000 patients are affected in the United States. There is an important association with pheochromocytoma in some patients with VHL that warrants consideration.

RCC occurs in up to 70% of patients with VHL. It is usually bilateral and the clear cell type. RCC affects younger patients with a mean age at presentation of 26 years. For a high-risk patient, the diagnosis of VHL is suggested by central nervous system or retinal hemangioblastoma, RCC, or pheochromocytoma. These patients should be referred for detailed assessment. When indicated, genetic testing can be performed to assess possible mutations of the *VHL* gene.

KIDNEY TUMORS

Each year, approximately 74,000 new cases of renal cancer are diagnosed and 15,000 deaths from RCC are reported in the United States. Most cases are sporadic, but there is an association between RCC and VHL and tuberous sclerosis that has helped to explain the cellular mechanisms involved.

RCC originates from renal epithelial cells and accounts for 85% of renal cancers. Based on histology, the five subtypes are clear cell, papillary (chromophilic), oncocytoma, collecting duct (Bellini duct), and chromophobe RCC. Clear cell carcinoma is the most common subtype and accounts for about 75% to 85% of all cases.

The classic triad of symptoms of flank pain, hematuria, and a palpable flank mass is uncommon (10%). About 50% of cases are identified

as a result of an incidental finding on radiographic imaging. Other clinical symptoms are nonspecific and include fatigue, anemia, and weight loss. Paraneoplastic syndromes associated with RCC include erythrocytosis (due to overproduction of erythropoietin), hypercalcemia (due to excess parathyroid hormone–related peptide), hepatic dysfunction (Stauffer syndrome), and cachexia.

The initial diagnosis of RCC is usually made by imaging. Unlike simple cysts, which are anechoic, round, and smooth walled, RCC is more likely to be a septate, irregular, thick-walled mass. When RCC is suspected, additional evaluation by CT urography or magnetic resonance imaging is usually required, along with complete staging and evaluation for metastases (Table 27.8). Biopsy is usually reserved, to confirm the diagnosis for medical treatment, for the patients who are not surgical candidates.

When possible, the primary treatment of localized RCC is surgical resection, which usually includes complete or partial nephrectomy. Locally advanced or metastatic RCC is treated medically with chemotherapy and immunomodulatory therapy with interleukin-2. Newer therapies include tyrosine kinase inhibitor (Sunitinib) and two immune checkpoint inhibitors, nivolumab and ipilimumab.

The prognosis for RCC depends primarily on the clinical stage at the time of presentation as assessed by the tumor-node-metastasis (TNM) criteria. TNM stages I through III have a better prognosis than TNM stage IV (metastatic) RCC. Poor prognostic factors include a lower Karnofsky performance status, elevated lactate dehydrogenase level, low hemoglobin level, and hypercalcemia. With documented

metastases, the 1-year survival rate is 12% to 71%, and the 3-year survival rate is 0% to 31%, but in the past decade with availability of newer drugs, survival has improved (see Chapter 59).

NEPHROLITHIASIS

Nephrolithiasis is a major public health problem. It imposes a substantial burden on human health and considerable financial expenditure for the nation. Calcium-containing stones are the most common stones, comprising approximately 80% of all stones. Uric acid, struvite, and cysteine stones are less common, accounting for approximately 9%, 10%, and 1% of all stones, respectively, but have high recurrence rates.

Epidemiology

The prevalence of stones has been substantially increasing. National Health and Nutrition Examination Survey (NHANES) demonstrated an increase in self-reported prevalence of kidney stones in the United States from 3.2% in 1976 to 1980, to 8.8% in 2007 to 2010, to 10.1% in 2014. Moreover, the incidence of kidney stones is also increasing and is estimated to be approximately 0.5% in North America and Europe. Diet and lifestyle factors likely play significant roles in the changing epidemiology.

Nephrolithiasis increases with age. It is more common in men than in women; however, in the last 2 decades, the male to female ratio has changed from 3:1 to about 2:1. Comparison of NHANES data over time showed prevalence of kidney stones was stable in males but increased in females, with the most significant increase noted in females of child-bearing age. Epidemiologic studies have noted a relationship between nephrolithiasis and metabolic syndrome, and the magnitudes of this association were greater for women compared with men. This may be one plausible explanation for the increasing incidence of kidney stones among women. The prevalence is higher in Caucasian males, intermediate in Hispanic and Asian males, and less frequent in black males. The highest risk of stone formation has been reported in men in the United Arab Emirates and Saudi Arabia and has been attributed to genetic and environmental factors. Stone recurrence is common with the relapse rate of kidney stones being 50% in 5 to 10 years and 75% in 20 years. Risk factors associated with recurrent stone formation include younger age of onset, positive family history, underlying medical conditions, and urinary infections. The Recurrence of Kidney Stone (ROKS) nomogram provides a clinical tool to estimate the risk of recurrence in first-time symptomatic stone formers. It uses participants' characteristics at baseline to estimate recurrence at varying times, thus identifying those who may benefit from dietary and medical interventions. An electronic version of the ROKS nomogram is available at https://qxmd.com/calculate/calculator_3/roks-recurrence-of-kidney-stone-2014.

Pathogenesis

Stone formation occurs as a result of supersaturation of urinary solutes, expressed as the ratio of solute concentration in urine to its known solubility. A ratio of greater than 1 indicates that urine is supersaturated with the given substance and promotes crystallization, whereas a ratio of less than 1 inhibits crystallization. Low urine volume increases supersaturation of all solutes, thereby promoting stone formation. Urine pH influences free ion activity. The main determinants for crystallization vary for different stones: low urine volume and high urinary calcium and oxalate concentration promote calcium oxalate crystals, whereas alkaline urine and high urinary calcium concentrations promote calcium phosphate crystals. Acidic urine is the main determinant for uric acid crystals, and for cystine crystals it is high urinary cystine concentration and acidic urine. Urine contains substances such as citrate, pyrophosphate, magnesium, Tamm-Horsfall glycoprotein, glycosaminoglycans, osteopontin, and calgranulin that can inhibit

TABLE 27.9 Medications Associated With Stone Formation

Mechanism	Medication
Hypocitraturia	Acetazolamide
	Zonisamide
	Vitamin C
	Topiramate
Hypercalciuria	Vitamin D
	Antacids
	Theophylline
	Nifedipine
Hyperuricosuria	Probenecid
	Aspirin
Precipitation within the tubule	Indinavir
	Atazanavir
	Acyclovir
	Sulfadiazine
	Triamterene
	Guaifenesin/ephedrine

crystal aggregation in urine. Of these, citrate is the only inhibitor that can be measured and modified in clinical settings; thus, it is a focus of therapeutic intervention.

Clinical Presentation

Patients are often asymptomatic, and calculi are detected as an incidental finding on imaging studies. Flank pain with or without gross hematuria is the most common presentation. Pain can vary in intensity from mild to severe and is classically abrupt in onset, paroxysmal, waxing and waning. Other associated symptoms include dysuria, urgency, nausea, and vomiting. Location of pain is suggestive of site of obstruction and may vary as the stone migrates. Upper ureteral obstruction (as in the ureteropelvic region) can cause flank pain, while lower ureteral obstruction can cause pain to radiate to the ipsilateral testes or labium. Some patients may pass gravel, more typical with uric acid stones. Complications associated with nephrolithiasis include obstruction, hydronephrosis, infection, and AKI from obstructive uropathy in the setting of bilateral obstruction or unilateral obstruction in case of the solitary kidney. Conditions that can mimic renal colic include ectopic pregnancy in women, bleeding within the kidney leading to formation of clots, hemorrhagic cysts, loin pain hematuria syndrome, and malingering.

Diagnosis

Detailed history is crucial and should include age at the first episode, number of stones, bilateral or unilateral stones, frequency of stone formation, type of stone if known, type and number of surgical interventions, family history of stone disease, and any associated infections. Certain clues elucidated on history may point towards a systemic etiology for nephrolithiasis; for example, patients with malabsorptive states may be predisposed calcium oxalate stones. History should also include detailed dietary habits, including amount of fluid intake, dietary sodium, protein, oxalate, and calcium intake to determine the potential cause or contributors of stone formation. Certain medications can potentiate stone formation and are shown in Table 27.9. Except during an acute episode of stone passing, most patients will have a normal physical examination. However, physical examination may sometimes reveal findings of systemic condition such as presence of tophi in patients with hyperuricosuria and uric acid stones.

Laboratory testing should include complete metabolic profile and uric acid. Hypokalemia and metabolic acidosis are suggestive of RTA.

TABLE 27.10 Urinalysis and Radiographic Findings of Renal Calculi (see also E-Fig. 27.6)

Stone Type	Urine Microscopy	Radiologic Findings
Calcium oxalate monohydrate	Dumbbell shaped, appear coarse, needle-like under polarized light	Opaque, round, multiple calculi
Calcium oxalate dihydrate	Envelope-shaped	
Struvite, magnesium aluminum phosphate	Coffin lid shaped	Opaque, may be staghorn
Uric acid	Pleomorphic, often rhomboid plates or rosettes	Radiolucent
Cystine	Hexagonal	Opaque

TABLE 27.11 Treatment Modalities for Different Nephrolithiasis Risk Factors

Urinary Abnormality	Dietary Change	Medication
Hypercalciuria	Adequate dietary calcium intake Reduce animal protein intake Reduce sodium intake to <2 g/day	Thiazide diuretic
Hyperoxaluria	Adequate dietary calcium intake Avoid high oxalate foods	Consider vitamin B ₆ (Pyridoxine)
Hyperuricosuria	Reduce purine intake	Allopurinol
Hypocitraturia	Increase fruit and vegetable intake Reduce animal protein intake	Potassium citrate (alkali)
Low urine volume	Increase fluid intake Goal urine output is >2-2.5 L per day.	

If hypercalcemia is noted, parathyroid hormone should be checked to assess for primary hyperparathyroidism. A careful urinalysis should be performed, and certain findings may point toward a specific diagnosis (Table 27.10 and E-Fig. 27.6). Uric acid crystals are formed in acidic urine, whereas calcium phosphate and struvite crystals are formed in alkaline urine. High urine specific gravity is suggestive of inadequate fluid intake. In patients with suspected struvite stones, urine culture should be obtained. Retrieving the stone for chemical analysis is essential to help identify the type of stone and thus guide therapy. All patients should strain their urine and retrieve any stone. A 24-hour urine collection is the cornerstone of evaluation in patients with nephrolithiasis and includes urine volume, pH, calcium, magnesium, potassium, uric acid, citrate, oxalate, sodium, urea nitrogen, ammonium, sulfate, phosphate, and creatinine (to assess the completeness of the collection). Preferably two collections should be done in outpatient settings when the patients are consuming their usual diet. Because individuals tend to change their dietary habits after an acute episode, the collection should be performed 6 weeks after an episode of renal colic. Urine collection should be repeated periodically to assess the impact of dietary changes and therapeutics.

Noncontrast helical CT has replaced intravenous urography (or intravenous pyelogram) as the diagnostic test of choice for evaluation of kidney stones. CT can detect both radiopaque and radiolucent stones with high sensitivity and specificity. Ultrasound can also detect radiolucent and radiopaque stones in kidneys but may miss ureteral stones. Ultrasound has a role in evaluating stones in pediatric and pregnant patients.

Treatment

Small (<4 mm), nonobstructive stones can be managed conservatively because they have a good chance passing spontaneously. With increase in stone size there is a progressive decrease in the spontaneous passage rate from 55% for stones smaller than 4 mm, to 35% for 4- to 6-mm stones, and 8% for stones greater than 6 mm, respectively.

During an acute colic episode, pain management is essential and can be controlled with use of NSAIDs or narcotics. Patients should

be instructed to increase their fluid intake in order to increase their urine output to at least 2 liters per day to hasten stone passage. α -1 Adrenergic-receptor blockers and calcium-channel blockers can be used to facilitate stone passage. α -1 Adrenergic-receptor blockers decrease ureteral smooth muscle tone as well as frequency and force of peristalsis, whereas calcium-channel blockers suppress smooth muscle contraction and reduce ureteral spasm. Presence of any signs of urinary tract infection, inability to take oral fluids, or obstruction of a single functioning kidney requires hospitalization. In the presence of AKI, anuria, or sepsis with an obstructive stone, urgent urologic consultation should be obtained. Urology consult should also be obtained for stones larger than 10 mm, failure of conservative management, and presence of anatomic abnormalities that would prevent passage of the stone. Type of surgical intervention is determined by stone size, type, location, and presence of infection. For proximal ureteral stones, both shock-wave lithotripsy and ureteroscopy are first-line therapy. Shock-wave lithotripsy is most effective for smaller (<10 mm) calculi. For mid- or distal ureteral stones, ureteroscopy is first-line therapy. Shock-wave lithotripsy has lower morbidity and lower complication rates compared to ureteroscopy; however, the latter has a greater stone-free rate with a single procedure. Percutaneous nephrolithotomy is recommended for larger (>20 mm) or complex calculi (e.g., staghorn calculi).

Prevention of Stones

General measures to prevent recurrent stones include increasing fluid intake to greater than 2 to 2.5 L/day and limiting dietary sodium intake to less than 2 g/day and protein intake to 0.8 to 1 g/day. Dietary calcium restriction is not recommended because calcium in food binds to oxalate in the bowel and reduces urinary excretion of the highly lithogenic oxalate. On the other hand, additional calcium supplements in between meals should be avoided in patients with calcium stones.

Specific Types of Stones

Specific treatment modalities may be implemented when the metabolic risk factors for stone formation are identified (Table 27.11).

TABLE 27.12 Principle Risk Factors for Formation of Calcium Stones

Low urinary volume
High urinary oxalate
High urinary calcium
Low urinary citrate
Dietary factors
Low dietary intake of fluids, calcium, phytates, potassium
High intake of oxalates, sodium, protein, sucrose
Medical conditions: obesity, metabolic syndrome, diabetes mellitus, primary hyperparathyroidism, gout, medullary sponge kidneys

Calcium Stones

Approximately 80% of stones are calcium stones, most of which are composed primarily of calcium oxalate, mixed oxalate and phosphate, and less often, pure calcium phosphate. Calcium oxalate supersaturation is not pH-dependent in the physiologic range whereas alkaline urine promotes calcium phosphate supersaturation. The pathophysiologic mechanisms for calcium kidney stone formation are complex, diverse, and can be associated with a number of metabolic derangements (Table 27.12).

Hypercalciuria. Hypercalciuria is the most common metabolic abnormality found in recurrent calcium stones formers, detected in 30% to 60% of adults with nephrolithiasis. It is defined as calcium excretion 250 mg/day or greater in women and 300 mg/day or greater in men. It is most often familial or idiopathic. Gut calcium absorption is increased in persons with idiopathic hypercalciuria, but serum calcium values remain unchanged as the absorbed calcium is promptly excreted. There are three primary pathophysiologic mechanisms for hypercalciuria. (1) Increased intestinal calcium absorption (absorptive hypercalciuria), which is the most common abnormality. (2) Enhanced calcium mobilization from bone (resorptive hypercalciuria), which leads to urinary loss of bone calcium. This can be seen in patients with primary hyperparathyroidism, immobilization, and metastatic tumors. (3) Decreased renal calcium reabsorption (renal leak), the pathogenesis of which is unclear and is thought to be due to a primary defect in renal tubular absorption of calcium. High sodium intake results in decrease in proximal sodium reabsorption. The ensuing urinary sodium excretion results in physiologic increase in calcium excretion, thus promoting stone formation. High animal protein intake can lead to increased acid load, causing calcium release from bones and resulting in increased urinary calcium excretion. Moreover, acidosis resulting in decreased tubular calcium reabsorption and depletion of urinary citrate.

Thiazide diuretics are commonly used to decrease urine calcium excretion in recurrent calcium stone formers. They are effective in treating hypercalciuria and reducing stone recurrence regardless of the underlying pathophysiologic mechanism. They cause volume contraction-induced increased proximal tubule calcium absorption. Thiazides can cause hypokalemia-induced hypocitraturia; therefore they should be supplemented with potassium. Potassium citrate has an advantage over other agents because it provides both potassium and citrate.

Hyperoxaluria. Hyperoxaluria (>45 mg/day in women and 55 mg/day in men) is detected in 10% to 50% of calcium stone formers. Hyperoxaluria increases calcium oxalate supersaturation and thus promotes calcium oxalate stone formation. Hyperoxaluria can result from increased dietary intake, increased gastrointestinal absorption of oxalate, or overproduction of oxalate as a result of an inborn error in metabolism. Foods known to increase urinary oxalate excretion include rhubarb, spinach, potatoes, beetroot, most nuts, chocolate,

tea, raspberries, figs, plums, and high amounts of vitamin C. Enteric hyperoxaluria occurs in patients with malabsorption of fat, which leads to binding of dietary calcium to excessive enteric fat, and subsequent increase in absorption of free oxalate in the colon. This is commonly seen in patients with chronic diarrhea, inflammatory bowel diseases, celiac disease, and intestinal resection or after bariatric surgery. In patients with enteric hyperoxaluria, cholestyramine can be used to bind bile acids and oxalate; however, it is not always well tolerated. Other concomitant stone risk factors include low urine volume, acidic urine, and hypocitraturia. Rarely, hyperoxaluria is caused by inborn errors in metabolism such as primary hyperoxaluria, a rare autosomal recessive genetic disorder of oxalate synthesis. Type I primary hyperoxaluria is more common and often presents in childhood with nephrolithiasis, nephrocalcinosis, and kidney failure. Type II primary hyperoxaluria has a milder course with similar clinical manifestations.

Treatment measures include a low-oxalate diet and increased calcium intake with meals to bind intestinal oxalate and prevent its absorption. Patients should be advised to avoid excessive vitamin C (>500 mg/day). In addition, for patients with enteric hyperoxaluria, measures to reduce steatorrhea such as low-fat diet, cholestyramine, and administration of medium-chain triglycerides should be instituted. Liver transplant is the definitive therapy for patients with primary hyperoxaluria. Pyridoxine, which promotes conversion of glyoxylate to glycine, may reduce oxalate production in patients with type I primary hyperoxaluria. *Oxalobacter formigenes*, a colonic bacteria that uses oxalate for cellular metabolism, has been shown to be associated with a decreased risk of recurrent calcium oxalate stone formation, presumably because the bacterium degrades oxalate, prevents its absorption, and thus promotes excretion. However, a randomized control trial comparing use of *Oxalobacter formigenes* to placebo in patients with primary hyperoxaluria did not show reduction in urinary oxalate levels.

Hypocitraturia. Citrate, an endogenous inhibitor of calcium stone formation, is the only inhibitor that is measured and can be modified in clinical settings. It is a tricarboxylic acid that mostly stems from endogenous oxidative metabolism, freely filtered through the glomerulus and actively reabsorbed in the proximal tubule. Citrate binds to urinary calcium to form a soluble complex and thus prevents precipitation of calcium with oxalates or phosphates. Citrate also directly inhibits crystal aggregation. Hypocitraturia, defined by citrate concentration of less than 325 mg/day, can be a consequence of metabolic acidosis, high protein intake, carbonic anhydrase inhibitors, hypokalemia, or as an idiopathic disorder. Fall in tubular fluid pH results in conversion of trivalent citrate anion into the divalent anion, which is more easily reabsorbed via the sodium-citrate cotransporter in the luminal membrane. In addition, acidosis results in increased cell citrate utilization and upregulation of proximal renal tubular reabsorption of citrate leading to hypocitraturia.

Both potassium and sodium alkali supplementation can effectively raise urinary pH and citrate. However, potassium citrate is more effective in preventing calcium stone formation compared to sodium citrate because the sodium load can worsen hypercalciuria. Required dose for potassium citrate is 15 to 25 mmol two or three times a day. One potential concern with alkali therapy is the risk of calcium phosphate stone formation. In addition, among patients with reduced kidney function, serum potassium needs to be monitored closely for hyperkalemia.

Calcium Phosphate Stones

Calcium phosphate stone formation is a result of hypercalciuria, hypocitraturia, and persistently alkaline urine. Calcium phosphate stones can be seen in conditions causing distal RTA (inherited defects,

E-Fig. 27.6 Microscopic images of various crystals in urine sediment. (A) Dumbbell-shaped calcium oxalate monohydrate crystals. (B) Envelope-shaped calcium oxalate dihydrate crystals. (C) Calcium oxalate dihydrate (left) and calcium oxalate monohydrate (right). Calcium oxalate monohydrate showing strong birefringence on polarized light (bottom). secondary to autoimmune conditions or idiopathic), with use of carbonic anhydrase inhibitors such as acetazolamide (which reduces bicarbonate reabsorption in the proximal tubule), or with use of antiepileptic drugs that have carbonic anhydrase inhibitory activity such as topiramate and zonisamide. In patients with distal RTA, correction of the systemic acidosis with oral alkali (usually potassium citrate or potassium bicarbonate) is recommended with the goal of increasing serum bicarbonate level and urinary citrate excretion. Administration of alkali to maintain the serum bicarbonate level with the risk associated with a higher urine pH should be balanced. Urinary pH should be monitored closely on alkali therapy and not increased above 7 (because of increased risk for precipitating calcium phosphate crystals). A thiazide diuretic can be added to lower urinary calcium if stone formation persists, even if the urine calcium is in the “normal” range or when low bone density is present. Among patients with stone disease due to the administration of medications, discontinuation of the medication, if feasible, will prevent new stone formation.

Uric Acid Stones

The three major urinary abnormalities causing uric acid precipitation are low urinary pH (urine pH <5.5), low urine volume, and hyperuricosuria (defined as uric acid excretion >800 mg/day in men and >750 mg/day in women). Acidic urine is a more important risk factor for uric acid stones than hyperuricosuria. In low urinary pH the relatively soluble urate gets converted into insoluble uric acid, thereby facilitating lithogenesis. Excessive acid load (high animal protein diet) or chronic bicarbonate loss in patients with chronic diarrhea can result in low urinary pH, thus increasing the propensity for uric acid stone formation. Increased incidence of uric acid stones can be seen in patients with insulin resistance and type 2 diabetes mellitus and has been linked to impaired ammonia synthesis resulting in reduced urinary pH. Hyperuricosuria may be seen in certain clinical conditions such as myeloproliferative disorders, tumor lysis syndrome, and rare genetic disorders of uric acid synthetic pathway or mutations in renal uric acid transporters.

Alkaline therapy along with increasing urine volume is the most effective treatment of uric acid stones. Potassium citrate 30 to 80 mmol in divided doses is prescribed to maintain urine pH greater than 6.5 to 7. Raising the urinary pH to greater than 7 may result in calcium phosphate precipitation and should be avoided. Other measures to decrease uric acid excretion and raise urinary pH include low animal protein and low purine diet. In situations where marked hyperuricosuria persists despite dietary measures, xanthine oxidase inhibitors such as allopurinol at doses of 100 to 300 mg/day can be prescribed.

Struvite Stones

Struvite stones or triple phosphate stones are composed of magnesium ammonium phosphate and calcium carbonate-apatite. They can grow rapidly and if left untreated can fill the entire renal pelvis (i.e., staghorn calculi) and may lead to CKD and ESRD. These stones result from chronic urinary tract infections with urea-splitting organisms (Table 27.13), which increase the urine pH by generating ammonium to produce stones composed of ammonium-magnesium-phosphate.

The cornerstone of treatment for struvite stones includes early surgical removal of the bacteria-laden stones and eradicating the infection with antibiotics. Also, it is important to define and treat any metabolic abnormality. Acetohydroxamic acid, a urease inhibitor, is the only drug approved for the treatment of infectious kidney stones; however, its use is limited by its side effects such as headache, thrombophlebitis, tremor, nausea, vomiting, rash, abdominal discomfort, anemia, and reticulocytosis. This treatment should only be used if other measures are ineffective. Medical management alone for struvite stones is rarely

successful and is not recommended unless patients are too ill for surgery or refuse stone removal.

Cystine Stones

Cystinuria is the most common of the rare hereditary kidney stone diseases and is caused by an autosomal recessive defect in renal transport of amino acid cystine. Mutations of one of the two subunits of the amino acid transporter in the kidney leads to defective renal tubular reabsorption of dibasic amino acids such as cystine, arginine, lysine, and ornithine. Cystine stones are the main complication of this defect due to the low solubility of cystine in urine. Characteristic hexagonal cystine crystals can be seen on urine sediment (see Table 27.10). Cystinuria is diagnosed by family history of stones, stone formation at a young age, mildly radiopaque stones, and measurement of urinary cystine excretion. Patients with cystinuria excrete 250 to 1000 mg of cystine per day (normal is approximately 30 mg/day). Treatment must be aimed at decreasing the urinary cystine concentration by increasing urine volume to greater than 4 liters per day, reducing sodium intake, and alkalinizing the urine (urine pH >6.5) with potassium citrate or sodium bicarbonate and by decreasing animal protein intake. Persistence of urine cystine excretion greater than 250 mg/L, cystine crystals on urine sediment, and failure to elevate pH to greater than 7.0 despite conservative measures may require initiation of thiol-derivatives such as D-penicillamine and α -mercaptopyrionylglycine (tiopronin). These drugs split cystine molecules into two cysteines and produce a highly soluble disulfide compound; however, their use may be limited by their side effect profile.

Vascular Disorders of the Kidney

Abdallah Geara, Jeffrey S. Berns

INTRODUCTION

The spectrum of vascular disorders of the kidneys is broad as a result of high renal blood flow and the intimate relationship between blood supply and fundamental glomerular and tubular functions. In this chapter, emphasis is placed on the clinical manifestations of hypertension, chronic kidney disease (CKD), end-stage kidney failure, and the many other causes of acute kidney injury (AKI).

RENAL VASCULAR ANATOMY

With a volume of around 150 mL each, the kidneys comprise less than 1% of the body mass and yet receive 20% to 25% of the cardiac output. The renal arteries arise directly from the aorta and enter the renal hilum. The right renal artery passes anterior to the inferior vena cava (IVC) and is longer than the left renal artery. In up to 30% of the population, accessory renal arteries arise from the aorta to provide blood to portions of one or both kidneys, which may become important when evaluating patients for renovascular hypertension.

The renal arteries give rise to segmental, interlobar, and arcuate arteries (Fig. 28.1). Arcuate arteries course along the corticomedullary junction and give rise to interlobular arterioles, which extend outward into the cortex before branching into afferent arterioles, from which the glomerular capillary tufts arise. The postglomerular efferent arterioles from more superficial glomeruli form a capillary network in the renal cortex, and those extending from glomeruli nearer the cortical-medullary junction (i.e., juxtamedullary glomeruli) form capillaries that extend deeper into the medulla in association with thin, descending and ascending loops of Henle as the vasa recta. The vasa recta provide the sole blood supply for the renal medulla, making this portion of the kidney particularly susceptible to ischemic injury. Venules from the ascending vasa recta and the cortical capillary network empty into the renal veins.

The left renal vein returns to the IVC anterior to the aorta and inferior to the inferior mesenteric artery, which may rarely cause compression of this vein, causing what is known as the “nutcracker syndrome,” typically presenting with hematuria with or without left flank pain. The left gonadal vein also empties into the left renal vein, and a left varicocele may be evident if the renal vein is occluded by thrombosis or tumor involvement. The right renal vein is much shorter and empties directly into the IVC. The right gonadal vein empties directly into the IVC rather than into the right renal vein.

We categorize vascular diseases of the kidney based on the blood vessels typically involved (glomerulonephritis is addressed in Chapter 26):

- Main renal artery and segmental branches: Renovascular disease, fibromuscular dysplasia (FMD), aortic dissection, thromboembolic diseases and large and medium vessels vasculitis.

- Interlobular arterioles and glomerular arterioles: Hypertensive nephrosclerosis, atheroembolic disease, preeclampsia, scleroderma renal crisis, thrombotic microangiopathy (TMA) and antiphospholipid antibody syndrome (APS).
- Renal veins: Renal vein thrombosis (RVT).

RENOVASCULAR DISEASE

Any process that narrows the lumen of the main or branch renal arteries sufficiently can elicit a humoral response mediated by increased renin release from the ipsilateral kidney, which leads to increases in circulating angiotensin II and aldosterone levels. Activation of the renin-angiotensin-aldosterone system increases systemic blood pressure and renal arterial perfusion pressure and single nephron glomerular filtration rate (GFR) beyond the stenosis. This is mediated through angiotensin II-mediated preferential efferent arteriolar vasoconstriction that counterbalances the increase in resistance imposed by narrowing of the main or branch arteries.

Hemodynamically significant renal artery stenosis (RAS) requires a reduction in lumen diameter of at least 50% to 60%. In the stenotic kidney, a decrease in the glomerular capillary pressure results in activation of the renin-angiotensin-aldosterone system, systemic vasoconstriction mediated by angiotensin II, and increased renal sodium and fluid reabsorption, resulting in elevation of systemic blood pressure. If the contralateral kidney has no stenosis, the increased systemic blood pressure increases sodium excretion by that kidney (i.e., pressure natriuresis). Thus, clinically, a patient with unilateral renal artery stenosis and two functioning kidneys has hypertension secondary to angiotensin II-mediated systemic vasoconstriction without significant hypervolemia. Because hypertension in this setting is maintained by increased vasoconstriction due to angiotensin II, treatment is aimed at blocking the synthesis or effect of the elevated angiotensin II levels with an angiotensin-converting enzyme (ACE) inhibitor or angiotensin-receptor blocker (ARB).

If the arteries to both kidneys are narrowed, pressure natriuresis does not occur, and hypertension is maintained chronically by the resulting intravascular volume expansion rather than by increased total peripheral resistance. Treatment with diuretics becomes more important in this circumstance. The latter situation also occurs when there is only a single functioning kidney that has stenosis or when an initially normal contralateral kidney suffers microvascular damage from long-standing hypertension (Fig. 28.2).

The pathophysiology of hypertension with RAS is such that its treatment may also compromise kidney function and reduce the GFR. If the kidney contralateral to the one with hemodynamically significant RAS has normal function, lowering the systemic blood pressure maintains the kidney with the stenosis in a hemodynamically compromised

Fig. 28.1 *Top*: Cross-section of the human kidney showing renal arteries and veins. *Bottom*: Schematic of the microcirculation of each nephron. (From Guyton AC, Hall JE: Textbook of medical physiology, ed 11, 2016, Saunders, Chapter 26, 323-333.)

state. However, this may not be detectable by measurement of the serum creatinine concentration because of the normally functioning contralateral kidney. A decline in the GFR may, however, be evident if there is underlying dysfunction of the contralateral kidney, as is often the case in long-standing hypertension, diabetes, or vascular disease. When a solitary functioning kidney or both kidneys are affected (i.e., bilateral RAS), AKI may result when ACE inhibitor or ARB treatment is initiated.

Atherosclerotic Renovascular Disease

Clinical Presentation

Atherosclerosis is the primary cause of RAS in adults, although any process that narrows one or both renal arteries may cause renal ischemia; others are discussed later in this chapter. Atherosclerotic renovascular disease is a common form of secondary hypertension, affecting up to 5% of patients with hypertension. Atherosclerotic RAS rarely occurs in patients younger than 40 years, and it is more common in men, white individuals, smokers, diabetics, and patients with atherosclerotic disease in other arterial systems. The prevalence of RAS increases to between 10% to 45% in patients with other atherosclerotic risk factors such as coronary artery disease, peripheral vascular disease, and aortic disease.

RAS should be suspected in patients with refractory hypertension or new-onset hypertension in patients older than 50 years, particularly if they have overt risk factors for atherosclerotic RAS (Table 28.1). Evaluation should always begin with a thorough history and physical examination, including attention to blood pressure and pulse amplitude in each extremity. A significant discrepancy between extremities may indicate peripheral vascular disease and increase the likelihood of RAS. An abdominal bruit is detected in about 50% of subjects but

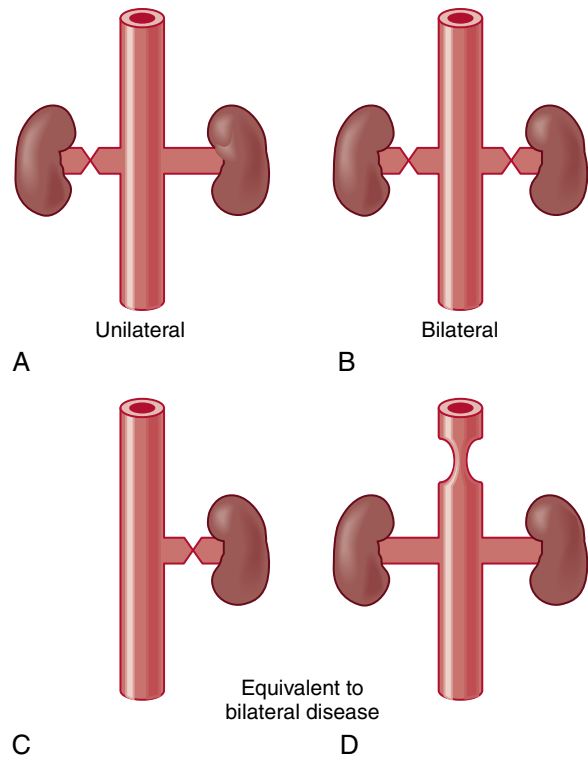

Fig. 28.2 Anatomy of renal artery stenosis. Renal artery stenosis may be unilateral (A), bilateral (B), or unilateral with a solitary kidney (C). Aortic disease may serve functionally as bilateral renal artery stenosis (D).

TABLE 28.1 Clinical Findings of Atherosclerotic Renovascular Disease

Onset of new, severe hypertension or sudden worsening of chronic hypertension at >55 years of age
Accelerated, resistant, or malignant hypertension
Unexplained atrophic kidney or size discrepancy >1.5 cm between kidneys
Sudden, unexplained ("flash") pulmonary edema
Unexplained chronic kidney disease in an individual with atherosclerotic vascular disease elsewhere
Development of acute kidney injury or worsening of chronic kidney disease after starting an ACE inhibitor or ARB

ACE, Angiotensin-converting enzyme; ARB, angiotensin II-receptor blocker.

is not specific for RAS. Edema is not typically found unless significant CKD or another edematous condition also exists.

Laboratory evaluation may reveal hypokalemia ($K^+ < 3.5$ mEq/L) or metabolic alkalosis ($HCO_3^- > 28$ mEq/L) due to secondary hyperaldosteronism, although neither may be present. A reduced GFR with an elevated serum creatinine concentration may be found, but a normal serum creatinine concentration does not rule out hemodynamically significant RAS. Plasma renin activity and aldosterone concentrations may be elevated, but their measurement is of limited clinical utility in assessing hypertensive patients for RAS or in making therapeutic decisions. Urinalysis results are usually normal, although low-grade proteinuria (usually <1 g/day) from long-standing hypertension may be seen.

Diagnosis

Standard renal ultrasound imaging may suggest the presence of underlying RAS if it reveals a significant discrepancy in kidney size or if both

are smaller than normal, because kidney size diminishes over time after prolonged ischemia. *Renal ultrasound with Doppler analysis* provides information about flow velocity in the renal arteries that may be helpful in detecting hemodynamically significant RAS. However, *renal duplex ultrasonography* is technically demanding, particularly in obese patients. Since at any given center, the sensitivity, specificity, and positive and negative predictive values of renal duplex ultrasonography are likely to be unknown, its clinical utility is mainly when positive for RAS; a negative test is not informative in patients with high clinical suspicion. Serial measurement of the kidney size and measurement of the renal resistive index ($[\text{peak systolic velocity} - \text{end-diastolic velocity}] / \text{peak systolic velocity}$) are helpful in assessing the potential benefit of revascularization. A high resistive index reflects an advanced degree of likely irreversible intrinsic kidney damage.

Computed tomography (CT) with intravenous iodinated contrast (i.e., CT angiography [CTA]) permits high-resolution evaluation of the arterial vasculature and can be a very useful diagnostic imaging study, particularly in patients with normal or near-normal kidney function. Its use is limited in patients with more significantly impaired kidney function due to the risk of contrast-induced AKI. Some newer CT imaging machines have a higher resolution and better tissue reconstruction allowing the visualization of RAS with lower amounts of contrast exposure.

Magnetic resonance angiography (MRA) with intravenous contrast is also useful for detecting RAS. Gadolinium administration to patients with advanced kidney disease (GFR <15 to 30 mL/min) may be contraindicated because of the risk of nephrogenic systemic fibrosis, although this appears to be much less of a concern with newer nonionic linear and macrocyclic gadolinium contrast agents. Overall, CTA and MRA appear to have similarly high sensitivity and specificity in the assessment of patients with atherosclerotic RAS. In RAS secondary to FMD, CTA and MRA are less sensitive because the disease involves the more distal part of the renal artery.

A *functional renal nuclear medicine test* might seem pathophysiologically ideal to detect RAS that is impacting kidney perfusion. Nuclear imaging has been used with various isotopes to assess isotopic uptake and excretion by each kidney before and after the administration of a short-acting ACE inhibitor (e.g., captopril). However, due to the high prevalence of baseline asymmetry of blood flow in patients with CKD and inability to accurately diagnose RAS when it is bilateral, radionuclear tests have fallen out of favor due to limited specificity and sensitivity for the diagnosis of RAS and are not commonly used any longer to assess for the presence of RAS or to determine whether RAS might be amenable to revascularization.

The most sensitive and specific test—but also the most invasive—is *renal arteriography*, which remains the gold standard for the detection of RAS. An advantage of arteriography is that angioplasty and stenting can be performed during the procedure (discussed later) if indicated. Because of the frequent occurrence of accessory renal arteries, an aortogram must be performed rather than selective renal angiography to ensure that all vessels are visualized. This also allows for detection of aortic atherosclerotic disease.

Treatment

Patients with atherosclerotic RAS typically have coexistent cerebrovascular, coronary, and peripheral vascular disease as the result of a long history of multiple risk factors such as cigarette smoking and hyperlipidemia. Clinicians should recognize this high cardiovascular risk and understand that long-term outcomes for patients with atherosclerotic RAS are often determined by coexisting atherosclerotic disease of the cerebral, cardiac, or peripheral vascular circulations. The absolute risk of developing end-stage renal disease (ESRD) is increased for patients

with atherosclerotic RAS compared with those without RAS, especially in patients with bilateral RAS or RAS of a solitary kidney.

As with atherosclerotic disease in other arterial circulations, atherosclerotic RAS should prompt efforts for intensive lipid lowering, use of aspirin, smoking cessation, and control of hypertension and diabetes mellitus.

Intervention for atherosclerotic RAS remains controversial despite several randomized clinical trials designed to investigate the benefits and risks of medical management compared with angioplasty and renal artery stenting. Small clinical studies have suggested that renal artery angioplasty and stenting may improve blood pressure control in selected cases of atherosclerotic RAS, but identifying which patients may benefit has been problematic, and many have little or no improvement in blood pressure or are not able to significantly reduce the number of required antihypertensive medications. Two major randomized, controlled clinical trials of treatment of RAS with angioplasty did not demonstrate significant clinical benefit in terms of blood pressure control, kidney function, or mortality for most patients with atherosclerotic RAS, although both have been criticized for selection bias (excluding some high-risk patients with recurrent flash pulmonary edema and patients whose doctors felt they were likely to benefit from revascularization) and recruiting significant numbers of low-risk patients who were not on optimal medical therapy.

Renal artery angioplasty and stenting carry a risk of acute worsening of kidney function due to atheroembolic disease, contrast nephropathy, or in-stent thrombosis, among other technical complications, and the procedures may lead to irreversible, progressive kidney dysfunction and ESRD. Decisions to correct atherosclerotic RAS with angioplasty and stenting or surgery must be made on a case-by-case basis, considering:

- Underlying kidney function and pace of kidney function loss, if any.
- Severity and duration of hypertension: persistence of uncontrolled HTN after optimal medical therapy, intolerance to optimal medical therapy, and the short duration of blood pressure elevation prior to the diagnosis of RAS.
- Atherosclerotic disease in other vascular beds and life expectancy based on age and other comorbid conditions.
- Flash pulmonary edema.

There is no role for angioplasty alone without stenting in most patients with atherosclerotic RAS due to the high risk of recurrent stenosis.

Medical management of hypertension in patients with atherosclerotic RAS must take into consideration other comorbid conditions. Use of an ACE inhibitor or ARB and diuretics is often very effective, but patients treated with these agents must be monitored closely for further compromise of their kidney function.

Fibromuscular Dysplasia

FMD is a nonatherosclerotic, noninflammatory disease that causes RAS. FMD typically affects young women more than other groups but men and older age groups can be affected. The cause is not established, but it is thought to be a developmental defect. FMD is responsible for 35% to 50% of renovascular hypertension in children and 5% to 10% of renovascular hypertension in adults.

FMD most commonly affects the renal arteries (bilaterally in about 35% of affected patients), but carotid and vertebral arteries can also be affected.

Classification of FMD is based on the histologic layer of the artery involved (i.e., intima, media, or adventitia) (Table 28.2). Medial fibroplasia with a mural aneurysm is the most common cause of FMD in adults (70% of cases). It consists of alternating fibromuscular

ridges and aneurysmal segments in the distal two thirds of the renal artery and has a classic string-of-beads appearance on angiography (Fig. 28.3). Perimedial fibroplasia of the outer one half of the media produces severe multifocal stenosis and causes about 15% of FMD in adults. Because histologic specimens are rarely obtained, FMD is classified by the angiographic appearance with multifocal disease identified as FMD involving the media and unifocal disease as FMD of the intima and/or adventitia.

Medial subtypes of FMD usually have a benign course and are responsive to angioplasty. The intimal subtype may have a higher likelihood of ischemic events and multiorgan system involvement. Symptoms are usually precipitated by stenosis, but FMD may rarely cause dissection or macroaneurysms that require intervention. Although CTA or MRA may be useful in the detection of FMD in the main renal arteries and main branch arteries, arteriography is necessary for detection of stenosis in smaller arteries.

Treatment for FMD depends on the severity of complications. Pharmacologic treatment alone may be adequate to control hypertension in many patients, with an ACE inhibitor or ARB the antihypertensives of choice. Intervention with angioplasty (with or without stenting) or surgery should be considered for patients with severe or difficult to control hypertension or declining kidney function. Angioplasty without stenting is successful in many patients, but recurrent stenosis is not uncommon, and new stenosis from FMD may develop at other sites. For this reason, regular monitoring of blood pressure and serum creatinine levels is essential, and many patients require imaging studies to detect new or recurrent lesions.

TABLE 28.2 Histologic Classification of Fibromuscular Dysplasia

Subtype	Percentage of All Cases (%)	Radiologic Appearance
Medial fibroplasia	60-70	String of beads with aneurysms
Perimedial fibroplasia	15	String of beads without large aneurysms
Medial hyperplasia	5-15	Smooth tubular stenosis
Intimal fibroplasia	1-2	Focal or smooth stenosis
Adventitial fibroplasia	<1	Focal or smooth tubular stenosis

Aortic Dissection

Aortic dissection occurs after disruption of the intimal layer of the aorta and propagation of blood flow that dissects along the wall of the aorta, producing a false lumen and compression of the true aortic lumen. Aortic dissection is classified by the site of origin (i.e., DeBakey classification) or the segment of the aorta involved (i.e., Stanford classification). DeBakey type I and II dissections originate in the ascending aorta, and type III dissections originate in the descending aorta. Stanford type A refers to dissections involving the ascending aorta, and type B refers to all others not involving the ascending aorta.

Major branch vessels of the aorta, including the renal arteries, may become obstructed or occluded as a result of extension of the dissection. Aortic dissection frequently compromises the renal arteries (the left more commonly than the right) when it extends into the abdominal aorta and causes renal failure in approximately 20% of patients with type B dissections. When disease is extensive enough to cause AKI, vascular compromise to the intestinal and cerebral vasculature and severe aortic regurgitation often contribute to the high mortality rate.

Aortic dissection most frequently affects older patients (>50 years of age) with coexistent vascular risk factors such as hypertension, smoking, and atherosclerosis. Men are affected more commonly than women. Occasionally, a genetic connective tissue defect such as Marfan syndrome or Ehlers-Danlos syndrome type IV (about 5% of cases) causes aortic dissection, and these conditions should be considered in younger patients (<40 years of age).

AKI occurs in about 20% of patients diagnosed with acute type B aortic dissection and is an independent predictor of in-hospital mortality. Trauma or procedures (e.g., aortic catheterization) can also cause dissection of the aorta or renal artery. Isolated, spontaneous renal artery dissection may rarely occur, most commonly in the setting of polyarteritis nodosa (PAN) or FMD. Segmental arterial mediolysis is another uncommon condition of unknown origin that is characterized by vacuolar degeneration of smooth muscle cells in the arterial media, which leads to disruption of the arterial medial layer, vessel dissection, hemorrhage, and ischemia. Segmental arterial mediolysis can affect abdominal visceral arteries and virtually any other arterial system.

The most frequent symptom during aortic dissection is chest pain, which may be described as a ripping sensation. Isolated loss of pulse in one or more extremities may provide a clinical clue, and the number of

Fig. 28.3 (A) Typical medial fibroplasia (i.e., string-of-beads appearance) on an angiogram of a right renal artery. (B) Gadolinium-enhanced magnetic resonance angiography in the same patient, revealing bilateral medial fibroplasia of the renal arteries and a large marginal artery of Drummond (*arrow*), indicates that there is disease of the superior mesenteric artery. (From Slovut DP, Olin JW: Fibromuscular dysplasia, *N Engl J Med* 350:1862-1871, 2004.)

arteries involved correlates with the severity of dissection. A common clue to the diagnosis on a routine chest radiograph is a widened mediastinum, with or without a pleural effusion (most often on the left).

After the diagnosis of aortic dissection is established, evaluation of renal artery involvement is best undertaken noninvasively to minimize further vascular injury. Contrast-enhanced CT, magnetic resonance imaging, or MRA usually provide images capable of confirming or excluding renal involvement, although each modality carries the same limitations as outlined for the evaluation of RAS. Transesophageal echocardiography is useful for establishing the diagnosis of aortic dissection, but it does not provide information about the aorta below the diaphragm. Renal duplex ultrasonography may be useful for evaluating renal perfusion in the setting of aortic dissection, but it is not recommended for the initial investigation of aortic dissection.

Aortic dissection is a hypertensive emergency that requires aggressive reduction of blood pressure; systolic blood pressure should be maintained between 100 and 120 mm Hg. Antihypertensive medications that reduce the rate of increase in blood pressure during the cardiac cycle, such as β -adrenergic receptor blockers, have a theoretical benefit in managing aortic dissection by reducing the rate of progression.

Surgical treatment options for renal involvement due to aortic dissection depend on individual circumstances, and careful evaluation by an experienced vascular surgeon is recommended. Thoracic aortic dissection requires surgical repair due to the high mortality rate if left untreated, but isolated abdominal aortic disease may be medically managed.

Thromboembolic Disease

Systemic arterial emboli, typically originating from the left atrium or left ventricle in patients with atrial fibrillation, infectious endocarditis, cardiac valvular disease, or atrial myxoma, may cause acute obstruction of the renal arteries. Rarely, a paradoxical embolus may occur from the venous system through an atrial septal defect.

Symptoms of acute renal ischemia and infarction include flank pain, gross hematuria, and fever. Laboratory findings are nonspecific but include an elevated level of lactate dehydrogenase (LDH), hematuria, and leukocytosis. A definitive diagnosis can be based on the finding of a focal nonenhancing region on contrast-enhanced CT. Imaging studies are necessary to differentiate renal artery embolic disease from renal artery dissection.

The renal mass affected by a renal artery embolus is usually not large enough to reduce kidney function so that dialysis is necessary, although some worsening of kidney function may be observed. The diagnosis of renal infarction is rarely made early enough to initiate treatment with intra-arterial thrombolysis or thrombectomy, and it is questionable whether the risks and marginal benefit of these procedures warrant aggressive treatment except in patients where the occlusion is affecting the main renal artery and is addressed soon after occurrence. Therapy should instead address the underlying source of renal emboli with symptomatic treatment of pain as necessary. Systemic anticoagulation may be indicated to reduce the risk of further thromboembolic events.

Large and Medium-Sized Vessel Vasculitis

Systemic vasculitides such as temporal (giant cell) arteritis and Takayasu's arteritis affect primarily large and medium-sized arteries. PAN and Kawasaki disease affect primarily medium-sized and smaller arteries. These vasculitides are not associated with antineutrophil cytoplasmic antibodies (ANCA) and do not typically cause glomerulonephritis. They are distinguished from ANCA-associated vasculitides that involve smaller blood vessels and more commonly cause glomerulonephritis.

Takayasu's arteritis and giant cell arteritis are typically associated with a granulomatous vasculitis of the aorta and its branches. Giant cell arteritis typically involves the carotid, vertebral, and temporal arteries, and renal involvement is rare. Both occur much more commonly in women than men. Takayasu's arteritis is usually diagnosed in patients younger than 50 years of age, whereas giant cell arteritis is diagnosed in those 50 years of age or older.

Involvement of the main renal arteries occurs in about 40% of patients with Takayasu's arteritis, producing areas of stenosis with renal ischemia or renal infarction. Common clinical features are constitutional symptoms, claudication, bruits, and hypertension. Pulses are often diminished or absent in one or more extremities, and a blood pressure discrepancy more than 10 mm Hg in the limbs is common. The diagnosis of Takayasu's arteritis is most often made on clinical grounds along with typical angiographic or other imaging findings. Corticosteroids are the primary treatment modality. The stenotic lesions are usually reversible when corticosteroid therapy is given during the early phase of the disease before the lesions become fibrotic and irreversible. About half of patients have chronic, persistent or corticosteroid-dependent disease and require therapy with additional or alternative immunosuppressants such as azathioprine, mycophenolate, methotrexate, leflunomide or cyclophosphamide. More recently targeted immunosuppression with antagonists of interleukin-6 (such as tocilizumab) and blockers of the tumor necrosis factor alpha (TNF α) pathway (such as infliximab or etanercept) may be effective in helping maintain remission.

PAN is a medium-sized or small vessel vasculitis with no gender predilection that predominantly occurs in adults between 40 and 60 years of age. It is an idiopathic systemic necrotizing vasculitis. Some cases may be secondary to hepatitis B virus infection, hepatitis C virus infection, or hairy cell leukemia. Peripheral neuropathy in the form of mononeuritis multiplex is one of the most frequent findings with PAN.

PAN affects the main renal arteries and renal interlobar arteries (less commonly, the arcuate and interlobular arteries) with a necrotizing vasculitis that typically produces microaneurysms of the intrarenal arteries. They can be seen on arteriograms in 40% to 90% of patients with renal involvement. Renal ischemia leads to loss of kidney function and renin-mediated hypertension. Low-grade proteinuria and hematuria may be seen, but the finding of acute glomerulonephritis indicates some other disorder. Renal infarction may occur, and rarely, a renal artery aneurysm may cause renal artery dissection or rupture.

The diagnosis is made on clinical grounds and by arteriography. There are no confirmatory serologic tests; PAN is not an ANCA-associated vasculitis. Arteriography appears to be superior for diagnosis compared with CTA and MRA. Progressive renal disease is not typical but may occur. Treatment with corticosteroids and immunosuppressive drugs is effective in reducing disease severity and mortality.

Kawasaki disease is an arteritis associated with the mucocutaneous lymph node syndrome that affects mostly medium-sized and small arteries, although the aorta may also be involved. It is primarily a self-limited disease of infants and young children. Renal involvement is extremely rare.

Hypertensive Nephrosclerosis

Chronic hypertension in susceptible individuals may lead to development of proteinuria, CKD, and ESRD. Hypertensive nephrosclerosis is cited as a cause of CKD and ESRD in African Americans at a much higher rate than white individuals, even with similar levels of blood pressure control and despite good control.

The renal manifestations of chronic hypertension include renal arterial and arteriolar intimal thickening and luminal narrowing with medial

hypertrophy and fibroblastic intimal thickening of arteries and deposition of hyaline-like material (plasma proteins) in the walls of arterioles. Glomeruli show global and focal glomerulosclerosis; the former likely results from glomerular ischemia and the latter from increased intracapillary pressure and compensatory hypertrophy and injury in response to nephron loss. Wrinkled glomerular basement membranes due to glomerular ischemia are seen on electron microscopy. Chronic interstitial nephritis with tubular atrophy and interstitial fibrosis is another manifestation of chronic ischemic tubular injury seen with hypertensive nephrosclerosis, particularly in patients with other disorders such as diabetes mellitus, atheroembolic disease, and atherosclerotic RAS.

The overall risk of hypertensive nephrosclerosis with progressive CKD is low in the general hypertensive population, and most patients with hypertensive nephrosclerosis have mild hypertension. The risk is greater for those who have had poorly controlled hypertension and for those of African descent, who are at particularly high risk for hypertensive nephrosclerosis. Polymorphisms in the gene that encodes for apolipoprotein L1 (*APOL1*) is found more commonly in African Americans compared with European Americans and strongly associated with the risk of hypertensive nephrosclerosis. A diagnosis of hypertensive nephrosclerosis as the cause of otherwise unexplained CKD is much less likely to be made in white patients compared with black patients, particularly in the absence of long-standing, severe hypertension or a history of malignant hypertension.

The diagnosis of hypertensive nephrosclerosis is typically made clinically based on a history of long-standing hypertension that precedes development of proteinuria and CKD in the absence of other causes. Kidney biopsy is rarely performed except when other disorders are suggested clinically or by laboratory evaluation. The urinary sediment is typically bland, with only low-grade proteinuria (<1 g/day). Symmetrical loss of renal cortical thickness is commonly found on renal ultrasound.

Pharmacologic treatment of severe hypertension reduces the risk for progression of CKD to ESRD in many patient populations, providing further evidence for the causative role of hypertension. The optimal blood pressure for patients with hypertensive nephrosclerosis has not been determined. For black patients, this was best addressed by the African American Study of Kidney Disease (AASK) trial, which examined more than 1000 African Americans with long-standing hypertension, slowly progressive CKD, and low-grade proteinuria. Subjects were allocated to treatment with ramipril, metoprolol, or amlodipine to a blood pressure goal of 125/75 mm Hg or 140/90 mm Hg. The mean rate of change in GFR and the rate of other secondary outcomes were similar in the two groups, suggesting that lowering blood pressure to less than 140/90 mm Hg does not provide further benefit in slowing CKD progression in black patients with hypertensive nephrosclerosis. However, there was a trend favoring the lower blood pressure goal for patients with higher baseline proteinuria.

Lower blood pressure goals may also be appropriate for patients with other comorbid conditions such as diabetes mellitus. Besides affecting CKD progression, blood pressure control reduces the risk of heart failure and stroke. Most patients with hypertensive nephrosclerosis and CKD require multiple antihypertensive medications to control blood pressure, typically including a thiazide or thiazide-like diuretic (when GFR is well preserved) and a loop diuretic (as the GFR declines to less than 25 to 30 mL/min), along with an ACE inhibitor or ARB, calcium-channel blocker, and β -blocker.

Atheroembolic Disease

Atheroembolic disease is the result of cholesterol embolization from atherosclerotic plaques, most commonly from the aorta and typically dislodged during an invasive arterial procedure such as cardiac

catheterization, aortic angiography, cardiac surgery, or surgery on the aorta. Cholesterol emboli may occur spontaneously or may be precipitated by systemic anticoagulation, such as with heparin, or during systemic administration of thrombolytic agents. Because patients must have underlying atherosclerosis, the incidence increases with age, and atheroembolic disease rarely occurs before 40 years of age.

As the result of systemic embolization from atheromatous plaques, cholesterol crystals lodge in small arterial vessels, including the arcuate or interlobular arteries of the kidneys. Cholesterol emboli frequently involve other organs, and the pattern of organ involvement depends in part on whether disrupted plaque is in the ascending or descending aorta. The extremities are commonly affected with digital ischemia and gangrene, the skin with livedo reticularis, and the gastrointestinal tract with intestinal ischemia, but any organ can be affected. Embolization from the ascending aorta can cause cardiac ischemia, and emboli arising from the ascending aorta or carotid arteries (e.g., after carotid endarterectomy) can cause stroke.

Cholesterol embolization to the eye may be recognized by finding Hollenhorst plaques on fundoscopic examination, which are whitish yellow flecks at retinal arteriole bifurcations. They are often asymptomatic but may cause retinal ischemia with usually transient visual field defects.

Patients with atheroembolic disease may have fever, eosinophilia, eosinophiluria, and hypocomplementemia, particularly acutely. Laboratory findings include an elevated erythrocyte sedimentation rate and elevated levels of amylase or liver enzymes. The widespread systemic clinical and laboratory manifestations of atheroemboli can lead to a clinical picture suggesting systemic vasculitis.

The typical pattern of renal atheroembolic disease is a decline in kidney function that first becomes apparent 3 or more days after an inciting procedure or other event. The degree of acute and chronic kidney injury that follows is determined by the magnitude of the embolic burden, whether atheroembolism is a one-time or ongoing process, and the degree of inflammation induced by the plaque material. Many patients have stabilization of the process after the initial insult, whereas others progress with various patterns and tempos to advanced CKD and ESRD. Cholesterol embolization also may cause severe hypertension due to acute renal ischemia leading to renin release.

Diagnosis of renal atheroembolic disease is usually made clinically in the appropriate setting, but for some patients, a kidney biopsy is needed to confirm the diagnosis and exclude others. Because the fixation process washes out the cholesterol crystals from the renal biopsy sample, the pathologic examination reveals a typical needle-shaped disruption in the arterial lumen surrounded by reactive inflammatory and fibrous intimal proliferation leading to a luminal occlusion and distal ischemic injury.

There is no specific treatment for cholesterol emboli. Because an inflammatory reaction typically results from the emboli, some physicians advocate corticosteroids, but their use is unproved for preventing further atheroembolism or progression of kidney failure. Avoidance of anticoagulation has been recommended to prevent dissolution and embolization of thrombus that may overlie an atheromatous plaque. Statin therapy is recommended for most patients for treatment of their underlying atherosclerotic disease, but it has not been shown to influence the renal manifestation of atheroemboli. Treatment with ACE inhibitors or ARBs may be effective for hypertension control in the acute setting, but worsening kidney function may limit their use. Dialysis may be necessary if AKI and ESRD develop.

Preeclampsia

Preeclampsia is characterized by the new onset of sustained hypertension (blood pressure \geq 140/90 mm Hg) and proteinuria (>300 mg/day)

that develops after 20 weeks' gestation in a previously normotensive woman. Although hypertension and proteinuria are the principal features of preeclampsia, it is a systemic vascular disease that may also cause central nervous system symptoms (e.g., visual disturbances, headache, altered mental status), abdominal pain, nausea and vomiting, liver dysfunction, thrombocytopenia, pulmonary dysfunction, impaired fetal growth, nephrotic-range proteinuria, and AKI. If grand mal seizures develop without other explanation, a diagnosis of eclampsia is made. The HELLP syndrome, characterized by hemolysis, elevated liver enzymes, and a low platelet count, may be a manifestation of severe preeclampsia, although some consider it to be a separate disorder. It is also associated with increased maternal and fetal mortality. History of hypertension and CKD are risk factors for preeclampsia. Other major risk factors are nulliparity, preeclampsia in previous pregnancy, multifetal gestation, autoimmune disease, and family history of preeclampsia.

Preeclampsia should be distinguished from other hypertensive conditions that can occur during pregnancy, including preexisting hypertension that occurs before 20 weeks' gestation and persists after delivery, preeclampsia superimposed on preexisting chronic hypertension, and gestational hypertension (i.e., new-onset hypertension after 20 weeks' gestation without proteinuria or other related manifestations).

Progress has been made in understanding the pathogenesis of preeclampsia, and maternal and placental or fetal factors have been implicated. Abnormal development of placental vasculature in early pregnancy is thought to lead to some degree of placental hypoperfusion that releases antiangiogenic factors into the maternal circulation, disturbing the delicate balance of angiogenic and antiangiogenic factors. This causes systemic endothelial dysfunction in the mother that leads to hypertension, proteinuria, and other manifestations of the disease.

Soluble FMS-related tyrosine kinase 1 (sFLT1) is a placenta-derived circulating antiangiogenic factor that appears to play a central role in the pathogenesis of preeclampsia. It antagonizes the proangiogenic effects of vascular endothelial growth factor (VEGF) and placental growth factor (PGF) by binding to them and preventing interaction with their receptors. Soluble endoglin (sENG), another antiangiogenic factor that is widely expressed on vascular endothelium, is thought to be an important mediator of preeclampsia. Endothelial dysfunction in preeclampsia is associated with increased sensitivity to vasopressor agents, including angiotensin II, systemic vasoconstriction, and reduced fibrinolytic function.

Kidney biopsy findings include glomerular endothelial cell swelling (i.e., endotheliosis) and occlusion of the capillary lumen with ischemia. These findings are also seen with other microangiopathic disorders, although fibrin thrombi in glomerular capillaries are less commonly seen than with other causes. Foot process effacement is not usually seen.

The only effective treatment for preeclampsia is delivery of the fetus and placenta. The timing of delivery must take into account gestational age, severity of preeclampsia, presence or absence of systemic features, and status of the fetus and mother. Proper obstetric care is essential to balance the risk to the mother against the risk for prematurity of the fetus. In high-risk pregnancies, low-dose aspirin is started in the second and third trimester to reduce the risk of developing preeclampsia.

Treatment of mild hypertension in women with preeclampsia should be avoided because it does not treat the underlying disease process, alter the course of disease, or reduce clinical sequelae. In the absence of clinical manifestations other than proteinuria, it is usually unnecessary to start antihypertensive medications unless the systolic blood pressure is greater than 150 mm Hg or the diastolic blood pressure is higher than 100 mm Hg. Labetalol and hydralazine, both of

which can be given intravenously or orally, are often recommended as first-line therapy for acute management. For chronic treatment, methyldopa or labetalol are often recommended initially, with extended-release nifedipine added if necessary. Diuretics and dietary sodium restriction usually are avoided unless the patient has pulmonary edema.

The risk profile of these medications is poorly defined in pregnancy. ACE inhibitors, ARBs, and direct renin inhibitors are contraindicated during pregnancy because of the risk of fetal abnormalities. Magnesium sulfate is used in severe cases of preeclampsia to reduce the risk of seizures, but it does not treat other manifestations of the disease or reduce maternal or fetal mortality rates.

Most manifestations of preeclampsia begin to improve shortly after delivery, but in some women, hypertension, proteinuria, and other manifestations may persist for several weeks or months before resolving completely. Because preeclampsia is a risk factor for future hypertension, kidney disease, and cardiovascular events, continued medical follow-up is essential.

Scleroderma Renal Crisis

Systemic sclerosis (i.e., scleroderma) is an idiopathic connective tissue disorder associated with deposition of collagen and other extracellular matrix proteins that produces inflammation and fibrosis of the skin and internal organs. Proliferative endovascular lesions may lead to obliteration of the vascular internal lumina and renal ischemia, with hypertension, increased renin activity, and elevated levels of angiotensin II and aldosterone.

AKI and rapidly worsening hypertension in patients with scleroderma is called *scleroderma renal crisis*. It occurs in approximately 5% to 10% of patients with scleroderma, typically within the first few years after onset and primarily in those with systemic rather than localized cutaneous scleroderma who also have progressive skin and cardiac involvement. Subclinical renal involvement with mild proteinuria, hypertension, and elevated serum creatinine concentration occurs much more frequently. Scleroderma renal crisis occasionally develops before the clinical diagnosis of scleroderma has been made.

Scleroderma renal crisis is often associated with rapid and severe loss of kidney function, oliguria, hypertensive encephalopathy, and heart failure. Microangiopathic hemolytic anemia (MAHA) may also occur. Low-grade proteinuria is often present but the urinalysis is not usually otherwise "active" (red blood cells, casts, etc.). About 10% of patients with scleroderma renal crisis do not have hypertension. This occurs more commonly among patients being treated with ACE inhibitors or high-dose corticosteroids.

Anti-RNA polymerase III antibodies are strongly associated with the risk of scleroderma renal crisis and have been suggested as markers for scleroderma renal crisis. Other risk factors include diffuse and rapidly progressive skin involvement and high-dose glucocorticoid use.

Renal biopsy may reveal interlobular artery involvement with intimal thickening, endothelial cell proliferation, and edema with obliteration of the vessel lumen with concentric onion-skinning of the wall of arterioles. Fibrinoid necrosis occurs in afferent arterioles with intravascular fibrin accumulation extending into the glomeruli, often with ischemic collapse, but without features of glomerulonephritis.

Activation of the renin-angiotensin-aldosterone system appears to play an important role in the progression of the disease. Before the advent of ACE inhibitors and hemodialysis, scleroderma renal crisis was fatal in about 75% of patients at 1 year. ACE inhibitor therapy has reduced this 1-year mortality rate to less than 15%. Captopril is often recommended as the ACE inhibitor of choice due to its short half-life and ease of dose titration. If the diagnosis of scleroderma renal crisis is made before advanced renal failure is established, ACE inhibition may halt or reverse the decline in renal function. Some experts recommend

continuing ACE inhibitors even if kidney function declines and temporary dialysis is necessary, citing an increased chance of renal recovery, which has been described in scleroderma renal crisis patients even after 18 to 24 months of dialysis dependence. ACE inhibitors are not useful for prevention of scleroderma renal crisis, and their use in this setting has been associated with a poorer outcome, including greater risk of requiring permanent dialysis if renal crisis occurs. Use of ACE inhibitors rather than ARBs is recommended because of the long track record of success with ACE inhibitors in this disease. Patients with ESRD secondary to scleroderma renal crisis have a high mortality on dialysis, poor dialysis access maturation, and reduced allograft survival following renal transplantation.

THROMBOTIC MICROANGIOPATHY OF THE KIDNEY

TMA is a pathologic lesion secondary to various distinct pathogenic mechanisms leading to endothelial injury, microvascular thrombosis, and MAHA. These syndromes each lead to organ dysfunction due to microvascular thrombosis, but each syndrome has distinct clinical, pathophysiologic, and epidemiologic features. AKI is commonly seen in TMA due to the propensity of the glomerular endothelium to damage.

The traditional classification of TMA into thrombotic thrombocytopenic purpura (TTP) and hemolytic uremic syndrome (HUS) has undergone evolution and currently TMAs are subclassified based on the underlying pathogenic process (Fig. 28.4 and Table 28.3). Although many processes cause microvascular endothelial injury, renal involvement from these disorders affects the vasculature at different levels. Renal involvement by HUS and TTP primarily affects the glomeruli, whereas scleroderma often extends to the interlobular arteries, and malignant hypertension more often affects the afferent arterioles. However, there is significant overlap and similar histologic features among these diseases, making careful clinical evaluation essential for accurate determination of the cause.

Thrombotic Thrombocytopenic Purpura

TTP is characterized by MAHA and thrombocytopenia. Patients may also have fever, AKI, and neurologic impairment. Purpura is only rarely observed, and it is not necessary to make the diagnosis. TTP occurs with a female-to-male ratio of 4:3 and a peak incidence in the third and fourth decades of life. MAHA and thrombocytopenia manifesting similar to TTP may occur in response to some drugs (e.g., ticlopidine, cyclosporine, tacrolimus), after stem cell transplantation, in association with human immunodeficiency virus (HIV) infection, and in patients with malignant hypertension, sepsis, disseminated intravascular coagulation, or advanced cancers.

TTP is caused by a deficiency or reduced activity of ADAMTS13 (a disintegrin-like and metalloproteinase with thrombospondin-1-like domains). ADAMTS13 is a plasma protease that normally cleaves von Willebrand factor (VWF) and limits the extent of intravascular thrombosis (Fig. 28.5). Microthrombi composed primarily of platelets and VWF accumulate in the vascular bed of multiple organs, leading to a MAHA. Deficiency in ADAMTS13 may be acquired, caused by anti-ADAMTS13 autoantibodies (mostly immunoglobulin G [IgG]), or, much less commonly, genetic.

Other laboratory abnormalities are manifestations of the MAHA and include thrombocytopenia; an elevated LDH concentration, indirect bilirubin concentration, and reticulocyte count; and a low haptoglobin concentration. Coagulation laboratory test results (e.g., prothrombin time, activated partial thromboplastin time, fibrinogen level) are typically normal, although levels of fibrin split products may be elevated. AKI, microscopic hematuria, and low-grade proteinuria are frequently detected.

Without treatment, TTP has a mortality rate of about 90%, with most deaths occurring within 3 months of the onset of symptoms. Treatment with plasma infusion can normalize ADAMTS13 levels, reducing intravascular hemolysis and mortality rates. Plasmapheresis and replacement with fresh-frozen plasma has the advantage of removing inhibitory autoantibodies in addition to normalizing ADAMTS13 levels because of the large volume of plasma that can be infused.

ADAMTS13 activity must be assayed before therapy is initiated to obtain accurate results, but treatment should not be delayed for the results to return. The severity of ADAMTS13 deficiency (<5%) predicts future relapse, although those with severe deficiency are just as likely to respond initially to plasmapheresis as those with a mild deficiency. Patients with MAHA due to other causes not associated with ADAMTS13 deficiency usually have a minimal response to plasmapheresis or plasma infusion. Patients with HUS do not have abnormalities in ADAMTS13 levels or function.

Hemolytic-Uremic Syndrome

Shiga Toxin-Producing *Escherichia coli*

Gastrointestinal tract infection with the Shiga-toxigenic *Escherichia coli* (STEC) strain O157:H7 produces a diarrheal illness that is complicated in about 15% of cases by a MAHA with intraglomerular thrombosis and AKI. STEC-HUS most commonly affects infants and children, although adults may also be affected. Cases are often clustered because of outbreaks of *E. coli* O157:H7, with peaks occurring in summer and autumn. *E. coli* is endemic in the gastrointestinal tract of cattle, and cases are often tracked to undercooked meat, exposure to bovine fecal matter, animal exposure, or other contaminated food products. In May 2011, an outbreak of STEC-HUS in Germany was tracked back to fenugreek sprouts grown from contaminated seeds. The pathogenic agent, *E. coli* O104:H4, was particularly virulent with 30% of infected patients, mostly adults, developing HUS.

Shiga-toxigenic bacterial strains commonly produce a prodrome of painful, bloody diarrhea, which precedes the development of HUS by 2 to 12 days (median, 3 days). Shiga toxin is directly thrombogenic in the renal vasculature. Although intravascular coagulation in STEC-HUS is usually limited to the kidney, the heart, gastrointestinal tract, and central nervous system may also be affected.

Laboratory abnormalities in HUS include elevated creatinine levels, anemia, schistocytes on the peripheral smear, elevated reticulocyte count, and thrombocytopenia. In contrast to disseminated intravascular coagulation, fibrinogen levels are normal or high, and the prothrombin time is normal or only slightly prolonged. Fresh stool should be sent for culture of *E. coli* O157:H7, which can aid in tracing the source of an outbreak. Stool studies should also be performed for patients without diarrhea because *E. coli* O157:H7 may rarely cause HUS in the absence of intestinal symptoms. If *E. coli* O157:H7 is not detected, culture for other Shiga-toxigenic organisms should be pursued.

The pathologic renal lesions of HUS include vessel wall thickening with endothelial cell swelling and intraglomerular thrombosis with platelet- and fibrin-rich thrombi. Fragmentation of red blood cells may be seen in the renal vasculature and within the vessel wall.

Treatment of STEC-HUS is supportive, including adequate volume repletion with isotonic intravenous fluids, transfusion for severe anemia, and avoidance of other nephrotoxic agents (e.g., nonsteroidal anti-inflammatory drugs, aminoglycoside antibiotics, iodinated contrast). Platelet transfusion is not recommended because it may worsen the ongoing microvascular thrombosis. Antibiotic treatment of patients with bloody diarrhea is controversial. Corticosteroids, anticoagulation (e.g., aspirin, heparin), thrombolytic agents, and plasma administration have proved ineffective for the treatment of STEC-HUS. In very severe cases, especially with central nervous system involvement, eculizumab (a complement pathway inhibitor) can be used.

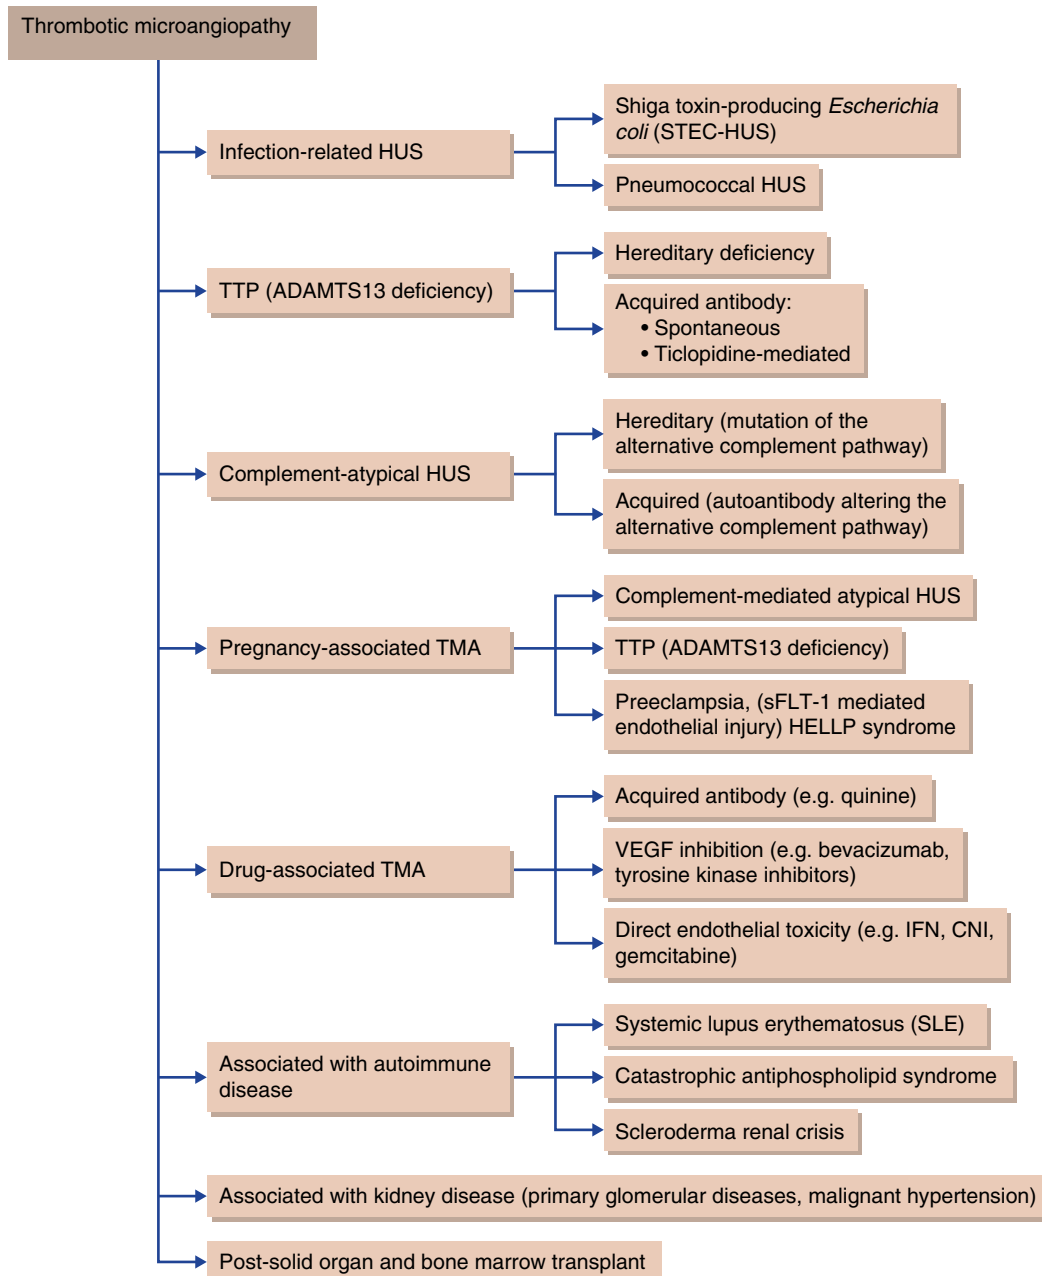

Fig. 28.4 Thrombotic microangiopathy (TMA). *CNI*, Calcineurin inhibitor; *HELLP*, hemolysis, elevated liver enzymes, and a low platelet count; *HUS*, hemolytic uremic syndrome; *IFN*, interferon; *sFLT-1*, soluble fms-like tyrosine kinase-1; *TTP*, thrombotic thrombocytopenic purpura; *VEGF*, vascular endothelial growth factor.

With supportive care alone, most patients with STEC-HUS recover with normalization of renal function or only mild residual CKD, although about 25% may develop advanced CKD or ESRD over the next 1 to 2 decades of life. Risk for CKD is increased with cortical necrosis and involvement of more than 50% of glomeruli identified on renal biopsy. The risk for complications and death increases with age, with the mortality rate increasing from about 5% to 10% for children to about 30% for adults.

Complement-Mediated Atypical HUS

The alternative complement pathway is the amplification loop of the complement system. Dysregulation of this pathway due to either hereditary or acquired causes may lead to complement-mediated endothelial damage and atypical HUS (aHUS). Mutations of genes for

components of the alternative complement pathway, including C3, factor B, regulators of factor H (CFH/CFHR fusions), factor I, and CD46, have been implicated. These mutations have an incomplete penetrance and frequently a triggering factor such as infection or pregnancy precedes the onset of clinical manifestations. In some childhood forms of complement-mediated aHUS, an acquired autoantibody against factor H can be detected and gastrointestinal prodrome is often reported. Failure to detect a genetic mutation or autoantibody does not rule out this disease because it is likely that not all responsible causes have been identified.

Complement-mediated aHUS historically has had a very poor prognosis with high likelihood of ESRD and death. The disease frequently recurs in a renal allograft with the recurrence rate depending on the underlying mutation, with the highest risk for CFH, CFB,

TABLE 28.3 Pathogenesis, Clinical/Diagnostic Characteristics, and Management of Main Thrombotic Microangiopathic Syndromes

	Pathogenesis	Clinical Characteristics	Diagnostic Characteristics	Management
Shiga toxin–producing <i>Escherichia coli</i> (STEC-HUS)	Enteric infection with Shiga toxin–producing pathogen (<i>E. coli</i> O157; <i>E. coli</i> O104)	All age groups with peak incidence in children for the <i>E. coli</i> O157 pathogen Enteric prodrome is common (5% do not have diarrhea)	Fibrin predominates intravascular thrombi Swollen endothelial cells STEC isolated in the stool	Supportive No role for plasma exchange Possible role for eculizumab in severe CNS involvement Antibiotics (controversial)
TTP	ADAMTS 13 deficiency (hereditary or acquired autoantibody) Ticlopidine-induced autoantibody	Other affected family members if hereditary In women with predisposition presents clinically in the 2nd and 3rd trimester of pregnancy No diarrheal prodrome Neurologic symptoms predominate	Low ADAMTS 13 activity (<10%) VWF predominates Intravascular thrombi Absence of swollen endothelial cells	Plasma exchange Immunosuppression (e.g. rituximab for acquired autoantibody) Stop ticlopidine
Complement-mediated aHUS	Dysregulation of the alternative complement pathway: Hereditary or acquired (anti-FH Ab)	Diarrhea can be present (30% at presentation) Hereditary disease has incomplete penetrance Trigger (e.g., infection, pregnancy) often identified High recurrence in kidney allograft	C3 can be low (normal levels do not exclude the disease) ADAMTS13 activity >10% Negative genetic and autoantibody testing does not exclude the diagnosis	Eculizumab Partial response to plasma exchange Liver transplant may be considered
Pneumococcal HUS	Neuraminidase-mediated exposure of the endothelium antigens leading to endothelial injury	Mainly children <2 years Frequently associated with pneumonia and empyema	Positive Coombs test	Supportive care Treatment of the infection
Quinine-induced TMA	Autoantibodies against GP Ib/IX or IIb/IIIa	Not dose related Can occur early (after single exposure) or late (up to 10 years after exposure)	ADAMTS13 activity \geq 10%	Supportive Plasma exchange not effective

ADAMTS3, A disintegrin and metalloproteinase with thrombospondin-1–like domains; *anti-FH Ab*, anti-factor H antibody; *CNS*, central nervous system; *GP*, glycoprotein platelets; *HUS*, hemolytic uremic syndrome; *TMA*, thrombotic microangiopathy; *TTP*, thrombotic thrombocytopenic purpura; *VWF*, von Willebrand factor.

and C3 mutations and the lowest with CD46 mutations. Eculizumab is a humanized monoclonal antibody that binds with high affinity to complement protein C5 and prevents the generation of C5a, C5b, and the terminal complement complex C5b-9. In patients with complement-mediated HUS, eculizumab inhibits complement-mediated TMA. It is used both to treat the disease and to prevent recurrence after kidney transplantation. Because complement components are mainly produced by the liver, a combined liver kidney transplant can be curative.

Malignancy-Associated TMA

In patients with a cancer diagnosis, TMA can be due to the cancer or its therapy. Disseminated malignancy can produce embolic tumor cells leading to endothelial damage and erythrocytes shearing. It has a very poor prognosis. TMA has also been described with cancer therapeutic agents that interfere with the VEGF pathway such as bevacizumab and tyrosine-kinase inhibitors (e.g., sunitinib). The VEGF pathway is upregulated in the majority of human tumors and it is thought to be important for expanding neovascularization of the tumor. In the kidney glomeruli, VEGF is produced locally by podocytes and endothelial cells express tyrosine kinase VEGF receptors. A disruption of this balance will lead to endothelial injury and TMA. Clinically, most patients present with hypertension and proteinuria. In rare cases, a severe

systemic TMA can develop, often associated with use of higher doses of the cancer therapeutic agents. Most of these disorders are reversible after stopping the medication.

Other chemotherapeutic agents associated with TMA include gemcitabine, mitomycin C, vincristine, and proteasome inhibitors (e.g., bortezomib, carfilzomib, and ixazomib). Gemcitabine-related TMA is directly related to the cumulative dose. Usually treated conservatively, in severe cases with persistent TMA eculizumab therapy may be considered.

In patients receiving an allogenic bone marrow transplant, TMA occurs in 10% to 40% of patients and is considered a manifestation of graft versus host disease (GVHD) or radiation therapy. Therapy for this form of TMA is controversial and mainly directed toward treating GVHD, although eculizumab may be tried.

Pregnancy-Related TMA

Pregnancy acts as a trigger for both TTP and complement-mediated aHUS. TTP occurs mainly during the second and third trimester of pregnancy. Normal pregnancy is associated with an augmentation of VWF antigen release leading to TTP in patients who are already predisposed by a congenital or acquired ADAMTS13 deficiency.

Pregnancy-related aHUS occurs in the postpartum period. Delivery acts as a triggering factor for aHUS in patients with certain genetic

Fig. 28.5 Relation between ADAMTS13 activity, excessive adhesion and activation of platelets, and thrombotic thrombocytopenic purpura. (A) In normal subjects, ADAMTS13 (i.e., von Willebrand factor–cleaving metalloprotease) molecules attach to binding sites on endothelial cell surfaces and cleave unusually large multimers of von Willebrand factor as they are secreted by stimulated endothelial cells. The smaller von Willebrand factor forms that circulate after cleavage do not induce the adhesion and aggregation of platelets during normal blood flow. (B) Absent or severely reduced activity of ADAMTS13 in patients with thrombotic thrombocytopenic purpura prevents timely cleavage of unusually large multimers of von Willebrand factor as they are secreted by endothelial cells. The uncleaved multimers induce the adhesion and aggregation of platelets in flowing blood. (From Moake JL: Thrombotic microangiopathies, *N Engl J Med* 347:589-600, 2002.)

mutations of the alternative complement pathway. Historically the outcomes were very poor, with more than 75% of patients developing ESRD. Eculizumab is an effective therapy and can be used during pregnancy.

The HELLP syndrome is a TMA of the liver sinusoids that can have a presentation similar to TTP or aHUS. Although rare, AKI can occur due to an acute tubular necrosis type of injury that is rapidly reversible with recovery from the HELLP syndrome.

ANTIPHOSPHOLIPID ANTIBODY SYNDROME

Antiphospholipid antibodies (APAs) refer to autoantibodies such as lupus anticoagulants or IgG or immunoglobulin M (IgM) anticardiolipin antibodies or anti- β_2 -glycoprotein that interfere with phospholipid-binding proteins and in vitro phospholipid-dependent clotting assays such as the partial thromboplastin time. Because not all lupus anticoagulants cause prolongation of the partial thromboplastin time, other tests of the coagulation system, such as the dilute Russell viper venom time, may need to be obtained. The diagnosis of APS is based on the occurrence of arterial or venous clotting events or fetal loss during pregnancy after 10 or more weeks' gestation or multiembryonic losses before 10 weeks' gestation in the setting of laboratory detection of an APA. Lupus anticoagulant and anticardiolipin antibodies are detectable in up to 10% of healthy populations, and their presence alone is insufficient for a diagnosis of APS. Apolipoprotein H (apo H, formerly β_2 -glycoprotein 1) is the main antigenic target of anticardiolipin antibodies.

In the absence of an underlying autoimmune disease, the syndrome is referred to as primary APS. Secondary APS occurs when associated with other diseases such as systemic lupus erythematosus (SLE). APAs are detectable in 30% to 50% of patients with SLE, and renal involvement is often observed in this setting.

The procoagulant effect of APAs may result from interference with the anticoagulant apo H, inhibition of fibrinolysis, direct endothelial injury, accelerated atherosclerosis, and activation of platelet, monocyte, and endothelial cells. Renal involvement occurs in about 25% of patients with primary APS and can occur in patients with SLE or other causes of APS. Thrombosis may occur throughout the renal vasculature, including main or branch renal arteries, arterioles, glomeruli, and veins. These findings resemble those found in other diseases associated with a TMA. Focal atrophy of the cortex in association with interstitial fibrosis may be observed due to resulting ischemia.

The renal manifestations of APS vary. Some patients have mild proteinuria with preserved kidney function, and others develop severe hypertension, nephrotic-range proteinuria, and AKI or CKD. Renal arterial thrombosis can cause infarction, acute onset of flank pain, hematuria, and decreased kidney function. RVT may be silent or, if acute and complete, may manifest with sudden flank pain and reduced kidney function. Pathologic changes seen on renal biopsy of patients with primary APS are small vessel vaso-occlusive disease with fibrous intimal hyperplasia of interlobular arteries, recanalizing thrombi in arteries and arterioles, focal cortical atrophy, and TMA. Other manifestations of APS include thrombocytopenia, hemolytic anemia, and

a prolonged activated partial thromboplastin time in the absence of heparin therapy. It is worth noting that a high prevalence of APAs has been reported in ESRD patients undergoing hemodialysis, with dialysis access thrombosis as a main manifestation.

Long-term warfarin anticoagulation with a target international normalized ratio (INR) between 2 and 3 is indicated for patients with primary or secondary APS and prior deep vein thrombosis, arterial thrombosis, or recurrent spontaneous abortion. Because warfarin is contraindicated during pregnancy, heparin with or without low-dose aspirin (81 mg) is necessary until the end of pregnancy.

Treatment of APA-positive patients in the absence of prior clinical events is controversial because of the high false-positive rate for the tests. Aspirin therapy for primary prevention in patients persistently positive for APAs has been advocated but not proved. Plasmapheresis, prednisone, and hydroxychloroquine have been advocated for the treatment of TMA due to APS and should be considered in severe cases.

RENAL VEIN THROMBOSIS

RVT is uncommon, occurring mostly in association with malignancy, but it also is a consequence of nephrotic syndrome, abdominal surgery or trauma, pancreatitis, and genetic or acquired hypercoagulable states. Most malignancy-associated RVT is caused by renal cell carcinoma with venous invasion, often with spreading to the contralateral kidney, which may cause bilateral renal vein occlusion.

The nephrotic syndrome is associated with a risk for venous thrombosis throughout the circulation, including RVT. The RVT risk in patients with nephrotic syndrome correlates with severity of proteinuria and hypoalbuminemia; patients with a serum albumin concentration of less than 2 g/dL and/or proteinuria more than 10 g/day are at particular risk. Some studies have documented an incidence of RVT as high as 30% among patients with nephrotic syndrome, but most cases are not clinically apparent. Patients with membranous nephropathy seem to be at greatest risk for RVT for reasons that are not known, but RVT can also occur with nephrotic syndromes due to focal segmental glomerular sclerosis, membranoproliferative glomerulonephritis, minimal change disease, and diabetic kidney disease. Hypercoagulability is thought to result from loss of the anti-thrombotic protein antithrombin III in urine, although other factors such as increased procoagulant factors and platelet activation may also be involved.

RVT may manifest with symptoms attributable to renal cell carcinoma, such as flank pain, gross hematuria, nausea, anorexia, or lower extremity swelling. In male patients, left renal vein occlusion may cause a left varicocele, a result of the venous drainage of the left gonadal vein. In patients without a malignancy, symptoms of RVT depend on the acuity of the thrombosis. Acute, complete thrombosis may manifest with hematuria, flank pain, abdominal distention, and acute renal failure. RVT in adults usually occurs gradually because of collateral venous drainage return; in this setting, symptoms of AKI are uncommon, although proteinuria and creatinine levels may be mildly elevated. In these cases of chronic RVT, patients will typically come to clinical attention for pulmonary embolus.

Because patients often do not have symptoms, RVT is likely more common than reported in the literature. Some have suggested CT screening of asymptomatic, high-risk patients, particularly those with membranous nephropathy and severe proteinuria and hypoalbuminemia.

The standard method for diagnosis is renal venography, but because it has the risks of clot dislodgment, bleeding, and use of iodinated contrast, less invasive methods are commonly used. Contrast-enhanced CT venography appears to have a relatively high sensitivity and specificity, although it carries some risk for contrast nephropathy. Magnetic resonance imaging using gadolinium-based contrast or time-of-flight sequencing without contrast may also be useful. Renal Doppler ultrasound is useful, but it is operator dependent and has lower sensitivity than CT venography.

Treatment with systemic anticoagulation is recommended in the absence of contraindications. Most clinicians maintain anticoagulation for 6 to 9 months, similar to the approach for nonrenal deep vein thrombosis and pulmonary embolism. The long-term recurrence risk is low if the underlying predisposition is successfully treated, and patients are unlikely to require indefinite anticoagulation. Direct intravenous thrombolysis or operative thrombectomy may be considered in severe cases, particularly if the RVT is a source of pulmonary emboli or is causing AKI. Prophylactic anticoagulation in high-risk patients, such as those with severe membranous nephropathy (serum albumin concentration <2.8 g/dL) should be considered for appropriate candidates.

For a deeper discussion on this topic, please see Chapter 116, “Vascular Disorders of the Kidney,” in *Goldman-Cecil Medicine*, 26th Edition.

Acute Kidney Injury

Mark A. Perazella, Jeffrey M. Turner

DEFINITION

Acute kidney injury (AKI) is a syndrome defined as an abrupt decrease in glomerular filtration rate (GFR) sufficient to promote the retention of nitrogenous waste products (blood urea nitrogen [BUN] and creatinine); disturb the regulation of extracellular fluid volume, electrolyte balance, and acid-base homeostasis; and impair drug excretion. Importantly, even mild abnormalities in kidney structure and function are associated with other end-organ complications and increased mortality.

AKI includes a spectrum of clinical conditions. The numerous causes of AKI vary based on individual comorbidities (and risk for AKI) and whether kidney injury develops in the outpatient setting or in hospital. The incidence of AKI is rising, and its complications include progression to more severe kidney failure, need for renal replacement therapy (RRT), chronic kidney disease (CKD), and death. Several consensus groups have produced definitions and diagnostic criteria for AKI. [Table 29.1](#) describes the diagnostic criteria for the Risk, Injury, Failure, Loss, and End-stage renal disease (ESRD) (RIFLE); Acute Kidney Injury Network (AKIN); and Kidney Disease: Improving Global Outcomes (KDIGO) classifications.

In 2004, the RIFLE classification was put forth to standardize the definition of AKI. Changes in serum creatinine concentration (over 7 days), reductions in estimated glomerular filtration rate (eGFR), and urine output parameters were used in this diagnostic system. The Risk (R), Injury (I), and Failure (F) categories were applicable to AKI, whereas the Loss (L) and ESRD (E) categories were CKD stages. In 2007, the AKIN group modified the RIFLE criteria definition of AKI by adding an absolute increase in serum creatinine of only 0.3 mg/dL, eliminating the eGFR criteria, and changing the time frame for AKI to develop (to 48 hours, compared with the 7 days for RIFLE diagnosis). Focusing on AKI, the AKIN criteria replaced the R, I, and F categories from the RIFLE criteria with stages 1, 2, and 3 and eliminated the L and E categories. In 2012, the KDIGO group combined parts of the RIFLE and AKIN criteria to capture AKI with increased sensitivity.

Understanding of the pathophysiology underlying development of AKI has advanced, and better diagnostic tools have moved the field forward. However, specific directed therapies remain limited for the most common forms of AKI. Although technical advances in RRT and supportive care have improved, patients commonly develop other end-organ disease in the setting of AKI. More concerning is the relatively high mortality rate associated with AKI, particularly when it develops in the hospital setting and requires RRT. [E-Table 29.1](#) shows some of the clinically important outcomes associated with AKI.

ETIOLOGY

In most cases, more than one process contributes to AKI, but for ease of classification, three broad categories ([Fig. 29.1](#)) are used: (1) *prerenal AKI*, the result of a decrease in renal blood flow and perfusion of the kidney; (2) *intrinsic AKI*, the result of disease affecting one of the renal parenchymal compartments; and (3) *postrenal AKI*, the result of obstruction to urinary flow anywhere along the urinary tract starting from the renal calyces/pelves and involving the ureters, bladder, or urethra.

The most common form of AKI is due to prerenal physiology, particularly in the outpatient setting, but also in the hospital. Postrenal AKI is more common in elderly men with prostatic hyperplasia, patients with bladder dysfunction, and patients with certain malignancies. Intrinsic AKI may be due to a vascular process, glomerular disease, interstitial disease, or tubular injury. The most common intrinsic AKI is an entity known as *acute tubular necrosis* (ATN), or more recently *acute tubular injury* (ATI), which is histologically more accurate. This is a clinical syndrome characterized by an abrupt and sustained decline in GFR due to an acute ischemic injury, nephrotoxic insult, or a combination of both. The clinical recognition of ATN is based primarily on exclusion of prerenal and postrenal causes of AKI, as well as other causes of intrinsic AKI (glomerulonephritis [GN], acute interstitial nephritis [AIN], and vasculitis). Once other intrinsic causes of AKI are excluded, it is reasonable to conclude ATN is the cause or major contributor to AKI. Although the name *acute tubular necrosis* is not an entirely valid histologic description of the lesion, the term will be utilized as it is part of the language of clinical medicine.

EPIDEMIOLOGY

AKI occurs more commonly in hospitalized patients as compared to the community setting. Community-acquired AKI defined by various step-wise increases in serum creatinine has an incidence of approximately 1%. Nearly half of the patients involve AKI superimposed on CKD. Prerenal AKI accounts for approximately 70% of cases, obstructive uropathy approximately 17%, and intrinsic AKI from various etiologies approximately 11% of the AKI cases. In contrast, hospital-acquired AKI has an incidence ranging from 4.9% to 7.2%. The incidence of AKI is higher in intensive care unit (ICU) admissions, approximating 30%. CKD, older age, and other comorbidities are important risk factors for AKI. Prerenal AKI remains the most common cause, followed by intrinsic AKI from nephrotoxic medications and ischemic ATN.

TABLE 29.1 Classification of Acute Kidney Injury

Stage	Serum Creatinine Increase Within 7 Days	Urine Output
Kidney Disease: Improving Global Outcomes (KDIGO) Classification (2012)		
1	1.5-1.9 times baseline <i>or</i> ≥ 0.3 mg/dL within 48 hr	< 0.5 mL/kg/hr \times 6-12 hr
2	2-2.9 times baseline	< 0.5 mL/kg/hr \times ≥ 12 hr
3	3 times baseline <i>or</i> an increase in the serum creatinine to ≥ 4 mg/dL with an absolute increase ≥ 0.3 mg/dL within 48 hr <i>or</i> 1.5 times baseline within 7 days <i>or</i> initiation of RRT <i>or</i> in patients aged < 18 yr, eGFR decreased to < 35 mL/min/1.73 m ²	< 0.3 mL/kg/hr \times ≥ 24 hr
Acute Kidney Injury Network (AKIN) Classification (2007)		
1	1.5-1.9 times baseline <i>or</i> ≥ 0.3 mg/dL within 48 hr	< 0.5 mL/kg/hr \times 6-12 hr
2	2-2.9 times baseline	< 0.5 mL/kg/hr \times ≥ 12 hr
3	3 times baseline <i>or</i> increase in serum creatinine ≥ 4 mg/dL with an increase ≥ 0.5 mg/dL <i>or</i> initiation of RRT	< 0.3 mL/kg/hr \times ≥ 24 hr <i>or</i> anuria ≥ 12 hr
RIFLE Classification (2004)		
Risk	1.5-1.9 times baseline <i>or</i> GFR decrease $> 25\%$	< 0.5 mL/kg/hr \times 6 hr
Injury	2-2.9 times baseline <i>or</i> GFR decrease $> 50\%$	< 0.5 mL/kg/hr \times 12 hr
Failure	3 times baseline <i>or</i> GFR decrease $> 75\%$ <i>or</i> serum creatinine ≥ 4 mg/dL with an increase ≥ 0.5 mg/dL	< 0.3 mL/kg/hr \times 24 hr <i>or</i> anuria \times 12 hr
Loss	Complete loss of renal function for > 4 wk	
ESRD	End-stage renal disease > 3 mo	

eGFR, Estimated glomerular filtration rate; GFR, glomerular filtration rate; RRT, renal replacement therapy.

DIAGNOSTIC EVALUATION

History and Physical Examination

Evaluation of the patient with AKI should be methodical and systematic to ensure that potentially reversible causes are diagnosed and treated expeditiously to preserve kidney function and limit development of permanent kidney injury, as depicted in Table 29.2. Part of the difficulty in arriving at a correct diagnosis is that several potential causes of AKI often coexist. Emphasis is placed on thorough analysis of available data and examination of the sequence of deterioration in kidney function and urine volume in relation to the chronologies of the potential causes of AKI.

Knowledge of the natural history of the various causes of AKI also is critical. The evaluation should include a thorough patient history and chart review to identify risk factors for prerenal AKI (e.g., vomiting, diuretics, diarrhea, heart failure, cirrhosis); potential nephrotoxic drugs (prescribed or over-the-counter, including alternative/complementary medications); risk factors for prostate disease, cervical cancer, or bladder cancer; and symptoms of urinary tract obstruction (e.g., prostatism, overflow incontinence, anuria). Some of the important chart review data are presented in E-Table 29.2. The urine volume is less than 400 mL/day with oliguric AKI, less than 100 mL/day with oligo-anuric AKI, and less than 50 mL/day with anuric AKI. Normal urine output does not exclude the diagnosis of AKI. Nonoliguric AKI (> 400 mL/day) can be associated with nephrotoxic AKI and partial urinary obstruction. Wide variation in daily urine output also suggests AKI due to partial urinary tract obstruction. Anuria has a limited differential diagnosis, suggesting complete urinary obstruction, a vascular catastrophe, or severe cortical necrosis.

A thorough physical exam is critical in patients with AKI, and particular attention should be given to determining the patient's volume status. Reduced body weight, hypotension, an orthostatic fall in blood pressure (BP), or flat neck veins may be present in patients with prerenal AKI or ischemic ATN caused by true volume depletion. On the other hand, the presence of edema, pulmonary rales, or an S₃ gallop signals venous congestion from cardiac dysfunction that can be the cause of cardiorenal syndrome. Alternatively, edema, ascites, and asterixis

suggest acute liver dysfunction or cirrhosis, which can be the cause of AKI due to hepatorenal syndrome. It is important to differentiate these disorders, because their appropriate therapies differ. Some individuals can have signs of increased total body water in the form of edema, while simultaneously having signs of reductions in their intravascular volume in the form of hypotension and weak pulses. In these individuals, invasive intravascular monitoring may be helpful. This includes measurement of cardiac filling pressures or central venous pressures with an indwelling catheter. In addition, recent research has shown that noninvasive techniques including respiratory variations in systolic blood pressure, pulse pressure, calculated stroke volume, or the collapsibility of the inferior vena cava measured on bedside ultrasound are also useful methods for volume assessment that do not require the placement of a vascular catheter.

Evidence of systemic disease also should be sought. Findings may include signs of pulmonary hemorrhage indicative of a vasculitis or Goodpasture's syndrome, skin rash as a manifestation of systemic lupus erythematosus, atheroemboli, vasculitis, cryoglobulins, or AIN, as well as joint disease making lupus or rheumatoid arthritis a consideration.

Basic Laboratory Tests

Laboratory tests are directed by the differential diagnosis that is postulated after a complete history, chart review, and physical examination have been performed. Basic tests include a complete blood count to assess for anemia (microangiopathic or immune-mediated) and thrombocytopenia (thrombotic thrombocytopenic purpura [TTP], hemolytic-uremic syndrome [HUS], and disseminated intravascular coagulation [DIC]). Other tests to evaluate the cause of AKI include various serologic measurements (antinuclear antibody [ANA], antineutrophil cytoplasmic antibodies [ANCA], anti-glomerular basement membrane antibody [anti-GBM], anti-double-stranded DNA antibodies [anti-dsDNA], and hepatitis B and C viral serologies), complement levels, cryoglobulin levels, blood cultures, serum lactate dehydrogenase (LDH) and haptoglobin measurements, serum and urine immunoelectrophoresis, and serum free light chain assay.

E-TABLE 29.1 Clinical Importance of Acute Kidney Injury

Elevations in serum creatinine as minimal as 0.3 mg/dL are associated with increased in-hospital mortality.

Hospitalized patients with AKI have up to a 30% higher risk for mortality.

Patients in the ICU with AKI who require RRT have up to a 60% higher risk for mortality.

Patients who develop AKI and recover have an increased risk for subsequently developing CKD and ESRD.

AKI has been associated with an increased risk for cardiovascular events.

Hospitalized patients with AKI are likely to have longer lengths of stay with higher costs.

AKI, Acute kidney injury; *CKD*, chronic kidney disease; *ESRD*, end-stage renal disease; *ICU*, intensive care unit; *RRT*, renal replacement therapy.

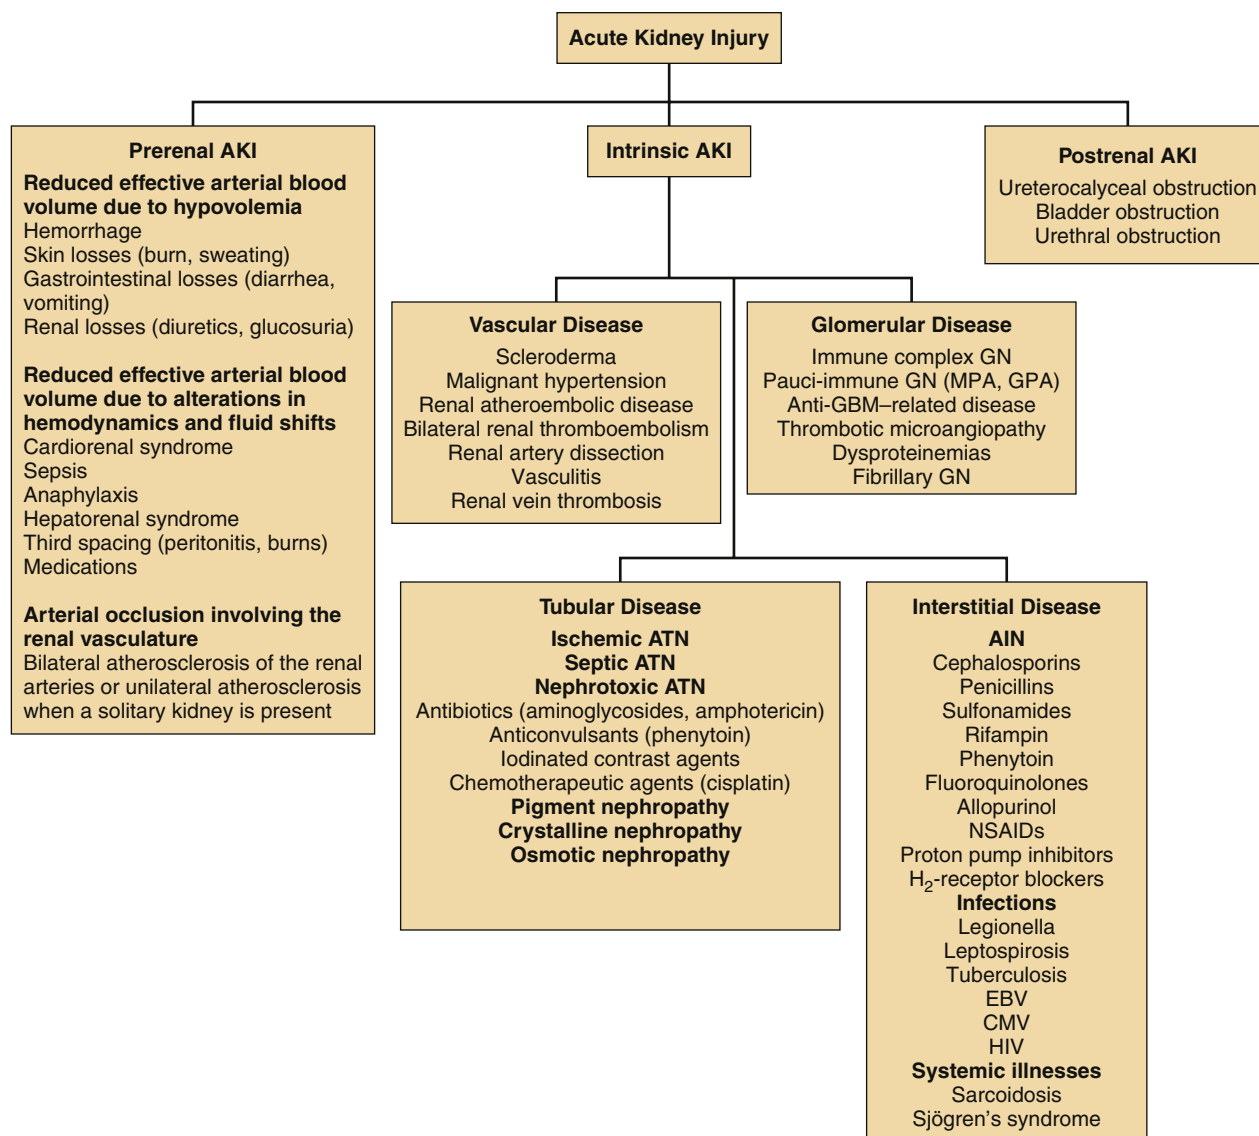

Fig. 29.1 Common causes of acute kidney injury (AKI). *AIN*, Acute interstitial nephritis; *ATN*, acute tubular necrosis; *CMV*, cytomegalovirus; *EBV*, Epstein-Barr virus; *GBM*, glomerular basement membrane; *GN*, glomerulonephritis; *GPA*, granulomatosis with polyangiitis; *H₂*, histamine 2; *HIV*, human immunodeficiency virus; *HUS*, hemolytic uremic syndrome; *MPA*, microscopic polyangiitis; *NSAIDs*, nonsteroidal anti-inflammatory drugs; *TTP*, thrombotic thrombocytopenic purpura.

TABLE 29.2 Diagnostic Approach to the Patient With Acute Kidney Injury

1. Record review (see E-Table 29.2); special attention to evidence of recent reduction in glomerular filtration rate and sequence of events leading to deterioration of kidney function to determine possible causative factors
2. Physical examination, including evaluation of hemodynamic status
3. Urinalysis and urine microscopy with thorough sediment examination
4. Determination of urinary indices, including fractional excretion of sodium and urea
5. Catheterization and measurement of postvoid residual urine volume if outlet obstruction is suspected
6. Fluid challenge in cases of suspected prerenal AKI
7. Radiologic studies, particular as dictated by the clinical setting (e.g., ultrasonography to look for obstruction)
8. Kidney biopsy

AKI, Acute kidney injury.

E-TABLE 29.2 Record Review in a Hospitalized Patient Who Develops Acute Kidney Injury

Finding	Comments
Prior kidney function	Determination of whether the azotemia is acute; patients with prior kidney disease are particularly susceptible to AKI due to use of contrast dyes
Presence of infection	Sepsis is a possible cause of AKI, even in the absence of hypotension
Nephrotoxic agents	Aminoglycosides (e.g., gentamicin) are an important cause of ATN in hospitalized patients, typically nonoliguric ATN during first 2 wk of therapy; antibiotics are a possible cause of AIN; cytotoxic drugs (e.g., cisplatin) are a possible cause of AKI
Contrast studies including oral cholecystography, IVP, angiography	Important cause of ATN in hospitalized patients; typically causes oliguric ATN within 24-48 hr after study
Episodes of hypotension	Suggestion of prerenal AKI or ischemic ATN
History of blood transfusions	Incompatible blood transfusion is an unusual cause of ATN
History of loss or sequestration of extracellular fluid volume, intake and output, serial weights	Important clues to the possibility of prerenal AKI
Type of surgery	Patients with prior cardiac or vascular surgery or with obstructive jaundice are particularly susceptible to ATN
Type of anesthesia	Methoxyflurane and the related, less toxic enflurane are causes of nonoliguric ATN
Amount of blood loss during surgery and whether associated with hypotension	Suggestion of prerenal AKI or ischemic ATN

AIN, Acute interstitial nephritis; *AKI*, acute kidney injury; *ATN*, acute tubular necrosis; *IVP*, intravenous pyelography.

TABLE 29.3 Urinalysis and Microscopic Examination of the Urine Sediment

Test	Prerenal	Vasculitis	GN	ATN	AIN	Postrenal
Specific gravity	High	Normal/high	Normal/high	Isosmotic	Isosmotic	Isosmotic
Dipstick blood	Negative	Positive	Positive	±	±	Negative
Dipstick protein	Negative	Positive	Positive	Negative	±	Negative
Urine sediment examination	Negative, hyaline casts	RBC casts, dysmorphic RBCs	RBC casts, dysmorphic RBCs	Granular casts, RTECs	WBC casts, eosinophils	Negative, sometimes WBCs/RBCs

AIN, Acute interstitial nephritis; ATN, acute tubular necrosis; GN, glomerulonephritis; RBCs, red blood cells; RTECs, renal tubular epithelial cells; WBCs, white blood cells.

Urinalysis and Urine Microscopy

Urinalysis is a key component of the diagnostic evaluation of AKI, as summarized in Table 29.3. It is important to evaluate urine specific gravity (SG), as well as the presence of blood (or heme), protein, or leukocyte esterase.

A very high urine SG typically suggests prerenal AKI, whereas isosthenuria (SG = 1.010) indicates intrinsic AKI (e.g., ATN). A thorough microscopic examination of the spun urine sediment, with quantification of the urinary elements, adds essential information to the case. Bland urine with no blood or protein and few to no cells or casts favors a diagnosis of prerenal AKI. Vascular causes of AKI have a variable urine tonicity and sometimes hematuria (isomorphic or dysmorphic red blood cells [RBCs]) and granular casts. GN exhibits variable urine tonicity, positive blood and protein on the dipstick, RBCs, and RBC casts. ATN shows isotonic urine with variable protein and variable heme on urine dipstick (heme is positive with rhabdomyolysis and hemolysis). Renal tubular epithelial cells (RTECs), RTEC casts, and fine or coarse pigmented granular casts (sometime muddy brown E-Fig. 29.1) may be present on the sediment examination.

Urine in patients with postrenal AKI is typically isotonic and bland unless there is associated infection (pyuria), nephrolithiasis (hematuria), or concomitant ATN (RTECs, RTEC casts, granular casts).

With certain processes, crystals may be indicative of the underlying cause of AKI. For example, calcium oxalate crystals may suggest enteric hyperoxaluria or ethylene glycol intoxication, uric acid crystals may point to acute urate nephropathy, and various other crystals may indicate a drug-induced form of AKI (see Figs. 24.2, 24.3, and 24.4).

Urinary Indices

Spot urine chemistry testing (sodium, creatinine, and urea), along with plasma samples (sodium, creatinine, and BUN), has been used to evaluate renal tubular function in the setting of AKI, primarily to distinguish prerenal AKI from ATN. These measures allow the clinician to calculate fractional excretion of sodium (FE_{Na}) and fractional excretion of urea (FE_{Urea}); they are thought to be more accurate indicators than urine sodium concentration, which is less than 10 to 20 mEq/L with prerenal AKI and greater than 20 mEq/L with ATN.

The ratio of the clearance of sodium (Na) to that of creatinine (Cr) is calculated as a percentage:

$$FE_{Na} = (U_{Na}/P_{Na}) \times P_{Cr}/U_{Cr} \times 100$$

where U and P are the concentrations in urine and plasma, respectively. Likewise, the ratio of urea clearance to creatinine clearance is

$$FE_{Urea} = (U_{Urea}/P_{Urea}) \times (P_{Cr}/U_{Cr}) \times 100$$

The rationale for the use of these indices is that the ratio of urine to plasma creatinine concentrations (U_{Cr}/P_{Cr}) provides an index of the fraction of filtered water excreted. Assuming that all of the creatinine filtered at the glomerulus is excreted into the urine, any increment in the concentration of creatinine in urine over that in plasma must result from the removal of water.

In prerenal AKI, because of the increased stimulus for salt and water retention, U_{Cr}/P_{Cr} typically is considerably greater than it is in ATN; moreover, FE_{Na} is less than 1%, and urine sodium concentrations are characteristically low. In contrast, in AKI due to ATN, the nephrons excrete a large fraction of their filtered sodium and water, resulting in a lower U_{Cr}/P_{Cr} , higher urine sodium concentrations, and a higher FE_{Na} (E-Table 29.3). An important clinical exception to this finding is that FE_{Na} can be high (>1% to 2%) with prerenal AKI in the setting of diuretic therapy. To counter this effect, calculation of FE_{Urea} has been used: An FE_{Urea} less than 35% favors a diagnosis of prerenal AKI and an FE_{Urea} greater than 50% favors ATN.

Interpretations of these tests, therefore, must be made in conjunction with other assessments of the patient, because clinically important exceptions to these generalizations exist. As an example, prerenal AKI can manifest with an elevated FE_{Na} or FE_{Urea} in the setting of glycosuria, metabolic alkalosis, bicarbonaturia, salt-wasting disorders, or CKD. Similarly, ATN with low FE_{Na} and FE_{Urea} occurs with pigmenturia, sepsis, radiocontrast injury, severe heart or liver failure, and non-oliguric ATN.

Renal Imaging

If either prerenal AKI or ATN is the likely cause of AKI, and if the clinical setting does not require the exclusion of another cause, then no further diagnostic evaluation is required. Further assessment may be necessary if the diagnosis is uncertain, especially if the clinical setting suggests other possibilities (e.g., obstruction, vascular accident); if clinical findings make the diagnosis of prerenal AKI or ATN unlikely; or if oliguria persists without a good reason. When indicated, diagnostic renal imaging is important in the evaluation of AKI. Retroperitoneal ultrasonography of the kidneys, ureters, and bladder is the first test used because it is readily available, noninvasive, free of radiation exposure, and fairly accurate.

Ultrasonography provides information about kidney size (large, normal, or small) and the parenchyma (normal or increased echogenicity), the status of the pelvis and urinary collecting system (normal or hydronephrotic), and the presence of structural abnormalities (e.g., stones, masses, enlarged lymph nodes). In the setting of AKI, this test can rapidly confirm or exclude the presence of hydronephrosis (E-Fig. 29.2) and a diagnosis of obstructive uropathy. Interrogation of the renal arteries by Doppler ultrasonography provides important information about renal blood flow and renal artery stenosis; however, this test is highly operator dependent.

Computed tomography (CT) of the retroperitoneum provides important information about the cause of postrenal AKI (e.g., tumor, stones, retroperitoneal fibrosis) when ultrasound findings are negative or inconclusive. CT angiography can also accurately diagnose renal artery disease and renal infarction, but there is a risk of nephrotoxicity in those patients with underlying acute or chronic kidney disease. *Magnetic resonance (MR) imaging* does not add much to CT scanning except in the diagnosis of retroperitoneal fibrosis. *Gadolinium MR* angiography can safely provide important information about renal artery stenosis or thrombosis, but it should be used cautiously in patients with AKI or stage 4 or greater CKD. Nephrogenic systemic fibrosis can develop in these patients, especially with nonionic or linear gadolinium contrast agents and in the setting of inflammation.

Radionuclide tests are used to assess the presence or absence of renal blood flow, differences in flow to the two kidneys, and excretory (secretory) function. However, these studies have limited utility in AKI and have reduced accuracy in quantitating absolute rates of flow.

Kidney Biopsy

When prerenal AKI, ATN, and obstructive uropathy are unlikely, percutaneous kidney biopsy is sometimes required to determine the cause of AKI and to direct appropriate therapy. Reasonable criteria to support use of kidney biopsy include absence of an obvious cause of AKI such as hypotension or nephrotoxin exposure and prolonged oliguria, usually for more than 2 to 3 weeks. Other potential indications include evaluation for myeloma-related kidney disease in an elderly patient with unexplained AKI; extrarenal manifestations of systemic diseases such as systemic lupus erythematosus, rheumatoid arthritis, or vasculitis; and determination of whether AIN is present in patients receiving a potential culprit drug.

Kidney tissue should be thoroughly examined with the use of light microscopy, immunofluorescence staining, and electron microscopy to facilitate an accurate diagnosis. This ensures a diagnosis of the cause of AKI in most patients. However, kidney biopsy should be employed judiciously to avoid complications such as traumatic renal arteriovenous malformation, severe bleeding requiring transfusion or embolization, other organ injury (liver, spleen, bowel), and nephrectomy for intractable bleeding.

Future Tests for AKI

The limitations of currently available tests to estimate GFR and kidney injury have led to proteomics-based studies to identify novel biomarkers of AKI. The hope is that novel biomarkers will improve the diagnosis and prognosis of AKI. For example, early AKI diagnosis would permit implementation of appropriate preventive strategies and treatment regimens to abrogate permanent loss of kidney function. In patients who develop AKI, biomarker concentrations demonstrate changes earlier than serum creatinine concentrations and appear to distinguish between prerenal AKI, ATN, and other glomerular disorders, which may allow directed interventions and avoidance of potentially harmful therapies. One such example is aggressive intravenous fluid therapy in patients with ATN, which risks volume overload and other end-organ consequences. Finally, biomarkers may allow clinicians to better predict outcomes such as worsening kidney function, RRT requirement, and mortality in patients with hospital-acquired AKI.

CLINICAL PRESENTATION, DIFFERENTIAL DIAGNOSIS, AND MANAGEMENT OF AKI

Prerenal AKI

Prerenal AKI is primarily the result of inadequate blood flow to the kidneys. Renal blood flow approximates more than 1 L/minute, which

is necessary to maintain GFR, preserve oxygen delivery, and sustain ion transport and other energy-requiring processes. Therefore, normal kidney function depends on adequate perfusion; a significant reduction in renal perfusion diminishes filtration pressure and lowers GFR.

Volume Depletion

Both “true” and “effective” hypovolemia activate several neurohormonal vasoconstrictor systems as mechanisms to protect circulatory stability. The substances released include catecholamines from the sympathetic nervous system, endothelin from the vasculature, angiotensin II from the renin-angiotensin system (RAS), and vasopressin. They raise BP through arterial and venous constriction but also can constrict afferent arterioles and reduce GFR, especially when systemic BP is inadequate to maintain renal perfusion pressure.

Structural lesions in the renal arterial and arteriolar tree can also reduce perfusion and promote prerenal AKI. Kidney adaptive responses are stimulated to counterbalance diminished renal perfusion in these circumstances. These adaptive processes include the myogenic reflex, which is activated by low distending pressures sensed in the renal baroreceptors and causes afferent arteriolar vasodilatation. Prostaglandins (e.g., PGE₂, PGI₂), nitric oxide, and products from the kallikrein-kinin system modify the effects of these vasoconstrictors on the afferent arteriole. Importantly, disturbance of the balance between afferent vasodilatation and efferent vasoconstriction can disrupt intrarenal hemodynamics and precipitate AKI.

Medications

The balance of vasoconstricting and vasodilating processes may be altered by medications such as nonsteroidal anti-inflammatory drugs (NSAIDs) and selective cyclooxygenase 2 (COX2) inhibitors. These drugs act to cause prerenal AKI through inhibition of vasodilatory prostaglandins in patients who require prostaglandin effects to maintain renal perfusion. Despite its vasoconstrictor properties, angiotensin II acutely preserves glomerular filtration pressure and GFR in states of reduced renal perfusion by constricting the efferent arteriole more than the afferent arteriole. This salutary effect in part explains the GFR reduction that occurs when a patient who is dependent on angiotensin II to constrict the efferent arteriole is treated with an ACE inhibitor or an angiotensin II receptor blocker (ARB).

Cardiorenal Syndrome

The cardiorenal syndrome (CRS) is an umbrella term that encompasses a number of coexistent cardiac or kidney derangements. Although there are five subtypes of CRS, hospital-acquired AKI due to CRS is most often of the type 1 variety. Reduced cardiac output, arterial underfilling, elevated atrial pressures, and venous congestion, independently or in combination, can impair the renal circulation and reduce GFR, thereby causing a form of prerenal AKI. These processes stimulate neurohumoral adaptations such as activation of the sympathetic nervous system and RAS and increases in vasopressin and endothelin-1, in an attempt to preserve perfusion to vital organs. However, these adaptations enhance salt and water retention and systemic vasoconstriction, which ultimately promote or exacerbate prerenal AKI by two mechanisms: (1) They increase cardiac afterload and further reduce cardiac output and renal perfusion, and (2) they increase central venous pressure, renal venous pressure, and/or intra-abdominal pressure, ultimately lowering GFR.

AKI in patients with heart failure is often caused by CRS type 1, but certainly these patients can also suffer true prerenal AKI from overzealous diuresis or from ischemic or nephrotoxic ATN. Prerenal AKI from true volume depletion is responsive to judicious administration of intravenous fluids and diuretic withdrawal, making it easy

E-Fig. 29.1 The presence of muddy brown casts in the urine sediment of a patient with acute kidney injury often points to acute tubular necrosis or apoptosis from ischemic or nephrotoxic tubular injury.

E-TABLE 29.3 Urine Chemistry Values

Laboratory Test	Prerenal AKI	ATN
Specific gravity	>1.020	<1.010
Urine osmolality (mOsm/kg)	>500	<400
Urine Na ⁺ (mEq/L)	<20	>20
FE _{Na} (%)	<1	>2
FE _{Urea} (%)	<35	>50

AKI, Acute kidney injury; ATN, acute tubular necrosis; FE_{Urea}, fractional excretion of urea; FE_{Na}, fractional excretion of sodium; Na⁺, sodium ion concentration; U, urine.

E-Fig. 29.2 Hydronephrosis. Dilatation of the urinary pelvis and calyces is a fairly sensitive and specific finding for obstruction as the cause of acute kidney injury.

to recognize. It is sometimes more difficult to distinguish CRS type 1 from ATN because the processes often coexist.

Identification of AKI in the setting of heart failure is clinically relevant because reduced GFR is generally associated with a worse prognosis. Therapy is directed at improving cardiac function, especially in patients with low cardiac output, and relieving pulmonary and renal congestion. Small to moderate increases in serum creatinine (0.5 mg/dL) that occur in the setting of effective therapy for venous congestion in acute heart failure are acceptable and typically lead to improved long-term outcomes at 30 days and beyond. Loop diuretics are part of the central treatment strategy for relieving venous congestion; however, these agents can directly stimulate maladaptive neurohormonal responses, transiently worsening kidney function after their introduction. Patients with congestive heart failure often have some degree of diuretic resistance. Strategies to overcome this resistance include combination therapy with thiazide diuretics and rarely device-driven ultrafiltration. With advanced AKI, RRT is required to treat uremia, metabolic complications, and volume overload. Therapies for end-stage cardiac failure include cardiac transplantation and placement of a left ventricular assist device for long-term destination therapy or as a bridge to transplantation.

Hepatorenal Syndrome

A strong physiologic interplay also occurs between liver disease and kidney impairment. Patients with advanced, decompensated cirrhosis or fulminant acute hepatic failure develop a unique form of prerenal AKI called hepatorenal syndrome (HRS). The International Ascites Club diagnostic criteria for HRS include (1) the presence of cirrhosis and ascites, (2) serum creatinine levels higher than 1.5 mg/dL, (3) no improvement in kidney function after at least 48 hours of diuretic withdrawal and volume expansion with albumin, (4) absence of shock, (5) no nephrotoxic drug exposure, and (6) absence of parenchymal kidney disease. There are two subtypes of HRS based on rapidity and severity of kidney impairment. Type 1 HRS is characterized by rapidly progressive renal failure, defined by doubling of the initial serum creatinine concentration (to >2.5 mg/dL in <2 weeks). Type 2 HRS is characterized by moderate kidney failure (serum creatinine increase from 1.5 to 2.5 mg/dL). The hallmark of HRS is profound renal vasoconstriction in the setting of systemic and splanchnic arterial vasodilatation. The hemodynamic changes that occur in HRS are summarized in [E-Fig. 29.3](#).

There is no test that is specific for the diagnosis of HRS, and diagnosis requires exclusion of other causes of AKI. The main differential diagnoses of type 1 HRS are prerenal AKI and ATN, which have an acute onset with progressive deterioration of kidney function. Recognition of prerenal AKI is typically easier, because it responds to intravenous fluids (albumin and saline), whereas HRS type 1 and ATN are more difficult to differentiate. Distinguishing ATN from HRS is crucial, because therapies for these two forms of AKI are very different, as are their prognoses and outcomes. For HRS, midodrine and octreotide, vasopressin (or its analogue terlipressin outside of the United States), or norepinephrine is used, whereas ATN requires primarily supportive therapy with initiation of RRT if necessary. Liver (or combined liver-kidney) transplantation is the definitive therapy for HRS.

Intrinsic AKI

Intrinsic AKI reflects kidney injury that arises from a process that damages one of the compartments of the renal parenchyma. To simplify the approach, kidney disease is organized into anatomic sites of injury in the vasculature, glomerulus, tubules, and interstitium.

Vascular Disease

Intrinsic AKI may result from vascular disease in large or medium-sized arteries, small arteries, and arterioles within the renal

parenchyma and veins draining the kidneys. Bilateral renal artery thrombosis superimposed on underlying high-grade stenoses, significant cardiac or aortic thromboembolism occluding the renal arteries, or dissection of the renal arteries may cause AKI. With acute presentations, the clinical features often include flank or abdominal pain, fever, hematuria, and oligo-anuria or anuria. Therapy with thrombolytics may reverse acute thrombosis and thromboembolism and restore renal blood flow with early diagnosis. Percutaneous angioplasty with stent placement can non-invasively correct significant underlying renal artery stenosis. Renal artery dissection often requires surgical repair, but at times stent placement may suffice. Vasculitis of large renal vessels (e.g., Takayasu's arteritis, giant cell arteritis) is an extremely rare cause of AKI.

Induction of AKI by renal atheroemboli occurs less commonly than before due to changes in techniques that now include more commonly inserting the catheter into the radial artery for cardiac procedures as opposed to the more traditional method of inserting the catheter into the femoral artery to approach the heart, and perhaps due to the use of softer wires during vascular procedures. Cholesterol crystal embolization is caused most often by invasive vascular procedures in patients with atherosclerotic disease that disrupt the fibrous cap on the ulcerated plaque. However, thrombolytic therapy and therapeutic anticoagulation can also precipitate embolization in patients who have a significant burden of renal artery or aortic plaque. When it occurs, atheromatous material may lodge in interlobar, arcuate, or interlobular arteries in the kidneys. In addition to AKI, clinical manifestations include abrupt onset of severe hypertension, livedo reticularis, digital or limb ischemia, abdominal pain from pancreatitis or bowel ischemia, gastrointestinal bleeding, muscle pain, central nervous system symptoms such as focal neurologic deficits, confusion, amaurosis fugax, and retinal ischemic symptoms. Peripheral eosinophilia, hypocomplementemia, elevated sedimentation rate, and eosinophiluria variably accompany the syndrome. Treatment is primarily preventive by avoiding the factors known to precipitate atheroembolization. BP control, treatment with statins, amputation of necrotic limbs, aggressive nutrition, avoidance of anticoagulation (to reduce the risk for further embolization), and RRT for severe AKI may improve the dismal prognosis associated with this syndrome. Steroids and iloprost are sometimes used, but their therapeutic role is uncertain.

AKI from vasculitis involving the medium and small vessels has been described with classical polyarteritis nodosa. It is either idiopathic or secondary to hepatitis B antigenemia and manifests with severe hypertension and AKI. Renal arteriography demonstrating beading in the arterial tree of the kidney (and other organs) is diagnostic. Scleroderma is a disorder characterized by arterial and arteriolar narrowing due to deposition of mucinous material. Scleroderma renal crisis manifests as AKI and severe hypertension, often malignant, in a patient with a disease flare. Urinalysis and urine microscopy may be bland or may show cellular activity. Fibrinoid necrosis with ischemic injury occurs in the kidney. ACE inhibitors effectively control BP and improve AKI.

Rarely, AKI may develop in the setting of renal vein thrombosis, a well-known complication of nephrotic syndrome. Imbalance of anticoagulant substances lost in the urine and procoagulant substances produced by the liver leads to a hypercoagulable state and renal vein thrombosis. AKI is thought to develop from raised intrarenal pressures and reduced kidney perfusion. Therapy includes acute thrombolysis and chronic anticoagulation as well as treatment of the underlying glomerular lesion (often membranous nephropathy) and reduction in proteinuria.

Glomerular Disease

A number of glomerular diseases can cause AKI, and the more common entities are reviewed here. Acute proliferative GN may be broadly classified as (1) immune complex disease, (2) pauci-immune disease, or (3) anti-GBM–related disease. They are all characterized by glomerular cell proliferation and necrosis, polymorphonuclear cell infiltration, and, with severe injury, epithelial crescent formation (E-Fig. 29.4). Acute proliferative GN manifests with hypertension and edema formation and with laboratory results pertinent for hematuria and proteinuria, described as *nephritic sediment*. Examination of the urine sediment classically reveals dysmorphic RBCs and RBC casts (see Figs. 24.2 and 24.3). Therapy is directed at the underlying cause, with supportive measures and RRT as necessary.

TTP and HUS are two of the more common causes of thrombotic microangiopathy, which is marked by platelet deposition and endothelial injury with thrombosis of arterioles and glomerular capillaries. AKI results from severe glomerular damage with profound ischemia and necrosis. The thrombotic microangiopathies may manifest with nephritic sediment. Patients with HUS may have severe AKI, or it may be mild, as in patients with TTP. Microangiopathic hemolytic anemia and thrombocytopenia are key features. Therapy often includes modulation of the immune system with plasma exchange or eculizumab, in addition to supportive measures.

The dysproteinemias, which deposit monoclonal immunoglobulin light or heavy chains (or both) in the kidney, may also promote glomerular lesions. The type, metabolism, and packaging of the immunoglobulin determine which type of glomerular lesion develops: light or heavy chain deposition disease, amyloidosis, or one of the fibrillary GNs. The immunoglobulin deposition diseases often manifest with nephrotic proteinuria and AKI, rarely with hematuria.

Light chain deposition disease, heavy chain deposition disease, and light/heavy chain deposition disease cause nodular glomerular lesions. Amyloidosis is also associated with the formation of acellular glomerular nodules. The fibrillary GNs (fibrillary and immunotactoid) may be associated with mesangial expansion or glomerular nodules. More commonly, they appear as a mesangial proliferative, mesangiocapillary, or membranous lesion, sometimes with formation of epithelial crescents. These diseases can be distinguished by electron microscopy. Light and heavy chain diseases produce granular deposits, whereas amyloidosis appears as haphazard fibrils in the 8- to 12-nm size range. Fibrillary GN has fibrils in the 20- to 30-nm range, and immunotactoid GN shows fibrils in the 30- to 50-nm range with organized microtubular fibrils. In addition, positive immunohistochemistry staining for DNAJB9 is highly specific for fibrillary GN.

Tubular Disease

Acute tubular necrosis. ATN is the most common form of hospital-acquired intrinsic AKI, accounting for more than 80% of AKI episodes. It is classically divided into ischemic ATN, which makes up almost 50% of the cases, nephrotoxic ATN, and combinations of both. In many instances, ATN results from multiple insults acting together to injure the kidney. The end result of either ischemic or toxic insult is tubular cell injury and death. E-Table 29.4 outlines the important factors underlying the pathogenesis of ATN.

Ischemic ATN. Ischemic ATN is, for the most part, an extension of severe and uncorrected prerenal AKI. Prolonged renal hypoperfusion causes tubular cell injury, which persists even after the underlying hemodynamic insult resolves and may be associated with ischemia-reperfusion injury. Intraoperative and postoperative hypotension impairs renal perfusion and occurs relatively frequently after cardiac and vascular surgical procedures. Ischemic, nephrotoxic, and

multifactorial ATN are common on the medical wards and in the ICU. Risk for ischemic ATN is increased by the comorbidities these patients possess. Sepsis and septic shock, severe intravascular volume depletion, cirrhotic physiology, and cardiogenic shock are examples of situations that confer high risk for development of ischemic ATN. Employment of vasopressors to restore BP may further reduce renal perfusion and exacerbate ischemia. In some cases, ischemic ATN is so profound that cortical necrosis (ischemic atrophy of the renal cortex) develops.

Nephrotoxic ATN. Nephrotoxic ATN occurs when exogenous substances injure the tubules, primarily through direct toxic effects but also through perturbations in intrarenal hemodynamics or a combination of these factors. In the past, organic solvents and heavy metals (e.g., mercury, cadmium, lead) were a frequent cause of ATN. Since then, many potentially toxic medications have been synthesized and observed to cause tubular injury by multiple mechanisms.

Aminoglycosides cause proximal tubular injury. AKI rarely develops within the first week of therapy, and injury initially manifests with subtle changes in urine concentrating ability and increased RTECs and granular casts in the urine sediment. The antifungal agent amphotericin B induces AKI through two distinct mechanisms: destruction of cellular membranes through sterol interactions and vasoconstriction-induced tubular ischemia. ATN develops in a dose-dependent fashion and manifests with increasing serum creatinine levels and RTECs and granular casts in the urine. Liposomal and lipid complex formulations are less nephrotoxic but can precipitate AKI in high-risk patients.

Radiocontrast material is a common cause of AKI because it is so widely used with imaging procedures. AKI develops in patients with underlying risk factors such as CKD (estimated GFR <30 mL/min), especially diabetic nephropathy, “true” or “effective” intravascular volume depletion, advanced age, and exposure to other nephrotoxins. The incidence of AKI may be 25% and approaches 50% in patients with underlying risk factors. ATN occurs from both ischemic tubular injury (prolonged decrease in renal blood flow) and direct toxicity (osmotic cellular injury, oxidative stress, inflammation). Large radiocontrast volumes increase risk, whereas low-osmolar and iso-osmolar radiocontrast agents are less nephrotoxic than high-osmolar material.

The antiviral agents cidofovir and tenofovir, once they have entered the cell from the peritubular blood via the human organic anion transporter 1 on the basolateral membrane, cause AKI through disruption of mitochondrial and other cellular functions. Several chemotherapeutic agents, including the platinum-based drugs, ifosfamide, mithramycin, imatinib, pentostatin, and pemetrexed, cause ATN through direct toxic effects. As with other nephrotoxins, part of their ability to induce ATN resides in the renal handling by the kidneys (transport through tubular cells) as they are being excreted. In addition, zoledronate, the polymyxins, high-dose vancomycin, foscarnet, and deferasirox also cause nephrotoxic ATN. Vancomycin may cause a unique form of AKI known as cast nephropathy. Also, the combination of vancomycin plus piperacillin-tazobactam increases risk for AKI. AKI prevention is best achieved by judicious prescription of these drugs to high-risk patients, appropriate dose adjustments, avoidance of superimposed volume depletion, and close monitoring with early markers of injury such as urine microscopy.

Pigment nephropathy. Pigment nephropathy represents the nephrotoxic renal tubular effects of endogenously produced substances. The most common examples are overproduction of heme moieties in serum that are eventually filtered at the glomerulus and excreted in urine. With severe rhabdomyolysis, the heme pigment released from muscle is myoglobin. AKI develops in the setting of myoglobinuria from the combination of direct myoglobin tubular toxicity (in an

E-Fig. 29.3 Decompensated cirrhosis is associated with hemodynamic changes that result in the development of acute kidney injury from hepatorenal syndrome.

E-Fig. 29.4 Crescentic glomerulonephritis is often a biopsy finding in patients with rapidly progressive glomerulonephritis.

E-TABLE 29.4 Pathogenesis of Acute Tubular Necrosis

Intrarenal Hemodynamics and Vasoconstriction →	Tubular Cell Injury and Necrosis →	Reperfusion Injury From Infiltrating Leukocytes and T Cells →	Role of Growth Factors in Renal Injury
Elevated endothelin	Disruption of actin cytoskeleton with loss of cell polarity	Recruitment of neutrophils and adhesion of cells	Growth factors participate in regenerative process after ischemic injury
Increased sympathetic discharge		Release of reactive oxygen species, proteases, elastases, other enzymes	
Reduced nitric oxide		Infiltration of T lymphocytes → unknown mechanism of injury	Growth factors may also promote renal injury
Loss of renal autoregulation	Generation of reactive oxygen species	Tubular cell death	Augmentation of tubulointerstitial injury and fibrosis
Reduction in cortical and medullary blood flow	Tubular shedding	Interstitial inflammatory infiltrate with fibrosis	
Ischemic tubular injury with apoptosis and cell necrosis	Backleak of filtrate		
	Cast formation with tubular obstruction		

acid urine), volume depletion, and obstructing myoglobin casts. Therapy includes intravenous fluids (the addition of bicarbonate is questionable), supportive care, and sometimes RRT. Most patients recover kidney function to near-baseline.

Massive intravascular hemolysis from various causes (e.g., immune-mediated, microangiopathic) is associated with hemoglobinuria, which induces tubular injury by promoting the formation of reactive oxygen species and by reducing renal perfusion through inhibition of nitric oxide synthesis. Therapy is directed at the primary cause, with intravenous fluids and supportive care. Most patients ultimately recover kidney function.

Crystalline nephropathy. AKI may result from crystal deposition in distal tubular lumens after massive rises in uric acid or therapy with certain medications. Risk factors for AKI due to crystal deposition are underlying kidney disease and intravascular volume depletion. Acute uric acid nephropathy from urate crystal deposition and tubular obstruction develops in patients with massive tumor lysis syndrome.

Drugs such as sulfadiazine promote intratubular deposition of sulfadiazine crystals in acid urine, whereas acyclovir crystal deposition occurs after large, rapid intravenous doses of the drug, and atazanavir and indinavir crystal deposition occurs in the setting of volume contraction and urine pH higher than 5.5. Ciprofloxacin can cause AKI due to intratubular crystal deposition when administered in excessive doses, primarily in patients with unrecognized kidney disease and those with alkaline urine. In addition, methotrexate or large doses of intravenous vitamin C (producing oxalate) can cause AKI due to intratubular crystal deposition.

Weight loss therapies such as bariatric surgery with small bowel bypass and orlistat, through induction of malabsorption, cause enteric hyperoxaluria and calcium oxalate crystal deposition, an entity known as acute oxalate nephropathy (E-Fig. 29.5). Sodium phosphate-containing bowel purgatives have also been associated with AKI due to acute phosphate nephropathy, an entity characterized by calcium phosphate intratubular crystal deposition.

Diagnosis of crystalline nephropathy is based on a history of exposure to a culprit agent or an underlying disease state associated with excessive crystal production (see Fig. 24.4).

Osmotic nephropathy. Osmotic nephropathy is a little known entity that can promote AKI through the induction of proximal tubular swelling, cell injury, and occlusion of intratubular lumens. The hyperosmolar and unmetabolizable nature of substances such as sucrose, dextran, mannitol, the sucrose excipient of intravenous immune globulin, and hydroxyethylstarch underlies the pathophysiology of this kidney lesion. Cells develop severe swelling with cytoplasmic vacuoles that form due to accumulation of the offending substance within intracellular lysosomes, disturbing cellular integrity and occluding tubular lumens. AKI results from this abnormal tubular process when patients with underlying kidney disease or other risk factors for kidney injury (e.g., intravascular volume depletion, older age) receive these hyperosmolar substances. AKI is dose related and may require RRT. Although most patients recover from AKI, CKD can result. Therapy is primarily supportive, along with avoidance of further exposure to these agents.

Interstitial Disease

Interstitial disease develops in the setting of infection with certain agents, systemic diseases, infiltrative malignancies, and exposure to some medications. Of these, drug-induced disease is by far the most common entity (E-Table 29.5), especially in the hospitalized patient. The syndrome of AIN is characterized by AKI and a variety of clinical findings. The clinical presentation varies based on the offending agent and the host response. As an example, β -lactam antibiotics frequently

cause the classic triad of fever, maculopapular skin rash, and eosinophilia. Arthralgias, myalgias, and flank pain may also occur. Aside from causing AKI, NSAIDs can rarely lead to allergic or extrarenal manifestations such as fever, rash, or eosinophilia.

Urinalysis may reveal dipstick-positive (trace to 1+) protein, blood, and leukocyte esterase. Urine microscopy may be bland ($\approx 20\%$), but more often, the urine sediment demonstrates white blood cells (WBCs), RBCs, WBC casts, and granular casts. Wright or Hansel stain may reveal eosinophils in the urine, but neither of these tests is sensitive or specific for AIN. The urine cytokine TNF-alpha and IL9 appear to possess excellent sensitivity and specificity for diagnosing AIN.

The diagnosis is best confirmed by kidney biopsy. A cellular infiltrate consisting of lymphocytes, monocytes, eosinophils, and plasma cells is typically present; interstitial edema and fibrosis vary based on the time of drug exposure (E-Fig. 29.6). Tubulitis, or invasion of lymphocytes into the tubular cells, is frequently part of AIN. Granuloma formation and interstitial inflammation occur with certain drugs such as anticonvulsants and sulfonamides, systemic diseases such as sarcoidosis, tubulointerstitial nephritis with uveitis, and idiopathic granulomatous interstitial nephritis. The glomeruli and vasculature are spared until very late in the disease. If kidney biopsy is not possible, gallium scanning or positron emission tomography of the kidneys may help with diagnosis, especially when the differential diagnosis is primarily between AIN and ATN.

Early diagnosis of AIN, coupled with rapid drug withdrawal before advanced tubulointerstitial fibrosis develops, maximizes successful renal recovery. Corticosteroid therapy is controversial but may reduce the duration of AKI and perhaps improve recovery of kidney function in patients with severe AKI if it is used early (within 2 weeks of diagnosis).

Before development of antibiotics and other drugs that have been associated with AIN, interstitial infection was the major cause of tubulointerstitial nephritis. Microbial agents such as staphylococci, streptococci, mycoplasma, diphtheroids, and legionella are well-described causes of AIN. Several viral agents including cytomegalovirus, Epstein-Barr virus, human immunodeficiency virus (HIV), Hantaan virus, parvovirus, and rubeola also are associated with AIN. In addition, infectious agents that cause rickettsial diseases, leptospirosis, and tuberculosis also invade the renal interstitium.

The renal interstitium is the target of a number of systemic illnesses. Sarcoidosis causes a lymphocyte-dominant AIN, which can be associated with noncaseating granulomas. AKI and urine sediment containing WBCs and WBC casts point to this disease, along with other systemic findings. Steroids reduce the severity of AIN, but CKD is a potential long-term complication. Systemic lupus erythematosus is more commonly associated with various forms of proliferative GN; AIN may coexist with glomerular disease, or, in rare instances, it may be present in isolation. The interstitial inflammatory lesion is caused by immune complex deposition in the tubulointerstitium. AIN usually responds to the cytotoxic therapy given for lupus nephritis. Sjögren's syndrome also causes a lymphocyte-dominant AIN; it appears to be another immune complex-mediated disease of the renal interstitium.

Patients with HIV infection may develop interstitial disease that appears immune related. Diffuse infiltrative lymphocytosis syndrome (DILS) is a Sjögren-like syndrome associated with multivisceral infiltration of CD8-positive T lymphocytes. DILS appears to be a host-determined response to HIV. Immune reconstitution inflammatory syndrome (IRIS) is another multivisceral disease characterized by an interstitial infiltrate. This disease occurs when combination antiretroviral therapy reconstitutes the immune system in the setting of a previous or occult opportunistic infection. An exuberant immune reaction results in T cell infiltration of several organs, including the kidneys, which develop AIN. Therapy involves treatment of the opportunistic

infection. Occasionally, corticosteroids are required to suppress the inflammatory response.

Infiltration of the kidney by cancer is an uncommon cause of AKI. Autopsy studies confirm a high rate of asymptomatic renal infiltration. The malignancies most often associated with interstitial infiltration are the lymphomas and leukemias. Lymphomatous infiltration of the kidney parenchyma can occur in the form of discrete nodules or diffuse interstitial infiltration. Lymphoma may cause massive kidney enlargement (nephromegaly) and AKI. Leukemic infiltration also causes nephromegaly, AKI, and, rarely, renal potassium wasting from either tubulointerstitial damage or lysozyme production. Successful treatment of the underlying malignancy typically improves the infiltrative lesion; however, irradiation of the kidneys may provide additional benefit. Exclusion of obstructive uropathy from bulky retroperitoneal lymph node disease is also required.

Postrenal AKI

AKI can develop when obstruction to urine flow occurs along the genitourinary system (E-Table 29.6). The process causing postrenal AKI is called *obstructive uropathy*, whereas the dilated urinary collecting system identified on imaging is termed *hydronephrosis*. Tubular defect with AKI that results from urinary obstruction is called *obstructive nephropathy*. AKI can develop only when obstruction is bilateral, involving both ureters or the bladder, or unilateral in a person with a single functioning kidney. Importantly, either complete or partial obstruction can cause AKI. In general, complete obstruction is associated with more severe AKI and hypertension, intravascular volume overload, hyperkalemia, metabolic acidosis, and hyponatremia.

A wide variety of disorders, originating anywhere from the renal calyces to the urethra, can cause AKI due to urinary obstruction. The most common causes of obstructive uropathy in the upper urinary tract are stones and retroperitoneal disease; in the lower tract, at the level of the bladder and below, prostatic hyperplasia and bladder dysfunction most often obstruct urinary flow. Obstructive uropathy should be considered in many patients with AKI, especially those with a history suggesting risk. A history of nephrolithiasis or certain cancers, along with flank pain, suggests upper tract disease; a history of prostate or bladder disease, together with symptoms of prostatism and urinary retention, points to lower tract obstruction. A directed physical examination of the flanks, suprapubic area, and prostate for flank tenderness, a palpable bladder, or prostatic enlargement is required. Large residual urine demonstrated on straight catheterization of the bladder bespeaks lower tract obstruction.

Ultrasonography of the kidneys and retroperitoneum is the most appropriate initial test to evaluate the patient with AKI and possible urinary tract obstruction. The sensitivity and specificity of renal ultrasonography for the detection of urinary obstruction are approximately 90%. Several processes blunt dilatation of the collecting system and the formation of hydronephrosis, including acute obstruction of less than 48 to 72 hours' duration, severe intravascular volume depletion superimposed on obstruction, and retroperitoneal disease involving the kidneys and ureters that encases the collecting system. If ultrasonographic findings are equivocal or negative but high suspicion for urinary obstruction persists, a CT scan may provide more information. One of the major benefits of CT imaging is the ability to detect stones, tumor, enlarged lymph nodes, and other processes causing obstruction despite the absence of hydronephrosis. As last resort, if obstruction as the cause of AKI is still considered likely, retrograde pyelography may provide a diagnosis of upper tract obstruction.

Therapy for AKI due to obstructive uropathy requires rapid diagnosis and intervention to relieve the obstructive process. Delayed interventions, especially in patients with complete obstruction,

compromise recovery of kidney function. Upper urinary tract obstruction requires either retrograde ureteral stent placement or nephrostomy tube insertion when it is caused by severe retroperitoneal disease such as ureteral or bladder cancer. Relief of lower tract obstruction with a bladder catheter, a suprapubic tube (rarely), or a nephrostomy tube is the first step in treatment. Electrolyte and fluid management also are required to ensure patient safety in developing postobstructive diuresis. It is a phenomenon that occurs primarily in patients with bilateral, complete obstruction and is characterized by large urine volumes after relief of obstruction. Postobstructive diuresis is physiologic in that excess sodium and water are being excreted from the hypervolemic patient, but impaired tubular function (sodium and water) may lead to excessive diuresis and volume depletion. In this setting, judicious fluid repletion is required to avoid iatrogenic postobstructive diuresis as well as underresuscitation and hypotension.

COMPLICATIONS OF AKI

Considering the normal functions of the kidneys, it is not surprising that a number of metabolic complications develop in the setting of AKI. Hyperkalemia is a potentially life-threatening complication that often requires urgent intervention. Hyperkalemia disturbs the magnitude of the action potential in response to a depolarizing stimulus. The electrocardiogram (ECG) is a better guide to therapy than a single measurement of potassium concentration. The sequential ECG changes observed in hyperkalemia are peaked T waves, PR prolongation, QRS widening, and a sine wave pattern. The presence of any of these ECG changes mandates prompt therapy.

Metabolic acidosis is common in AKI. However, it is usually well tolerated and does not require therapy unless arterial pH declines to less than 7.1. Hyperkalemia and severe metabolic acidosis not responsive to medical therapy are indications for initiation of RRT. Hypocalcemia is a common but asymptomatic finding and usually does not require therapy. Significant hyperphosphatemia may occur but often can be managed with oral phosphate binders. Anemia typically does not require treatment unless it is severe, is symptomatic, or contributes to cardiac dysfunction. Uremic manifestations of AKI are listed in E-Table 29.7. They may be subtle findings, or they may be obvious and life-threatening, requiring urgent RRT.

Importantly, infectious complications are the main cause of death because of the immune compromise, edema with end-organ dysfunction and skin breakdown, and numerous indwelling catheters in these patients.

GENERAL MANAGEMENT OF AKI

Management of AKI begins with identification of the cause and pathogenesis of the inciting process. In addition, the complications associated with AKI need to be recognized and rapidly treated to avoid serious adverse events. Prerenal AKI requires optimization of renal perfusion by repletion of intravascular volume in those who are volume depleted and correction of heart failure, liver failure, and other "effective" causes of reduced intravascular volume. Intrinsic AKI requires directed therapy of the disturbed kidney compartment. Management of postrenal AKI mandates early intervention to relieve obstruction and preserve kidney function.

Most consequences of AKI are managed initially with conservative measures. These include interventions to correct hypovolemia or hypervolemia, improvement of hemodynamics, and correction of hyponatremia, hyperkalemia, metabolic acidosis, and hyperphosphatemia. Conversion of patients from oliguric to nonoliguric AKI makes management easier but does not improve outcomes in terms

E-Fig. 29.5 Oxalate nephropathy. Calcium oxalate crystal deposition in the renal tubules can cause acute kidney injury. The crystals are strongly birefringent crystals on polarized light microscopy.

E-Fig. 29.6 Acute kidney injury can result from acute interstitial nephritis, which is characterized by an inflammatory infiltrate consisting of lymphocytes, eosinophils, plasma cells, and monocytes with interstitial edema or fibrosis or both.

E-TABLE 29.5 Drugs Commonly Associated With Interstitial Nephritis

Antibiotics	β-Lactam drugs Fluoroquinolones Sulfa-based antibiotics Rifampin, vancomycin
Antacid medications	Proton pump inhibitors Histamine-2 antagonists
Analgesics	NSAIDs
Immunotherapies	Immune checkpoint inhibitors (PD-1 inhibitors, CTLA-4 inhibitors)
Anti-angiogenesis drugs	Bevacizumab, aflibercept, tyrosine kinase inhibitors
Diuretics	Loop diuretics Thiazide diuretics
Antiviral agents	Acyclovir Abacavir Indinavir Atazanavir Foscarnet
Anticonvulsants	Phenytoin Carbamazepine Phenobarbital

Impairment	Complications
Impairment of Fluid and Electrolyte Excretion	
Water	Hyponatremia
Sodium chloride	Volume expansion Congestive heart failure
Potassium	Hyperkalemia Arrhythmias
Hydrogen	Acidosis
Phosphate	Hyperphosphatemia Hypocalcemia Metastatic calcifications
Magnesium	Hypermagnesemia
Uric acid	Hyperuricemia Gouty arthritis
Retention of urea and other solutes	Uremia <i>Cardiac:</i> Pericarditis <i>Neurologic:</i> Asterixis, confusion, somnolence, coma, seizures <i>Hematologic:</i> Anemia, coagulopathy, bleeding diathesis Infection <i>Gastrointestinal:</i> Nausea, vomiting, gastritis, bleeding <i>Skin:</i> Pruritus Glucose intolerance
Synthetic Impairment	
1,25-Dihydroxyvitamin D ₃	Hypocalcemia
Erythropoietin	Anemia
Impaired drug metabolism and excretion	Drug toxicity, decreased diuretic effectiveness

of morbidity or mortality. Manifestations of severe uremia and the other consequences of AKI, as listed in E-Table 29.7, may necessitate RRT if conservative measures are unsuccessful or incompletely reverse the complication. Despite significant research efforts in recent years to determine if earlier versus later initiation of RRT improves outcomes in those with AKI, mixed results amongst the various studies has left clinicians with no clear consensus on this topic. Therefore, the timing of RRT initiation is often individualized to each clinical scenario based on a number of factors including the severity of metabolic disturbances, the likelihood of rapid renal recovery in subsequent hours and days, and the preferences of both the treating clinician and the patient and his or her surrogates.

Hospital-based RRT, which includes primarily acute hemodialysis and continuous renal replacement therapies (CRRTs), is required in certain patients with AKI. Continuous therapies, which can be employed only in the ICU, include continuous venovenous hemofiltration, hemodialysis, hemodiafiltration, slow low-efficiency dialysis, and extended daily dialysis. Emergent indications include severe hyperkalemia, uremic end-organ damage (e.g., pericarditis, seizure), refractory metabolic acidosis, and severe volume overload including pulmonary edema. Although the data do not support a cutoff BUN value to initiate RRT, it is sensible to initiate therapy before severe uremic complications develop. Intractable volume overload with anasarca complicated by skin breakdown is another potential indication. Acute hemodialysis is the modality most commonly employed to treat the consequences of AKI. However, critically ill patients who are hemodynamically unstable benefit most from continuous therapies. CRRT allows more precise control of volume, uremia, acid-base disturbances, and electrolyte disorders with less hemodynamic instability. CRRT also allows aggressive nutritional support. Peritoneal dialysis is rarely used for AKI but is a reasonable modality.

OUTCOME AND PROGNOSIS OF AKI

Despite the significant advances in supportive care and RRT technology, acute and long-term complications, including mortality, remain common. The mortality associated with AKI in the hospital setting depends on the patient's severity of illness and burden of organ dysfunction. As the number of failed organs increases from 0 to 4, the mortality rate associated with AKI increases from less than 40% to more than 90%. Also, in-hospital mortality increases with AKI that develops in the medical or surgical ICU. Long-term outcomes for

patients with AKI include increased risk for death (compared with hospitalized patients without AKI). Furthermore, patients with CKD who have a prehospitalization eGFR lower than 45 mL/min/1.73 m² who develop RRT-requiring AKI have a much higher mortality rate than patients with CKD not complicated by AKI. On the whole, all forms of AKI, including the RRT-requiring forms, appear to be associated with an increased risk for development of new CKD, progression of CKD, ESRD, and death.

For a deeper discussion on this topic, please see Chapter 112, “Acute Kidney Injury,” in *Goldman-Cecil Medicine*, 26th Edition .

Chronic Kidney Disease

T. Alp Ikizler, Anna Marie Burgner, Beatrice P. Concepcion

DEFINITION AND EPIDEMIOLOGY

Chronic kidney disease (CKD) is defined as persistent abnormalities of kidney structure or function. Markers of kidney damage or glomerular filtration rate (GFR) less than 60 mL/1.73 m² per minute must be present to meet the diagnostic criteria of CKD. The CKD spectrum includes patients with a normal GFR and kidney damage characterized by proteinuria or electrolyte abnormalities, to elevated serum creatinine, representing a decrease in GFR, to kidney failure or end-stage renal disease (ESRD). Additionally, these must be present and persistent for at least 3 months to differentiate CKD from acute kidney injury (AKI). According to the Kidney Disease Improving Global Outcomes (KDIGO) 2012 guidelines, CKD is classified based upon the underlying cause of kidney disease, GFR category, and albuminuria category. There are six GFR category levels ranging from normal or high (G1 ≥90 mL/min/1.73 m²) to kidney failure (G5 <15 mL/min/1.73 m²), and three albuminuria category levels based upon severity (Table 30.1). The rationale for these classification domains is because of differences in observed risk of health consequences and prognosis depending upon each domain's severity.

CKD is a worldwide public health problem. In the United States, the prevalence of CKD is estimated to affect 14.8% of the population, and most have mildly decreased GFR with mild to moderate increased albuminuria (Fig. 30.1). Yet, many people with CKD will progress to ESRD and require maintenance dialysis or kidney transplantation. The crude rate of new ESRD patients in the United States was relatively stable from 2000 to 2010 but started rising again in 2011; however, the United States Renal Data System (USRDS) reported in 2016 that the standardized incidence rate has appeared to plateau (348.2 per million population) (E-Fig. 30.1). Trends in overall prevalence of ESRD suggest a continuing increase in the numbers of patients requiring care, although in 2016 the increase was only 3%—the lowest rate recorded since the inception of the USRDS (E-Fig. 30.2). Care of the ESRD patient is costly, accounting for \$35.4 billion (7.2%) of the U.S. Medicare budget in 2016. In addition to concern about progression to ESRD, decreased GFR and proteinuria have each been increasingly recognized as independent risk factors for cardiovascular disease and death. Thus, diagnosis of CKD will identify those at risk not only for kidney function loss but also for decreased survival.

The most common causes of ESRD include diabetes mellitus (40%), hypertension (28%), glomerulonephritis (6% to 7%), and cystic or congenital conditions (2% to 3%). During the evaluation of CKD, every attempt should be made to arrive at the specific cause of kidney disease. Kidney biopsy is the most specific tool to reach a definitive diagnosis and guides treatment, informs prognosis, and determines suitability for kidney transplantation. However, the procedure itself has potential complications, and clinical information, including present, past, and family histories, serology, examination of the urine sediment, and kidney imaging may be sufficient to provide a conclusive diagnosis.

PATHOLOGY

To ensure adequate solute, water, and acid-base balance, the surviving nephrons must adjust by increasing their filtration and excretion rates. Patients with CKD, especially more advanced stages, are vulnerable to edema formation and severe volume overload, hyperkalemia, hyponatremia, and azotemia. During progressive kidney disease, sodium balance is maintained by increasing fractional excretion of sodium by the nephrons. Acid excretion is maintained until late stages of CKD, when the GFR falls to less than 30 mL per minute. Initially, increased tubular ammonia synthesis provides an adequate buffer for hydrogen in the distal nephron. Later, a significant decrease in distal bicarbonate regeneration results in hyperchloremic metabolic acidosis. Further nephron loss leads to retention of organic ions such as sulfates, which results in an anion gap metabolic acidosis. Metabolic acidosis appears to contribute to progression of CKD, and correction by base supplementation may be a potential treatment, although large multicenter randomized clinical trials are lacking.

Once GFR has decreased to below a critical level, CKD tends to progress to ESRD, regardless of the initial insult. Fig. 30.2 shows how risk factors may interact with pathophysiologic mechanisms to accelerate CKD progression. Detailed studies have elucidated interrelated mechanisms, including glomerular hemodynamic responses to nephron loss, proteinuria, and proinflammatory responses. Activation of the renin-angiotensin-aldosterone system (RAAS) pathway and increased transforming growth factor-β (TGF-β) also contribute to kidney fibrosis. Interventions that reduce intraglomerular pressure, such as protein restriction and the use of angiotensin-converting enzyme (ACE) inhibitors or angiotensin-receptor blockers (ARBs), help attenuate progression of kidney disease and further support the importance of glomerular hemodynamics and RAAS in progressive kidney disease.

CLINICAL PRESENTATION

General Features of Uremic Syndrome

Evidence of kidney disease commonly presents not with overt signs or symptoms, but first as abnormalities on laboratory or other diagnostic tests. Patients with CKD may not have symptoms until advanced stages where the GFR is less than 15 mL per minute. *Uremia* is a syndrome that affects every organ system. Uremic syndrome is likely the consequence of many factors, including retained molecules, deficiencies of important hormones, and metabolic abnormalities, rather than the effect of a single uremic toxin (E-Fig. 30.3). Among these toxins, urea can cause symptoms of fatigue, nausea, vomiting, and headaches. Its breakdown product (cyanate) can result in carbamylation of lipoproteins and peptides, leading to multiple organ dysfunctions. Guanidines, byproducts of protein metabolism, are increased and can inhibit α₁-hydroxylase activity within the kidney leading to secondary hyperparathyroidism.

TABLE 30.1 Categories of Glomerular Filtration Rate and Albuminuria in CKD

Category	GFR (mL/1.73 m ² /min)		Terms	
G1 ^a	≥90		Normal or high	
G2 ^a	60-89		Mildly decreased	
G3a	45-59		Mildly to moderately decreased	
G3b	30-44		Moderately to severely decreased	
G4	15-29		Severely decreased	
G5	<15		Kidney failure	

Category	AER		ACR		Terms
	(mg/24 hours)	(mg/g)	(mg/g)	(mg/mmol)	
A1	<30	<30	<3	<3	Normal to mildly increased
A2	30-300	30-300	3-30	3-30	Moderately increased
A3	>300	>300	>30	>30	Severely increased

ACR, Albumin-to-creatinine ratio; AER, albumin excretion rate; GFR, glomerular filtration rate.

^aG1 and G2 alone, without other evidence of kidney damage, do not meet the criteria for CKD.

				Albuminuria categories			Total
				A1	A2	A3	
				Normal to mildly increased	Moderately increased	Severely increased	
				<30 mg/g <3 mg/mmol	30-300 mg/g 3-30 mg/mmol	>300 mg/g >30 mg/mmol	
GFR categories (ml/min/1.73 m ²)	G1	Normal to high	≥90	54.9	4.2	0.5	59.6
	G2	Mildly decreased	60–89	30.2	2.9	0.3	33.5
	G3a	Mildly to moderately decreased	45–59	3.6	0.8	0.3	4.7
	G3b	Moderately to severely decreased	30–44	1.0	0.4	0.2	1.7
	G4	Severely decreased	15–29	0.13	0.10	0.15	0.37
	G5	Kidney failure	<15	0.01	0.04	0.09	0.13
Total				89.9	8.5	1.6	100

Fig. 30.1 Distribution of CKD in the United States by GFR and albuminuria categories.

β₂-microglobulin accumulation in patients with ESRD has been associated with neuropathy, carpal tunnel syndrome, and amyloid infiltration of the joints. Finally, certain protein-bound solutes such as indoxyl sulfate and the conjugates of p-cresol, may confer cardiovascular toxicity by affecting leukocyte, endothelial, and vascular smooth muscle cell function. Major manifestations of uremia are summarized in Fig. 30.3.

Cardiovascular

In addition to hypertension, cardiovascular disorders are common in patients with CKD. More than 60% of patients with ESRD who start dialysis have echocardiographic manifestations of left ventricular hypertrophy, dilation, and systolic or diastolic dysfunction. Metabolic consequences of CKD, including accelerated atherogenesis, contribute to metastatic calcification in the myocardium, cardiac valves, and arteries. Arrhythmias, including those resulting in sudden death, may be caused by electrolyte abnormalities, cardiac structural changes or ischemic cardiovascular disease. Pericarditis can occur in patients with uremia before they start dialysis, as well as in ESRD patients receiving inadequate dialysis.

Gastrointestinal

Gastrointestinal disturbances are among the earliest and most common signs of the uremic syndrome. Patients describe a metallic taste and loss of appetite. Later, they experience nausea, vomiting, and

weight loss, and those with severe uremia may also experience stomatitis and enteritis. There may be gastrointestinal bleeding caused by gastritis, peptic ulceration, and arterial venous malformations in the setting of platelet dysfunction.

Neurologic

Central nervous system (CNS) manifestations are frequent in advanced CKD and characterized predominantly by changes in cognitive function and sleep disturbances. Lethargy, irritability, asterixis, seizures, and frank encephalopathy with coma are late manifestations of uremia and are usually avoided by timely initiation of kidney replacement therapy. Peripheral neurologic manifestations appear as a progressive symmetrical sensory neuropathy in a glove-and-stocking distribution. Patients have decreased distal tendon reflexes and loss of vibratory perception. Peripheral motor impairment can result in restless legs, foot-drop, or wristdrop. The majority of these neurologic manifestations reverse with maintenance dialysis or kidney transplantation.

Musculoskeletal

Alterations in calcium and phosphate homeostasis, with hyperparathyroidism and disturbance of vitamin D metabolism, are also common. Hypocalcemia and secondary hyperparathyroidism are the result of phosphate retention and the lack of α₁-hydroxylase activity in the failing

kidney, with consequent deficiency of the most active form of vitamin D. Over time, maladaptive parathyroid hypertrophy (i.e., tertiary hyperparathyroidism) leads to bone disease and tissue calcification.

Hematologic and Immunologic

Erythropoietin (EPO), a hormone produced by the kidney that regulates erythrocyte production, becomes progressively deficient as CKD

progresses. EPO and iron deficiency are common causes of anemia in CKD. Administration of synthetic EPO results in correction of anemia, improved quality of life and anemia-related symptoms, and decreased dependence on blood transfusions. Caution must be exercised because higher doses of EPO resulting in elevations of the serum hemoglobin to more than 13 g/dL may be associated with a higher risk for adverse cardiovascular events. Bleeding disorders, primarily from defects in

platelet adherence and aggregation, are common in patients with uremia. Uremic bleeding can be generally controlled with cryoprecipitate, desmopressin, conjugated estrogens, treatment of anemia, and dialysis.

Defects occur in both the humoral and cellular immune systems in patients with CKD. Although the leukocyte count is normal and appropriately responsive in advanced CKD, patients are generally immunosuppressed and susceptible to infections. This may be due to functional abnormalities of polymorphonuclear leukocytes, lymphocytes, and other cellular host defenses. Additionally, patients with CKD may have a variable immune response to vaccination.

Endocrine and Metabolic

Thyroid function testing may be less reliable in uremia. Common laboratory findings include an increased triiodothyronine resin uptake, a low triiodothyronine level resulting from the impaired conversion of thyroxine to triiodothyronine peripherally, and normal thyroxine levels. Thyroid-stimulating hormone levels are usually normal.

A deranged pituitary-gonadal axis can result in sexual dysfunction exhibited by impotence, decreased libido, amenorrhea, sterility, and uterine bleeding. Patients have decreased plasma levels of testosterone, estrogen, and progesterone, with normal or increased levels of follicle-stimulating hormone, luteinizing hormones, and prolactin. Pregnancy is uncommon in female patients who have a GFR of less than 30 mL per minute.

Lipid abnormalities are also common in CKD. They are most consistent with type IV hyperlipoproteinemia, with a marked increase in plasma triglycerides and less of an increase in total cholesterol. The activity of lipoprotein lipase is decreased in uremia, with a reduction in the conversion of very-low-density lipoprotein to low-density lipoprotein and thus hypertriglyceridemia. The treatment of choice is the hydroxymethylglutaryl-coenzyme A reductase (HMG-CoA) inhibitor class of drugs, especially in CKD patients not yet on maintenance dialysis, because of their pluripotent effects on inflammation and atherosclerosis.

Electrolytes

Hyperkalemia occurs in patients with CKD as a result of decreased renal clearance of potassium, intracellular to extracellular shifts of potassium in the setting of metabolic acidosis related to kidney failure, and the concomitant use of medications such as RAAS blockers. The primary method of treatment is dietary reduction of potassium but may also include use of loop diuretics or potassium-binding medications. Hypokalemia is much less common in CKD but may occur in the setting of very poor nutritional intake or use of high-dose potassium-wasting diuretic medications.

Skin

Uremic hue, a yellowish skin color, is likely the result of retained liposoluble pigments, such as lipochromes and carotenoids. Uremic hue usually responds to dialysis, control of hyperparathyroidism, improved calcium and phosphate balance, and, occasionally, ultraviolet rays. Nail findings of uremia include the half-and-half nail, characterized by red, pink, or brownish discoloration of the distal nail bed, pale nails, and splinter hemorrhages. Other common signs and symptoms include pruritus, and ecchymoses due to disorders of bleeding. Calciphylaxis, or calcific uremic arteriopathy, results in painful skin calcification and is often seen in patients with uncontrolled hyperparathyroidism. Use of warfarin is suggested to be a risk factor for this condition.

DIAGNOSIS

Comprehensive care of kidney disease includes screening, diagnosing, and treating CKD and complications of CKD to prevent CKD

development and progression (E-Fig. 30.4). Screening for CKD is recommended in patients with high-risk comorbid disease, including diabetes mellitus and hypertension and those with a family history of kidney disease. The diagnosis of chronic kidney disease requires demonstrating evidence of kidney damage that has been persistent for at least 3 months. Imaging abnormalities may be consistent with kidney damage, but more commonly this is shown by detection of albuminuria or by reductions in the clearance of toxins by the kidney. Albuminuria may be detected in a spot collection of urine and is best when reported as an albumin-to-creatinine ratio (ACR). In general, an ACR of 30 mg/g or greater confirmed on repeat sample and without evidence of urinary infection raises concern for a diagnosis of CKD and warrants additional investigation.

Measurement of clearance of toxins by the kidney is most often estimated as the glomerular filtration rate (eGFR). Initial assessment should be performed using a serum creatinine-based estimating equation. These include the Modification of Diet in Renal Disease (MDRD) Study Equation and the Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) equation. Each of these has limitations and cautions regarding application of its results, and a detailed overview can be found in the KDIGO 2012 Clinical Practice Guidelines. Another serum biomarker, cystatin C, may be considered and integrated into another estimating equation for patients who have an eGFR 45-59 mL/min/1.73 m² and who may not have albuminuria or kidney imaging abnormalities to confirm evidence of CKD.

Once a diagnosis of CKD is established, management goals include (1) prevention of progression of CKD, (2) identifying and treating symptoms and complications of CKD, and (3) preparing patients for renal replacement therapy (RRT) where appropriate.

TREATMENT

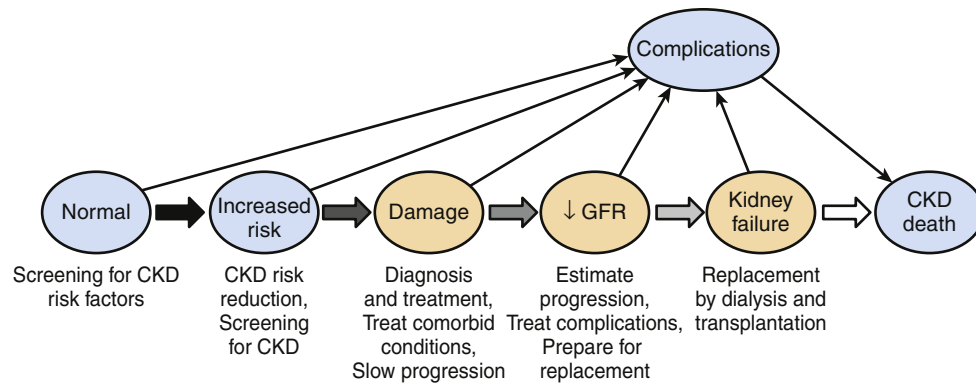

Prevention of Progression

In addition to treatment of the specific underlying cause of kidney disease, methods used to slow progression of CKD include optimal control of hypertension, diabetes, and other cardiovascular disease risk factors (i.e., tobacco cessation), use of medications that block the RAAS pathway, diet modifications, avoidance of nephrotoxins, and addressing potentially reversible causes of acute kidney injury in the setting of CKD.

Management of Hypertension and Diabetes

Several controlled trials have conclusively confirmed that treatment of hypertension attenuates the rate of progression of kidney disease. The present recommendation is to target blood pressure to lower than 130/80 mm Hg in patients with diabetes or kidney disease. However, the evidence supporting this recommendation in CKD is limited and there is debate suggesting a higher target may be acceptable. Medications that block the production or effect of angiotensin II prevent the progression of CKD above and beyond control of hypertension in patients with proteinuria. Dihydropyridine calcium-channel blockers have not been shown to be as beneficial as ACE inhibitors or ARBs in slowing CKD progression.

For patients with diabetes mellitus, adequate glycemic control has been shown to prevent progression of CKD. Recommended goal glycosylated hemoglobin (A_{1c}) measures are less than 7% irrespective of a concurrent diagnosis of CKD, although this level of glycemic control warrants caution due to hypoglycemic risk (see Chapter 68). ACE inhibitors and ARBs may be considered in patients with diabetes and proteinuria, but without hypertension, to slow CKD progression. More recently, use of sodium-glucose cotransporter-2 (SGLT2) inhibitors have shown beneficial effects on kidney outcomes mainly in patients

E-Fig. 30.4 Approach to care for patients with chronic kidney disease (CKD) and its complications: screening, diagnosis, and treatment. *GFR*, Glomerular filtration rate. TABLE 30.2 Drug Dosages in Chronic Kidney Disease

Major Dosage Reduction	Minor or No Reduction	Avoid Usage
Antibiotics		
Aminoglycosides	Erythromycin	
Penicillin	Nafcillin	Nitrofurantoin
Cephalosporins	Clindamycin	Nalidixic acid
Sulfonamides	Chloramphenicol	Tetracycline
Vancomycin	Isoniazid, rifampin	
Quinolones	Amphotericin B	
Fluconazole	Aztreonam, tazobactam	
Acyclovir, ganciclovir	Doxycycline	
Foscarnet		
Imipenem		
Others		
Digoxin	Antihypertensives	Aspirin
Procaainamide	Benzodiazepines	Sulfonylureas
H ₂ antagonists	Quinidine	Lithium carbonate
Meperidine	Lidocaine	Acetazolamide
Codeine	Spirolactone	NSAIDs
Propoxyphene	Triamterene	Phosphate-containing bowel-preparation agents
<i>NSAIDs, Nonsteroidal anti-inflammatory drugs.</i>		

with type 2 diabetes and established atherosclerotic cardiovascular disease. Several other studies suggested that treatment with glucagon-like peptide-1 (GLP-1) receptor agonists could also have beneficial effects on kidney outcomes in patients with type 2 diabetes.

Diet

Dietary protein restriction is advocated to slow progression of CKD. Several meta-analyses indicate that reduced protein diets may be modestly beneficial to slow CKD progression, but the largest clinical trial, the MDRD study, did not show a significant benefit. The recommended dietary protein intake in advanced CKD is 0.60 g/kg per day with at least 50% of the protein being of high biologic value. The present consensus is that aggressive dietary management in patients with CKD, with proper restriction of sodium, potassium, phosphorus, and protein intake under the supervision of a dietician, may reduce progression of CKD, albeit to a small extent.

Avoidance of Toxic Drug Effects

Many drugs that are excreted by the kidney should be avoided, or their doses should be reduced, as shown in Table 30.2. Drugs may injure the kidney in many ways, including direct toxicity leading to acute tubular necrosis, induction of interstitial nephritis, or development of urinary crystals that obstruct the kidney. Common classes of medications that injure the kidney include antibiotics, specifically aminoglycosides; nonsteroidal anti-inflammatory drugs, including cyclo-oxygenase-2 (COX-2) inhibitors; and antiretroviral medications. Over-the-counter herbal medications, including aristolochic acids, may cause CKD. Others, such as St. John's Wort, may interact with kidney transplant medications and should be avoided. Iodinated radiocontrast agents can cause acute worsening of kidney function, especially in patients with CKD. Iso-osmolar contrast agents are less toxic than high-osmolar agents. Patients at high risk for contrast-induced kidney injury should receive adequate hydration, and the volume of the contrast should be minimized. The magnetic resonance imaging (MRI) contrast agent gadolinium, has been associated with the severe fibrotic skin condition of nephrogenic systemic fibrosis in patients with advanced CKD.

Reversible Causes of Acute Deterioration in Kidney Function

The rate of decline in GFR for individual patients is generally log linear. Accordingly, plotting 1/serum creatinine against time usually predicts the rate at which a specific patient will reach ESRD (E-Fig. 30.5). When such a patient suddenly shows acute worsening of kidney function, the differential diagnosis should be considered and investigated, as described in Chapter 29.

Care for the Patient With End-Stage Renal Disease

As CKD progresses to kidney failure, preparation is needed for RRT. Patients with moderate CKD should be referred to a nephrologist for co-management, including evaluation of risk for CKD progression, estimation of timing until initiation of RRT, and education related to RRT. Late referral (<3 months before ESRD) is associated with a higher risk for death after initiation of RRT.

Renal Replacement Therapies

For patients who are suspected to progress to ESRD, discussions to inform patients and their family about available options of RRT should occur early and be paired with an assessment of the expectations and values of the patient. Options include kidney transplantation, dialysis or medical management without dialysis, sometimes referred to as conservative care. In suitable candidates, kidney transplantation is encouraged because it allows a better quality of life, increased survival rate, and greater chance for rehabilitation. In 2016, 87.3% of incident individuals began renal replacement therapy with hemodialysis (HD), 9.7% started with peritoneal dialysis (PD), and 2.8% received a preemptive kidney transplant. Kidney transplants may be from either deceased or living donors. In the United States in 2016, 20,161 kidney transplants were performed, 28% of which were from living donors. There are two types of dialysis, hemodialysis and peritoneal dialysis. The distribution of patients receiving various modalities differs in other countries. Maintenance dialysis is initiated when the patient displays signs of uremia, usually when eGFR is 10 mL per minute or less and there are no apparent reversible causes of kidney failure. However, maintenance dialysis may be started at any time when complications of ESRD, such as volume overload and hyperkalemia, cannot be controlled medically.

E-Fig. 30.5 Use of the reciprocal of plasma creatinine concentration ($1/P_{cr}$) to follow the progress of glomerular disease in a patient. C_{cr} , Creatinine clearance rate. (Data from Sullivan LP, Grantham JJ: Physiology of the kidney, ed 2, Philadelphia, 1982, Lea & Febiger.)

Fig. 30.4 Essential components of a dialysis delivery system that, together with the dialyzer, make up an *artificial kidney*. In isolated ultrafiltration, no dialysis fluid is used (bypass mode). Also shown is the apparatus for using a single needle for inflow and outflow of blood from the patient. (From Keshaviah PR: Hemodialysis monitors and monitoring. In Maher JF [ed]: Replacement of renal function by dialysis, 3rd ed. Boston, Kluwer Academic Publishers, 1989. Reprinted by permission of Kluwer Academic Publishers.)

Hemodialysis

As illustrated in Fig. 30.4, blood is pumped from a vascular access into tubing that leads to a large number of capillaries bundled together in a dialyzer (E-Fig. 30.6). The capillaries are made up of semisynthetic materials and are semipermeable, capable of allowing exchange of small molecules. Moving in the opposite direction to blood is a dialysate solution that is passing through outside the capillaries, thus allowing countercurrent exchange. This solution contains sodium chloride, bicarbonate, and varying concentrations of potassium. Diffusion through the membrane allows low-molecular-weight substances such as urea and organic acids to move across according to the concentration gradient. Fluid is removed by *ultrafiltration*, which is achieved by applying transmembrane hydrostatic pressure across the dialyzer.

In the setting of ESRD, an average patient undergoing *intermittent* maintenance hemodialysis requires 4 hours of dialysis 3 times a week. Common complications during hemodialysis include hypotension and muscle cramping. Avoiding excessive fluid weight gain can minimize these complications.

Access for hemodialysis. The recommended access for hemodialysis is a permanent access such as an arteriovenous fistula (AVF) or arteriovenous graft (AVG), rather than an indwelling catheter. Although the goal is for more than 70% of prevalent hemodialysis patients to use an AVF or AVG for dialysis access (<http://www.healthypeople.gov/2020/>), many patients continue to use catheters, especially at the time of initiation of maintenance hemodialysis. Temporary catheters are placed into the internal jugular, subclavian, or femoral veins similar to other central venous lines. Permanent catheters have a cuff around the outer wall of the tubing and tunnel under the chest wall skin for some distance before entering the internal jugular vein. Catheters have higher rates of infection and a higher risk for mortality compared with AVF and AVG.

Peritoneal Dialysis

In peritoneal dialysis, the peritoneal capillaries act as a semipermeable membrane like a hemodialysis dialyzer. This technique has several

advantages over hemodialysis because it allows independence from the long time spent in dialysis units, it does not require as stringent dietary restrictions, and more patients return to full-time employment. In continuous ambulatory peritoneal dialysis, dialysate of 2- to 3-L volumes is instilled through a peritoneal catheter (E-Fig. 30.7) into the peritoneal cavity for varying amounts of time and exchanged 4 to 6 times daily. In continuous cyclic peritoneal dialysis, the patient is connected to a machine referred to as a *cycler* that allows inflow of smaller volumes of dialysate with shorter dwell time overnight while the patient sleeps. Modifications in this regimen can be made to fit a patient's lifestyle and still achieve adequate clearance of toxins and removal of fluid. Ultrafiltration is achieved through increasing dextrose concentration in the dialysate. Two major drawbacks of peritoneal dialysis are peritonitis and difficulty in achieving adequate clearances in patients with excess body mass. Peritonitis can be treated with intraperitoneal antibiotics. Additionally, a slow deterioration occurs in the permeability of the peritoneal membrane, especially after one or more peritonitis episodes, leading to inadequate dialysis and, ultimately, the need to change the modality of RRT.

Kidney Transplantation

Kidney transplantation is the preferred modality of RRT. In suitable candidates, it provides patients with superior survival and a better quality of life compared to remaining on maintenance dialysis. It is also a more cost-effective long-term treatment option compared to maintenance dialysis. The variety of available immunosuppressive therapies, including calcineurin inhibitors (cyclosporine and tacrolimus), mammalian target of rapamycin (mTOR) inhibitors (sirolimus and everolimus), mycophenolate mofetil/mycophenolic acid, and novel agents such as belatacept have resulted in excellent short- and long-term graft survival.

Types of kidney transplants. Kidney transplant donors may be deceased or living and, among those living, may be related or unrelated. The majority of deceased donation occurs after brain death but can also occur after cardiac death. Deceased donor 1-year and 5-year graft survival is 93% and 75%, and a living donor is 98% and 85%, respectively.

There is an effort to increase living donation because the deceased donor supply is inadequate, resulting in prolonged waiting times for recipient candidates on the deceased donor waiting list. The advantages and disadvantages of living versus deceased donor transplantation are summarized in Table 30.3. The use of kidney paired donation and/or desensitization allows for transplantation of recipients with potential donors who are blood group or immunologically incompatible. Kidney paired donation utilizes exchange algorithms to bypass incompatibility by matching blood group or human leukocyte antigen (HLA)-incompatible recipient-donor pairs with other incompatible pairs, resulting in each donor donating a kidney to the other person's intended recipient. On the other hand, desensitization utilizes antibody-directed therapy such as plasmapheresis or intravenous immunoglobulin to reduce donor-specific HLA antibodies or blood group antibodies in recipients to prevent acute rejection despite blood group or HLA incompatibility. As a means of expanding the supply of deceased donor kidneys and reducing deceased donor waiting times, kidneys from marginal donors such as those of advanced age or with comorbid conditions such as hypertension and cerebrovascular disease are utilized in selected recipients who would benefit from earlier transplantation. In addition, increased Public Health Service risk donors, such as those who have a history of intravenous drug abuse, are increasingly being utilized. In the setting of negative nucleic acid testing, the absolute risk of transmission of hepatitis C, human immunodeficiency virus, and hepatitis B virus from these donors is less than 1%.

E-Fig. 30.6 Dialyzers for hemodialysis.

TABLE 30.3 Comparison of Donor Sources for Kidney Transplantation

Advantages	Disadvantages
Living Donor	
Waiting time for transplant reduced	Small potential postoperative risks for the donor
Sequelae of long-term dialysis avoided	Small potential long-term risk of kidney function decline in the donor
Elective surgical procedure	Requirement of a willing, medically suitable donor
Better early graft function with shorter hospitalization	
Better short-term and long-term success	
Deceased Donor	
Availability to any recipient	Waiting time variable
Availability of other organs for combined transplants (i.e., kidney-pancreas transplant)	Operation performed urgently
Availability of vascular conduits for complex vascular reconstruction	Higher rates of delayed or slow graft function
	Short-term and long-term success not as good as from a living donor

Fig. 30.5 Pathways of T-cell activation and site of action of immunosuppressive agents. *ATG*, Antithymocyte globulin; *AZA*, azathioprine; *IL*, interleukin; *MHC*, major histocompatibility complex; *MMF*, mycophenolate mofetil; *mTOR*, mammalian target of rapamycin; *NFAT*, nuclear factor of activated T cells; *TCR*, T-cell receptor.

Immunosuppressant drug therapy. Achieving adequate immunosuppression while minimizing drug toxicity and the risk of infection is at the heart of the success of kidney transplantation. All protocols for immunosuppression aim to inhibit the T lymphocyte, targeting different sites or pathways in the 3-signal model of T-cell activation and proliferation. The mechanisms of action of commonly used immunosuppressants is illustrated in Fig. 30.5. Additionally, antibody-directed therapy is usually employed in those who require desensitization due to preexisting HLA or blood group antibodies.

Induction immunosuppression is administered at the time of transplant and the immediate postoperative period in the form of high-dose steroids, with or without a T lymphocyte-depleting agent such as antithymocyte globulin or a nondepleting agent such as basiliximab (an interleukin-2 inhibitor). *Maintenance immunosuppression* is initiated postoperatively and is composed of at least two drugs, with or without corticosteroids. In the United States, the most common regimen at the time of discharge from the hospital after a transplant is tacrolimus, mycophenolate, and prednisone.

The hepatic cytochrome P-450 system is essential for cyclosporine, tacrolimus, and mTOR inhibitor metabolism. Significant changes in the levels of these drugs may occur when patients start or discontinue taking any of several drugs that can induce or inhibit this system. Therefore, evaluation for drug-drug interactions is critical to prevent toxic or even subtherapeutic effects of either the immunosuppressant drug or the other prescribed therapy. *Cyclosporine* exerts its activity by initially binding to cyclophilin. The cyclosporine-cyclophilin complex subsequently inhibits calcineurin, a calcium-dependent phosphatase that dephosphorylates nuclear factor of activated T cells (NFAT). The inhibition of NFAT dephosphorylation prevents transcription of T-cell activation genes. Side effects of cyclosporine include hypertension, hyperkalemia, hypomagnesemia, exacerbation of gout, dyslipidemia, hypertrichosis, and gingival hypertrophy. *Tacrolimus* has a mechanism of action and side-effect profile like those of cyclosporine. However, it binds to FK-binding protein instead of cyclophilin. It also has additional problems of hyperglycemia and an increased tendency toward neurotoxicity. Rather than causing hypertrichosis, it causes alopecia. Both cyclosporine

and tacrolimus can cause calcineurin inhibitor nephrotoxicity, and this is often related to afferent arteriolar vasoconstriction leading to decreased glomerular blood flow. Nephrotoxicity can be acute or chronic and ultimately may contribute to chronic allograft nephropathy and graft loss.

Mycophenolate mofetil or *mycophenolic acid* specifically inhibits T-lymphocyte and B-lymphocyte proliferation by interfering with purine synthesis and thus DNA synthesis. Side effects include leukopenia, anemia, and upper and lower gastrointestinal symptoms.

Sirolimus and *everolimus* bind to FK-binding protein and subsequently inhibit mTOR, thus blocking the phosphorylation of *p70(s6)* kinase and the eukaryotic initiation factor 4E-binding protein, PHAS-I. This action leads to the dampening of cytokine and growth factor activity on T, B, and nonimmune cells. The major side effects are thrombocytopenia, proteinuria, impaired wound healing, and dyslipidemia. mTOR inhibitors can also cause mouth ulcerations, lymphedema, and pneumonitis.

Due to the persistence of episodes of rejection and graft loss over time, novel immunosuppressive agents continue to be developed. Most recently, *belatacept*, a fusion protein that inhibits T-cell activation by blocking the CD80 and CD86 sites on antigen presenting cells, has been shown to confer superior long-term graft function compared to a cyclosporine-based maintenance regimen. This is despite an increased risk of developing early severe acute rejection episodes. Belatacept is administered intravenously and its most serious adverse effect is an increased incidence of post-transplant lymphoproliferative disorder (PTLD) compared to cyclosporine. It is therefore contraindicated in recipients who have not been exposed to Epstein-Barr virus because these patients are at an already higher risk for PTLT at baseline.

Acute rejection. Clinically, acute rejection is detected by a rise in serum creatinine or the development of new proteinuria. In severe cases, graft tenderness and oliguria can occur. *Acute cellular rejection* occurs when T lymphocytes recognize foreign antigens, especially when presented in association with class II histocompatibility antigens. This prompts lymphocyte activation and subsequent invasion of the tubulointerstitium, and in severe cases the blood vessel wall, by activated cytotoxic lymphocytes, resulting in tubulitis and/or endothelitis. This type of rejection is usually treated with high-dose steroids with or without antithymocyte globulin depending on the severity of the rejection and the initial response to steroid therapy. *Acute humoral rejection* usually occurs in the presence of preexisting or de novo donor-specific HLA antibodies and manifests in the transplanted kidney as microvascular inflammation with or without C4d staining on immunofluorescence. This type of rejection is usually treated with intravenous immune globulin and plasmapheresis, with or without B-cell directed therapy.

Post-transplantation infection. Infection is second only to cardiovascular disease as the leading cause of mortality in kidney transplant recipients. Prophylaxis is used immediately after kidney transplantation to prevent opportunistic infections such as *Pneumocystis jirovecii* pneumonia, cytomegalovirus infection, herpes simplex virus infection, and *Candida* infections. In addition to common community-acquired bacterial and viral infections, kidney transplant recipients are also susceptible to numerous viral, fungal, and other opportunistic infections that normally do not cause severe illness in the immunocompetent host.

Post-transplantation malignant disease. Immunosuppression increases the risk for developing malignant disease. Skin cancer (mostly squamous cell) has the highest incidence in transplant recipients compared with all other types of malignancy. With continuous

surveillance and aggressive management, metastasis from skin cancers is rare. Transplant recipients are also at increased risk for developing non-Hodgkin lymphoma and Kaposi sarcoma. In addition to age-appropriate screening, cancer surveillance should be an essential part of post-transplantation care.

PROGNOSIS

The prognosis of CKD varies depending upon the underlying cause, its severity at presentation, and the response to therapy. Yet, it is important to recognize that CKD in general is a significant risk factor for cardiovascular disease and death. Mortality from cardiovascular disease in CKD patients, especially those with stage 3 to 5 disease, is 3.5 times that of an age-matched population (E-Fig. 30.8) and accounts for more than 50% of the deaths in ESRD patients. Research to understand the underlying mechanisms and final pathway, as well as those specific to patients with unique characteristics, will be necessary to advance our efforts to reduce related risks and cure kidney disease.

Common Clinical Manifestations of Gastrointestinal Disease: Abdominal Pain

Charles M. Bliss, Jr.

DEFINITION AND EPIDEMIOLOGY

Abdominal pain is a frequent manifestation of intra-abdominal disease. However, abdominal pain is difficult to localize or grade because the sensation of pain often is colored by emotional and physical factors. Abdominal pain may be classified as acute or chronic. Acute pain occurs suddenly and more often suggests serious physiologic alterations. Chronic pain may be present for several months; although it does not mandate immediate attention, chronic pain may lead to prolonged evaluation. According to a recent survey of 71,812 patients, 25% of the respondents reported abdominal pain within the past week. Appropriate evaluation of abdominal pain requires knowledge of pain mechanisms, close attention to history and physical examination findings, and recognition of important accompanying symptoms as well as awareness of the strengths and weaknesses of the tests that might be used.

PHYSIOLOGY

Abdominal pain results from stimulation of receptors specific for thermal, mechanical, or chemical stimuli. Once these receptors are excited, pain impulses travel through sympathetic fibers. Abdominal pain can be characterized as somatic or visceral. Somatic pain originates from the abdominal wall and parietal peritoneum, whereas visceral pain originates in internal organs and from the visceral peritoneum. Two types of neurons carry pain: *A fibers*, which have rapid conduction, and *C fibers*, which have slow conduction. Most visceral neurons are of the C type, and the pain resulting from their stimulation tends to be variable with regard to sensation and localization. In contrast, both A and C fibers originate from the parietal peritoneum and abdominal wall, and somatic pain tends to be sharp and distinctly localized.

Because of this pattern of innervation, abdominal viscera are not sensitive to cutting, tearing, burning, or crushing. However, visceral pain results from stretching of the walls of hollow organs or of the capsule of solid organs, as well as from inflammation or ischemia.

CAUSES OF ABDOMINAL PAIN

Multiple intra-abdominal and extra-abdominal disorders can produce abdominal pain. Distinguishing acute from chronic symptoms is helpful. The approach varies with each specific cause, but acute abdominal pain usually demands prompt intervention.

CLINICAL PRESENTATION

History

The differential diagnosis of abdominal pain, whether acute or chronic, requires thorough history taking with regard to pain characteristics, location and radiation, timing, and the presence of any accompanying symptoms. Recognition of characteristic patterns is essential to narrowing the differential diagnosis.

Pain location often indicates the organ responsible for the problem. For instance, epigastric pain is usually typical of peptic ulcer or dyspepsia, whereas right upper quadrant pain is more suggestive of cholecystitis and other biliary disorders. Early in the course of illness, pain may be perceived in one location and subsequently felt in another; this pattern of progression may be suggestive of specific pain syndromes. In acute cases, abdominal pain tends to be sharp and severe. The pain of a perforated viscus is intense, and the pain from a dissecting aneurysm may be described as tearing or crushing. Chronic pain may be less severe; pain from irritable bowel or dyspepsia is constant and dull, and the pain of chronic peptic ulcer is described as gnawing or hunger pain. The pattern of pain relief is helpful for diagnosing some conditions. The physician should also inquire about whether the pain is steady or intermittent and whether it occurs at night. For nocturnal pain, a distinction should be made between pain that awakens the patient and pain that is felt when the patient wakes up for other reasons.

Table 31.1 outlines characteristics, location, and radiation of pain for a few common acute and chronic abdominal conditions.

Physical Examination

Examination of the abdomen provides valuable clues to the diagnosis, but the examination should start with the general appearance of the patient. A patient who is writhing in bed and unable to find a comfortable position may be suffering from obstruction. In contrast, a patient lying with the lower extremities flexed and avoiding any motion may be suffering from peritonitis because movement makes peritoneal pain worse. Abdominal distention indicates obstruction or ascites. Visual inspection for peristalsis is helpful for the diagnosis of small bowel obstruction, but this sign is present only in the early stages. Focal areas of distention may indicate hernias; notice should also be taken of any scars from prior surgeries.

Auscultation should be performed in several areas to evaluate the timbre and pattern of bowel sounds and to search for bruits or hums. Absence of bowel sounds suggests ileus, whereas the presence of hyperactive, high-pitched sounds may indicate obstruction. Multiple bruits

TABLE 31.1 Key Abdominal Pain Syndromes

Condition	Type	Location	Radiation
Acute Abdominal Pain			
Appendicitis	Crampy, steady	Periumbilical, RLQ	Back
Cholecystitis	Intermittent, steady	Epigastric, RUQ	Right scapula
Pancreatitis	Steady	Epigastric, periumbilical	Back
Perforation	Sudden, severe	Epigastric	Entire abdomen
Obstruction	Crampy	Periumbilical	Back
Infarction	Severe, diffuse	Periumbilical	Entire abdomen
Chronic Abdominal Pain			
Esophagitis	Burning	Retrosternal	Left arm, back
Peptic ulcer	Gnawing	Epigastric	Back
Dyspepsia	Bloating, dull	Epigastric	None
IBS	Crampy	LLQ, RLQ	None

IBS, Irritable bowel syndrome; LLQ, left lower quadrant; RLQ, right lower quadrant; RUQ, right upper quadrant.

alert the examiner to the possibility of significant vascular disease, suggesting ischemia.

The abdomen should be palpated gently, starting in an area away from the pain. The examiner searches for areas of localized tenderness and rebound as well as for masses and enlarged organs. Percussion is performed to identify the size of organs or to determine the presence of ascites. Pain on percussion of the abdomen indicates peritoneal reaction, as does severe rebound tenderness.

A rectal examination is important for identifying a rectal tumor in the case of colon obstruction or tenderness high in the rectum in acute appendicitis. A pelvic examination should be performed in women to rule out pelvic inflammatory disease, or masses.

ACUTE ABDOMEN

The evaluation of a patient with an acute abdomen is a challenge in medical practice. The acute abdomen is caused by sudden inflammation, perforation, obstruction, or infarction of an intra-abdominal organ. The urgent question to be answered is whether immediate surgery is needed; a quick but complete evaluation is necessary to avoid undue delay in intervention for patients who require surgery. The physician must assess for abdominal tenderness, rebound, and guarding. Early surgical consultation should be obtained, even in doubtful cases, rather than awaiting confirmation of the diagnosis via laboratory or radiologic studies. However, many extra-abdominal conditions such as pneumonia, myocardial infarction, nephrolithiasis, and metabolic disorders can cause acute abdominal pain.

In some instances of the acute abdomen in its early stages, there are few findings. The examiner should be aware that patients with benign chronic conditions may have severe pain at presentation that is out of proportion to any physical findings. The context provided by the medical history, particularly previous abdominal surgery, is very valuable. Indeed, a patient with sudden crampy pain and abdominal distention may have an intestinal obstruction caused by adhesions or an incarcerated hernia. Therefore, examination of the entire patient, looking for jaundice, skin lesions, evidence of prior surgery, or evidence of chronic liver disease, is important.

In evaluating a patient with acute abdominal symptoms, a complete blood cell count with differential, a urinalysis, and measurements of serum amylase, lipase, bilirubin, and electrolytes are necessary components of the laboratory examination. Additional studies may be

done but usually do not aid in the rapid decision making required. An elevated white blood cell count may indicate inflammatory disease, and extremely high values are typical of acute intestinal ischemia. An elevated serum amylase concentration usually indicates acute pancreatitis, although a perforated ulcer or mesenteric thrombosis can also cause hyperamylasemia.

Radiographic examination with an abdominal film is important to reveal the intra-abdominal gas pattern, and an upright film that includes the diaphragm or a left lateral decubitus film may identify intra-abdominal air suggesting perforation of a hollow viscus. Ultrasonography can be helpful in the diagnosis of acute cholecystitis or appendicitis. Computed tomography (CT) scans have become more helpful with technologic improvements in scanners; early CT scans allow prompt diagnosis of sometimes unsuspected abdominal diseases. Examination with a radiopaque medium should be used judiciously, especially if surgery is anticipated. **E-Figs. 31.1 through 31.4** are CT images of appendicitis, diverticulitis, pancreatitis, and ulcerative colitis, respectively.

CHRONIC ABDOMINAL PAIN

In the evaluation of chronic abdominal pain, it can be challenging to distinguish between organic pain resulting from a specific pathologic process and functional pain. The location and characteristics of pain, as already discussed, serve as important guides, as do other accompanying symptoms. The presence of postprandial nausea and vomiting suggests chronic peptic ulcer, disorders of gastric emptying, or outlet obstruction. Documentation of weight loss mandates the search for an organic cause, such as inflammatory bowel disease or celiac disease. If anorexia accompanies weight loss, particularly in elderly patients, cancer must be excluded. If no cancer can be found and all objective tests are normal, the possibility of chronic depression must be entertained.

The most frequent causes of chronic abdominal pain are functional. Dyspepsia is characterized by chronic intermittent epigastric discomfort, sometimes accompanied by nausea or bloating. These symptoms are not always relieved by acid suppression and may be the result of an underlying motor disorder. Furthermore, when *Helicobacter pylori* is found in a patient with dyspeptic symptoms, its eradication may not necessarily lead to the resolution of symptoms. Controversy exists regarding the most effective strategy for the treatment of dyspepsia when *H. pylori* organisms are found in the absence of peptic ulcer disease.

Irritable bowel syndrome (IBS) is a very common disorder. Estimates are that 15% of Americans suffer from IBS on a regular basis and that 40% to 50% of referrals to gastroenterologists are related to IBS. The syndrome consists of abdominal distention, flatulence, and disordered bowel function. There are two important variants of IBS: constipation predominant IBS (IBS-C) is characterized by pain in the setting of constipation, and diarrhea predominant IBS (IBS-D) involves pain in the setting of diarrhea. IBS with both diarrhea and constipation is sometimes denoted as IBS mixed. The abdominal pain of IBS tends to be in the left lower quadrant, but it can be located elsewhere or be more generalized. Any patient with weight loss, anemia, nocturnal symptoms, steatorrhea, or onset of symptoms after age 50 years should be evaluated carefully for organic disease because these symptoms are not associated with IBS.

The Rome criteria, developed for research studies, may be helpful in the diagnosis of IBS. These criteria include pain that is associated with change in bowel habits, relieved with defecation, or accompanied by distention or bloating. Patients are reassured, counseled, and treated with anticholinergic agents and stool softeners. Although serotonin (5-HT) agonists such as alosetron and

tegaserod showed promise initially, they have been relegated to limited use due to unacceptable side effects. Eluxadoline, which targets opioid receptors, has been helpful in some cases of IBS-D in controlling pain and diarrhea in patients who have failed loperamide. Linaclotide causes increased secretion of chloride and bicarbonate into the intestinal lumen via a cyclic guanosine monophosphate (cGMP) pathway. This pathway also may be responsible for relief of visceral pain in patients with IBS-C. However, its use has been limited by unacceptable side effects, though a lower 72 mcg dose is now available. A new member of this class, plecanatide, has shown promise in initial studies but has not yet proved to be more effective than linaclotide. Tenapanor is a member of a new class of small molecule medications that act by inhibiting transport of sodium from the lumen of the large intestine, leading to improvements in constipation and pain in patients with IBS-C. This medication is still in the process of study but has been approved by the FDA. It represents a new method of treatment.

The more challenging clinical problem is *functional abdominal pain syndrome*. This term describes a condition in which the pain has been present for months or years. The complaints of pain often are not related to eating, defecation, or menses, unlike other causes of chronic pain. The patient is most likely to be a woman who has undergone numerous examinations and diagnostic studies with negative findings and, in many cases, surgical operations without any relief. Lengthy or repeated diagnostic work-ups are counterproductive and only convince the patient that one more test is what is needed to determine the source of the pain. The physician must establish that organic disease is not present and must also realize that the pain is real. These patients are not malingerers despite the fact that the pain does not fit any familiar pattern. Depression may be the result rather than the cause of the pain.

Management of chronic abdominal pain is demanding and requires as much tact, diplomacy, and compassion as scientific knowledge. An effort should be made to inquire about social factors, including history

of physical and sexual abuse, particularly in women. Psychiatric evaluation may be necessary, but the suggestion for such a consultation may be interpreted by the patient as evidence that the physician believes “the pain is in my head.” Referral to a competent pain management specialist is helpful in some cases. This approach offers the possibility of providing relief with nerve blocks if the pain is localized or with other pain-relieving devices. If this approach fails, referral to a psychologist or psychiatrist may be acceptable to the patient.

Because of the challenges involved with chronic pain treatment, especially in light of the current issues with opioids, new approaches using less traditional methods are being tried.

A new study done in the Netherlands showed that use of tetrahydrocannabinol, one of the active substances in marijuana, is not effective in the treatment of chronic pain from prior surgery or chronic pancreatitis.

Fig. 31.1 presents a practical approach to chronic abdominal pain.

Common Clinical Manifestations of Gastrointestinal Disease: Gastrointestinal Hemorrhage

Waihong Chung, Abbas Rupawala

INTRODUCTION

Gastrointestinal bleeding (GIB) is a major cause of morbidity, accounting for over 844,000 emergency department visits and 513,000 hospitalizations in the United States in 2014. GIB also accounts for over 2.2 million days of productivity loss and \$5 billion in direct cost annually. Despite increasing costs of care, mortality due to GIB has declined in recent years in part due to increased rates of endoscopy and improved endoscopic therapy. GIB can result from a variety of etiologies (Table 32.1), its presentation can vary greatly depending on age and comorbidity, and its clinical course can evolve rapidly over time and in response to treatment. It is, therefore, essential to apply a systematic approach to the management of all cases of suspected GIB. We advocate a four-step approach that can be encapsulated by a simple mnemonic *PRET*: Prioritize, Resuscitate, Evaluate, and Treat.

APPROACH TO PATIENTS WITH GASTROINTESTINAL BLEEDING

Prioritize

The first step in the approach to GIB is to prioritize and triage patients based on acuity and severity of blood loss. The objective of this step is to guide the pace of evaluation and ensure that the patient is managed in a timely and cost-effective manner.

GIB can be broadly classified as overt GIB, when patients present with hematemesis, coffee-ground emesis, melena, or hematochezia (Table 32.2), and occult GIB, when symptoms of overt bleeding are absent but patients are anemic with heme (occult blood) positive stools. In addition to symptoms of bleeding, patients may also present with some combination of weakness, dizziness, lightheadedness, shortness of breath, postural changes in blood pressure or pulse, cramping abdominal pain, and diarrhea. Intuitively, overt GIB likely represents faster or higher volume blood loss; thus, patients presenting with overt GIB should be prioritized to receive an expedited work-up in the emergency room or in the inpatient setting. Meanwhile, patients with occult GIB, who are otherwise asymptomatic, may be evaluated safely and more efficiently in the outpatient setting.

GIB can also be classified into acute GIB, arbitrarily defined as bleeding duration of less than 3 days, and chronic GIB. The authors, however, find this classification less useful in guiding prioritization because it fails to convey the difference in severity between protracted or continual occult GIB versus ongoing or recurrent overt GIB.

Resuscitate

The second step is to resuscitate and stabilize the patient's hemodynamic parameters and to alleviate symptoms. The objective of this step

is to prevent and reverse the complications of blood loss and restore end-organ perfusion. It is worth emphasizing that adequate resuscitation is *the most important step* in the management of GIB and must take priority over the subsequent steps of evaluation and treatment.

In cases of overt GIB, the resuscitative effort should follow the basic principle of airway, breathing, and circulation. Airway management and respiratory support should be considered in patients presenting with massive or recurrent hematemesis as well as those with altered mental status to minimize risk of aspiration. Restoration of normal circulatory function should be achieved by rapid infusion of an isotonic crystalloid fluid, such as normal saline or lactated Ringer's solution. Concerns regarding volume overload and pulmonary edema in patients with heart failure or renal failure should not delay initiation of fluid resuscitation but may necessitate the use of positive-pressure ventilation. A restrictive transfusion threshold of hemoglobin less than 7 g/dL has been shown to improve survival (95% vs. 91%) and decreased rebleeding (10% vs. 16%) compared to a threshold of 9 g/dL. This is especially true in cirrhotic patients presenting with suspected variceal bleeding where over-transfusion may increase portal hypertension, bleeding and mortality.

In cases of occult GIB, resuscitation should aim at relieving the symptoms of anemia. Those with severe, symptomatic anemia and signs of end-organ ischemia, such as angina or renal insufficiency, may be transfused. Those with nonsevere symptoms of anemia, such as weakness, fatigue, exercise intolerance, or exertional dyspnea, can receive oral or parenteral iron replacement therapy.

Evaluate

The third step is performing a focused history and physical exam and obtaining relevant laboratory and imaging tests (Table 32.3). The goal of this step is to localize the potential bleeding site and identify the most likely etiology of the bleed.

From a diagnostic and therapeutic perspective, it is most useful to distinguish GIB into upper GIB (UGIB), historically defined as bleeding emanating from a source proximal to the ligament of Treitz, and lower GIB (LGIB). LGIB can be further subdivided into small bowel bleeding, originating proximal to the terminal ileum, and colonic bleeding. UGIB has traditionally been considered to account for 76% to 82% of GIB cases and is associated with a significantly higher emergency room to hospital admission rate (78% vs. 40%) as well as in-hospital mortality (1.5% vs. 0.5%) compared to LGIB. Patients with suspected UGIB should, therefore, be managed more aggressively, including offering an early endoscopy within 24 hours of presentation, while those with self-limiting LGIB may be observed clinically. Up to 15% of patients presenting with presumed LGIB may have UGIB. The term *obscure*

TABLE 32.1 Common Etiologies of GIB

Source	Associated Clinical Features	Management
Upper Gastrointestinal Tract		
Esophagitis/esophageal ulcer	Reflux, dysphagia, odynophagia	Acid suppression, antireflux surgery
Esophageal cancer	Dysphagia, weight loss	Chemoradiation, surgery
Gastroesophageal varices/portal gastropathy	Chronic liver disease, portal hypertension	Octreotide, endoscopic therapy, antibiotics
Mallory-Weiss tear	Repeated retching, vomiting, alcoholics	Supportive care, endoscopy
Gastritis/gastric ulcer/duodenitis/duodenal ulcer	NSAIDs, alcohol, <i>Helicobacter pylori</i> , epigastric pain	Hold NSAIDs, treat <i>H. pylori</i> , acid suppression, endoscopic therapy
Gastric cancer	Early satiety, weight loss, abdominal pain	Surgery, chemotherapy
Gastric antral vascular ectasia	Cirrhosis, systemic sclerosis	Endoscopic therapy
Angioectasias	Painless bleeding, may be present throughout GI tract, aortic stenosis (Heyde syndrome)	Endoscopic therapy
Cameron lesion	Hiatal hernia	Surgery for hiatal hernia repair
Dieulafoy lesion	Cardiovascular disease, chronic kidney disease, NSAIDs, alcohol	Endoscopic therapy
Aortoenteric fistula	History of open abdominal aortic aneurysm repair, sentinel bleed, large-volume bleeding	Surgery
Hemobilia	History of biliary tract instrumentation, biliary malignancy	Repeat endoscopy, vascular interventional radiology (VIR), surgery
Hemosuccus pancreaticus	Pancreatic pseudocyst, pancreatic tumor	VIR
Lower Gastrointestinal Tract		
Diverticular bleed	Diverticulosis, painless hematochezia in older patients	Endoscopic therapy, VIR
Infectious colitis	History of exposure, diarrhea, abdominal pain	Treat underlying infection
Inflammatory bowel disease	History of colitis, diarrhea, abdominal pain, fever, tenesmus	Treat underlying inflammation
Ischemic colitis	History of profound hypotension, abdominal pain, followed by bleeding	Supportive care, surgery
Angioectasia	Obscure overt or occult bleeding	Endoscopic therapy
Radiation-induced telangiectasia	Pelvic radiation	Endoscopic therapy
Meckel's diverticulum	Painless hematochezia in younger patients	Surgery
Colorectal cancer	Weight loss, change in bowel habits, anemia	Surgery, chemotherapy
Colon polyp	Painless hematochezia	Endoscopic resection
Post-polypectomy bleed	Recent colonoscopy with polypectomy	Endoscopic therapy
Hemorrhoidal bleed	Hematochezia with bowel movement	Supportive care, surgery, banding
Stercoral ulcer	Severe constipation	Supportive care, treat constipation

TABLE 32.2 Definitions of Overt GIB

Hematemesis

Vomiting of bright red blood or partially digested blood that resembles coffee grounds.

Source of bleeding is likely to be proximal to the ligament of Treitz. Consider swallowed blood from nasopharynx (e.g., epistaxis) or the respiratory tract (hemoptysis).

Melena

Passing of black, tarry, and usually foul-smelling stool, representing digested blood.

Source of bleeding is likely to be in the upper gastrointestinal tract, the small bowel, or occasionally the proximal colon.

As little as 50-100 mL of blood can result in melena.

Hematochezia

Passing of bright red blood or maroon stool per rectum.

Source of bleeding is likely to be in the lower gastrointestinal tract (small bowel and colon).

10-15% of severe UGIB with brisk bleeding may present with hematochezia.

GIB, which was previously used interchangeably with small intestinal bleeding, is now reserved to describe cases of overt or occult GIB where the bleeding source is not readily identified after complete evaluation of the entire GI tract including the small bowel.

Signs and symptoms that are strongly predictive of an UGIB include the presence of bright red blood or coffee-ground emesis as well as a markedly elevated blood urea nitrogen (BUN)-to-creatinine ratio in a patient without chronic kidney disease. Melena refers to black, tarry, foul-smelling stools formed as a result of blood being altered by gastric acid, digestive enzymes, and intestinal bacteria. Although the presence of melena is often indicative of UGIB, it can also be seen in cases of small intestinal as well as right-sided colonic bleed. The use of nasogastric lavage for ruling out UGIB has largely fallen out of favor due to its poor negative likelihood ratio and its association with significant patient discomfort.

A critical decision point in the evaluation step is assessing the odds of variceal bleeding being the etiology, as it is a serious gastrointestinal emergency that is associated with a high (>30%) mortality rate and is managed somewhat differently than other etiologies of GIB. Any patients with known varices, acute alcoholic hepatitis, or cirrhosis of any etiologies, especially those with signs and symptoms of portal

TABLE 32.3 Key Information in the Evaluation of GIB

History	Physical Exam	Laboratory Test
<ul style="list-style-type: none"> Nature of bleeding (hematemesis, melena, hematochezia) Other gastrointestinal symptoms Systemic (cardiopulmonary, constitutional, and other) symptoms Medications: NSAIDs, corticosteroids, bisphosphonates, anticoagulants, and antiplatelets Illicit drug and alcohol exposure Surgical history Past medical history <ul style="list-style-type: none"> Peptic ulcer disease <i>Helicobacter pylori</i> infection and treatment Gastrointestinal bleed Chronic liver disease Inflammatory bowel disease Malignancy Pelvic radiation Recent endoscopic interventions (e.g., polypectomy) 	<ul style="list-style-type: none"> Vital signs Presence of gross blood in oropharynx Presence of abdominal tenderness Digital rectal exam 	<ul style="list-style-type: none"> Complete blood count Basic metabolic panel Hepatic function panel Prothrombin Time/INR Blood type and cross match

hypertension as evident by the presence of *caput medusae*, jaundice, splenomegaly, and/or ascites on exam as well as coagulopathy and thrombocytopenia on laboratory tests, should be managed as a potential variceal hemorrhage.
