Penetration and uncoating of the virus are required to deliver the viral genome into the cytoplasm of the host cell. Arildone, disoxaril, pleconaril, and other methylisoxazole compounds block uncoating of picornaviruses by fitting into a cleft in the receptor-binding canyon of the capsid and preventing disassembly of the capsid. For viruses that enter through endocytic vesicles, uncoating may be triggered by conformational changes in attachment proteins that promote fusion or by membrane disruption resulting from the acidic environment of the vesicle. **Amantadine, rimantadine,** and other hydrophobic amines (weak organic bases) are antiviral agents that can neutralize the pH of these compartments and inhibit virion uncoating. Amantadine and rimantadine only have activity against influenza A. These compounds act specifically by binding to and blocking the hydrogen ion (H^+) channel formed by the viral M_2 protein. Without the influx of H^+, the M_1 matrix proteins do not dissociate from the nucleocapsid (uncoating), so movement of the nucleocapsid to the nucleus, transcription, and replication are prevented. Blockage of this proton pore also disrupts proper processing of the hemagglutinin protein late in the replication cycle. In the absence of a functional M_2 proton pore, the hemagglutinin inopportunely changes its conformation into its "fusion form" and is inactivated as it traverses the normally acidic Golgi environment. **Docosanol** inhibits the fusion of enveloped viruses, including HSV, with cellular membranes. **Tromantadine,** a derivative of amantadine, also inhibits penetration of HSV. Penetration and uncoating of HIV are blocked by a 33-amino acid peptide, T20 **(enfuvirtide [Fuzeon]),** which inhibits the action of the viral fusion protein gp41.

RNA SYNTHESIS

Although messenger ribonucleic acid (mRNA) synthesis is essential for the production of virus, it is not a good target for antiviral drugs because it is difficult to inhibit viral RNA synthesis without affecting cellular mRNA synthesis. Even so, **sofosbuvir,** a prodrug for a nucleoside analog, is approved as an inhibitor of the hepatitis C virus (HCV) RNA-dependent RNA polymerase. **Baloxavir marboxil** inhibits influenza A and B by inhibiting the cap snatching endonuclease activity

of the viral polymerase. Guanidine and 2-hydroxybenzylbenzimidine are two compounds that can block picornavirus RNA synthesis by binding to the 2*C* picornavirus protein, which is essential for RNA synthesis. **Ribavirin** resembles riboguanosine and promotes hypermutation and inhibits nucleoside biosynthesis, mRNA capping, and other processes (cellular and viral) important to the replication of many viruses. Isatin-β-thiosemicarbazone induces mRNA degradation in poxvirus-infected cells and was used as a treatment for smallpox.

The proper processing (splicing) and translation of viral mRNA can be inhibited by antisense oligonucleotides and **type 1 interferons**. Viral infection of an interferon-treated cell triggers a cascade of biochemical events that block viral replication. Specifically, the degradation of viral and cellular mRNA is enhanced, and ribosomal assembly is blocked, preventing protein synthesis and viral replication. Interferon is described further in Chapter 10. Interferon is approved for clinical use (papilloma, hepatitis C).

GENOME REPLICATION

Most antiviral drugs are **nucleoside analogs,** which are compounds with modifications of the base, sugar, or both (Fig. 40.1). The viral **DNA-dependent DNA polymerases** of the herpesviruses and the **reverse transcriptases** of HIV and hepatitis B virus (HBV) *are the prime targets for most antiviral drugs because they are essential for virus replication and are different from host enzymes*. Before being used by the polymerase, the nucleoside analogs must be phosphorylated to the triphosphate form by viral enzymes (e.g., HSV thymidine kinase), cellular enzymes, or both. For example, the thymidine kinase of HSV and varicella-zoster virus (VZV) applies the first phosphate to **acyclovir (ACV),** and cellular enzymes apply the rest. HSV mutants lacking thymidine kinase activity are resistant to ACV. Cellular enzymes phosphorylate **azidothymidine (AZT)** and many other nucleoside analogs.

Nucleoside analogs selectively inhibit viral polymerases because these enzymes are less accurate than host cell enzymes. The viral enzyme binds nucleoside analogs that have modifications of the base, sugar, or both several hundred times better than the host cell enzyme. These drugs either **prevent chain elongation,** as a result of the absence of a 3′-hydroxyl on the sugar, or **alter recognition and base pairing,** as a result of a base modification, and induce inactivating mutations (see Fig. 40.1). Hypermutation of a viral genome by an antiviral drug (like ribavirin) is the equivalent of replacing every fourth letter in an essay with a random letter. Antiviral drugs that cause termination of the DNA chain by means of modified nucleoside sugar residues include ACV, ganciclovir (GCV), valacyclovir, penciclovir, famciclovir, adefovir, cidofovir, adenosine arabinoside (vidarabine, ara-A), zidovudine (AZT), lamivudine (3TC), dideoxycytidine, and dideoxyinosine. Antiviral drugs that become incorporated into the viral genome and cause errors in replication (mutation) and transcription (inactive mRNA and proteins) because of modified nucleoside bases include **ribavirin, 5-iododeoxyuridine (idoxuridine),** and **trifluorothymidine (trifluridine).** The rapid rate and large extent of nucleotide incorporation by HIV- and

BOX 40.1 Viruses Treatable with Antiviral Drugs

Herpes simplex virus
Varicella-zoster virus
Cytomegalovirus
Human immunodeficiency virus
Influenza A and B viruses
Respiratory syncytial virus
Hepatitis B and C viruses
Adenovirus
Papillomavirus

TABLE 40.1 Examples of Targets for Antiviral Drugs

Replication Step or Target	Agent	Targeted Virus
Attachment	Peptide analogs of attachment protein	HIV (CCR5 coreceptor antagonist)
	Neutralizing antibodies	Most viruses
	Heparan and dextran sulfate	HIV, HSV
Penetration and uncoating	Amantadine, rimantadine	Influenza A virus
	Tromantadine, docosanol	HSV
	Arildone, disoxaril, pleconaril	Picornaviruses
Transcription	Interferon	HCVs, papillomavirus
	Sofosbuvir, dasabuvir	HCV
	Baloxavir marboxil	Influenza A and B
	Antisense oligonucleotides	—
Hypermutation/guanosine analog	Ribavirin	HCV, respiratory syncytial virus, Lassa fever virus
Protein synthesis	Interferon	HCV, papillomavirus
DNA replication (polymerase)	Nucleoside analogs	Herpesviruses, HIV, hepatitis B virus, poxviruses, adenovirus, etc.
	Phosphonoformate, phosphonoacetic acid	Herpesviruses
Nucleoside scavenging (thymidine kinase)	Nucleoside analogs	HSV, varicella-zoster virus
Assembly (protease)	Hydrophobic substrate analogs	HIV, HCV
Assembly (neuraminidase)	Oseltamivir, zanamivir	Influenza A, B virus

CCR5, C-C chemokine receptor 5; *HCV,* hepatitis C virus; *HSV,* herpes simplex virus.

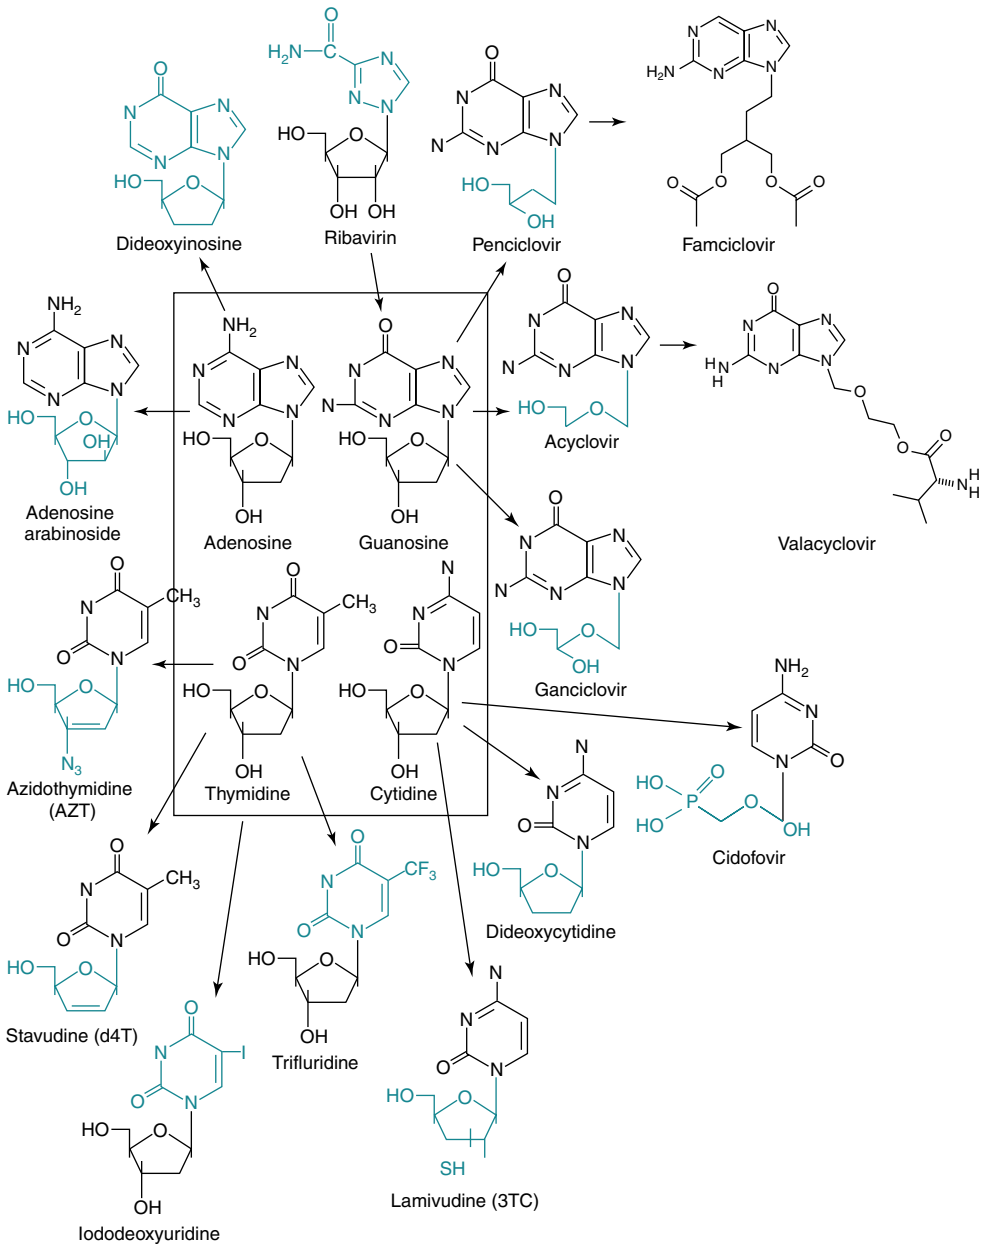

Fig. 40.1 Structure of the most common nucleoside analogs that are antiviral drugs. The chemical distinctions between the natural nucleoside and the antiviral drug analogs are highlighted. *Arrows* indicate related drugs. Valacyclovir is the L-valyl ester of acyclovir. Famciclovir is the diacetyl 6-deoxy-analog of penciclovir. Both of these drugs are metabolized to the active drug in the liver or intestinal wall.

herpesvirus-encoded polymerases make these viruses especially susceptible to these drugs. A variety of other nucleoside analogs are also being developed as antiviral drugs.

Pyrophosphate analogs resembling the by-product of the polymerase reaction, such as **phosphonoformic acid (foscarnet, PFA)** and **phosphonoacetic acid (PAA),** are classic inhibitors of the herpesvirus polymerases. **Nevirapine, delavirdine,** and other nonnucleoside reverse transcriptase inhibitors bind, as noncompetitive inhibitors of the enzyme, to sites on the polymerase other than the substrate site.

Deoxyribonucleotide scavenging enzymes (e.g., the thymidine kinase and ribonucleoside reductase of the herpesviruses) are also potential enzyme targets of antiviral drugs. Inhibition of these enzymes reduces the levels of deoxyribonucleotides necessary for the replication of the DNA virus genome, preventing virus replication.

Integration of the cDNA of HIV into the host chromosome is catalyzed by the viral integrase enzyme and essential for virus replication. **Raltegravir** inhibits the HIV integrase.

PROTEIN SYNTHESIS

Although bacterial protein synthesis is the target for several antibacterial compounds, viral protein synthesis is a poor target for antiviral drugs. The virus uses host cell ribosomes and synthetic mechanisms for replication, so selective

inhibition is not possible. **Type 1 interferons (IFNs) α and β,** stop a virus by promoting the inhibition of protein synthesis in the virus-infected cell.

Inhibition of the posttranslational modification of proteins, such as the proteolysis of a viral polyprotein **(protease inhibitors)** or glycoprotein processing (castanospermine, deoxynojirimycin), can also inhibit virus replication. **Boceprevir** and **telaprevir** are two protease inhibitors for treatment of HCV. Proteases of other viruses, especially HIV (see later), are also targets for antiviral drugs.

VIRION ASSEMBLY AND RELEASE

The **HIV protease** is unique and **essential** to the assembly of virions and the production of infectious virions. Computer-assisted molecular modeling was used to design inhibitors of the HIV protease, such as **saquinavir, ritonavir,** and **indinavir** (*navir,* "no virus"), that would fit into the active site of the enzyme. The enzyme structures were defined by x-ray crystallography and molecular biology studies.

The **neuraminidase of influenza** is essential to prevent intracellular and cell-surface aggregation of viral glycoproteins and allow their incorporation into the envelope. **Zanamivir (Relenza), oseltamivir (Tamiflu),** and **peramavir (Rapivab)** act as enzyme inhibitors and, unlike amantadine and rimantadine, can inhibit both influenza A and B. Amantadine and rimantadine also inhibit release of influenza A.

STIMULATORS OF HOST INNATE IMMUNE PROTECTIVE RESPONSES

Stimulation or supplementation of the natural response is an effective approach to limit or treat viral infections. Innate responses of dendritic cells, macrophages, and other cells can be stimulated by **imiquimod, resiquimod, and CpG oligodeoxynucleotides,** which bind to Toll-like receptors to stimulate release of protective cytokines, activation of natural killer cells, and subsequent cell-mediated immune responses. **Interferon** and interferon inducers, including mismatched polynucleotides and double-stranded RNA (e.g., **Ampligen, poly rI:rC**), facilitate the treatment of chronic diseases of hepatitis C and papillomaviruses. **Antibodies,** acquired naturally or by passive immunization (see Chapters 10 and 11), prevent both acquisition and spread of the virus. For example, passive immunization is administered after exposure to rabies and hepatitis A virus (HAV) and HBV.

Nucleoside Analogs

Most of the antiviral drugs approved by the U.S. Food and Drug Administration (FDA) (Table 40.2) are nucleoside analogs that inhibit viral polymerases. Resistance to the drug is usually caused by a mutation of the polymerase.

ACYCLOVIR, VALACYCLOVIR, PENCICLOVIR, AND FAMCICLOVIR

ACV (acycloguanosine) and its valyl derivative, valacyclovir, differ in pharmacologic ways. ACV differs from the nucleoside guanosine by having an acyclic (hydroxyethoxymethyl) side chain instead of a ribose or deoxyribose sugar. *ACV has selective action against HSV and VZV, the herpesviruses that encode a thymidine kinase* (Fig. 40.2). The viral thymidine kinase is required to activate the drug by phosphorylation, and host cell enzymes complete the progression to the diphosphate form and finally to the triphosphate form. Because there is no initial phosphorylation in

TABLE 40.2 Some Antiviral Drug Therapies Approved by the U.S. Food and Drug Administration

Virus	Antiviral Drug	Trade Name
Herpes simplex and varicella-zoster viruses	Acyclovir[a] Valacyclovir[a] Penciclovir Famciclovir[a] Trifluridine	Zovirax Valtrex Denavir Famvir Viroptic
Cytomegalovirus	Ganciclovir Valganciclovir Cidofovir Phosphonoformate (foscarnet)	Cytovene Valcyte Vistide Foscavir
Adenovirus	Cidofovir	Vistide
Influenza A virus	Amantadine Rimantadine	Symmetrel Flumadine
Influenza A and B viruses	Zanamivir Oseltamivir Peramivir Baloxavir marboxil	Relenza Tamiflu Rapivab Xofluza
Chronic hepatitis B virus	Lamivudine Adefovir dipivoxil	Epivir Hepsera
Hepatitis C virus	Interferon-α, ribavirin Boceprevir Telaprevir Sofosbuvir	Various Victrelis Incivek Sovaldi
Papillomavirus	Interferon-α Imiquimod	Various Aldara
Respiratory syncytial virus and Lassa virus	Ribavirin	Virazole
HUMAN IMMUNODEFICIENCY VIRUS[b]		
Nucleoside analog reverse transcriptase inhibitors	Azidothymidine (zidovudine) Dideoxyinosine (didanosine) Stavudine (d4T) Lamivudine (3TC)	Retrovir Videx Zerit Epivir
Nonnucleoside reverse transcriptase inhibitors	Nevirapine Delavirdine	Viramune Rescriptor
Protease inhibitors	Saquinavir Ritonavir Darunavir Fosamprenavir Atazanavir	Invirase Norvir Prezista Lexiva Reyataz
Integrase inhibitor	Raltegravir	Isentriss
CCR5 coreceptor antagonist	Maraviroc	Selzentry
Fusion inhibitor	Enfuvirtide	Fuzeon

[a]Also active against varicella-zoster virus.
[b]A more complete list is found in Chapter 54.
CCR5, C-C chemokine receptor 5.

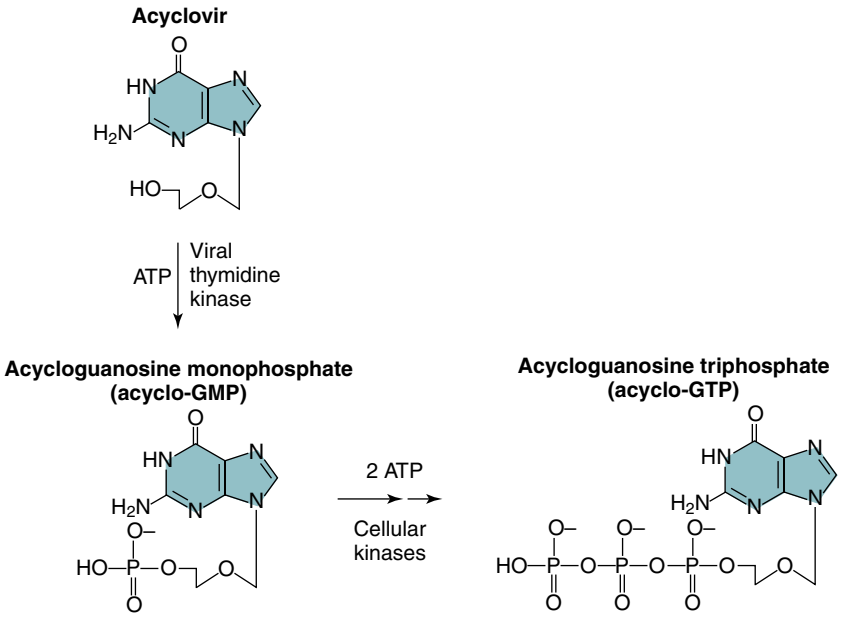

Fig. 40.2 Activation of acyclovir (ACV) (acycloguanosine) in herpes simplex virus–infected cells. ACV is converted to acycloguanosine monophosphate *(acyclo-GMP)* by herpes-specific viral thymidine kinase and then to acycloguanosine triphosphate *(acyclo-GTP)* by cellular kinases. *ATP,* Adenosine triphosphate.

uninfected cells, there is no active drug to inhibit cellular DNA synthesis or cause toxicity. The ACV triphosphate causes termination of the growing viral DNA chain because there is no 3′-hydroxyl group on the ACV molecule to allow chain elongation. The minimal toxicity of ACV is also a result of a 100-fold or greater use by the viral DNA polymerase than by cellular DNA polymerases. **Resistance to ACV** develops by mutation of *either* the thymidine kinase, so that activation of ACV cannot occur, or the DNA polymerase, to prevent ACV binding.

Valacyclovir, the valyl ester derivative of ACV, is more efficiently absorbed after oral administration and rapidly converted into ACV, increasing the bioavailability of ACV for the treatment of HSV and serious VZV. ACV and valacyclovir can also be used for the treatment of VZV infection, although higher doses are required. VZV is less sensitive to the agent in part because ACV is phosphorylated less efficiently by the VZV thymidine kinase.

Penciclovir inhibits HSV and VZV in the same way as ACV but is concentrated and persists in the infected cells to a greater extent than ACV. Penciclovir also has some activity against the Epstein-Barr virus and cytomegalovirus (CMV). **Famciclovir** is a prodrug derivative of penciclovir that is well absorbed orally and then is converted to penciclovir in the liver or intestinal lining. Resistance to penciclovir and famciclovir develops in the same manner as for ACV.

GANCICLOVIR

GCV (dihydroxypropoxymethyl guanine) differs from ACV in having a single hydroxymethyl group in the acyclic side chain (see Fig. 40.1). The remarkable result of this addition is that it confers considerable activity against CMV. CMV does not encode a thymidine kinase; instead, a viral-encoded protein kinase phosphorylates GCV. Once activated by phosphorylation, GCV inhibits all herpesvirus DNA polymerases. The viral DNA polymerases have nearly 30 times greater affinity for the drug than the cellular DNA polymerase. Similar to ACV, a valyl ester of GCV **(valganciclovir)** was developed to improve the pharmacologic properties of GCV.

The potential for bone marrow and other toxicity to GCV limits its use. Of interest, this potential toxicity has been used as the basis for the development of an antitumor therapy. In one application, an HSV thymidine kinase gene was incorporated into the cells of a brain tumor with the use of a retrovirus vector. The retrovirus replicated only in the growing cells of the tumor, and the thymidine kinase was expressed only in the tumor cells, making the tumor cells susceptible to GCV.

CIDOFOVIR AND ADEFOVIR

Cidofovir and **adefovir** are both nucleotide analogs and contain a phosphate attached to the sugar analog. This obviates the need for the initial phosphorylation by a viral enzyme. Compounds with this type of sugar analog are substrates for DNA polymerases or reverse transcriptases and have an expanded spectrum of susceptible viruses. Cidofovir, a cytidine analog, is approved for CMV infections in AIDS patients but can also inhibit replication of polyomavirus and papillomaviruses and inhibit the polymerases of other herpesviruses, adenoviruses, and poxvirus. Adefovir and adefovir dipivoxil (a diester prodrug) are analogs of adenosine and are approved for treatment of HBV.

AZIDOTHYMIDINE

Originally developed as an anticancer drug, **AZT** was the first useful therapy for HIV infection. AZT (Retrovir), a nucleoside analog of thymidine, inhibits the reverse transcriptase of HIV (see Fig. 40.1). Similar to other nucleosides,

AZT must be phosphorylated by host cell enzymes. It lacks the 3′-hydroxyl necessary for DNA chain elongation and prevents complementary DNA synthesis. The selective therapeutic effect of AZT stems from the 100-fold lower sensitivity of the host cell DNA polymerase compared with the HIV reverse transcriptase.

Continuous oral AZT treatment is administered to HIV-infected people with depleted CD4 T-cell counts to prevent progression of disease. AZT treatment of pregnant HIV-infected women can reduce the likelihood of, or prevent transmission of the virus to the baby. Side effects of AZT range from nausea to life-threatening bone marrow toxicity.

The high error rate of the HIV polymerase creates extensive mutations and promotes the development of antiviral drug-resistant strains. This problem is being addressed by the administration of multidrug therapy as initial therapy **(highly active antiretroviral therapy [HAART]).** It is more difficult for the HIV to develop resistance to multiple drugs with multiple target enzymes. Multidrug-resistant HIV strains are likely to be much weaker than the parent strains.

DIDEOXYINOSINE, DIDEOXYCYTIDINE, STAVUDINE, AND LAMIVUDINE

Several other nucleoside analogs have been approved as anti-HIV agents. Dideoxyinosine (didanosine) is a nucleoside analog that is converted to dideoxyadenosine triphosphate (see Fig. 40.1). Similar to AZT, dideoxyinosine, **dideoxycytidine,** and **stavudine** (d4T) lack a 3′-hydroxyl group. The modified sugar attached to **lamivudine** (2′-deoxy-3′-thiacytidine [3TC]) inhibits the HIV reverse transcriptase by preventing DNA chain elongation and HIV replication. Lamivudine and related drugs are also active on the reverse transcriptase polymerase of HBV. Most of the anti-HIV agents have potential toxic side effects.

RIBAVIRIN

Ribavirin is an analog of the nucleoside guanosine (see Fig. 40.1) but differs from guanosine in that its base ring is incomplete and open. Similar to other nucleoside analogs, ribavirin must be phosphorylated. The drug is active in vitro against a broad range of viruses.

Ribavirin monophosphate resembles guanosine monophosphate and inhibits nucleoside biosynthesis, mRNA capping, and other processes important to the replication of many viruses. Ribavirin depletes the cellular stores of guanine by inhibiting inosine monophosphate dehydrogenase, which is an enzyme important in the synthetic pathway of guanosine. It also prevents the synthesis of the mRNA 5′ cap by interfering with the guanylation and methylation of the nucleic acid base. In addition, ribavirin triphosphate inhibits RNA polymerases and promotes hypermutation of the viral genome. Its multiple sites of action may explain the lack of ribavirin-resistant mutants.

Ribavirin is administered in an aerosol to children with severe respiratory syncytial virus bronchopneumonia and potentially to adults with severe influenza or measles. The drug may be effective for the treatment of influenza B, as well as Lassa, Rift Valley, Crimean-Congo, Korean, and Argentine hemorrhagic fevers, for which it is administered orally or intravenously. Ribavirin is approved for use against HCV in combination with IFN-α and protease inhibitors. Treatment can have serious side effects.

OTHER NUCLEOSIDE ANALOGS

Idoxuridine, trifluorothymidine (see Fig. 40.1), and **fluorouracil** are analogs of thymidine. These drugs either (1) inhibit the biosynthesis of thymidine, which is a nucleotide essential for DNA synthesis, or (2) replace thymidine and become incorporated into the viral DNA. These actions inhibit further synthesis of the virus or cause extensive misreading of the genome, leading to mutation and inactivation of the virus. These drugs target cells in which extensive DNA replication is taking place, such as those infected with HSV, and spare the nongrowing cells from harm.

Idoxuridine was the first anti-HSV drug approved for human use but has been replaced by **trifluridine** and other more effective, less toxic agents. **Fluorouracil** is an antineoplastic drug that kills rapidly growing cells but also has been used for topical treatment of warts caused by human papillomaviruses.

Adenine arabinoside was the principal anti-HSV drug until ACV was introduced, but it is no longer used because of difficulties in administration and toxicity. Ara-A is an adenosine nucleoside analog with an arabinose substituted for deoxyribose as the sugar moiety (see Fig. 40.1). Many other nucleoside analogs that have antiviral activity are being investigated for clinical use against the herpesviruses, HBV, and HIV.

Baloxavir marboxil is also a nucleoside analogue that inhibits the subunit of the influenza polymerase that snatches the cap portion of cellular mRNAs to use as primers for transcription of the viral mRNA.

Nonnucleoside Polymerase Inhibitors

Foscarnet (PFA) and the related PAA are simple compounds that resemble pyrophosphate (Fig. 40.3). These drugs inhibit viral replication by binding to the pyrophosphate-binding site of the DNA polymerase to block nucleotide binding. PFA inhibits the DNA polymerase of all

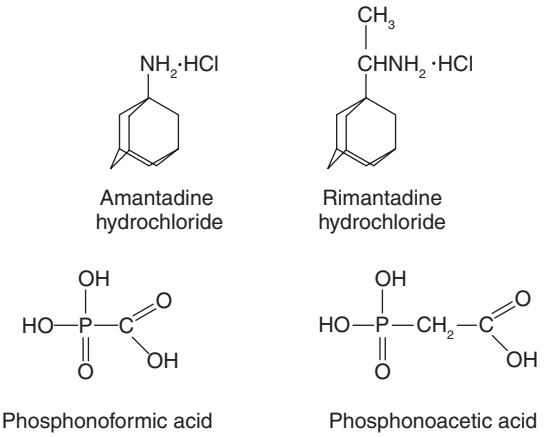

Fig. 40.3 Structures of antiviral drugs.

herpesviruses and the HIV reverse transcriptase without having to be phosphorylated by nucleoside kinases (e.g., thymidine kinase). PFA and PAA can cause renal and other problems because of their ability to chelate divalent metal ions (e.g., calcium) and they become incorporated into bone. PFA has been approved for the treatment of CMV retinitis in patients with AIDS.

Nevirapine, delavirdine, efavirenz, and other nonnucleoside reverse transcriptase inhibitors bind to sites on the enzyme different from the substrate. Because these drugs' mechanisms of action differ from those of the nucleoside analogs, the mechanism of HIV resistance to the agents is also different. As a result, these drugs are very useful in combination with nucleoside analogs for the treatment of HIV infection.

Protease Inhibitors

The unique structure of the HIV protease and its essential role in the production of a functional virion have made this enzyme a good target for antiviral drugs. **Saquinavir, indinavir, ritonavir, nelfinavir,** and other agents work by slipping into the hydrophobic active site of the enzyme to inhibit its action. Drug-resistant strains arise through mutation of the protease. Use of protease inhibitors significantly improved the outcomes for HIV patients. The combination of a protease inhibitor with AZT and a second nucleoside analog (HAART) can reduce blood levels of HIV to undetectable levels.

Protease inhibitors **(boceprevir, telaprevir, simeprevir)** have also improved the treatment of patients with chronic hepatitis C.

Antiinfluenza Drugs

Amantadine and **rimantadine** are amphipathic amine compounds with clinical efficacy against the influenza A but not the influenza B virus (see Fig. 40.3). These drugs have several effects on influenza A replication. Both compounds are acidotrophic and concentrate in and buffer the contents of the endosomal vesicles involved in the uptake of the influenza virus. This effect can inhibit the acid-mediated change in conformation in the hemagglutinin protein that promotes fusion of the viral envelope with cell membranes. However, the specificity for influenza A is a result of its ability to bind to and block the proton channel formed by the M_2 membrane protein of the influenza A virus. Resistance is the result of an altered M_2 or hemagglutinin protein.

Amantadine and rimantadine may be useful in ameliorating an influenza A infection if either agent is taken within 48 hours of exposure. They are also useful as a prophylactic treatment in lieu of vaccination. In addition, amantadine is an alternative therapy for Parkinson disease. The principal toxic effect is on the central nervous system, with patients experiencing nervousness, irritability, and insomnia.

Zanamivir (Relenza) and **oseltamivir (Tamiflu)** inhibit influenza A and B as enzyme inhibitors of the neuraminidase of influenza. Without the neuraminidase to cleave sialic acid, the hemagglutinin of the virus binds to these sugars on other glycoproteins, forming clumps and preventing assembly and virus release. These drugs can be taken prophylactically as an alternative to vaccination or, if taken within the first 48 hours of infection, to reduce the length of illness. Mutations in the neuraminidase cause resistance.

Immunomodulators

Genetically engineered forms of IFN-α have been approved for human use. Interferons work by binding to cell-surface receptors and by initiating a cellular antiviral response. In addition, interferons stimulate the immune response and promote the immune clearance of viral infection.

IFN-α is active against many viral infections. It has been approved for the treatment of condyloma acuminatum (genital warts, a presentation of papillomavirus) and hepatitis C (in combination therapy). Attachment of polyethylene glycol to IFN-α (pegylated IFN-α) increases its potency. Pegylated IFN-α can be used with ribavirin to treat hepatitis C infections. Natural interferon causes the influenza-like symptoms observed during many viremic and respiratory tract infections, and the synthetic agent has similar side effects during treatment. Interferon is discussed further in Chapters 10 and 37.

Imiquimod, a Toll-like receptor ligand, stimulates innate responses to attack the virus infection. This therapeutic approach can activate local protective responses against papillomas, which generally escape immune control.

Infection Control

Infection control is essential in hospital and health care settings. The spread of respiratory viruses is the most difficult to prevent. Viral spread can be controlled in the following ways:

1. Limiting personnel contact with sources of infection (e.g., wearing gloves, mask, goggles; using quarantine)
2. Improving hygiene, sanitation, and disinfection
3. Ensuring that all personnel are immunized against common diseases
4. Educating all personnel regarding points 1, 2, and 3 and in the ways to decrease high-risk behaviors

Methods for disinfection differ for each virus and depend on its structure. Naked capsid viruses are much more difficult to inactivate than enveloped viruses. Most viruses are inactivated by 70% ethanol, 15% chlorine bleach, 2% glutaraldehyde, 4% formaldehyde, or autoclaving (as described in *Guidelines for Prevention of Transmission of Human Immunodeficiency Virus and Hepatitis B Virus to Health-Care and Public-Safety Workers,* issued in 1989 by the U.S. Centers for Disease Control and Prevention [CDC]). Most enveloped viruses do not require such rigorous treatment and are inactivated by soap and detergents. Other means of disinfection are also available.

Special "universal" precautions are required for the handling of human blood; that is, all blood should be assumed to be contaminated with HIV or HBV and should be handled with caution. In addition to these procedures, special care must be taken with syringe needles and surgical tools contaminated with blood. Specific guidelines are available from the CDC.

Control of an outbreak usually requires identification of the source or reservoir of the virus, followed by cleanup, quarantine, immunization, or a combination of these measures. The first step in controlling an outbreak of gastroenteritis or hepatitis A is identification of the food, water, or possibly the day-care center that is the source of the outbreak.

Education programs can promote compliance with immunization programs and help people change lifestyles associated with viral transmission. Such programs have had a significant effect in reducing the prevalence of vaccine-preventable diseases such as smallpox, polio, measles, mumps, and rubella. It is hoped that educational programs will also promote changes in lifestyles and habits to restrict the spread of the blood-borne and sexually transmitted HBV and HIV.

Questions

1. List the steps in viral replication that are poor targets for antiviral drugs. Why?

2. Which viruses can be treated with an antiviral drug? Distinguish the viruses treatable with an antiviral nucleoside analog.

3. A mutation in the gene for which enzymes or proteins would confer resistance to the following antiviral drugs: ACV, phosphonoformate, amantadine, and AZT?

4. A patient has been exposed to influenza A virus and is in his sixth day of symptoms. He has heard that an antiinfluenza drug is available and requests therapy. You tell him that therapy is not appropriate. To what therapeutic agents is the patient referring, and why did you decline to use the treatment?

5. What disinfection procedures are sufficient for inactivating the following viruses: HAV, HBV, HSV, and rhinovirus?

6. What precautions should health care workers take to protect themselves from infection with the following viruses: HBV, influenza A virus, HSV (whitlow), and HIV?

41 Papillomaviruses and Polyomaviruses

A 47-year-old divorced, sexually active woman is seen for a routine gynecologic exam. She is a pack-a-day smoker. A Papanicolaou (Pap) smear is performed, and the report indicates high-grade squamous intraepithelial lesion (SIL) corresponding to a moderate dysplasia and cervical intraepithelial neoplasia (CIN) score of 2. Polymerase chain reaction (PCR) analysis indicates that cells in the lesion are infected with human papillomavirus 16 (HPV-16).

1. What properties of HPV-16 promote the development of cervical cancer?
2. How is the virus transmitted?
3. What is the nature of the immune response to the virus?
4. How can transmission and disease be prevented?

A 42-year-old man comes to his physician 9 months after a lung transplant, complaining that he has double vision, difficulty speaking, feels that his muscles do not work right, has difficulty with balance, has tingling of his hands and feet, and keeps forgetting things. A month later, he has difficulty speaking and needs assistance with normal daily functions. His mental and physical functions become progressively worse. He is treated with cidofovir, and his immunosuppressive therapy is eased, but his disease progresses to paralysis and he dies. A biopsy of the brain shows lesions with sites of demyelination, astrocytosis with atypical nuclei, and many histiocytes. PCR analysis demonstrates the presence of JC polyomavirus in the lesion, confirming a diagnosis of progressive multifocal leukoencephalopathy (PML).

5. What properties of JC virus (JCV) promote the development of PML?
6. Why is this disease also prevalent in individuals with acquired immunodeficiency syndrome (AIDS)? Who else is at risk for this disease and why?

Answers to these questions are available on StudentConsult.com.

Summaries Clinically Significant Organisms

PAPILLOMAVIRUSES

Trigger Words

HPV, warts, koilocytes, cervical cancer, STD, CIN

Biology, Virulence, and Disease

- Small naked capsid, DNA genome
- E6 and E7 proteins inactivate p53 and RB to promote cell growth.
- Virus is acquired by close contact and infects the epithelial cells of the skin or mucous membranes
- Tissue tropism and disease presentation depend on the papillomavirus type
- Virus persists in the basal layer and then produces virus in terminally differentiated keratinocytes
- Viruses cause benign outgrowth of cells into warts
- HPV infection is hidden from immune responses and persists
- Warts resolve slowly but spontaneously, possibly as a result of immune response
- Certain types (HPV-16, HPV-18, etc.) are associated with cervical, anal, penile, and oropharyngeal cancers

Epidemiology

- Transmitted by direct contact, sexual contact (sexually transmitted disease), fomites, passage through infected birth canal for laryngeal papillomas (types 6 and 11)
- Warts common; STD
- Asymptomatic transmission, found worldwide, no seasonal incidence

Diagnosis

- PCR genome analysis of cervical swabs and tissue specimens

Treatment, Prevention, and Control

- Vaccine for HPV types 6, 11, 16, 18, 31, 33, 45, 52, and 58

POLYOMAVIRUSES

Trigger Words

- JCV: PML, opportunistic disease, abnormal oligodendrocytes, demyelination; BK virus: kidney; MCPyV: Merkel cell carcinoma

Biology, Virulence, and Disease

- Small naked capsid, DNA genome
- T antigen inactivates p53 and RB to promote cell growth
- Virus infects tonsils and lymphocytes, and spreads by viremia to the kidneys early in life
- Virus is ubiquitous and infections are asymptomatic
- Virus establishes persistent and latent infection in organs such as kidneys and lungs
- In immunocompromised people, JCV is activated, spreads to the brain, and causes PML, which is a conventional slow virus disease
- In PML, JCV partially transforms astrocytes and kills oligodendrocytes, causing characteristic lesions and sites of demyelination
- PML lesions are demyelinated, with unusual large astrocytes and oligodendroglial cells with very large nuclei
- BK virus is benign but may cause kidney disease in immunocompromised patients

Epidemiology

- Transmitted by inhalation or contact with contaminated water or saliva
- Ubiquitous; immunocompromised people at risk for PML by JCV and kidney damage by BK virus
- Found worldwide; no seasonal incidence

Diagnosis

- JC: Presence of PCR-amplified viral DNA in cerebrospinal fluid and MRI or CT evidence of lesions

Treatment, Prevention, and Control

- No modes of control

CIN, Cervical intraepithelial neoplasia; *CT,* computerized tomography; *HPV,* human papilloma virus; *JCV,* JC virus; *MRI,* magnetic resonance imaging; *PCR,* polymerase chain reaction; *PML,* progressive multifocal leukoencephalopathy; *STD,* sexually transmitted disease.

What used to be called the **papovavirus family** (Papovaviridae) has been divided into two families, Papillomaviridae and Polyomaviridae (Table 41.1). These viruses are capable of causing lytic, chronic, latent, and transforming infections, depending on the host cell. HPVs cause **warts,** and several genotypes are associated with human cancer (e.g., **cervical carcinoma**). **BK virus (BKV)** and **JCV**, members of the **Polyomaviridae,** usually cause asymptomatic infection but are associated with renal disease and **PML,** respectively, in immunosuppressed people. **Simian virus 40 (SV40)** is the prototype polyomavirus.

The papillomaviruses and polyomaviruses are small, nonenveloped, icosahedral capsid viruses with double-stranded circular deoxyribonucleic acid (DNA) genomes (Box 41.1). They encode proteins that promote cell growth. The promotion of cell growth facilitates lytic viral replication in a permissive cell type but **may oncogenically transform a cell that is nonpermissive.** The polyomaviruses, especially SV40, have been studied extensively as model oncogenic viruses.

Human Papillomaviruses

STRUCTURE AND REPLICATION

HPVs are distinguished and typed by DNA sequence homology. At least 100 types have been identified and classified into 16 (A through P) groups. HPV can be distinguished further as **cutaneous HPV** or **mucosal HPV** on the basis of the susceptible tissue. Within the mucosal HPV, there is a group associated with cervical, penile, anal, and laryngeal cancer. Viruses in a group cause similar types of warts.

The **icosahedral capsid** of HPV is 50 to 55 nm in diameter and consists of two structural proteins that form 72 capsomeres (Fig. 41.1). The HPV genome is **circular** and has approximately 8000 base pairs. The HPV DNA encodes seven or eight early genes (*E1* to *E8*), depending on the virus, and two late or structural genes (*L1* and *L2*). An upstream regulatory region contains the control sequences for transcription, the shared N-terminal sequence for the early proteins, and the origin of replication. All the genes are located on one strand (the plus strand) (Fig. 41.2).

The replication cycle of HPV is linked to the life cycle of the keratinocyte and epithelial cell of the skin and mucosa. The virus accesses the basal cell layer through breaks in the skin (Fig. 41.3). The L1 protein of HPV is the viral attachment protein and initiates replication by binding to heparin proteoglycans and other receptors to trigger endocytosis from the cell surface. The early genes of the virus stimulate cell growth, which facilitates replication of the viral genome by the host cell DNA polymerase when the cells divide. Binding of the E1 and E2 proteins to viral DNA target cellular replication machinery to the genome. The virus-induced increase in cell number causes the basal and the prickle cell layer (stratum spinosum) to thicken (wart, condyloma, or papilloma). As the basal cell differentiates, the specific nuclear factors expressed in the different layers and types of skin and mucosa promote transcription of different viral genes. Expression of the viral genes correlates with the expression of specific keratins. The late genes encoding the structural proteins are expressed only in the terminally differentiated upper layer, and the virus assembles in the nucleus. As the infected skin cell matures and works its way to the surface, the virus matures and is shed with the dead cells of the upper layer and takes up to 3 weeks.

TABLE 41.1 Human Papillomaviruses and Polyomaviruses and Their Diseases

Virus	Disease
Papillomavirus	Warts, condylomas, papillomas; cervical, penile, and anal cancer[a]
Polyomavirus	
BK virus	Renal disease[b]
JC virus	Progressive multifocal leukoencephalopathy[b]
Merkel cell virus	Merkel cell carcinoma

[a]High-risk genotypes are present in 99.7% of these carcinomas.
[b]Disease occurs in immunosuppressed patients.

PATHOGENESIS

Papillomaviruses infect and replicate in the squamous epithelium of skin **(warts)** and mucous membranes **(genital, oral, and conjunctival papillomas)** to induce epithelial proliferation. The HPV types are very tissue specific, causing different disease presentations. The wart develops because of virus stimulation of cell growth and thickening of the basal and prickle layers (stratum spinosum), as well as the stratum granulosum. **Koilocytes,** characteristic of papillomavirus infection, are enlarged keratinocytes with clear halos around shrunken nuclei. It usually takes 3 to 4 weeks to months for the wart to develop (Fig. 41.4). The viral infection remains local and generally regresses spontaneously but can recur. The HPV pathogenic mechanisms are summarized in Box 41.2.

Innate and cell-mediated immunity are important for control and resolution of HPV infections. HPV can suppress or hide from protective immune responses. In addition to very low levels of antigen expression (except in the

BOX 41.1 Unique Properties of Polyomaviruses and Papillomaviruses

Papillomavirus: HPV types 1 to 100+ (as determined by genotype; types defined by DNA homology, tissue tropism, and association with oncogenesis)
Polyomavirus: SV40, **JC virus, BK virus,** KI, WU, Merkel cell polyomavirus (MCPyV)
Small icosahedral capsid virion
Double-stranded circular DNA genome replicated and assembled in nucleus
Viruses have defined tissue tropisms determined by receptor interactions and transcriptional machinery of cell
Viruses encode proteins that promote cell growth by binding to cellular growth-suppressor proteins p53 and p105RB (p105 retinoblastoma gene product); polyoma **T antigen** binds to p105RB and p53; high-risk **papillomavirus E6 protein binds to p53, activates telomerase, and suppresses apoptosis, and E7 protein binds to p105RB**
Viruses can cause lytic infections in permissive cells but cause abortive, persistent, or latent infections or **immortalize (transform)** nonpermissive cells

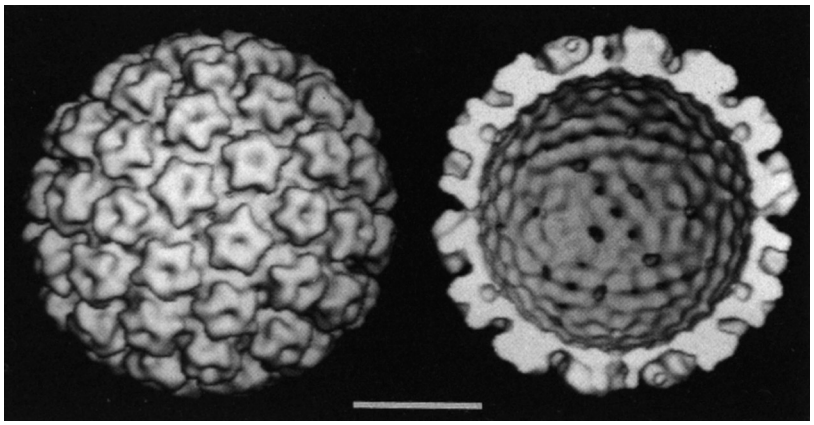

Fig. 41.1 Computer reconstruction of cryoelectron micrographs of human papillomavirus (HPV). *Left,* View of the surface of HPV shows 72 capsomeres arranged in an icosadeltahedron. All the capsomeres appear to form a regular five-point star shape. *Right,* Computer cross-section of the capsid shows the interaction of the capsomeres and channels in the capsid. (From Baker, T.S., Newcomb, W.W., Olson, N.H., et al., 1991. Structures of bovine and human papillomaviruses. Analysis by cryoelectron microscopy and three-dimensional image reconstruction. Biophys. J. 60, 1445–1456.)

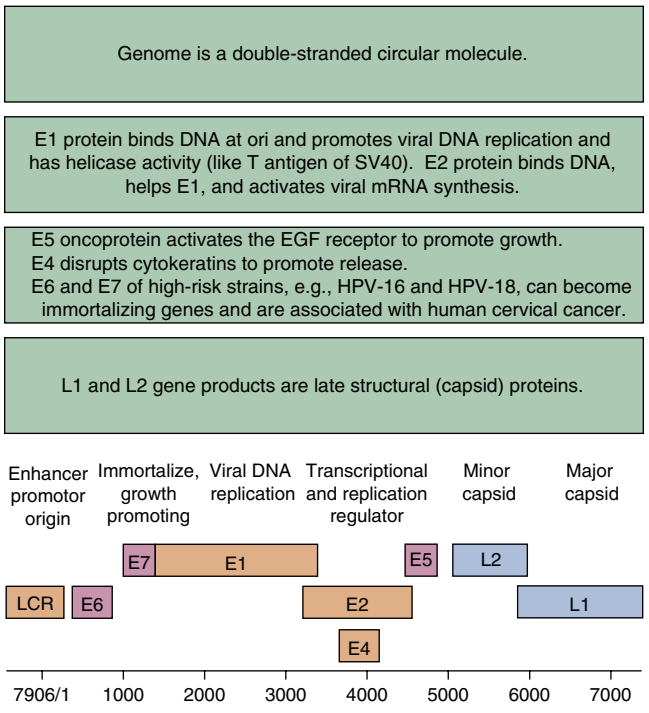

Fig. 41.2 Genome of human papillomavirus type 16 *(HPV-16).* Genomic DNA is normally a double-stranded circular molecule, but it is shown here in a linear form. *E5,* Oncogene protein that enhances cell growth by stabilizing and activating the epidermal growth factor receptor; *E6,* oncogene protein that binds p53 and promotes its degradation; *E7*, oncogene protein that binds p105RB (p105 retinoblastoma gene product); *EGF,* epidermal growth factor; *L1,* major capsid protein; *L2,* minor capsid protein; *LCR* (URR), long control region (upstream regulatory region); *ori,* origin of replication. (Courtesy Tom Broker, Baltimore.)

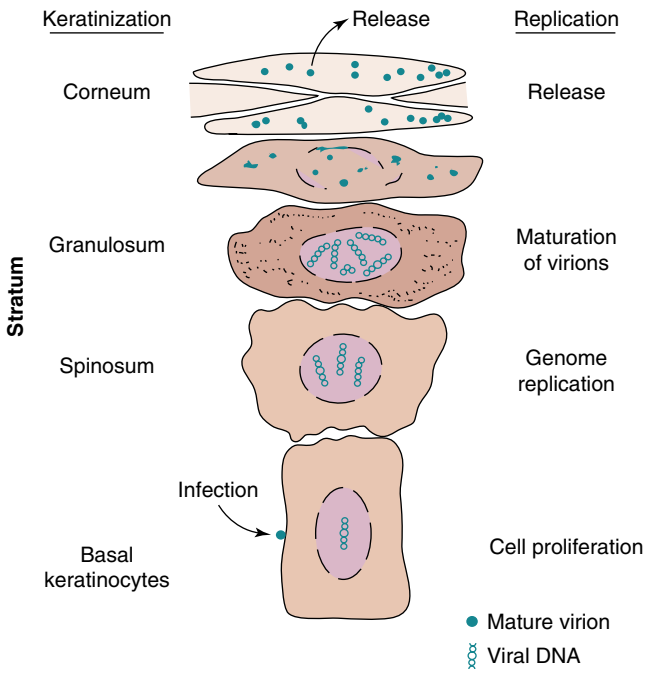

Fig. 41.3 Development of a papilloma (wart). Human papillomavirus infection promotes the outgrowth of the basal layer, increasing the number of prickle cells of the stratum spinosum (acanthosis). These changes cause the skin to thicken and promote the production of keratin (hyperkeratosis), causing epithelial spikes to form (papillomatosis). Virus is produced in the granular cells close to the final keratin layer.

"near-dead" terminally differentiated skin cell), the keratinocyte is an immunologically privileged site for replication. Inflammatory responses are required to activate protective cytolytic responses and promote resolution of warts. Immunosuppressed persons have recurrences and more severe presentations of papillomavirus infections. Antibody to the L1 protein neutralizes the virus. IgG produced by vaccination is secreted into the vagina and elsewhere and can protect against infection.

High-risk HPV types (e.g., HPV-16, HPV-18; Table 41.2) can initiate the development of cervical carcinoma and oropharyngeal, esophageal, penile, and anal cancers. Viral DNA is found in benign and malignant tumors, especially mucosal papillomas. **Almost all cervical carcinomas contain integrated HPV DNA, with 70% from HPV-16 or HPV-18.** Breaking of the circular genome within the *E1* or *E2* genes to promote integration causes these genes to be inactivated, preventing viral replication without preventing expression of other HPV genes, including the *E5*, *E6*, and *E7* genes (Fig. 41.5). The E5, E6, and E7 proteins of HPV-16 and HPV-18 have been identified as **oncogenes.** The E5

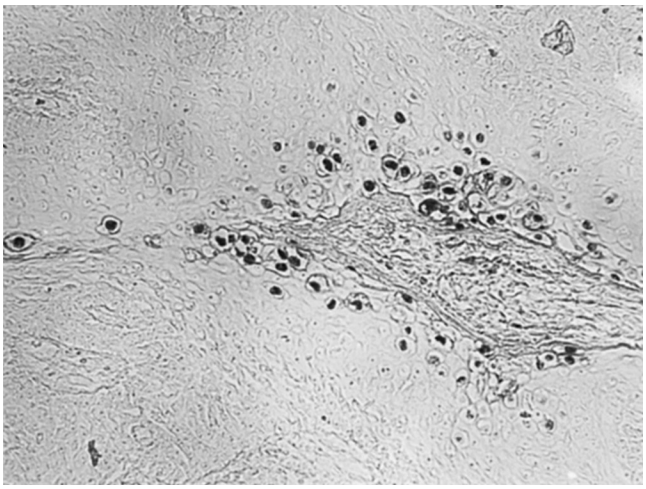

Fig. 41.4 DNA probe analysis of a human papillomavirus 6–induced anogenital condyloma. A biotin-labeled DNA probe was localized by horseradish peroxidase–conjugated avidin conversion of a substrate to a chromogen precipitate. Dark staining is seen over the nuclei of koilocytotic cells. (From Belshe, R.B., 1991. Textbook of Human Virology, second ed. Mosby, St Louis, MO.)

protein enhances cell growth by stabilizing the epidermal growth factor receptor to make the cell more sensitive to growth signals, whereas the E6 and E7 proteins bind and prevent function of the cellular growth-suppressor (transformation-suppressor) proteins, p53, and the *p105* retinoblastoma gene product (RB). E6 binds the p53 protein and targets it for degradation, and E7 binds and inactivates p105. Enhanced cell growth and inactivation of p53 makes the cell more susceptible to mutation, chromosomal aberrations, or the action of a cofactor and promotes the development of cancer.

BOX 41.2 Disease Mechanisms of Papillomaviruses and Polyomaviruses

Papillomaviruses

Virus is acquired by **close contact** and infects the epithelial cells of the skin or mucous membranes.
Tissue tropism and disease presentation depend on the papillomavirus type.
Virus persists in the basal layer and then produces virus in terminally differentiated keratinocytes.
Viruses cause benign outgrowth of cells into **warts.**
HPV infection is hidden from immune responses and persists.
Warts resolve spontaneously as a result of immune response.
Certain types are associated with **dysplasia** that may become **cancerous** with the action of cofactors.
DNA of specific HPV types is present (integrated) in the tumor cell chromosomes.

Polyomaviruses (JCV and BKV)

Virus is acquired through the respiratory or oral route, infects tonsils and lymphocytes, and spreads by viremia to the kidneys early in life.
Virus is ubiquitous, and infections are **asymptomatic.**
Virus establishes **persistent** and **latent** infection in organs such as the kidneys and lungs.
In **immunocompromised** people, JCV is activated, spreads to the brain, and causes **PML,** which is a conventional slow virus disease.
In PML, JCV partially transforms astrocytes and kills oligodendrocytes, causing characteristic lesions and sites of demyelination.
PML lesions are demyelinated, with unusual large astrocytes and oligodendroglial cells with very large nuclei.
BKV is benign but may cause kidney disease in immunocompromised patients.

BKV, BK virus; *HPV,* human papillomavirus; *JCV,* JC virus; *PML,* progressive multifocal leukoencephalopathy.

EPIDEMIOLOGY

HPV resists inactivation and can be transmitted on fomites such as the surfaces of countertops or furniture, bathroom floors, and towels (Box 41.3). Asymptomatic shedding may promote transmission. HPV infection is acquired (1) by direct contact through small breaks in the skin or mucosa, (2) during sexual intercourse, or (3) while an infant is passing through an infected birth canal.

Common, plantar, and flat warts are most common in children and young adults. Laryngeal papillomas occur in young children and middle-aged adults.

HPV only infects humans. It is possibly the most prevalent sexually transmitted infection in the world, with certain HPV types common among sexually active men and women. At least 79 million people in the United States are infected with HPV, with approximately14 million new anogenital cases per year.

High-risk HPV types, including HPV-16 and HPV-18, are present in oropharyngeal, penile, cervical, vaginal, and anal cancers. According to the Centers for Disease Control and Prevention, oropharyngeal squamous cell carcinoma is now the most common HPV-associated cancer.

HPV is present in 99.7% of all cervical cancers, with HPV-16 and HPV-18 in 70% of them. Other high-risk genotypes are more prevalent in different socioethnic groups. Types 33, 35, 58, and 68 are common high-risk HPV types for African American women. Other high-risk strains are listed in Table 41.2. Cervical cancer is the second leading cause of cancer death in women (≈14,000 cases and 4000 deaths per year in the United States).

Approximately 5% of all Pap smears contain HPV-infected cells, and 10% of women infected with the high-risk HPV types will develop cervical **dysplasia,** which is a precancerous state. Multiple sexual partners, smoking, a family history of cervical cancer, and immunosuppression are the major risk factors for infection and progression to cancer.

HPV-6 and HPV-11 are low-risk HPV types for cervical carcinoma but cause condyloma acuminatum and oral and laryngeal papillomas.

CLINICAL SYNDROMES

The clinical syndromes and the HPV types that cause them are summarized in Table 41.2.

Warts

A **wart** is a benign self-limited proliferation of skin that regresses with time. Most people with HPV infection have the common types of the virus (HPV-1 through HPV-4), which infect keratinized surfaces, usually on the hands and feet (Fig. 41.6). Initial infection occurs in childhood or early

TABLE 41.2 Clinical Syndromes Associated with Papillomaviruses

Syndrome	HUMAN PAPILLOMAVIRUS TYPES: Common	Less Common
CUTANEOUS SYNDROMES		
Skin Warts		
Plantar wart	1	2, 4
Common wart	2, 4	1, 7, 26, 29
Flat wart	3, 10	27, 28, 41
Epidermodysplasia verruciformis	5, 8, 17, 20, 36	9, 12, 14, 15, 19, 21-25, 38, 46
MUCOSAL SYNDROMES		
Benign Head and Neck Tumors		
Laryngeal papilloma	6, 11	—
Oral papilloma	6, 11	2, 16
Conjunctival papilloma	11	—
Anogenital Warts		
Condyloma acuminatum	6, 11	1, 2, 10, 16, 30, 44, 45
Cervical intraepithelial neoplasia, cancer (high-risk types)	16, 18	31, 33, 35, 39, 45, 51, 52, 56, 58, 59, 66, 68, 69, 73, 82

Modified from Balows, A., Hausler Jr., W.J., Lennette, E.H. (Eds.), 1988. Laboratory Diagnosis of Infectious Diseases: Principles and Practice, vol 2. Springer-Verlag, New York, NY. Data from Centers for Disease Control and Prevention, 2001. Epidemiology and Prevention of Vaccine-Preventable Diseases, 12th ed. Public Health Foundation, Washington, DC.

BOX 41.3 Epidemiology of Polyomaviruses and Papillomaviruses

Disease/Viral Factors

Capsid virus is resistant to inactivation.
Virus persists in host.
Asymptomatic shedding is likely.

Transmission

Papillomavirus: **direct contact, sexual contact** (sexually transmitted disease) for certain virus types, or passage through infected birth canal for laryngeal papillomas (types 6 and 11)
Polyomavirus: inhalation or contact with contaminated water, stool, urine, or saliva

Who Is at Risk?

Papillomavirus: warts are common; sexually active people at risk for infection with human papillomavirus types correlated with oral and genital cancers
Polyomavirus: ubiquitous; immunocompromised people at risk for progressive multifocal leukoencephalopathy

Geography/Season

Viruses are found worldwide.
There is no seasonal incidence.

Modes of Control

Vaccine for HPV types 6, 11, 16, 18, 31, 33, 45, 52, 58

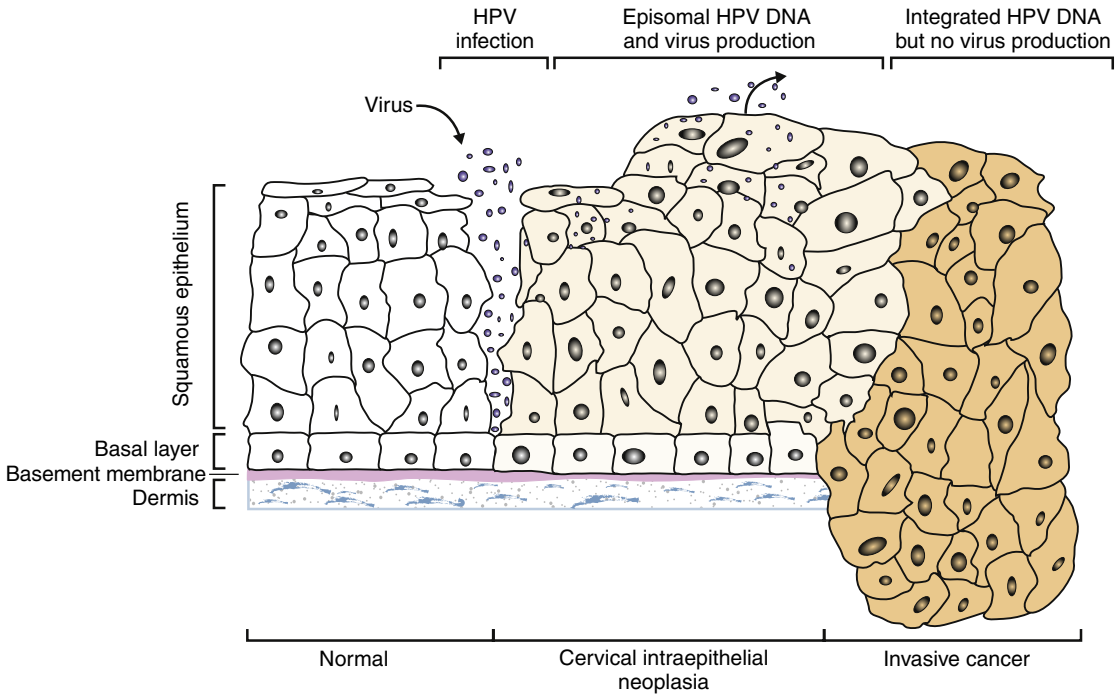

Fig. 41.5 Progression of human papillomavirus *(HPV)*–mediated cervical carcinoma. HPV infects and replicates in the epithelial cells of the cervix, maturing and releasing virus as the epithelial cells progress through terminal differentiation. Growth stimulation of the basal cells produces a wart. In some cells, the circular genome integrates into host chromosomes, inactivating the *E2* gene, which is necessary for replication. Expression of the other genes without virus production stimulates growth of the cells and possible progression to neoplasia. (Adapted from Woodman, C.B.J., Collins, S.I., Young, L.S., 2007. The natural history of cervical HPV infection: unresolved issues. Nat. Rev. Cancer 7, 11–22.)

Fig. 41.6 Common warts. (From Habif, T.P., 1985. Clinical Dermatology: A Color Guide to Diagnosis and Therapy. Mosby, St Louis, MO.)

adolescence. The incubation period before a wart develops may be as long as 3 to 4 months. The appearance of the wart (dome shaped, flat, or plantar) depends on the HPV type and the infected site.

Head and Neck Papillomas and Tumors

Single oral papillomas are the most benign epithelial tumors of the oral cavity. They are pedunculated with a fibrovascular stalk, and their surface usually has a rough, papillary appearance. They can occur in people of any age group, are usually solitary, and rarely recur after surgical excision. **Laryngeal papillomas** are commonly associated with HPV-6 and HPV-11 and are the most common benign epithelial tumors of the larynx. Infection of children probably occurs at birth and can be life-threatening if the papillomas obstruct the airway. Occasionally, papillomas may be found farther down in the trachea and into the bronchi. As many as 80% of **oropharyngeal carcinomas** contain high-risk HPV DNA.

Anogenital Warts

Anogenital warts **(condylomata acuminata)** occur almost exclusively on the squamous epithelium of the external genitalia and perianal areas and are common for promiscuous individuals. Approximately 90% are caused by HPV-6 and HPV-11. Anogenital lesions infected with these types of HPV can be problematic but rarely become malignant in otherwise healthy people. Anal and penile warts can progress to cancer if caused by high-risk oncogenic strains of HPV.

Cervical Dysplasia and Neoplasia

HPV infection of the genital tract is a very common sexually transmitted disease. Infection is usually asymptomatic but may result in slight itching. Genital warts may

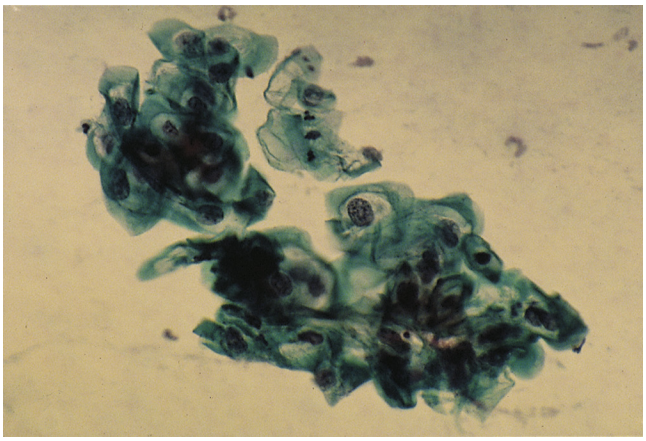

Fig. 41.7 Papanicolaou stain of exfoliated cervicovaginal squamous epithelial cells, showing the perinuclear cytoplasmic vacuolization termed *koilocytosis* (vacuolated cytoplasm), which is characteristic of human papillomavirus infection (400× magnification).

appear as soft, flesh-colored warts that are flat, raised, and sometimes cauliflower shaped. The warts can appear within weeks or months of sexual contact with an infected person. Cytologic changes indicating HPV infection **(koilocytotic cells)** are detected in **Papanicolaou-stained cervical smears** (Pap smears) (Fig. 41.7). Infection of the female genital tract by high-risk HPV types is associated with intraepithelial cervical neoplasia and cancer. The first neoplastic changes are termed **dysplasia.** Approximately 40% to 70% of the mild dysplasias spontaneously regress.

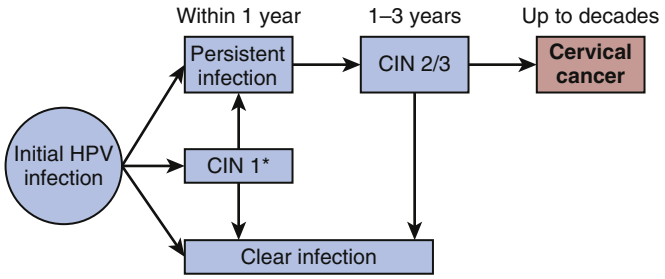
Cervical cancer is thought to develop through a continuum of progressive cellular changes from mild (CIN 1) to moderate neoplasia (CIN 2) to severe neoplasia or carcinoma in situ (Fig. 41.8; see Fig. 41.5). This sequence of events can occur over 1 to 4 years. Routine and regular Pap smears can promote early detection, treatment, and cure of cervical cancer.

LABORATORY DIAGNOSIS

A wart can be confirmed microscopically on the basis of its characteristic histologic appearance, which consists of hyperplasia of the **prickle cells** and an excess production of keratin **(hyperkeratosis)**. Papillomavirus infection can be detected in Pap smears by the presence of koilocytotic (vacuolated cytoplasm) squamous epithelial cells, which are rounded and occur in clumps (Fig. 41.4; and Fig. 41.7). **DNA molecular probe, PCR, and real-time PCR** analysis of cervical swabs and tissue specimens are the methods of choice for establishing the diagnosis and typing of the HPV infection. Papillomaviruses do not grow in cell cultures, and tests for HPV antibodies are rarely used except in research studies.

TREATMENT, PREVENTION, AND CONTROL

Warts spontaneously regress, but the regression may take many months to years. Warts are removed because of pain and discomfort, for cosmetic reasons, and to prevent spread to other parts of the body or to other people. They are removed through the use of surgical cryotherapy,



*CIN: cervical intraepithelial neoplasia

Fig. 41.8 Progression of high-risk HPV infection to cervical carcinoma. Most HPV infections resolve spontaneously, but the virus can establish a persistent infection that can progress to low-grade cervical intraepithelial neoplasia (CIN 1). This may resolve or progress directly to a higher grade CIN (CIN2 or CIN3) and if untreated progress to cervical cancer. (Adapted from https://www.cdc.gov/vaccines/pubs/pinkbook/hpv.html.)

TABLE 41.3 Laboratory Diagnosis of Papillomavirus Infections

Test	Detects
Cytology	Koilocytotic cells

PCR, Polymerase chain reaction.

electrocautery, or chemical means (e.g., 10% to 25% solution of podophyllin), although recurrences are common. Surgery may be necessary for the removal of laryngeal papillomas.

Stimulators of innate and inflammatory responses, such as **imiquimod** (Aldara), **interferon,** and even stripping off duct tape, can promote more rapid healing. Topical or intralesional delivery of **cidofovir** can treat warts by selectively killing the HPV-infected cells. Cidofovir induces apoptosis by inhibiting the host cell DNA polymerase.

Immunization with a nine-valent (Gardasil 9: 6, 11, 16, 18, 31, 33, 45, 52, and 58) HPV vaccine is recommended for girls and boys starting at age 11 years (before sexual activity) to prevent cervical cancer and penile and anogenital warts. A bivalent (Cervarix) and a tetravalent vaccine (Gardasil) are no longer offered in the United States. In 2018 the U.S. Food and Drug Administration approved immunization of adults aged 27 to 45. These vaccines consist of the L1 major capsid protein assembled into virus-like particles. Vaccinated women are not protected against all possible high-risk HPV strains. The HPV vaccine **is not a replacement for a Pap smear,** and women should continue to be tested. At present, the best way to prevent transmission of warts is to avoid coming in direct contact with infected tissue. Proper precautions (e.g., use of condoms) can prevent sexual transmission of HPV.

Polyomaviridae

The human polyomaviruses, **BKV** and **JCV,** are ubiquitous but usually do not cause disease. Less prevalent human polyomaviruses include the KI, WU, and Merkel cell polyomaviruses (MCVs). The human viruses are difficult to grow in cell culture. SV40 (a simian polyomavirus) and murine polyomaviruses, in particular, have been studied extensively as models of tumor-causing viruses, but only recently has a polyomavirus been associated with human cancers.

STRUCTURE AND REPLICATION

The polyomaviruses are smaller (45 nm in diameter), contain less nucleic acid (5000 base pairs), and are less complex than the papillomaviruses (see Box 41.1). The genomes of BKV, JCV, and SV40 are closely related and are divided into early, late, and noncoding regions (Fig. 41.9). The early region on one strand codes for nonstructural **T (transformation) proteins** (including **large T, T′, and small t antigens**), and the late region, which is on the other strand, codes for **three viral capsid proteins (VP1, VP2,** and **VP3)** (Box 41.4). The noncoding region contains the origin of DNA replication and transcriptional control sequences for both early and late genes.

For JCV infection of glial cells, the virus binds to sialylated carbohydrates and serotonin receptors and then enters the cell by endocytosis. The DNA genome is uncoated and delivered to the nucleus. The early genes encode the large T and small t antigens, which are proteins that promote cell growth. Viral replication requires the transcriptional and DNA replication machinery provided by a growing cell. The large T antigens of SV40, BKV, and JCV have several functions. For example, the T antigen of SV40 binds to DNA and controls early and late gene transcription, as well as viral DNA replication. In addition, the T antigen binds to and inactivates the two major cellular growth-suppressor proteins, p53 and p105RB, promoting cell growth.

Similar to replication of the HPVs, replication of polyomavirus is highly dependent on host cell factors. Permissive cells allow the transcription of late viral messenger ribonucleic acid (mRNA) and viral replication, which results in cell death. Immune factors can promote a block in replication causing the virus to establish latency in these nonpermissive cells. Some animal cells allow only the early genes, including the T antigen, to be expressed, promoting cell growth and potentially leading to oncogenic transformation of the cell.

The polyomavirus genome is used very efficiently. The noncoding region of the genome contains the initiation sites for the early and late mRNAs and the origin of DNA replication. The three late proteins are produced from mRNAs, which have the same initiation site and then are processed into three unique mRNAs.

The circular viral DNA is maintained and replicated bidirectionally, similar to the way a bacterial plasmid is maintained and replicated. DNA replication precedes late mRNA transcription and protein synthesis. The virus is assembled in the nucleus and is released by cell lysis.

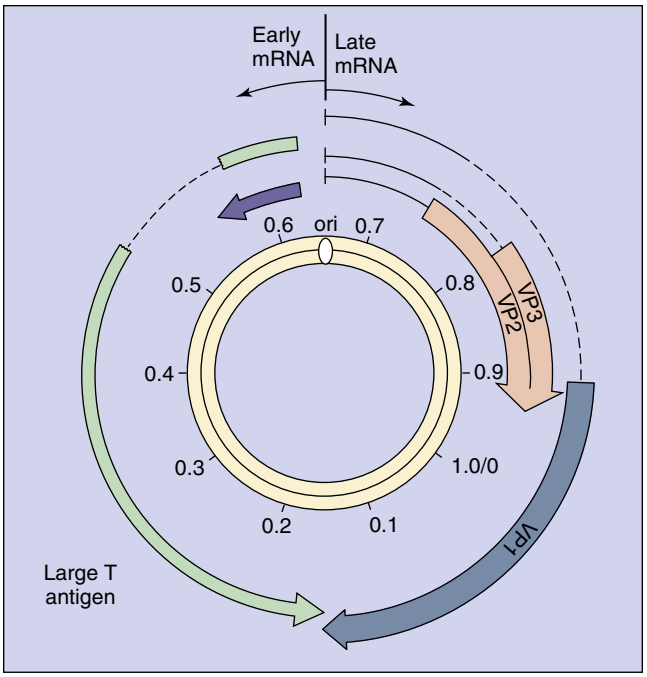

Fig. 41.9 Genome of the SV40 virus. The genome is a prototype of other polyomaviruses and contains early, late, and noncoding regions. The noncoding region contains the start sequence for the early and late genes and for DNA replication *(ori)*. The individual early and late mRNAs are processed from the larger nested transcripts. (Modified from Butel, J.S., Jarvis, D.L., 1986. The plasma-membrane-associated form of SV40 large tumor antigen: biochemical and biological properties. Biochim. Biophys. Acta 865, 171–195.)

BOX 41.4 Polyomavirus Proteins

Early

Large T: regulation of early and late messenger RNA transcription; DNA replication; cell growth promotion and transformation
Small t: viral DNA replication

Late

VP1: major capsid protein and viral attachment protein
VP2: minor capsid protein
VP3: minor capsid protein

PATHOGENESIS

Each polyomavirus is limited to specific hosts and cell types within that host. For example, JCV and BKV are human viruses that probably enter the respiratory tract or tonsils, after which they infect lymphocytes and then the kidney with a minimal cytopathologic effect. BKV establishes latent infection in the kidney, and JCV establishes infection in the kidneys, B cells, monocyte-lineage cells, and other cells. Replication is blocked in immunocompetent persons.

In T-cell–deficient patients, such as those with the acquired immunodeficiency syndrome (AIDS), reactivation of the virus in the kidney leads to viral shedding in the urine and potentially severe urinary tract infections (BKV) or viremia and central nervous system infection (JCV) (Fig. 41.10). JCV crosses the blood-brain barrier by replicating in the endothelial cells of capillaries. An abortive infection

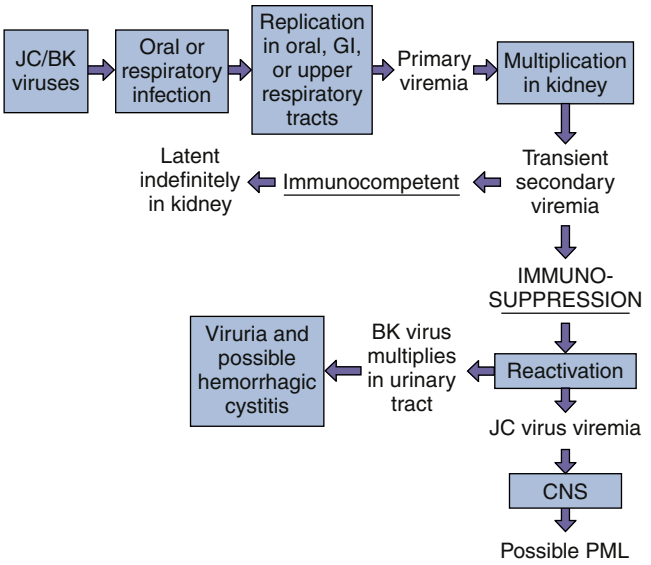

Fig. 41.10 Mechanisms of spread of polyomaviruses within the body. *CNS*, Central nervous system; *GI*, gastrointestinal; *PML*, progressive multifocal leukoencephalopathy.

of astrocytes results in partial transformation, yielding enlarged cells with abnormal nuclei resembling glioblastomas. Productive lytic infections of oligodendrocytes cause demyelination. Although SV40, BKV, and JCV can cause tumors in hamsters, these viruses are not associated with any human tumors. Integration and a mutation of the T antigen that prevents replication of the MCV allow this virus to convert the cell into a tumor.

EPIDEMIOLOGY

Polyomavirus infections are ubiquitous, and most people are infected with both JCV and BKV by the age of 15 years (see Box 41.3). The viruses are spread in urine, in feces, and potentially in aerosols. Latent infections can be reactivated in people whose immune systems are suppressed because of AIDS, organ transplantation, or pregnancy. Approximately 10% of people with AIDS develop PML, and the disease is fatal in approximately 90% of all cases. The incidence has decreased with the success of the highly active antiretroviral therapy (HAART).

Early batches of live attenuated polio vaccine were contaminated with SV40 that was undetected in the primary monkey cell cultures used to prepare the vaccine. Although many people were vaccinated with the contaminated vaccines, no SV40-related tumors have been reported.

CLINICAL SYNDROMES

Primary infection is almost always asymptomatic (Box 41.5). BKV and JCV can be activated in immunocompromised patients, as indicated by the presence of virus in the urine of as many as 40% of these patients. The viruses are also reactivated during pregnancy, but no effects on the fetus have been noted. During pregnancy, cell-mediated immunity, including those activities that restrict the replication of polyomaviruses, are suppressed so that the fetus (a tissue graft) is not rejected.

BOX 41.5 Clinical Summaries

Wart: A 22-year-old patient develops a conical, flesh-colored, hard, scaly round area (papule) over the index finger. It has a rough surface and is nontender. Otherwise, the patient is healthy and has no other complaints. The wart is treated topically on a daily basis with salicylic acid to kill the cells harboring the virus and remove the wart.

Cervical papilloma: On cervical examination, a large, flat papule was observed, which turned white with application of 4% acetic acid. The Pap smear from this 25-year-old sexually active woman had koilocytotic cells.

Cervical carcinoma: A 32-year-old woman comes in for her routine Pap smear, which shows evidence of abnormal cells. A biopsy shows squamous cell carcinoma. PCR analysis of cellular DNA yields HPV-16 DNA.

PML: A 42-year-old AIDS patient has become forgetful and has difficulty speaking, seeing, and keeping his balance, which is suggestive of lesions in many sites in the brain. The condition progresses to paralysis and death. Autopsy shows foci of demyelination, with oligodendrocytes containing inclusion bodies only in the white matter.

A 37-year-old woman with multiple sclerosis was treated with natalizumab and interferon-β and developed PML.

HPV, Human papillomavirus; *Pap,* Papanicolaou; *PCR,* polymerase chain reaction; *PML,* progressive multifocal leukoencephalopathy.

The ureteral stenosis observed in renal transplant recipients appears to be associated with BKV, as is the hemorrhagic cystitis observed in bone marrow transplant recipients. **PML** caused by **JCV** is a subacute demyelinating disease that occurs in immunocompromised patients, including those with AIDS (Clinical Case 41.1). Immunotherapy that inhibits the α4-integrin adhesion protein (natalizumab) also increases risk for PML. Although rare, the incidence of PML has increased because of the increased numbers of people with AIDS and immunosuppressive therapy. As the name implies, patients may have multiple neurologic symptoms unattributable to a single anatomic lesion. Speech, vision, coordination, mentation, or a combination of these functions is impaired, followed by paralysis of the arms and legs and finally death. People who are diagnosed with PML live 1 to 4 months, and most die within 2 years.

The genome of a new polyomavirus, MCV (or MCPyV), was recently discovered integrated into the chromatin of Merkel cell carcinomas, which is a highly aggressive type of skin cancer. This is the first example of a polyomavirus associated with a human cancer.

Clinical Case 41.1 Progressive Multifocal Leukoencephalopathy (PML)

Liptai and associates (*Neuropediatrics* 38:32–35, 2007) described a case in which a 15½-year-old human immunodeficiency virus (HIV)–infected boy presented with fatigue and depression. Symptoms included dizziness, double vision, and loss of motor coordination, as indicated in his handwriting, computer usage, and unsteady gait. He had acquired HIV as an infant by injection with an unclean syringe needle in a Transylvanian hospital. Over the years, his CD4 T-cell count slowly decreased, and his HIV genome load increased, most likely because of poor compliance with his anti-HIV therapy and a refusal of highly active antiretroviral therapy. A 30-mm nonenhancing lesion of the right cerebellar hemisphere was seen by magnetic resonance imaging. PML was diagnosed, based on detection of JC virus sequences in cerebrospinal fluid by polymerase chain reaction. Within 10 days, the boy lost the ability to walk and developed facial and hypoglossal palsies, with further neurologic deterioration, including severe depression and loss of ability to communicate. He died 4 months after the onset of symptoms. Microscopic analysis of the cerebellum and brainstem indicated broad areas of demyelination and necrosis, astrocytosis, and oligodendrocytes with nuclear inclusion bodies. Although JC virus infection is ubiquitous and normally benign, it only causes PML in immunocompromised individuals. Previously rare, PML has become more prevalent because of increased numbers of immunocompromised individuals including acquired immunodeficiency syndrome patients who are not on or are not compliant with anti-HIV therapy or for whom anti-HIV therapy is ineffective.

PML, Progressive multifocal leukoencephalopathy.

LABORATORY DIAGNOSIS

The diagnosis of PML is confirmed by the presence of PCR-amplified viral DNA in cerebrospinal fluid and magnetic resonance imaging or computed tomographic evidence of lesions. Histologic examination of brain tissue obtained by biopsy or at autopsy will show foci of demyelination surrounded by oligodendrocytes with inclusions adjacent to areas of demyelination. The term *leukoencephalopathy* refers to the presence of lesions in only the white matter. There is little if any inflammatory cell response. In situ immunofluorescence; immunoperoxidase; DNA probe analysis; and PCR analysis of cerebrospinal fluid, urine, or biopsy material for the particular genetic sequences can also be used to detect virus. Urine cytologic tests can reveal the presence of JCV or BKV infection by revealing the existence of enlarged cells with dense basophilic intranuclear inclusions resembling those induced by cytomegalovirus. It is difficult to isolate BKV and JCV in tissue cultures; therefore this procedure is not attempted.

TREATMENT, PREVENTION, AND CONTROL

Decreasing the immunosuppression responsible for allowing the polyomavirus to be reactivated is the best treatment for JC and BK viruses. Cidofovir may also be helpful. The ubiquitous nature of polyomaviruses and the lack of understanding of their modes of transmission make it unlikely that the primary infection can be prevented.

Case Study and Questions

A 25-year-old carpenter notices the appearance of several hyperkeratotic papules (warts) on the palm side of his index finger. They do not change in size and cause him only minimal discomfort. After a year, they spontaneously disappear.

1. Will this virus infection spread to other body sites?

2. After its disappearance, is the infection likely to be completely resolved or to persist in the host?

3. What viral, cellular, and host conditions regulate the replication of this virus and other HPVs?

4. How would the papillomavirus type causing this infection be identified?

5. Is it likely that this type of HPV is associated with human cancer? If not, which types are associated with cancers, and which cancers are they?

42 Adenoviruses

A 19-year-old army recruit complained that he had a high fever, chills, cough, runny nose, and sore throat. Several other members of his unit complained of similar symptoms.

1. How is adenovirus transmitted?
2. Which adenovirus types are most likely to cause acute respiratory distress syndrome?
3. What other diseases can adenoviruses cause?
4. What type of immune response would protect against infection?
5. Why did the military develop an attenuated vaccine for adenovirus strains 4 and 7?

Answers to these questions are available on Student Consult.com.

Summaries Clinically Significant Organisms

ADENOVIRUSES

Trigger Words

Pharyngitis, conjunctivitis, atypical pneumonia, icosadeltahedral capsid

Biology, Virulence, and Disease

- Medium-sized icosadeltahedral capsid with fibers, linear DNA genome with terminal proteins
- E1A and E1B proteins inactivate E6 and E7 to promote growth
- Virus encodes polymerase
- Capsid virus resistant to inactivation
- Lytic virus
- Causes pharyngitis, conjunctivitis, atypical pneumonia, infantile gastroenteritis, acute respiratory disease
- Can be used as vector for making vaccines and gene therapy

Epidemiology

- Transmitted by aerosols, direct contact, fecal-oral, contaminated swimming pools

Diagnosis

- Immunological assays and PCR genome analysis

Treatment, Prevention, and Control

- Adenovirus types 4 and 7 vaccine only for military

Adenoviruses were first isolated in 1953 in a human adenoid cell culture. Since then, approximately 100 serotypes have been recognized, at least 52 of which infect humans. All human serotypes are included in a single genus within the family Adenoviridae. There are seven subgroups for human adenoviruses (A through G) (Table 42.1). The viruses in each subgroup share many properties.

The human adenoviruses numbered 1 to 7 are the most common. Common disorders caused by the adenoviruses include **respiratory tract infection, pharyngoconjunctivitis (pinkeye), hemorrhagic cystitis,** and **gastroenteritis.** Immunocompromised individuals are at risk for more serious presentations. Several adenoviruses have oncogenic potential in animals but not humans, and for this reason they have been extensively studied by molecular biologists. These studies have elucidated many viral and eukaryotic cellular processes. For example, analysis of the gene for the adenovirus hexon protein led to the discovery of introns and the splicing of eukaryotic messenger ribonucleic acid (mRNA). Adenovirus is also being used in genetic therapies to deliver deoxyribonucleic acid (DNA) for gene replacement and modification therapy (e.g., cystic fibrosis) to express genes for other viruses (e.g., human immunodeficiency virus [HIV]) as a vaccine, and as oncolytic therapy.

Structure and Replication

Adenoviruses are double-stranded DNA viruses with a genome of approximately 36,000 base pairs, which is large enough to encode 30 to 40 genes. The adenovirus genome is a **linear double-stranded DNA** with a **terminal protein** (molecular mass, 55 kDa) covalently attached at each 5′ end. The virions have a unique structure. The **nonenveloped icosadeltahedral capsid** comprises 240 capsomeres that consist of hexons and pentons and has a diameter of 70 to 90 nm (Fig. 42.1 and Box 42.1). The 12 pentons, which are located at each of the vertices, have a penton base and a fiber. The **fiber** contains the **viral attachment proteins.** The penton base and fiber are toxic to cells. The pentons and fibers also carry type-specific antigens.

The core complex within the capsid includes viral DNA and at least two major proteins. There are at least 11 proteins in the adenovirus virion, 9 of which have an identified structural function (Table 42.2).

The virus replication cycle takes approximately 32 to 36 hours and produces approximately 10,000 virions. Attachment of the viral fiber proteins to a glycoprotein member of the immunoglobulin superfamily of proteins (≈100,000 fiber receptors are present on each cell) initiates infection for most adenoviruses. This same receptor is used by many coxsackievirus B viruses; thus it is given the name **coxsackie adenovirus receptor.** Some adenoviruses use the class I major histocompatibility complex (MHC I) molecule as a receptor. Internalization is initiated by the interaction of the penton base with an α_v integrin followed by receptor-mediated endocytosis in a clathrin-coated vesicle. The virus lyses the endosomal vesicle, and the capsid delivers the DNA genome to the nucleus. The penton and fiber proteins of the capsid are toxic to the cell and can inhibit cellular macromolecular synthesis.

Table 42.1 Illnesses Associated with Adenoviruses

Disease	Types	Patient Population
RESPIRATORY DISEASES		
Febrile, undifferentiated upper respiratory tract infection	1, 3, 5, 7, 14, 21, etc.	Infants, young children
Pharyngitis and pharyngoconjunctival fever	1, 2, 3, 4, 5, 6, 7, 14	Children, adults
Acute respiratory disease	1, 2, 3, 4, 5, 6, 7, 14, 21	Infants, young children, military recruits
Pertussis-like syndrome	1, 2, 3, 4, 7, 14, 21, 30	Infants, young children
Pneumonia		Infants, young children, military recruits, immunocompromised patients
OTHER DISEASES		
Acute hemorrhagic cystitis/nephritis	11, 21	Children, immunocompromised patients
Epidemic keratoconjunctivitis	8, 9, 11, 19, 35, 37	Any age
Gastroenteritis	31, 40, 41, 52	Infants, young children, immunocompromised patients
Hemorrhagic cystitis	11, 21, 34, 35	Infants, young children
Hepatitis	1, 2, 5, 7, 31	Immunocompromised patients
Meningoencephalitis	7	Children, immunocompromised patients
Myocarditis	7, 21	Children
Obesity/adipogenesis	31	Any age

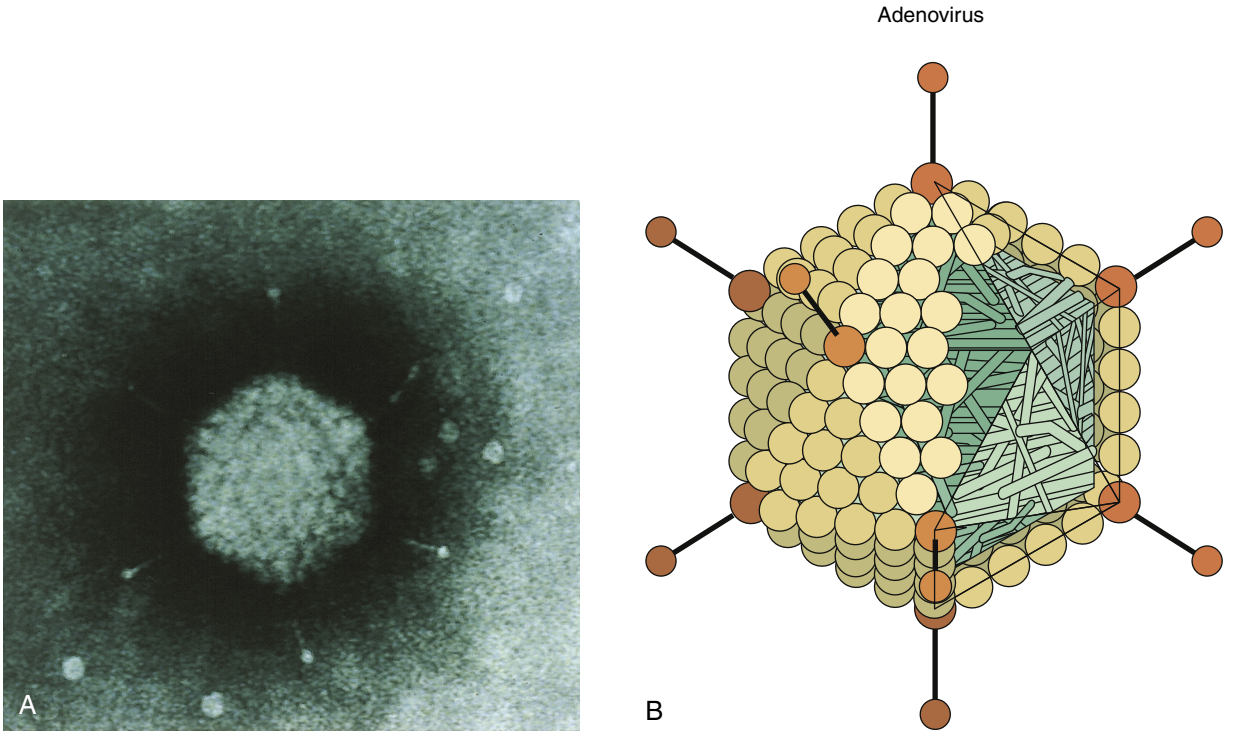

Fig. 42.1 (A) Electron micrograph of adenovirus virion with fibers. (B) Model of adenovirus virion with fibers. (A, From Valentine, R.C., Pereira, H.G., 1965. Antigens and structure of the adenovirus. J. Mol. Biol. 13, 13–20. B, From Cohen, J., Powderly, W.G., Opal, S.M., 2010. Infectious Diseases, third ed. Mosby, Philadelphia, PA.)

A map of the adenovirus genome shows the locations of the viral genes (Fig. 42.2). The genes are transcribed from both DNA strands and in both directions at different times during the replication cycle. Genes for related functions are clustered together. Most of the RNA transcribed from the adenovirus genome is processed into several individual mRNAs in the nucleus. Adenovirus encodes its own DNA polymerase and proteins that promote cell growth and suppress apoptosis and host immune and inflammatory responses.

Transcription of mRNA occurs in two phases. Early proteins promote cell growth and include a DNA polymerase that is involved in the replication of the genome. As for the papovaviruses, several adenovirus mRNAs are transcribed

BOX 42.1 Unique Features of Adenovirus

Naked icosadeltahedral capsid has **fibers** (viral attachment proteins) at vertices.
Linear double-stranded genome has 5′ terminal proteins.
Synthesis of viral DNA polymerase activates a switch from early to late genes.
Virus encodes its own **DNA polymerase** and other proteins to facilitate growth and immune escape.
Human adenoviruses are grouped A through G by DNA homologies and by serotype (>55 human types).
Serotype is mainly a result of differences in the penton base and fiber protein, which determine the nature of tissue tropism and disease.
Virus causes **lytic, persistent,** and **latent** infections in humans, and some strains can **immortalize certain animal cells.**

Table 42.2 Major Adenovirus Proteins

Gene	Number	Molecular Mass (kDa)	Functions of Proteins
E1A[a]	—	—	Activates viral gene transcription Binds cellular growth suppressor (p105RB) to promote cell growth and transformation Deregulates cell growth Inhibits activation of interferon response elements
E1B	—	—	Binds cellular growth suppressor (p53) to promote cell growth and transformation Blocks apoptosis
E2	—	—	Activates some promoters Terminal protein on DNA DNA polymerase
E3	—	—	Prevents TNF-α action; MHC I expression
E4	—	—	Limits viral cytopathologic effect
VA RNAs	—	—	Inhibits interferon response
Capsid	II	120	Contains family antigen and some serotyping antigens
	III	85	Penton base protein Toxic to tissue culture cells
	IV	62	Fiber Responsible for attachment; contains some serotyping antigens
	VI	24	Hexon-associated proteins
	VIII	13	Penton-associated proteins
	IX	12	"Capsid cement" nonessential
	IIIa	66	"Facilitates assembly"
Core	V	48	Core protein 1: DNA-binding protein
	VII	18	Core protein 2: DNA-binding protein

[a]Early genes encode several messenger RNAs and proteins by alternative splicing patterns.
E, Early; *MHC I,* major histocompatibility complex I; *RB,* retinoblastoma gene product; *TNF-α,* tumor necrosis factor-α; *VA,* virus-associated.

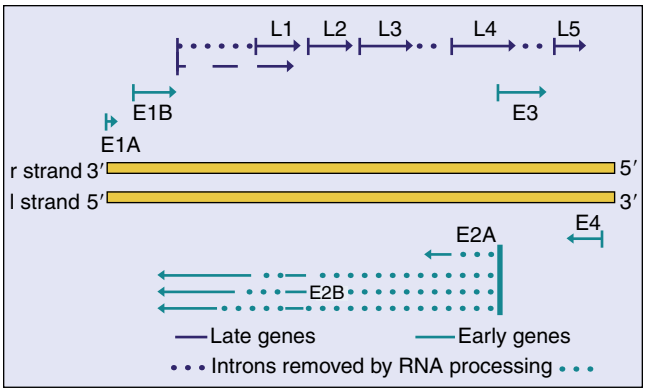

Fig. 42.2 Simplified genome map of adenovirus type 2. Genes are transcribed from both strands (*l* and *r*) in opposite directions. The early genes are transcribed from four promoter sequences, and each generates several messenger RNAs by processing the primary RNA transcripts. This produces the full repertoire of viral proteins. The splicing pattern for only the E2 transcript is shown as an example. All of the late genes are transcribed from one promoter sequence. *E,* Early protein; *L,* late protein. (Modified from Jawetz, E., Adelberg, E.A., Melnick, J.L., 1987. Review of Medical Microbiology, 17th ed. Appleton & Lange, Norwalk, CT.)

from the same promoter and share initial sequences but are produced through the splicing out of different introns. Transcription of the early *E1* gene, processing of the primary transcript (splicing out of introns to yield three mRNAs), and translation of the immediate early **E1A transactivator** protein are required for transcription of early proteins. The early proteins include more DNA-binding proteins, the DNA polymerase, and proteins to help the virus escape the immune response. The **E1A** protein together with the **E1B** protein can stimulate cell growth by binding to the cellular growth-suppressor proteins **p105RB** (*p105RB* retinoblastoma gene product) (E1A) and **p53** (E1B). In permissive cells, stimulation of cell division facilitates transcription and replication of the genome, with cell death resulting from virus replication. In nonpermissive cells, the virus establishes latency, and the genome remains in the nucleus. For rodent, not human, cells, the E1A and E1B proteins may promote cell growth but without cell death; therefore the virus oncogenically transforms the cell.

Viral DNA replication occurs in the nucleus and is mediated by the **viral-encoded DNA polymerase.** The polymerase uses the 55-kDa viral protein (terminal protein) with an attached cytosine monophosphate as a primer to replicate both strands of the DNA. The terminal protein remains attached to the DNA.

Late gene transcription starts after DNA replication. Most of the individual late mRNAs are generated from a large (83% of the genome) primary RNA transcript that is processed into at least 18 individual mRNAs.

Capsid proteins are produced in the cytoplasm and then transported to the nucleus for viral assembly. Empty procapsids first assemble, and then the viral DNA and core proteins enter the capsid through an opening at one of the vertices. The replication and assembly processes are inefficient and prone to error, producing as few as one infectious unit per 2300 particles. DNA, protein, and numerous defective particles accumulate in nuclear inclusion bodies. The virus remains in the cell and is released when the cell degenerates and lyses.

BOX 42.2 Disease Mechanisms of Adenoviruses

Virus is spread in **aerosols, in fecal matter,** and by **close contact.** Fingers spread virus to eyes.
Virus infects **mucoepithelial cells** in the respiratory tract, gastrointestinal tract, and conjunctiva or cornea, causing cell damage directly.
Disease is determined by the tissue tropism of the specific group or serotype of the virus strain.
Virus **persists** in lymphoid tissue (e.g., tonsils, adenoids, Peyer patches).
Antibody is important for prophylaxis and resolution, but cell-mediated immunity is also important.

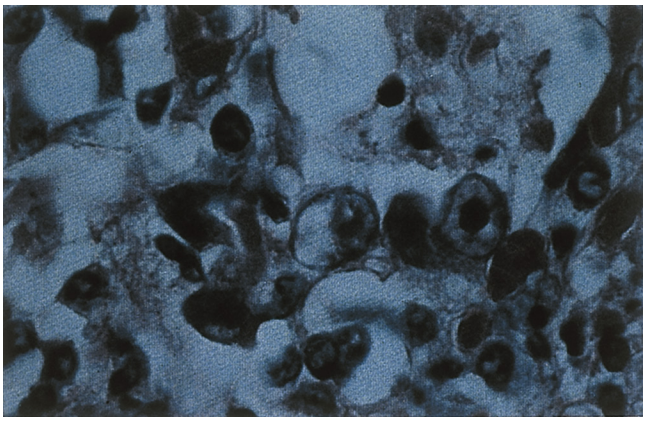

Fig. 42.3 Histologic appearance of adenovirus-infected cells. Inefficient assembly of virions yields dark basophilic nuclear inclusion bodies containing DNA, proteins, and capsids.

Pathogenesis and Immunity

Adenoviruses are capable of causing **lytic** (e.g., mucoepithelial cells), **latent** (e.g., macrophage, T cells, adenoid cells and other cells), and **transforming** (hamster, not human) infections. These viruses initially infect epithelial cells lining the oropharynx, as well as the respiratory and enteric organs (Box 42.2). The viral fiber proteins determine the target cell specificity. The toxic activity of the penton base protein can result in the inhibition of cellular mRNA transport and protein synthesis, cell rounding, and tissue damage.

The histologic hallmark of adenovirus infection is a dense, central intranuclear inclusion (that consists of viral DNA and protein) within an infected epithelial cell (Fig. 42.3). These inclusions may resemble those seen in cells infected with cytomegalovirus, but adenovirus does not cause cellular enlargement (cytomegaly). Mononuclear cell infiltrates and epithelial cell necrosis are seen at the site of infection.

Initial infection occurs to the pharynx, conjunctiva, or upper respiratory tract for most types and then spreads to lymph nodes and possibly the lower respiratory tract. The infection may resolve or the virus may become **latent and persist** in lymphoid and other tissue such as adenoids, tonsils, and Peyer patches, and can be reactivated in immunosuppressed patients. Viremia may occur after local replication of the virus, with subsequent spread to visceral organs. This dissemination is more likely to occur in immunocompromised patients than in immunocompetent ones.

BOX 42.3 Epidemiology of Adenoviruses

Disease/Viral Factors

Capsid virus is resistant to inactivation by gastrointestinal tract, drying, and detergents.
Disease symptoms may resemble those of other respiratory virus infections.
Virus may cause asymptomatic shedding.

Transmission

Direct contact, respiratory droplets and fecal matter on hands and fomites (e.g., towels, contaminated medical instruments), and inadequately chlorinated swimming pools and ponds

Who Is at Risk?

Children <14 years of age
People in crowded areas (e.g., day-care centers, military training camps, swimming clubs)

Geography/Season

Virus is found worldwide.
There is no seasonal incidence.

Modes of Control

Live vaccine for serotypes 4 and 7 is available for military use.

Although certain adenoviruses (groups A and B) are **oncogenic in certain rodents,** adenovirus transformation of human cells has not been observed.

Innate responses limit the initial spread of the virus and activate protective NK and T-cell responses. Cell-mediated immunity is important in limiting virus outgrowth, and immunosuppressed people suffer more serious and recurrent disease. Antibody is important for resolving lytic adenovirus infections and protects the person from reinfection with the same serotype but not other serotypes. Neutralizing antibody is directed at the fiber proteins. Adenoviruses have several mechanisms to evade host defenses and help them persist in the host. They encode small virus-associated RNAs (VA RNAs) that prevent activation of the interferon-induced protein kinase R–mediated inhibition of viral protein synthesis. The viral E3 and E1A proteins block apoptosis induced by cellular responses to the virus or by T-cell or cytokine (e.g., tumor necrosis factor [TNF]-α) actions. Some strains of adenoviruses can inhibit $CD8^+$ cytotoxic T-cell action by preventing proper expression of MHC I molecules and therefore antigen presentation.

Epidemiology

Adenovirus virions resist drying, detergents, gastrointestinal tract secretions (acid, protease, and bile), and even mild chlorine treatment (Box 42.3). These virions are spread in aerosols and by the fecal-oral route, by fingers, by fomites (including towels and medical instruments), and in ponds or poorly chlorinated swimming pools. Crowds and close proximity, as occurs in classrooms and military barracks, promotes spread of the virus. Adenoviruses may be shed intermittently and over long periods from the pharynx and especially in feces. Most infections are asymptomatic,

BOX 42.4 Clinical Summaries

Pharyngoconjunctival fever: A 7-year-old student develops sudden onset of red eyes, sore throat, and a fever of 38.9° C (102° F). Several children in the local elementary school have similar symptoms.

Gastroenteritis: An infant has diarrhea and is vomiting. Adenovirus serotype 41 is identified by polymerase chain reaction analysis of stool for epidemiologic reasons.

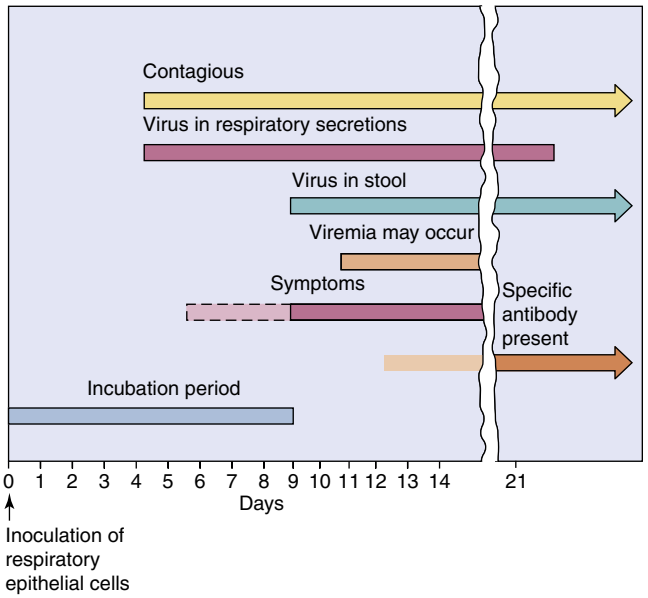

Fig. 42.4 Time course of adenovirus respiratory infection.

which is a feature that greatly facilitates their spread in the community.

Adenoviruses 1 through 7 are the most prevalent serotypes. From 5% to 10% of cases of pediatric respiratory tract disease are caused by adenovirus types 1, 2, 5, and 6, and the infected children shed virus for months after infection. Adenovirus causes 15% of the cases of gastroenteritis requiring hospitalization. Serotypes 4 and 7 seem especially able to spread among military recruits because of their close proximity and rigorous lifestyle. Immunosuppressed individuals are at highest risk to serious disease.

Clinical Syndromes

Adenoviruses primarily infect children and, less commonly, adults (Box 42.4). Disease from reactivated virus occurs in immunocompromised children and adults. Specific clinical syndromes are associated with specific adenovirus types (see Table 42.1). The time course of adenovirus respiratory infection is shown in Fig. 42.4.

ACUTE FEBRILE PHARYNGITIS AND PHARYNGOCONJUNCTIVAL FEVER

Adenovirus causes **pharyngitis,** which is often accompanied by **conjunctivitis (pharyngoconjunctival fever).** Pharyngitis alone occurs in young children, particularly those younger than 3 years, and may mimic streptococcal infection. Affected patients have mild, flulike symptoms (including nasal congestion, cough, coryza, malaise, fever, chills, myalgia, and headache) that may last 3 to 5 days. Pharyngoconjunctival fever occurs more often in outbreaks involving older children.

Clinical Case 42.1 **Pathogenic Adenovirus 14**

The Centers for Disease Control and Prevention (*MMWR* 56:1181–1184, 2007) reported that analysis of isolates from trainees during an outbreak of febrile respiratory infection at Lackland Air Force Base showed 63% resulting from adenovirus, and 90% of these were adenovirus 14. Of the 423 cases, 27 were hospitalized with pneumonia, 5 required admission to the intensive care unit, and 1 patient died. In an analogous case reported by CNN (www.cnn.com/2007/HEALTH/conditions/12/19/killer.cold/index.html), an 18-year-old high school athlete complained of flulike symptoms with vomiting, chills, and fever of 104° F that progressed to life-threatening pneumonia within days. The adenovirus causing these infections is a mutant of the adenovirus 14, which was first identified in 1955. The adenovirus 14 mutant has spread around the United States, putting adults at risk for severe disease. Adenovirus 14 infection usually causes a benign respiratory infection in adults, with newborns and the elderly at higher risk for severe outcomes. Although most virus mutations produce a weaker virus, occasionally a more virulent antibody-escape or antiviral drug–resistant virus may occur.

ACUTE RESPIRATORY DISEASE

Acute respiratory disease is a syndrome consisting of fever, runny nose, cough, pharyngitis, and possible conjunctivitis (Clinical Case 42.1). The high incidence of infection of military recruits stimulated the development and use of a vaccine for serotypes 4 and 7.

OTHER RESPIRATORY TRACT DISEASES

Adenoviruses cause coldlike symptoms, laryngitis, croup, and bronchiolitis. They can also cause a pertussis-like illness in children and adults that consists of a prolonged clinical course and true viral pneumonia.

CONJUNCTIVITIS AND EPIDEMIC KERATOCONJUNCTIVITIS

Adenoviruses cause **follicular conjunctivitis** (pinkeye) in which the mucosa of the palpebral conjunctiva becomes pebbled or nodular, and both conjunctivae (palpebral and bulbar) become inflamed (Fig. 42.5). Such conjunctivitis may occur sporadically or in outbreaks that can be traced to a common source. **Swimming pool conjunctivitis** is a familiar example of a common-source adenovirus infection. **Epidemic keratoconjunctivitis** may be an occupational hazard for industrial workers. The most striking such epidemic occurred in people working in the naval shipyards of Pearl Harbor in Hawaii, in which it caused more than 10,000 cases during 1941 and 1942. Irritation of the eye

Fig. 42.5 Conjunctivitis caused by adenovirus.

by a foreign body, dust, debris, and so forth is a risk factor for acquisition of this infection.

GASTROENTERITIS AND DIARRHEA

Adenovirus is a major cause of acute viral gastroenteritis, especially in infants. The enteric adenoviruses (types 40 to 42) do not replicate in the same tissue culture cells as do other adenoviruses and rarely cause fever or respiratory tract symptoms.

OTHER MANIFESTATIONS

Adenovirus has also been associated with intussusception in young children, acute hemorrhagic cystitis with dysuria and hematuria in young boys, musculoskeletal disorders, and genital and skin infections. Adenovirus (type 36) is also associated with obesity.

SYSTEMIC INFECTION IN IMMUNOCOMPROMISED PATIENTS

Immunocompromised patients, especially those deficient in T-cell function, are at risk for serious adenovirus infections. Adenoviral disease in immunocompromised patients includes pneumonia, acute diarrhea, hepatitis, and life-threatening systemic disease affecting multiple organs. Infection can originate from infection or reactivation from latency.

Laboratory Diagnosis

For the results of virus isolation to be significant, the isolate should be obtained from a site or secretion relevant to the disease symptoms. The presence of adenovirus in the throat of a patient with pharyngitis is usually diagnostic if laboratory findings eliminate other common causes of pharyngitis, such as *Streptococcus pyogenes*.

Direct analysis of the clinical sample without virus isolation can be used for rapid detection and identification of adenoviruses. Immunoassays (e.g., fluorescent antibody and enzyme-linked immunosorbent assay) and genome assays (e.g., different variations of polymerase chain reaction [PCR] and DNA probe analysis) can be used to detect, type, and group the virus in clinical samples and tissue cultures. These approaches must be used for enteric adenovirus serotypes 40 to 42, which do not grow readily in available cell cultures. Serologic testing is rarely used except for epidemiologic purposes.

The isolation of most adenovirus types is best accomplished in cell cultures derived from epithelial cells (e.g., primary human embryonic kidney cells, continuous [transformed] lines, such as HeLa and human epidermal carcinoma cells). Within 2 to 20 days, the virus causes a lytic infection with characteristic inclusion bodies and cell death. Recovery of virus from cell culture requires an average of 6 days. The characteristic intranuclear inclusions can be seen in infected tissue during histologic examination. However, such inclusions are rare and must be distinguished from those produced by cytomegalovirus.

Treatment, Prevention, and Control

Careful handwashing and chlorination of swimming pools can reduce transmission of adenovirus. There is no approved treatment for routine adenovirus infections. Cidofovir and also ribavirin can be used to treat adenovirus-infected immunosuppressed individuals. Live oral vaccines have been used to prevent infections with adenovirus types 4 and 7 in military recruits but are not used in civilian populations.

Therapeutic Adenoviruses

Adenoviruses have been used and are being considered for gene delivery for correction of human diseases, including immune deficiencies (e.g., adenosine deaminase deficiency), cystic fibrosis, and lysosomal storage diseases. The virus is inactivated by deletion or mutation of the *E1* and other viral genes (e.g., *E2, E4*). The appropriate gene is inserted into the viral genome, replacing this DNA, and it is controlled by an appropriate promoter. The resultant virus vector must be grown in a cell that expresses the missing viral functions (E1, E4) to complement the deficiency and allow production of virus. Types 4 and 7 and replication defective mutants of types 5, 26, and 35 are being developed to carry genes of HIV, Ebola, and other viruses as hybrid attenuated vaccines for these deadly viruses. Oncolytic therapy can be provided by adenoviruses lacking a functional *E1B* gene, which selectively grows and kills tumor cells that lack a functional p53 protein. Despite the genetically engineered attenuation, these viruses still may cause serious disease in immunocompromised individuals.

Case Study and Questions

A 7-year-old boy attending summer camp complains of sore throat, headache, cough, red eyes, and tiredness and is sent to the infirmary. His temperature is 40° C. Within hours, other campers and counselors visit the infirmary with similar symptoms. Symptoms last for 5 to 7 days. All the patients have gone swimming in the camp pond. More than 50% of the people in the camp complain of symptoms similar to those in the initial case. The Public Health Department identifies the agent as adenovirus serotype 3.

1. Toward which adenovirus syndrome do the symptoms point?

2. An outbreak as large as this indicates a common source of infection. What was the most likely source or sources? What were the most likely routes by which the virus was spread?

3. What physical properties of the virus facilitate its transmission?

4. What precautions should the camp owners take to prevent other outbreaks?

5. What sample or samples would have been used by the Public Health Department to identify the infectious agent, and what tests would be required to diagnose the infection?

43 Human Herpesviruses

(a) A vesicular lesion erupts at the corner of a 27-year-old man's mouth 3 days after returning from a skiing trip.
(b) A 26-year-old pediatric medical resident develops serious pneumonia, and then vesicular lesions erupt in crops on his head, trunk, and elsewhere.
(c) Several high school cheerleaders developed a sore throat, fever, swollen glands, and were very tired. They shared a water bottle at a football game three weeks earlier.
(d) A 57-year-old heart transplant recipient had an outbreak of herpes simplex virus (HSV) lesions, cytomegalovirus (CMV) pneumonitis, and subsequently an Epstein-Barr virus (EBV)–related lymphoma. The lymphoma resolved after immunosuppressive therapy was decreased.

1. Which viruses cause these diseases?
2. What features are similar/different for these viruses?
3. How were each of these infections obtained?
4. What are the risk factors for serious herpes disease?
5. Which of the infections can be prevented by vaccine or treated with antiviral drugs?

Answers to these questions are available on Student Consult.com.

Summaries Clinically Significant Organisms

HERPESVIRUSES

Trigger Words

- HSV-1 and HSV-2: neurotropic, Cowdry type A inclusion bodies, syncytia, vesicle, Tzanck smear
- VZV: neurotropic, (V) all stages of lesions, (Z) lesions along single dermatome
- EBV: lymphotropic: B cell, heterophile-positive mononucleosis, Burkitt lymphoma
- CMV: large cell and owl's eye inclusion body, opportunistic, mononucleosis, congenital disease
- and HHV7: lymphotropic, roseola
- HHV-8: Kaposi sarcoma, AIDS-related disease
- B virus: monkey, fatal encephalopathy

Biology, Virulence, and Disease

- Large, enveloped, icosadeltahedral capsid, DNA genome
- Encodes polymerase and other proteins (HSV and VZV: thymidine kinase)
- Cell-mediated immune response essential for control
- Lytic, latent, recurrent infections; EBV and HHV-8 also associated with cancers
- HSV: oral/genital, encephalitis, keratoconjunctivitis, neonatal HSV; recurs from neurons
- VZV: pneumonia in adults, varicella, zoster; recurs from neurons
- EBV: heterophile-positive mononucleosis, B-cell lymphomas; recurs from memory B cell
- CMV: opportunistic disease, congenital CMV, retinitis; recurs from monocyte and stem cell
- HHV-6: roseola
- HHV-8: Kaposi sarcoma

Epidemiology

- Ubiquitous viruses
- Transmitted by direct contact, bodily fluids
- VZV transmitted by aerosol and direct contact

Diagnosis

- Culture, immunologic tests (EBV serology), PCR and genome analysis

Treatment, Prevention, and Control

- Vaccines for varicella and zoster
- Antiviral drugs for HSV, VZV, and CMV

CMV, Cytomegalovirus; *EBV,* Epstein-Barr virus; *HHV,* human herpesvirus; *HSV,* herpes simplex virus; *PCR,* polymerase chain reaction; *VZV,* varicella-zoster virus.

The herpesviruses are an important group of large deoxyribonucleic acid (DNA)–enveloped viruses with the following features in common: virion morphology, basic mode of replication, and capacity to establish latent and recurrent infections. Cell-mediated immunity is important for causing symptoms and controlling infection with these viruses. Herpesviruses encode proteins and enzymes that facilitate replication and interaction of the virus with the host. EBV and human herpesvirus 8 (HHV-8) are associated with human cancers (Box 43.1).

HHVs are grouped into three subfamilies on the basis of differences in viral characteristics (genome structure, tissue tropism, cytopathologic effect, and site of latent infection), as well as the pathogenesis of the disease and disease manifestation (Table 43.1). HHVs are HSV types 1 and 2 (HSV-1 and HSV-2), VZV, EBV, CMV, HHV-6 and HHV-7, and HHV-8.

Herpesvirus infections are common, and the viruses, except HHV-8, are **ubiquitous.** Although these viruses usually cause benign disease, especially in children, they can also cause significant morbidity and mortality, especially in immunosuppressed people. Fortunately, some herpesviruses encode targets for antiviral agents, and there are vaccines for VZV.

Structure of Herpesviruses

The herpesviruses are **large, enveloped** viruses that contain **double-stranded DNA.** The virion is approximately 150 nm in diameter and has the characteristic morphology shown in Fig. 43.1. The DNA core is surrounded by an **icosadeltahedral capsid** containing 162 capsomeres. This capsid is enclosed by a glycoprotein-containing envelope. Herpesviruses encode several glycoproteins for viral attachment, fusion, and escaping immune control. Attached to the capsid and in the space between the envelope and the capsid (the **tegument**) are viral proteins and enzymes that help initiate replication. As enveloped viruses, the herpesviruses are sensitive to acid, solvents, detergents, and drying.

Herpesviral genomes are linear, double-stranded DNA, but they differ in size and gene orientation (Fig. 43.2). Direct or inverted repeat sequences bracket unique regions of the genome (unique long [U_L], unique short [U_S]), allowing circularization and recombination within the genome. Recombination among inverted repeats of HSV, CMV, and VZV allows large portions of the genome to flip the orientation of their U_L and U_S gene segments with respect to each other to form isomeric genomes.

BOX 43.1 Unique Features of Herpesviruses

Have large, enveloped, icosadeltahedral capsids containing double-stranded DNA genomes.
Encode many proteins that manipulate the host cell and immune response.
Encode enzymes (DNA polymerase) that promote viral DNA replication and are good targets for antiviral drugs.
DNA replication and capsid assembly occurs in the nucleus.
Virus is released by exocytosis, by cell lysis, and through cell-to-cell bridges.
Can cause lytic, persistent, latent, and (for Epstein-Barr virus) immortalizing infections.
Ubiquitous.
Cell-mediated immunity is required for control.

Herpesvirus Replication

Herpesvirus replication is initiated by the interaction of viral glycoproteins with cell-surface receptors (see Fig. 36.11). The tropism of some herpesviruses (e.g., EBV) is highly restricted because of the species and tissue-specific expression of their receptors. Viral glycoproteins facilitate the fusion of its envelope with the plasma membrane, releasing the nucleocapsid into the cytoplasm. Enzymes and transcription factors are carried into the cell in the tegument of the virion. The nucleocapsid docks with the nuclear membrane and delivers the genome into the nucleus, in which the genome is transcribed and replicated.

Transcription of the viral genome and viral protein synthesis proceeds in a coordinated and regulated manner in three phases:

1. **Immediate early proteins (α),** consisting of proteins important for the regulation of gene transcription and takeover of the cell
2. **Early proteins (β),** consisting of more transcription factors and enzymes, including the DNA polymerase
3. **Late proteins (γ),** consisting mainly of structural proteins, which are generated after viral genome replication has begun

TABLE 43.1 Properties Distinguishing the Herpesviruses

Subfamily	Virus	Primary Target Cell	Site of Latency	Means of Spread
ALPHAHERPESVIRINAE				
HHV-1	Herpes simplex type 1	Mucoepithelial cells	Neuron	Close contact (STD)
HHV-2	Herpes simplex type 2	Mucoepithelial cells	Neuron	Close contact (STD)
HHV-3	Varicella-zoster virus	Mucoepithelial and T cells	Neuron	Respiratory and close contact
GAMMAHERPESVIRINAE				
HHV-4	Epstein-Barr virus	B cells and epithelial cells	Memory B cell	Saliva (kissing disease)
HHV-8	Kaposi sarcoma–related virus	Lymphocytes and ?	B cell	Close contact (sexual), saliva
BETAHERPESVIRINAE				
HHV-5	Cytomegalovirus	Macrophages, lymphocytes, epithelial cells, and ?	HPC, myeloid stem cell, monocyte	Close contact (STD), transfusions, tissue transplant, and congenital
HHV-6	HHV-6	T lymphocytes, epithelial cells, neuronal cells	HPC, T cells	Saliva
HHV-7	HHV-7	Like HHV-6	HPC and T cell	Saliva

HHV, Human herpesvirus; *HPC,* hematopoietic progenitor cells *STD,* sexually transmitted disease; *?,* indicates that other cells may also be the primary target or site of latency.

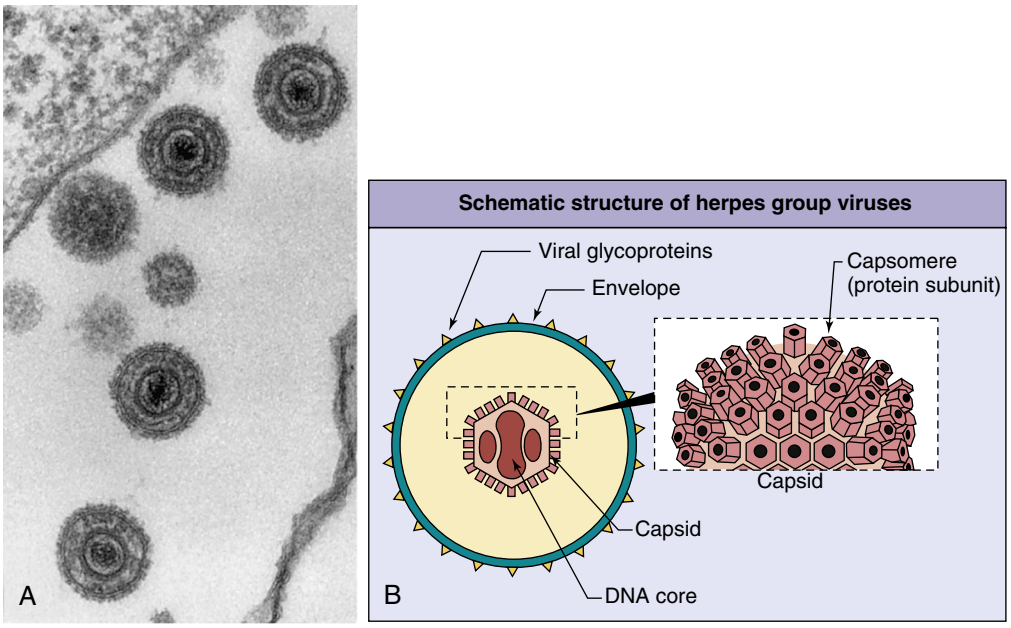

Fig. 43.1 (A) Electron micrograph and (B) general structure of the herpesviruses. The DNA genome of the herpesvirus in the core is surrounded by an icosadeltahedral capsid and an envelope. Glycoproteins are inserted into the envelope. (A, From Cohen, J., Powderly, W.G., Opal, S.M., 2010. Infectious Diseases, third ed. Mosby, Philadelphia, PA.)

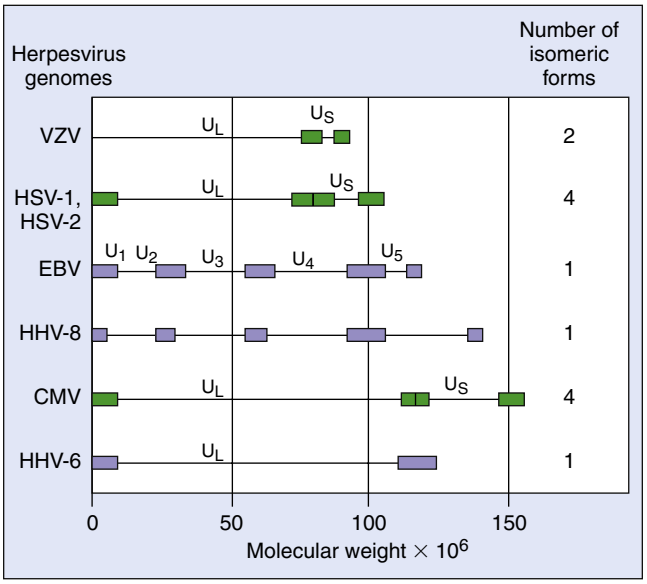

Fig. 43.2 Herpesvirus genomes. The genomes of herpesviruses are doubled-stranded DNA. The length and complexity of the genome differ for each virus. Inverted repeats in herpes simplex virus *(HSV),* varicella-zoster virus *(VZV),* and cytomegalovirus *(CMV)* allow the genome to recombine with itself to form isomers. Large genetic repeat sequences are boxed. The genomes of HSV and CMV have two sections, the unique long *(U_L)* and the unique short *(U_S),* each of which is bracketed by two sets of inverted repeats of DNA. The inverted repeats facilitate the replication of the genome and also allow the U_L and U_S regions to invert independently of each other to yield four different genomic configurations, or isomers. VZV has only one set of inverted repeats and can form two isomers. Epstein-Barr virus *(EBV)* exists in only one configuration, with several unique regions surrounded by direct repeats. *Blue bars* indicate direct repeat DNA sequences; *green bars* indicate inverted repeated DNA sequences. *HHV-6,* Human herpesvirus 6; *HHV-8,* human herpesvirus 8.

The viral genome is transcribed by the cellular DNA-dependent ribonucleic acid (RNA) polymerase and is regulated by viral-encoded and cellular nuclear factors. The interplay of these factors determines whether a lytic, persistent, or latent infection occurs. Cells that promote latent infection transcribe a special set of viral genes without genome replication. *Progression to early and late gene expression results in virus production and usually cell death.*

The **viral-encoded DNA polymerase,** which is a target of antiviral drugs, replicates the viral genome. **Viral-encoded scavenging enzymes** provide deoxyribonucleotide substrates for the polymerase. These and other viral enzymes facilitate replication of the virus in nongrowing cells that lack sufficient deoxyribonucleotides and enzymes for viral DNA synthesis (e.g., neurons). Other proteins manipulate cellular machinery to optimize replication, inhibit immune responses, and inhibit apoptosis or establish latency.

Empty procapsids assemble in the nucleus, are filled with DNA, bud into and out of the endoplasmic reticulum (ER), acquire tegument-associated proteins and bud into the Golgi membrane to acquire their envelope, and exit the cell by exocytosis or by lysis of the cell. Transcription, protein synthesis, glycoprotein processing, and exocytotic release from the cell are performed by cellular machinery. During replication, herpesviruses disrupt cellular processes, degrade cellular DNA, and alter the cytoskeleton of the cells. The replication of HSV is discussed in more detail as the prototype of the herpesviruses.

Herpes Simplex Virus

The name *herpes* is derived from a Greek word meaning "to creep." "Cold sores" were described in antiquity, and their viral etiology was established in 1919.

The two types of HSVs, HSV-1 and HSV-2, share many characteristics, including DNA homology, antigenic determinants, tissue tropism, and disease signs. However, they can still be distinguished by subtle but significant differences in these properties.

HERPES SIMPLEX VIRUS PROTEINS

The HSV genome is large enough to encode approximately 80 proteins. Only half the proteins are required for viral replication; the others facilitate HSV's interaction with different host cells and the immune response. The HSV genome encodes enzymes that include a DNA-dependent DNA polymerase and scavenging enzymes such as deoxyribonuclease, thymidine kinase, ribonucleotide reductase, and protease. Ribonucleotide reductase converts ribonucleotides to deoxyribonucleotides, and thymidine kinase phosphorylates the deoxyribonucleosides to provide substrates for replication of the viral genome. The substrate specificities of these enzymes and the DNA polymerase are less selective than those of their cellular analogs and thus represent potentially good targets for antiviral chemotherapy.

HSV encodes at least 10 glycoproteins that serve as viral attachment proteins (gB, gC, gD, gE/gI), fusion proteins (gB, gH/gL), structural proteins, immune escape proteins (gC, gE, gI), and provide other functions.

REPLICATION

HSV can infect most types of human cells, and even cells of other species. The virus generally causes lytic infections of fibroblasts and epithelial cells and latent infections of neurons (see Fig. 36.11, for a diagram).

HSV-1 binds quickly and efficiently to cells through an initial interaction with heparan sulfate, which is a proteoglycan found on the outside of many cell types, and then through a tighter interaction with receptor proteins at the cell surface. Penetration into the cell requires interaction with nectin-1 (herpesvirus entry mediator C), which is an intercellular adhesion molecule that is a member of the immunoglobulin protein family and similar to the poliovirus receptor. Nectin-1 is found on most cells and neurons. Another receptor is HveA, which is a member of the tumor necrosis factor receptor family expressed on activated T cells, neurons, and other cells. HSV can penetrate the host cell by fusion of its envelope with the cell-surface membrane. On fusion, the virion releases its capsid into the cytoplasm, along with a protein that promotes the initiation of viral gene transcription, a viral-encoded protein kinase, and cytotoxic proteins. The capsid docks with a nuclear pore and delivers the genome into the nucleus.

The **immediate early gene products** include DNA-binding proteins that stimulate DNA synthesis and promote transcription of the early viral genes. During a latent infection of neurons, the only region of the genome to be transcribed generates the **latency-associated transcripts (LATs).** These RNAs are not translated into protein but encode micro-RNAs that inhibit expression of important immediate early and other genes.

The **early proteins** include the DNA-dependent DNA polymerase and a thymidine kinase. As catalytic proteins, relatively few copies of these enzymes are required to promote replication. Other early proteins inhibit production and initiate degradation of cellular messenger RNA (mRNA) and DNA. Expression of the early and late genes generally leads to cell death.

The genome is replicated as soon as the polymerase is synthesized. Circular end-to-end concatemeric forms of the genome are made initially. Later in the infection, the DNA is replicated by a rolling-circle mechanism to produce a linear string of genomes that, in theory, resemble a roll of toilet paper. The concatemers are cleaved into individual genomes as the DNA is sucked into a procapsid.

Genome replication triggers transcription of the late genes from which structural and other proteins are encoded. Many copies of the structural proteins are required. The capsid proteins are then transported to the nucleus, in which they are assembled into empty procapsids and filled with DNA. DNA-containing capsids associate with viral protein-disrupted nuclear membranes and bud into and then out of the ER into the cytoplasm. The viral glycoproteins are synthesized and processed like cellular glycoproteins. Tegument proteins associate with the viral capsid in the cytoplasm, and then the capsid buds into a portion of the trans-Golgi network to acquire their glycoprotein-containing envelope. The virus is released by exocytosis or cell lysis. Virus can also spread between cells through intracellular bridges, which allows the virus to escape antibody detection. Virus-induced syncytia formation also spreads the infection.

HSV infection of neurons may result in virus replication or establishment of latency, depending on which viral genes the neuron is capable of transcribing. Transcription of the LAT and no other viral gene will result in latency. As for other alphaherpesviruses, HSV encodes a thymidine kinase (scavenging enzyme) to facilitate replication in nondividing cells such as neurons. HSV also encodes ICP34.5, which is a protein unique to HSV, that has multiple functions to facilitate virus growth in neurons and neuroinvasive disease. ICP34.5 removes a block to protein synthesis activated in response to virus infection or as part of the antiviral response of type 1 interferons, inhibits autophagy, and promotes release of capsids from the nucleus and virus at cell–cell junctions.

PATHOGENESIS AND IMMUNITY

The mechanisms involved in the pathogenesis of HSV-1 and HSV-2 are very similar (Box 43.2). Both viruses initially infect, replicate in mucoepithelial cells, cause disease at the site of infection, and then establish latent infection of the innervating neurons. HSV-1 and HSV-2 differ in growth characteristics and antigenicity, and HSV-1 has a greater potential to cause encephalitis, whereas HSV-2 has a greater potential to cause viremia with associated systemic flulike symptoms.

HSV can cause **lytic** infections of most cells and **latent** infection of neurons. Cytolysis generally results from the virus-induced inhibition of cellular macromolecular synthesis, the degradation of host cell DNA, membrane permeation, cytoskeletal disruption, and senescence of the cell. Visible changes in the nuclear structure and margination of the chromatin occur, and **Cowdry type A acidophilic intranuclear inclusion bodies** are produced.

BOX 43.2 Disease Mechanisms for Herpes Simplex Viruses

Disease is initiated by direct contact and depends on infected tissue (e.g., oral, genital, brain).
Virus causes direct cytopathologic effects.
Virus avoids antibody by cell-to-cell spread and syncytia.
Virus establishes latency in neurons (hides from immune response).
Virus is reactivated from latency by stress, ultraviolet B light, or immune suppression.
Cell-mediated immunity is required for resolution, with a limited role for antibody.
Cell-mediated immunopathologic effects contribute to symptoms.

BOX 43.3 Triggers of Herpes Simplex Virus Recurrences

Ultraviolet B radiation (skiing, tanning)
Fever (hence the name "fever blister")
Emotional stress (e.g., final examinations, big date)
Physical stress (irritation)
Menstruation
Foods: spicy, acidic, allergies
Immunosuppression:
  Transient (stress related)
  Chemotherapy, radiotherapy
  Human immunodeficiency virus

Many strains of HSV also initiate **syncytia** formation. In tissue culture, HSV rapidly kills cells, causing them to appear rounded.

HSV initiates infection through mucosal membranes or breaks in the skin. The virus replicates in the cells at the base of the lesion and infects the innervating neuron, traveling by retrograde transport to the ganglion (the trigeminal ganglia for oral HSV and the sacral ganglia for genital HSV) (see Fig. 43.5) to establish latent infection. CD8 T cells and interferon (IFN)-γ are important to maintain latency of HSV and other herpesviruses. On reactivation, the virus then returns to the initial site of infection, and the infection may be inapparent or may produce **vesicular lesions.** The vesicle fluid contains infectious virions. Tissue damage is caused by a combination of viral pathology and immunopathology. The lesion generally heals without producing a scar.

Innate protections, including interferon and natural killer (NK) cells, may be sufficient to limit the initial progression of the infection. *T-helper 1 (TH1)–associated and CD8 cytotoxic killer T-cell responses are required to kill infected cells and resolve acute disease*. The immunopathologic effects of the cell-mediated and inflammatory responses are also a major cause of the disease signs. Antibody directed against the glycoproteins of the virus neutralizes extracellular virus, limiting its spread, but it is not sufficient to resolve the infection. In the absence of functional cell-mediated immunity, HSV infection is likely to recur and be more severe, and it may disseminate to the vital organs and the brain.

HSV has several ways to escape host protective responses. The virus blocks the interferon-induced inhibition of viral protein synthesis and encodes a protein to plug the transporter associated with processing (TAP) channel, preventing delivery of peptides into the ER, which blocks their association with class I major histocompatibility complex (MHC I) molecules and prevents CD8 T-cell recognition of infected cells. The virus can escape antibody neutralization and clearance by direct cell-to-cell spread and syncytia formation and by going into hiding during latent infection of the neuron. In addition, the virion and virus-infected cells express glycoproteins, which are antibody (Fc) (gE/gI) and complement receptors (gC) that weaken these humoral defenses.

Latent infection occurs in neurons and results in no detectable damage. A **recurrence** can be activated by various stimuli (e.g., stress, trauma, fever, sunlight [ultraviolet B]) (Box 43.3). These events trigger virus replication in an individual nerve cell within the bundle and allow the virus to travel back down the nerve to cause lesions to develop at the same dermatome and location each time. The stress triggers reactivation by promoting replication of the virus in the nerve, by transiently depressing cell-mediated immunity, or by inducing both processes. The virus can be reactivated despite the presence of antibody. However, recurrent infections are generally less severe, more localized, and of shorter duration than the primary episodes because of the nature of the spread and the existence of memory immune responses.

EPIDEMIOLOGY

HSV infection is common with more than 700,000 new HSV-1 and HSV-2 infections in the United States per year. Because HSV can establish latency with the potential for asymptomatic recurrence, the infected person is a lifelong source of contagion (Box 43.4). HSV is transmitted in secretions and by close contact. As an enveloped virus, HSV is very labile and is readily inactivated by drying, detergents, and the conditions of the gastrointestinal tract. Although HSV can infect animal cells, HSV infection is exclusively a human disease.

HSV is transmitted in vesicle fluid, saliva, and vaginal secretions (the **"mixing and matching of mucous membranes"**). The site of infection, and hence the disease, is determined primarily by which mucous membranes are mixed. *Both types of HSV can cause oral and genital lesions.*

HSV-1 is readily spread by oral contact (kissing) or through the sharing of drinking glasses, toothbrushes, or other saliva-contaminated items. HSV-1 can infect the fingers or body through a cut or abraded skin. HSV-1 is also a major cause of genital and pharyngeal herpes. Autoinoculation may also cause infection of the eyes or fingers.

HSV-2 is spread mainly by sexual contact or autoinoculation or from an infected mother to her infant at birth. Depending on a person's sexual practices and hygiene, HSV-2 may infect the genitalia, anorectal tissues, or oropharynx. HSV-1 and HSV-2 may cause symptomatic or asymptomatic primary genital infection or recurrences.

Neonatal infection usually results from the excretion of HSV-2 from the cervix during vaginal delivery (Clinical Case 43.1) but can occur from an ascending in utero infection during a primary infection of the mother or infection soon after birth. Neonatal infection results in disseminated and neurologic disease with severe consequences.

BOX 43.4 Epidemiology of Herpes Simplex Virus

Disease/Viral Factors

Virus causes lifelong infection.
Recurrent disease is a source of contagion.
Virus may cause asymptomatic shedding.

Transmission

Virus is transmitted in saliva, in vaginal secretions, and by contact with lesion fluid (mixing and matching of mucous membranes).
Virus is transmitted orally and sexually and by placement into eyes and breaks in skin.
HSV-1 is generally transmitted orally; HSV-2 is generally transmitted sexually, but not exclusively.

Who Is at Risk?

Children and sexually active people are at risk for primary disease of HSV-1 and HSV-2, respectively.
Physicians, nurses, dentists, and others in contact with oral and genital secretions are at risk for infections of fingers (herpetic whitlow).
Immunocompromised people and neonates are at risk for disseminated life-threatening disease.

Geography/Season

Virus is found worldwide.
There is no seasonal incidence.

Modes of Control

Antiviral drugs are available for treatment and prophylaxis.
No vaccine is available.
Health care workers should wear gloves to prevent herpetic whitlow.
People with active genital lesions should refrain from intercourse until lesions are completely reepithelialized.

Clinical Case 43.1 Neonatal Herpes Simplex Virus

Parvey and Ch'ien (*Pediatrics* 65:1150–1153, 1980) reported a case of neonatal HSV contracted during birth. During a breech presentation, a fetal monitor was placed on the buttocks of the baby, and because of the greatly prolonged labor, the baby was delivered by cesarean section. The 5-pound boy had minor difficulties that were successfully treated, but on the sixth day, vesicles with an erythematous base appeared at the site in which the fetal monitor had been placed. HSV was grown from the vesicle fluid and from spinal fluid, cornea, saliva, and blood. The baby became moribund, with frequent apneic episodes and seizures. Intravenous treatment with adenosine arabinoside (Ara-A; vidarabine) was initiated. The baby also developed bradycardia and occasional vomiting. The vesicles spread to cover the lower extremities and were also on the back, palm, nares, and right eyelid. Within 72 hours of Ara-A treatment, the baby's condition started to improve. Treatment was continued for 11 days but discontinued because of a low platelet count. The baby was discharged on the 45th day after his birthday, and normal development was reported at 1 and 2 years of age. At 6 weeks after the birth, a herpes lesion was found on the mother's vulva. This baby was successfully treated with Ara-A and was able to overcome the damage caused by the infection. The virus, most likely HSV-2, was probably acquired through an abrasion caused by the fetal monitor while the neonate was in the birth canal. Ara-A has since been replaced with antiviral drugs that are better, less toxic, and easier to administer, such as acyclovir, valacyclovir, and famciclovir.

HSV, Herpes simplex virus.

Initial infection with HSV-2 occurs later in life than infection with HSV-1 and correlates with increased sexual activity. The current statistics indicate that 20% of adults in the United States are infected with HSV-2, which amounts to approximately 65 million people.

CLINICAL SYNDROMES

HSV-1 and HSV-2 are common human pathogens that can cause painful, but usually benign, lesions and recurrent disease (Fig. 43.3). The same diseases may be caused by either HSV-1 or HSV-2, unless noted. *HSV can cause significant morbidity and mortality on infection of the eye or brain and on disseminated infection of an immunosuppressed person or a neonate*. In the classic manifestation, the lesion is a clear vesicle on an erythematous base ("dewdrop on a rose petal") and then progresses to pustular lesions, ulcers, and crusted lesions (Fig. 43.4).

The lesions of oral herpes, herpes labialis or gingivostomatitis, begin as clear vesicles that rapidly ulcerate. The vesicles are usually at the crimson border of the lips but may be widely distributed around or throughout the mouth, involving the palate, pharynx, gingivae, buccal mucosa, and tongue (Fig. 43.5). Many other conditions (e.g., coxsackievirus lesions, canker sores, acne) may resemble HSV lesions.

Infected people may experience recurrent mucocutaneous HSV infection **(cold sores, fever blisters)** (Fig. 43.6) even though they never had a clinically apparent primary infection. The lesions usually occur at the corners of the mouth or next to the lips. Recurrent facial herpes infections are generally reactivated from the trigeminal ganglia. As noted earlier, the symptoms of a recurrent episode are less severe, more localized, and of shorter duration than those of a primary episode. **Herpes pharyngitis** is becoming a prevalent diagnosis in young adults with sore throats.

Herpetic keratitis is almost always limited to one eye. It can cause recurrent disease, leading to permanent scarring, corneal damage, and blindness. TH17 immune responses are important for control but contribute to the pathogenesis of eye infections.

Herpetic whitlow is an infection of the finger, and **herpes gladiatorum** is an infection of the body. The virus establishes infection through cuts or abrasions in the skin. Herpetic whitlow often occurs in nurses or physicians who attend patients with HSV infections, in thumb-sucking children (Fig. 43.7), and in people who have genital HSV infections. Herpes gladiatorum is often acquired during wrestling or rugby.

Eczema herpeticum is acquired by children with active eczema. The underlying disease promotes the spread of the infection along the skin and potentially to the adrenal glands, liver, and other organs.

TABLE 43.2 Laboratory Diagnosis of Herpes Simplex Virus Infections

Approach	Test/Comment
Direct microscopic examination of cells from base of lesion (Tzanck smear)	Multinucleated giant cells and Cowdry type A inclusion bodies in cells
Cell culture	Identifiable cytopathologic effect in most cell cultures
Assay of tissue biopsy, smear, cerebrospinal fluid, or vesicular fluid for HSV antigen or genome	**Enzyme immunoassay, immunofluorescent stain, in situ DNA probe analysis, or PCR[a]**
HSV type distinction (HSV-1 versus HSV-2)	Type-specific antibody, DNA probe analysis, and PCR
Serology	Serology is not useful except for epidemiology

HSV, Herpes simplex virus; *PCR,* polymerase chain reaction.
[a]currently favored approaches currently favored approaches

Genital herpes can be caused by HSV-1 or HSV-2. In male patients, the lesions typically develop on the glans or shaft of the penis and occasionally in the urethra. In female patients, the lesions may be seen on the vulva, vagina, cervix, perianal area, or inner thigh and are frequently accompanied by itching and a mucoid vaginal discharge. Anal sex can lead to HSV proctitis, which is a condition in which the lesions are found in the lower rectum and anus. The lesions are usually painful. In patients of both sexes, a primary infection may be accompanied by fever, malaise, and myalgia, which are symptoms related to a transient viremia. The symptoms and time course of primary and recurrent genital herpes are compared in Fig. 43.4.

Recurrent HSV disease is shorter in duration and less severe than the primary episode. In approximately 50% of patients, recurrences are preceded by a characteristic prodrome of burning or tingling in the area in which the lesions eventually erupt. Episodes of recurrence may be as frequent as every 2 to 3 weeks or may be infrequent. Unfortunately, any infected person may shed the virus asymptomatically. Such individuals are important vectors for spread of this virus.

Herpes encephalitis is usually caused by HSV-1. The lesions are generally limited to one of the temporal lobes. The viral pathology and immunopathology cause destruction of the temporal lobe and give rise to erythrocytes in the cerebrospinal fluid, seizures, focal neurologic abnormalities, and other characteristics of viral encephalitis. HSV is the most common viral cause of sporadic encephalitis and results in significant morbidity and mortality, even in patients who receive appropriate treatment. Unlike arbovirus encephalitis, the disease occurs at all ages and at any time of the year. **HSV meningitis** may be a complication of genital HSV-2 infection, and if so, symptoms often resolve by themselves.

HSV infection in the neonate is a devastating and often fatal disease. It may be acquired in utero, but more commonly, it is contracted either during passage of the infant through the vaginal canal (possibly at the baby's scalp-monitor site) because the mother is shedding herpesvirus at the time of delivery, or it is acquired postnatally from family members or hospital personnel. The baby initially appears septic, and vesicular lesions may or may not be present. Because the cell-mediated immune response is not yet developed in the neonate, HSV disseminates to the liver, lung, and other organs, as well as to the central nervous system (CNS). Progression of the infection to the CNS results in death, mental retardation, or neurologic disability, even with treatment.

LABORATORY DIAGNOSIS

Direct Analysis of a Clinical Sample

Characteristic cytopathologic effects (CPEs) can be identified in a **Tzanck smear** (a scraping of the base of a lesion), Papanicolaou (Pap) smear, or biopsy specimen (Table 43.2). CPEs include syncytia, "ballooning" cytoplasm, and Cowdry type A intranuclear inclusions (see Fig. 39.2). A definitive diagnosis can be made by demonstrating viral antigen (using immunofluorescence or the immunoperoxidase method) or DNA (using in situ hybridization or PCR) in the tissue sample or vesicle fluid.

Virus Isolation

Virus isolation allows archiving and additional testing. Virus can be obtained from vesicles but not crusted lesions. Specimens are collected by aspiration of the lesion fluid or by application of a cotton swab to the vesicles and kept cold but not frozen at −20° C. The sample is inoculated directly into cell cultures.

HSV produces CPEs within 1 to 3 days in HeLa cells, human embryonic fibroblasts, and other cells. Infected cells become enlarged and rounded (see Fig. 39.4). Some isolates induce fusion of neighboring cells, giving rise to multinucleated giant cells (syncytia). A sensitive approach for identification uses a cell line that expresses β-galactosidase on HSV infection of cells (enzyme-linked viral-inducible system [ELVIS]). Addition of the appropriate substrate produces color and allows detection of the enzyme in the infected cells.

Genome Detection

HSV type-specific DNA probes, specific DNA primers for PCR, and quantitative PCR are used to detect and differentiate HSV-1 and HSV-2. **PCR analysis** of the clinical sample or infected tissue culture media has become the method of choice for detection and distinction of HSV-1 and HSV-2 for most patients.

Serology

Serologic procedures are useful only for diagnosing a primary HSV infection and for epidemiologic studies. They are not useful for diagnosing recurrent disease because a significant rise in antibody titers does not usually accompany recurrent disease.

TREATMENT, PREVENTION, AND CONTROL

HSV encodes several target enzymes for antiviral drugs (Box 43.5) (see Chapter 40). Most antiherpes drugs are nucleoside analogs that are activated by the viral thymidine kinase and inhibit the viral DNA polymerase, which is an enzyme essential for viral replication and the best antiviral drug target. Treatment prevents or shortens the course of primary or recurrent disease. None of the drug treatments can eliminate latent infection.

The prototype anti-HSV drug is **acyclovir (ACV). Valacyclovir** (the valyl ester of ACV), **penciclovir,** and **famciclovir** (a derivative of penciclovir) are related to ACV in their mechanisms of action but have different pharmacologic properties (see Fig. 40.1).

Phosphorylation of ACV and penciclovir by the viral **thymidine kinase** and cellular enzymes activates the drug as a substrate for the viral **DNA polymerase.** These drugs are then incorporated into and **prevent elongation of the viral DNA** (see Fig. 40.2). ACV, valacyclovir, penciclovir, and famciclovir are relatively nontoxic, effective in treating serious presentations of HSV disease and first episodes of genital herpes, and are also used for prophylactic treatment.

The most prevalent form of resistance to these drugs results from mutations that inactivate the thymidine kinase, preventing conversion of the drug to its active form. Mutation of the viral DNA polymerase also produces resistance. Fortunately, resistant strains appear to be less virulent.

ACV and its analogs are effective against all HSV infections, including encephalitis, disseminated herpes, and other serious herpes diseases. The fact that it is not toxic to uninfected cells allows use of it and its analogs as a suppressive treatment to prevent recurrent outbreaks, especially in immunosuppressed people. A recurrent episode may be prevented if it is treated before or soon after the triggering event. The replication of HSV can be inhibited, but treatment cannot resolve the latent HSV infection.

Although cidofovir and adefovir are active against HSV, cidofovir is only approved for treatment of CMV. Vidarabine (adenosine arabinoside [Ara A]) is less soluble, less potent, and more toxic than ACV and is no longer in use. Trifluridine, penciclovir, and ACV have replaced iododeoxyuridine as topical agents for the treatment of herpetic keratitis. Tromantadine, an amantadine derivative, is approved for topical use in countries other than the United States. It works by inhibiting penetration and syncytia formation. Docosanol inhibits entry of the virus, and other nonprescription treatments may be effective for specific individuals.

Avoidance of direct contact with lesions reduces the risk of infection. Unfortunately, the symptoms may be inapparent; thus the virus can be transmitted unknowingly. Physicians, nurses, dentists, and technicians must be especially careful when handling potentially infected tissue or fluids. Wearing gloves can prevent acquisition of infections of the fingers (herpetic whitlow). People with recurrent herpetic whitlow disease are very contagious and can spread the infection to patients.

HSV is readily inactivated by soap, disinfectants, bleach, and 70% ethanol. Washing with soap readily disinfects the virus.

Patients who have a history of genital HSV infection must be instructed to refrain from sexual intercourse while they have prodromal symptoms or lesions and to resume sexual intercourse only after lesions are completely reepithelialized because the virus may be transmitted from lesions that have crusted over. Condoms may be useful and are undoubtedly better than nothing but may not be fully protective.

A pregnant woman who has active genital HSV infection or who is asymptomatically shedding the virus in the vagina at term may transmit HSV to the neonate if the infant is delivered vaginally. Such transmission can be prevented by cesarean section.

No vaccine is currently available for HSV. However, killed, subunit, vaccinia hybrid, genetically attenuated, and DNA vaccines are being developed to prevent acquisition of the virus or to treat infected people. The glycoprotein D is being used in several of these experimental vaccines.

Cidofovir[a]

[a]Also inhibits herpes simplex and varicella-zoster viruses.

Varicella-Zoster Virus

VZV causes **chickenpox (varicella)** and, on recurrence, causes herpes **zoster, or shingles.** As an alphaherpesvirus, VZV shares many characteristics with HSV, including (1) the ability to establish latent infection of neurons and recurrent disease, (2) the importance of cell-mediated immunity in controlling and preventing serious disease, and (3) the characteristic blister-like lesions. Like HSV, VZV encodes a **thymidine kinase** and is susceptible to the same **antiviral drugs.** Unlike HSV, VZV spreads predominantly by the **respiratory route** and, after local replication of the virus in the respiratory tract, by **viremia** to form skin lesions over the entire body.

STRUCTURE AND REPLICATION

VZV has the smallest genome of the HHVs. VZV replicates in a similar manner but slower and in fewer types of cells than HSV. Human diploid fibroblasts in vitro and activated T cells, epithelial cells, and epidermal cells in vivo support productive VZV replication. Newly synthesized VZV is sequestered into lysosomes and degraded in most cells because of its binding to the mannose-6-phosphate receptor but is released from terminally differentiated skin cells that lack this protein. As such, it spreads within the body by cell–cell contact. Like HSV, VZV establishes a latent infection of neurons, but unlike HSV, several viral RNAs and specific viral proteins can be detected in the latently infected cells.

PATHOGENESIS AND IMMUNITY

VZV-infected cells show similar CPE to those seen in HSV-infected cells with Cowdry type A intranuclear inclusions and syncytia.

VZV is generally acquired by inhalation, and primary infection begins in the tonsils and mucosa of the respiratory tract. The virus progresses via the bloodstream and lymphatic system to the cells of the reticuloendothelial system (Figs. 43.8 and 43.9; Box 43.6). A secondary viremia then occurs and spreads the virus throughout the body and to the skin. The virus infects T cells, and these cells can home to the skin and transfer virus to skin epithelial cells. The virus overcomes inhibition by IFN-α, and vesicles are produced in the skin. The virus remains cell associated and is transmitted by cell-to-cell interaction, except for terminally differentiated epithelial cells in the lungs and keratinocytes of skin lesions, which can release infectious virus. Virus replication in the lung is a major source of contagion. The virus causes a dermal vesiculopustular rash that develops over time in successive crops. Fever and systemic symptoms occur with the rash.

The virus becomes latent in the dorsal root, cranial nerve, and other ganglia after the primary infection. The virus can be reactivated in older adults when immunity wanes or in patients with impaired cellular immunity. On reactivation, the virus replicates and is released along the length of the neuron to infect the skin, causing a vesicular rash along the entire dermatome, which is known as **herpes zoster,** or **shingles.** This damages the neuron and may result in very painful postherpetic neuralgia.

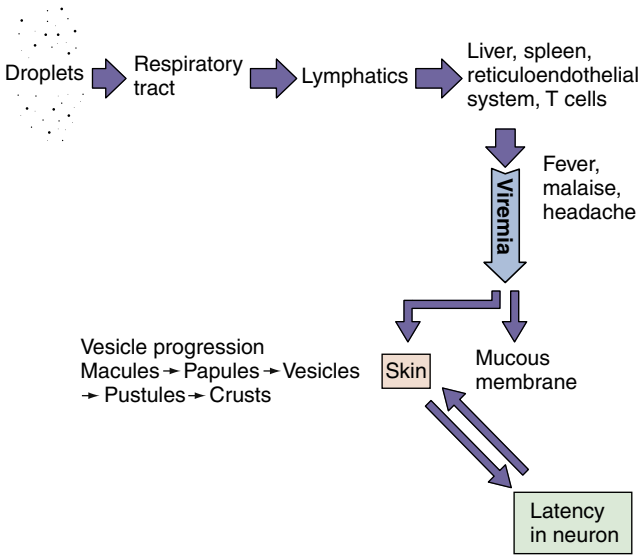

Fig. 43.8 Mechanism of spread of varicella-zoster virus (VZV) within the body. VZV initially infects the respiratory tract and is spread to the reticuloendothelial system and T cells and then by cell-associated viremia to the skin.

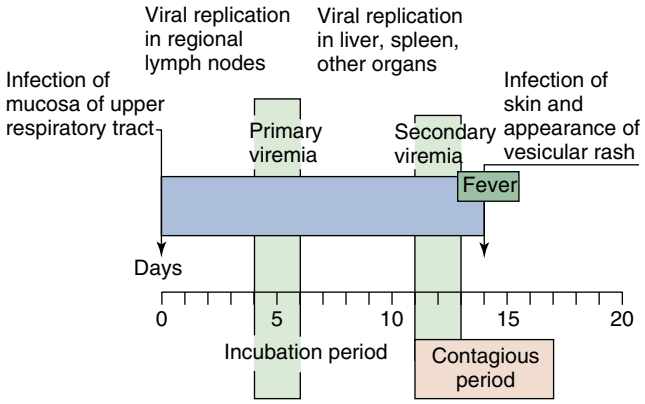

Fig. 43.9 Time course of varicella (chickenpox). The course in young children, as presented in this figure, is generally shorter and less severe than that in adults.

BOX 43.6 Disease Mechanisms of Varicella-Zoster Virus

Initial replication is in the respiratory tract.
Infects epithelial cells, fibroblasts, T cells, and neurons.
Can form syncytia and spread directly from cell to cell.
Spread by viremia in T cells to skin and causes lesions in successive crops.
Life-threatening pneumonia occurs in adults with primary infection caused by vigorous inflammatory response.
Can evade antibody clearance, and cell-mediated immune response is essential to control infection.
Disseminated life-threatening disease can occur in immunocompromised people.
Establishes latent infection of neurons, usually dorsal root and cranial nerve ganglia.
Herpes zoster is a recurrent disease; it results from virus replication along the entire dermatome.
Herpes zoster results from depression of cell-mediated immunity.

VZV, Varicella-zoster viurs.

IFN-α, interferon-stimulated protections, and NK and T cells limit the spread of the virus in tissue, but **antibody** is important for limiting the viremic spread of VZV. Passive immunization with **varicella-zoster immunoglobulin (VZIg)** within 4 days of exposure is protective. Cell-mediated immunity is essential for resolving the acute disease and controlling the latent infection. The virus causes more disseminated and more serious disease in the absence of cell-mediated immunity (e.g., in children with leukemia) and may recur on immunosuppression. Although important for protection, cell-mediated immune responses contribute to the symptomatology. An overzealous response in adults is responsible for causing more extensive cell damage and a more severe manifestation (especially in the lung) in primary infection than that seen in children. T-cell and antibody levels decrease later in life, allowing VZV recurrence and herpes zoster disease.

EPIDEMIOLOGY

VZV is extremely communicable, with rates of infection exceeding 90% among susceptible household contacts (Box 43.7). The disease is spread principally by the respiratory route but may also be spread through contact with skin vesicles. Patients are contagious before and during symptoms. More than 90% of adults in developed countries have the VZV antibody. Herpes zoster results from the reactivation of a patient's latent virus. The disease develops in approximately 10% to 20% of the population infected with VZV, and the incidence rises with age. Herpes zoster lesions contain viable virus and therefore may be a source of varicella infection in a nonimmune person (i.e., a child).

BOX 43.7 Epidemiology of Varicella-Zoster Virus

Disease/Viral Factors

Causes lifelong infection.
Recurrent disease is a source of contagion.

Transmission

Virus is transmitted mainly by respiratory droplets but also by direct contact.

Who Is at Risk?

Children (aged 5 to 9 years) experience mild classic disease.
Teenagers and adults are at risk for more severe disease with potential pneumonia.
Immunocompromised people and newborns are at risk for life-threatening pneumonia, encephalitis, and progressive disseminated varicella.
Elderly and immunocompromised people are at risk for recurrent disease (herpes zoster [shingles]) caused by a waning immune response.

Geography/Season

Virus is found worldwide.
There is no seasonal incidence.

Modes of Control

Antiviral drugs are available.
Varicella-zoster immunoglobulin is available for immunocompromised people and staff exposed to virus, as well as newborns of mothers showing symptoms within 5 days of birth.
Live vaccine (Oka strain) is available for children (varicella) and adults (zoster). Adjuvanted subunit vaccine also is available for zoster.

CLINICAL SYNDROMES

Varicella (chickenpox) is one of the five **classic childhood exanthems** (along with rubella, roseola, fifth disease, and measles). The disease results from a primary infection with VZV; it is usually a mild disease of childhood and is normally symptomatic, although asymptomatic infection can occur (see Fig. 43.9). Varicella characteristics include fever and a maculopapular rash that appear after an incubation period of approximately 14 days (Fig. 43.10). Within hours, each maculopapular lesion forms a thin-walled vesicle on an erythematous base ("dewdrop on a rose petal") that measures approximately 2 to 4 mm in diameter. This vesicle is the hallmark of varicella. Within 12 hours, the vesicle becomes pustular and begins to crust, after which scabbed lesions appear. Successive crops of lesions appear for 3 to 5 days, and at any given time, all stages of skin lesions can be observed.

The rash spreads across the entire body but is more prevalent on the trunk and head than on the extremities. Its presence on the scalp distinguishes it from many other rashes. The lesions itch and cause scratching, which may lead to bacterial superinfection and scarring. Lesions on the mucous membrane typically occur in the mouth, conjunctivae, and vagina.

Primary infection is usually more severe in adults than in children. **Interstitial pneumonia** may occur in 20% to 30% of adult patients and may be fatal. The pneumonia results from inflammatory reactions at this primary site of infection.

As noted earlier, **herpes zoster** (*zoster* means "belt" or "girdle") is a recurrence of a latent varicella infection acquired earlier in the patient's life. Severe pain in the area innervated by the nerve usually precedes the appearance of the chickenpox-like lesions. The rash is limited to a dermatome and resembles varicella (Fig. 43.11). Common sites of

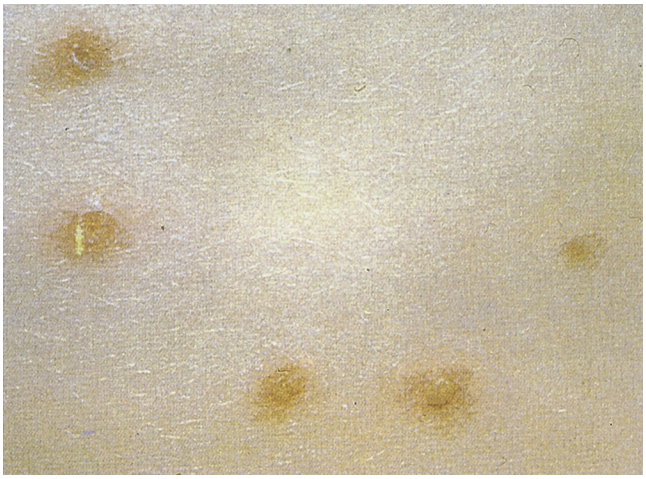

Fig. 43.10 Characteristic rash of varicella in all stages of its evolution. (From Hart, C.A., Broadhead, R.L., 1992. A Color Atlas of Pediatric Infectious Diseases. Wolfe, London, UK.)

Fig. 43.11 Herpes zoster ("shingles") in a thoracic dermatome.

presentation are a quadrant of the head or along a thoracic dermatome. A chronic pain syndrome called **postherpetic neuralgia,** which can persist for months to years, occurs in as many as 30% of patients in whom herpes zoster develops.

VZV infection in immunocompromised patients or neonates can result in serious, progressive, and potentially fatal disease. Defects of cell-mediated immunity in such patients increase the risk for dissemination of the virus to the lungs, brain, and liver, which may be fatal. The disease may occur in response to a primary exposure to varicella or because of recurrent disease.

LABORATORY DIAGNOSIS

Isolation of VZV is not routinely done because the virus is labile during transport to the laboratory and replicates poorly in vitro. PCR and genome detection techniques are especially useful for confirming a diagnosis. A direct fluorescent antibody to membrane antigen (FAMA) test can also be used to examine skin lesion scrapings or biopsy specimens.

Serologic tests that detect antibodies to VZV are used to screen populations for immunity to VZV. However, antibody levels are normally low, so sensitive tests such as immunofluorescence and enzyme-linked immunosorbent assay (ELISA) must be performed to detect the antibody. A significant increase in antibody level can be detected in people experiencing herpes zoster.

TREATMENT, PREVENTION, AND CONTROL

Treatment may be appropriate for adults and immunocompromised patients with VZV infections and for people with zoster, but no treatment is usually necessary for children with varicella. **ACV, famciclovir,** and **valacyclovir** have been approved for the treatment of VZV infections. The VZV DNA polymerase is much less sensitive to ACV treatment than the HSV enzyme, requiring larger doses of ACV or the improved pharmacodynamics of famciclovir and valacyclovir (see Box 43.5). There is no good treatment, but analgesics and other painkillers, topical anesthetics, or capsaicin cream may provide some relief from the postherpetic neuralgia that follows zoster.

As with other respiratory viruses, it is difficult to limit the transmission of VZV. Because VZV infection in children is generally mild and induces lifelong immunity, exposure of children to VZV early in life is often encouraged. However, high-risk people (e.g., immunosuppressed children) should be protected from exposure to VZV.

Immunocompromised patients susceptible to severe disease may be protected from serious disease through the administration of **VZIg.** VZIg is prepared through the pooling of plasma from seropositive people. VZIg prophylaxis can prevent viremic spread leading to disease but is ineffective as a therapy for patients already suffering from active varicella or herpes zoster disease.

A **live attenuated vaccine** for VZV (Oka strain) (Varivax) has been licensed for use in the United States and elsewhere and is administered after 1 year of age on the same schedule as the measles, mumps, and rubella vaccine. The vaccine induces production of protective antibody and cell-mediated immunity. A stronger version of this vaccine (Zostavax) is available for adults older than 60 years; it boosts antiviral responses to limit the onset of zoster. A subunit vaccine (Shingrix) consisting of the VZV glycoprotein E and an adjuvant is given in two doses and is also available.

Epstein-Barr Virus

EBV is the ultimate B-lymphocyte parasite, and the diseases it causes reflect this association. EBV was discovered by electron-microscopic observation of characteristic herpes virions in biopsy specimens of a B-cell neoplasm, African Burkitt lymphoma (AfBL). Its association with infectious mononucleosis was discovered accidentally when serum collected from a laboratory technician convalescing from infectious mononucleosis was found to contain the antibody that recognized AfBL cells. This finding was later confirmed in a large serologic study performed on college students.

EBV causes *heterophile antibody–positive infectious mononucleosis* and *stimulates the growth and immortalizes B cells* in tissue culture. EBV has been causally associated with **AfBL (endemic Burkitt lymphoma), Hodgkin disease,** and **nasopharyngeal carcinoma.** EBV has also been associated with B-cell lymphomas in patients with acquired or congenital immunodeficiencies.

STRUCTURE AND REPLICATION

EBV is a member of the subfamily Gammaherpesvirinae, with a very limited host range and a **tissue tropism** defined by the limited cellular expression of its receptor. The primary receptor for EBV is also *the receptor for the C3d component of the complement system* (*also called CR2 or CD21*). It is expressed on B cells of humans and New World monkeys and on some epithelial cells of the oropharynx and nasopharynx. EBV also binds to MHC II.

EBV infection has the following three potential outcomes, it can

1. Replicate in B cells or epithelial cells permissive for EBV replication and produce virus,
2. Cause latent infection of memory B cells in the presence of competent T cells, and
3. Stimulate growth and immortalize B cells.

EBV encodes more than 70 proteins, different groups of which are expressed for the different types of infections.

TABLE 43.3 Markers of Epstein-Barr Virus Infection

Name	Abbreviation	Characteristics	Biological Association	Clinical Association
EBV nuclear antigens	EBNAs	Nuclear	EBNAs are nonstructural antigens and first antigens to appear; EBNAs seen in all infected and transformed cells	Anti-EBNA develops after resolution of infection
Early antigen	EA-R	Only cytoplasmic	EA-R appears before EA-D; appearance is first sign that infected cell has entered lytic cycle	—
	EA-D	Diffuse in cytoplasm and nucleus	—	Anti–EA-D seen in infectious mononucleosis
Viral capsid antigen	VCA	Cytoplasmic	VCA are late proteins; found in virus-producing cells	Anti-VCA IgM is transient; anti-VCA IgG is persistent
Membrane antigen	MA	Cell surface	MAs are envelope glycoproteins	Same as VCA
Heterophile antibody	—	Recognition of Paul-Bunnell antigen on sheep, horse, or bovine erythrocytes	EBV-induced B-cell proliferation promotes production of heterophile antibody	Early symptom occurs in more than 50% of patients

EA, Early antigen; *EBNA,* Epstein-Barr nuclear antigen; *EBV,* Epstein-Barr virus; *Ig,* immunoglobulin; *MA,* membrane antigen; *VCA,* viral capsid antigen.

EBV in saliva infects epithelial cells and then naive resting B cells in the tonsils. The growth of the B cells is stimulated first by virus binding to the C3d receptor, a B-cell growth-stimulating receptor, and then by expression of the transformation and latency proteins. These include **Epstein-Barr nuclear antigens (EBNAs)** 1, 2, 3A, 3B, and 3C; latent proteins **(LPs); latent membrane proteins (LMPs) 1 and 2;** and two small Epstein-Barr–encoded RNA (EBER) molecules, EBER-1 and EBER-2. The EBNAs and LPs are DNA-binding proteins that are essential for establishing and maintaining the infection (EBNA-1), immortalization (EBNA-2), and other purposes. The LMPs are membrane proteins with oncoprotein-like activity. The genome becomes circularized; the cells proceed to follicles that become germinal centers in the lymph node, in which the infected cells differentiate into memory cells. EBV protein synthesis ceases, and the virus establishes latency in these memory B cells. EBNA-1 is present at cell division to hold onto and retain the genome in the cells.

Antigen stimulation of the B cells and infection of certain epithelial cells allow transcription and translation of the ZEBRA (peptide encoded by the Z-gene region) transcriptional activator protein, which activates the immediate early genes of the virus and the lytic cycle. After synthesis of the DNA polymerase and replication of DNA, the structural and other late proteins are synthesized. They include gp350/220 (related glycoproteins of 350,000 and 220,000 Da), which is the viral attachment protein, and other glycoproteins. These glycoproteins bind to CD21 and MHC II molecules, receptors on B cells and epithelial cells, and promote fusion of the envelope with cell membranes.

The viral proteins produced during a productive infection are serologically defined and grouped as **early antigen (EA), viral capsid antigen (VCA),** and the glycoproteins of the **membrane antigen (MA)** (Table 43.3). An early protein mimics a cellular inhibitor of apoptosis, and a late protein mimics the activity of human interleukin (IL)-10 (BCRF-1), which enhances B-cell growth and inhibits TH1 immune responses.

PATHOGENESIS AND IMMUNITY

EBV has adapted to the human B cell and manipulates and uses the different phases of B-cell development to establish a lifelong infection. The diseases of EBV result from either an overactive immune response (infectious mononucleosis) or the lack of effective immune control (lymphoproliferative disease and hairy cell leukoplakia).

The productive infection of B cells and epithelial cells of the oropharynx, such as in the tonsils (Fig. 43.12 and Box 43.8), promotes virus shedding into saliva to transmit the virus to other hosts and establishes a viremia to spread the virus to other B cells in lymphatic tissue and blood.

EBV proteins replace host factors that normally activate B-cell growth and development. In the absence of T cells (e.g., in tissue culture), EBV can immortalize B cells and promote the development of B-lymphoblastoid cell lines. In vivo, B-cell activation and proliferation occurs and is indicated by the spurious production of an IgM antibody to the Paul-Bunnell antigen, termed the **heterophile antibody** (see later discussion of serology).

The outgrowth of the B cell is controlled by a normal T-cell response to B-cell proliferation and to EBV antigenic peptides. B cells are excellent antigen-presenting cells and present EBV antigens on both MHC I and MHC II molecules. The activated T cells appear as **atypical lymphocytes** (also called **Downey cells**) (Fig. 43.13). They increase in number in the peripheral blood during the second week of infection, accounting for 10% to 80% of the total white blood cell count at this time (hence the "mononucleosis").

Infectious mononucleosis is essentially *a "civil war" between the EBV-infected B cells and the protective T cells.* The classic **lymphocytosis** (increase in mononuclear cells), swelling of lymphoid organs (lymph nodes, spleen, and liver), and malaise associated with infectious mononucleosis results mainly from the activation and proliferation of T cells. A large amount of energy is required to power the T-cell response, leading to great fatigue. The sore throat of infectious mononucleosis is a response to EBV-infected epithelium and B cells in the tonsils and throat. Children have

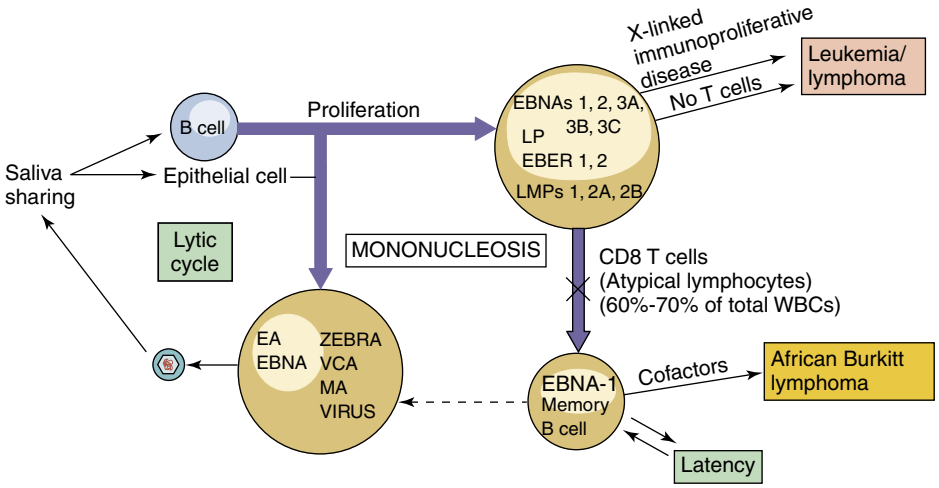

Fig. 43.12 Progression of Epstein-Barr virus (EBV) infection. Infection may result in lytic, latent, or immortalizing infection, which can be distinguished on the basis of production of virus and expression of different viral proteins and antigens. T cells limit the outgrowth of the EBV-infected cells and maintain the latent infection. *CD,* Cluster of differentiation; *EA,* early antigen; *EBER,* Epstein-Barr–encoded RNA; *EBNA,* Epstein-Barr nuclear antigen; *LMPs,* latent membrane proteins; *LP,* latent protein; *MA,* membrane antigen; *VCA,* viral capsid antigen; *WBCs,* white blood cells; *ZEBRA,* peptide encoded by the *Z* gene region.

BOX 43.8 Disease Mechanisms of Epstein-Barr Virus

Virus in saliva initiates infection of oral epithelia and tonsillar B cells.
There is productive infection of epithelial cells and B cells.
Virus promotes growth of B cells (immortalizes).
T cells are stimulated by infected B cells; they kill and limit B-cell outgrowth. T cells are required for controlling infection.
Antibody role is limited.
EBV establishes latency in memory B cells and is reactivated when the B cell is activated.
T-cell response (lymphocytosis) contributes to symptoms of **infectious mononucleosis.**
There is causative association with lymphoma in immunosuppressed people and African children living in malarial regions (African Burkitt lymphoma) and with nasopharyngeal carcinoma in China.
EBV-associated B-cell lymphomas may result from immunosuppression.

EBV, Epstein-Barr virus.

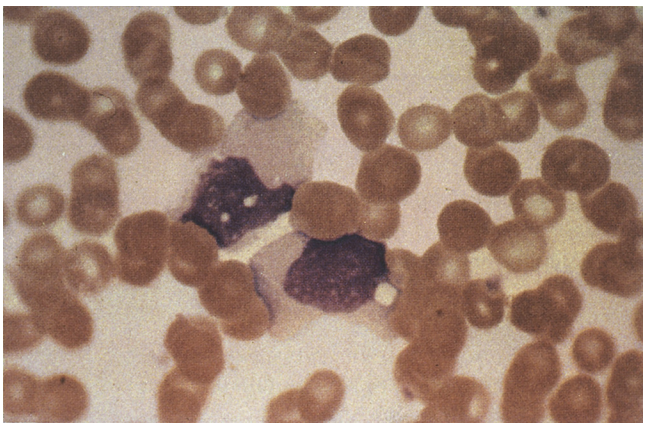

Fig. 43.13 Atypical T-cell (Downey cell) characteristic of infectious mononucleosis. The cells have a more basophilic and vacuolated cytoplasm than normal lymphocytes, and the nucleus may be oval, kidney shaped, or lobulated. The cell margin may seem to be indented by neighboring red blood cells.

a less active immune response to EBV infection and therefore have mild disease.

During productive infection, antibody is first developed against the components of the virion, VCA, and MA, and later against the EA. After resolution of the infection (lysis of the productively infected cells), antibody against the nuclear antigens (EBNAs) is produced. T cells are essential for limiting the proliferation of EBV-infected B cells and controlling the disease (Fig. 43.14). EBV counteracts some of the protective action of TH1 CD4 T-cell responses during productive infection by producing an IL-10 analog (BCRF-1) that inhibits the protective TH1 CD4 T-cell responses and stimulates B-cell growth.

The virus persists in peripheral blood memory B cells and in the tonsils. They can be detected in at least one memory B cell per milliliter of blood for the infected person's lifetime. EBV may be reactivated when the memory B cell is activated (especially in the tonsils or oropharynx) and may be shed in saliva.

EPIDEMIOLOGY

At least 70% of the population of the United States is infected by age 30. EBV is transmitted in saliva (Box 43.9). More than 90% of EBV-infected people intermittently shed the virus for life, even when totally asymptomatic. Children can acquire the virus at an early age by sharing contaminated drinking glasses. *Children generally have subclinical disease.* Saliva sharing between adolescents and young adults often occurs during kissing; thus EBV mononucleosis has earned the nickname "the kissing disease." Disease in these people may go unnoticed or may manifest in varying degrees of severity.

The geographic distribution of some EBV-associated neoplasms indicates a possible association with cofactors.

Malaria appears to be a cofactor in the progression of chronic or latent EBV infection to AfBL. The restriction of nasopharyngeal carcinoma to people living in certain regions of China indicates a possible genetic predisposition to the cancer or the presence of cofactors in the food or environment. More subtle mechanisms may facilitate the role of EBV in 30% to 50% of cases of Hodgkin disease and other cancers.

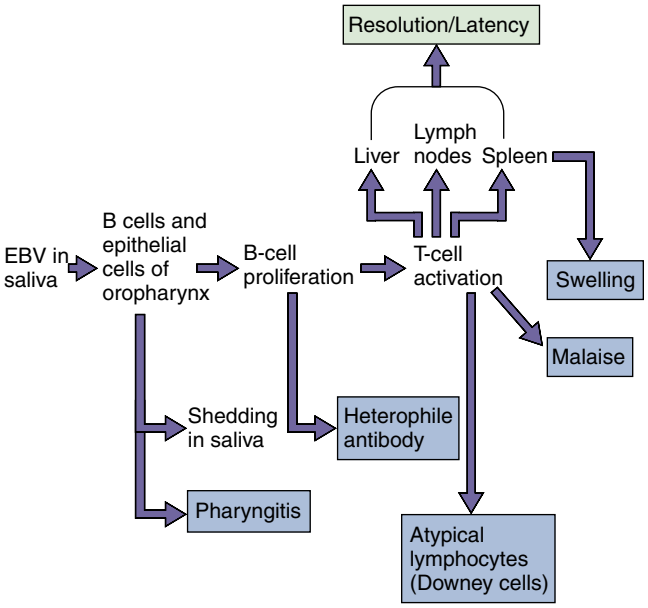

Fig. 43.14 Pathogenesis of Epstein-Barr virus *(EBV)*. EBV is acquired by close contact between persons through saliva and infects B cells. Resolution of the EBV infection and many of the symptoms of infectious mononucleosis result from activation of T cells in response to the infection.

BOX 43.9 Epidemiology of Epstein-Barr Virus

Disease/Viral Factors

Virus causes lifelong infection.
Recurrent disease is primary source of contagion.
Virus may cause asymptomatic shedding.

Transmission

Transmission occurs via saliva, close oral contact ("kissing disease"), or sharing of items such as toothbrushes and cups.

Who Is at Risk?

Children experience asymptomatic disease or mild symptoms.
Teenagers and adults are at risk for infectious mononucleosis.
Immunocompromised people are at highest risk for life-threatening neoplastic disease.

Geography/Season

Infectious mononucleosis has worldwide distribution.
There is causative association with African Burkitt lymphoma in the malarial belt of Africa.
There is no seasonal incidence.

Modes of Control

There are no modes of control.

Transplant recipients, patients with the acquired immunodeficiency syndrome (AIDS), and genetically immunodeficient people are at high risk for lymphoproliferative disorders initiated by EBV. These disorders may appear as polyclonal and monoclonal B-cell lymphomas. Such people are also at high risk for a productive EBV infection in the form of **hairy oral leukoplakia.**

CLINICAL SYNDROMES

Heterophile Antibody–Positive Infectious Mononucleosis

The triad of classic symptoms for infectious mononucleosis is **lymphadenopathy** (swollen glands), **splenomegaly** (large spleen), and **exudative pharyngitis** accompanied by high fever, malaise, and often hepatosplenomegaly (large liver and spleen) (Clinical Case 43.2). A rash may occur, especially after ampicillin treatment (for a possible strep throat). The major complaint of people with infectious mononucleosis is fatigue (Fig. 43.15). The disease is rarely fatal in healthy people but can cause serious complications resulting from neurologic disorders, laryngeal obstruction, or rupture of the spleen. Neurologic complications include meningoencephalitis and Guillain-Barré syndrome. Similar to infections caused by other herpesviruses, EBV infection in a child is much milder than infection in an adolescent or adult. In fact, infection in children is usually subclinical.

Clinical Case 43.2 Epstein-Barr Virus in the Immunocompromised Individual

Purtilo and associates (*Ann Intern Med* 101:180–186, 1984) reported on a boy with Duncan disease who presented with reduced levels of IgA, a history of thrush, and recurrent episodes of otitis media. This member of the Duncan family had an X-linked recessive, progressive, combined, variable immunodeficiency disease caused by a mutation in the SH2D1A protein, which prevents proper communication between B and T cells. After exposure to EBV at age 11 years, the boy did not develop antibodies to EBV, but generic serum IgM levels increased, and EBNA-positive immortalized B-cell lines readily grew from his peripheral blood. Establishment of the B-cell lines is indicative of aberrant T-cell control of the virus-induced B-cell proliferation. At age 18 years, he was treated with packed red cells for red cell aplasia; then 9 weeks later he developed infectious mononucleosis with fever, generalized lymphadenomegaly, tender liver and swollen spleen, lymphocytosis with a predominance of atypical lymphocytes, and a positive Monospot test. Within another 6 months, he was agammaglobulinemic with no detectable B cells and suffered from *Haemophilus influenzae* and *Mycobacterium tuberculosis* pneumonias. After an additional 5 months, B cells were again detected. The onset of infectious mononucleosis at age 18 years may have resulted from new infection or a reactivation of the earlier infection. This case illustrates the unusual nature of EBV and other virus infections when the immune response is compromised.

EBNA, Epstein-Barr nuclear antigen; *EBV*, Epstein-Barr virus; *Ig*, immunoglobulin.

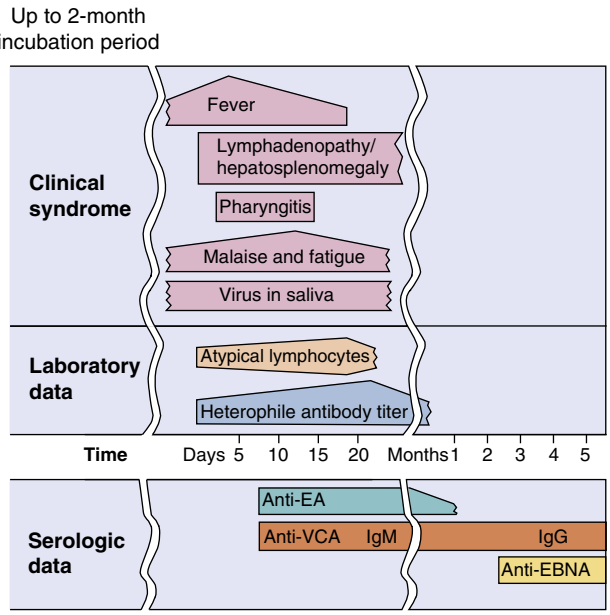

Fig. 43.15 Clinical course of infectious mononucleosis and laboratory findings of those with the infection. Epstein-Barr virus infection may be asymptomatic or may produce the symptoms of mononucleosis. The incubation period can last as long as 2 months. *EA,* Early antigen; *EBNA,* Epstein-Barr nuclear antigen; *Ig,* immunoglobulin; *VCA,* viral capsid antigen.

Mononucleosis-like syndromes can also be caused by CMV, HHV-6, *Toxoplasma gondii,* and human immunodeficiency virus (HIV). As for EBV, mononucleosis syndrome is caused by T-cell proliferation in response to infection of an antigen-presenting cell; a B cell; a macrophage; or a dendritic cell, which stimulates CD4 and CD8 T cells with antigenic peptides on MHC II and MHC I. Heterophile antibody is not generated during these syndromes.

Chronic Disease

EBV can cause cyclic recurrent disease in some people. These patients experience chronic tiredness and may also have low-grade fever, headaches, and a sore throat. This disorder is different from chronic fatigue syndrome, which has an unknown etiology.

Epstein-Barr Virus–Induced Lymphoproliferative Diseases

On infection with EBV, people lacking T-cell immunity are likely to suffer life-threatening polyclonal leukemia-like B-cell proliferative disease and lymphoma instead of infectious mononucleosis. Men with congenital deficiencies of T-cell function are likely to suffer life-threatening X-linked lymphoproliferative disease. One such X-linked genetic defect in a T-cell gene (signaling lymphocyte activation molecule [SLAM]–associated protein) prevents the T cell from controlling B-cell growth during a normal immune response to antigen or because of EBV. Transplant recipients undergoing immunosuppressive treatment are at high risk for **posttransplant lymphoproliferative** disease, instead of infectious mononucleosis, after exposure to the virus or on reactivation of latent virus. The disease dissipates on reduction of immunosuppression. Similar diseases are seen in patients with AIDS.

BOX 43.10 Diagnosis of Epstein-Barr Virus

1. Symptoms
   a. Mild headache, fatigue, fever
   b. Triad: lymphadenopathy, splenomegaly, exudative pharyngitis
   c. Other: hepatitis, ampicillin-induced rash
2. Complete blood cell count
   a. Hyperplasia
   b. Atypical lymphocytes (Downey cells, T cells)
3. Heterophile antibody (transient)
4. EBV–antigen-specific antibody
5. Genome detection by PCR

EBV, Epstein-Barr virus; *PCR,* polymerase chain reaction.

EBV was first associated with **AfBL (endemic lymphoma)** and then Burkitt lymphoma elsewhere in the world, Hodgkin lymphoma, and several other lymphoproliferative diseases. AfBL is a poorly differentiated monoclonal B-cell lymphoma of the jaw and face that is endemic in children living in the malarial regions of Africa. EBV infection facilitates the survival of cells that undergo a chromosomal translocation that juxtaposes the *c-MYC* oncogene to a very active promoter, such as an immunoglobulin gene promoter [t(8;14), t(8;22), t(8;2)], to allow tumor growth. Virions can occasionally be seen on electron micrographs of infected material. The tumor cells are also relatively invisible to immune control. Malaria may enhance the development of AfBL by promoting the proliferation of EBV-bearing memory B cells.

EBV is also associated with **nasopharyngeal carcinoma,** which is endemic in adults in Asia. The tumor cells contain EBV DNA, but unlike Burkitt lymphoma, in which the tumor cells are derived from lymphocytes, the tumor cells of nasopharyngeal carcinoma are of epithelial origin.

Hairy Oral Leukoplakia

Hairy oral leukoplakia is an unusual manifestation of a productive EBV infection of epithelial cells characterized by lesions of the tongue and mouth. It is an opportunistic manifestation that occurs in patients with AIDS.

LABORATORY DIAGNOSIS

EBV-induced infectious mononucleosis is diagnosed on the basis of the **symptoms** (Box 43.10), the finding of atypical lymphocytes, the presence of **lymphocytosis** (mononuclear cells constituting 60% to 70% of the white blood cell count, with 30% atypical lymphocytes), **heterophile antibody,** antibody to viral antigens, and viral DNA. Virus isolation is not practical. PCR and DNA probe analysis for the viral genome and amount of virus (virus load) and immunofluorescent identification of viral antigens are used to detect and follow the course of infection.

Atypical lymphocytes are probably the earliest detectable indication of an EBV infection. These cells appear with the onset of symptoms and disappear with resolution of the disease.

Heterophile antibody results from the nonspecific, mitogen-like activation of B cells by EBV and the production

TABLE 43.4 Serologic Profile for Epstein-Barr Virus Infection

	Mononucleosis	Heterophile Antibodies	EBV-SPECIFIC ANTIBODIES				Comment
			VCA-IgM	VCA-IgG	EA	EBNA	
Susceptible	–	–	–	–	–	–	Heterophile antibody present early in disease, anti-VCA and anti-MA present during disease, and anti-EBNA only present during convalescence
Acute primary infection	+	+	+	+	±	–	
Chronic primary infection	–	–	–	+	+	–	
Past infection	–	–	–	+	–	+	
Reactivation infection	–	–	–	+	+	+	
Burkitt lymphoma	–	–	–	+	+	+	
Nasopharyngeal carcinoma	–	–	–	+	+	+	

EA, Early antigen; *EBNA,* Epstein-Barr nuclear antigen; *IgG,* immunoglobulin G; *IgM,* immunoglobulin M; *MA,* membrane antigen; *VCA,* viral capsid antigen.
Modified from Balows, A., Hausler, W.J., Lennette, E.H. (Eds.), 1988. Laboratory Diagnosis of Infectious Diseases: Principles and Practices. Springer-Verlag, New York, NY.

of a wide repertoire of antibodies. These antibodies include an IgM heterophile antibody that recognizes the Paul-Bunnell antigen on sheep, horse, and bovine erythrocytes but not that on guinea pig kidney cells. The heterophile antibody response can usually be detected by the end of the first week of illness and lasts for as long as several months. It is an excellent indication of EBV infection in adults but is not as reliable in children or infants. The horse cell (Monospot) test and ELISA are rapid and widely used for detection of the heterophile antibody.

Serologic tests for antibody to viral antigens are a more dependable method than heterophile antibody to confirm the diagnosis of EBV mononucleosis (Table 43.4; see Fig. 43.15). EBV infection is indicated by the finding of any of the following: (1) IgM antibody to the VCA, (2) the presence of VCA antibody and the absence of EBNA antibody, or (3) elevation of antibodies to VCA and EA. The finding of both VCA and EBNA antibodies in serum indicates that the person had a previous infection. Generation of antibody to EBNA requires lysis of the infected cell and usually indicates T-cell control of active disease and its presence indicates resolution of the disease.

TREATMENT, PREVENTION, AND CONTROL

No effective treatment or vaccine is available for EBV disease. After being activated by the viral protein kinase, acyclovir will reduce viral shedding but not disease. The ubiquitous nature of the virus and the potential for asymptomatic shedding make control of infection difficult. However, infection elicits lifelong immunity. Therefore the best means of preventing infectious mononucleosis is exposure to the virus early in life because the disease is more benign in children.

Cytomegalovirus

CMV is a common human pathogen, infecting approximately 1% of all newborns and at least 50% to 80% of adults by age 40. It is the most common viral cause of **congenital defects** with 1 in 150 children born infected with the virus and 1 in 750 born with or will develop permanent disabilities caused by congenital CMV. Although usually causing mild or asymptomatic disease in children and adults, CMV is particularly important as an **opportunistic pathogen in immunocompromised patients.**

BOX 43.11 Disease Mechanisms of Cytomegalovirus

Acquired from blood, tissue, and most body secretions.
Causes productive infection of macrophages, epithelial cells, and other cells.
Establishes latency in hematopoietic stem cells and monocytes
Cell-mediated immunity is required for resolution and maintenance of latency and contributes to symptoms.
The role of antibody is limited.
Suppression of cell-mediated immunity allows recurrence and severe disease.
CMV generally causes subclinical infection.

CMV, Cytomegalovirus.

STRUCTURE AND REPLICATION

CMV is a member of the subfamily Betaherpesvirinae. It has the largest genome of the HHVs. Only a quarter of its genes are required for replication, whereas most of the other genes manipulate host interactions and the immune response. In contrast to the traditional definition of a virus, which states that a virion particle contains DNA or RNA, CMV carries specific mRNAs into the cell in the virion particle to facilitate infection. Human CMV replicates only in human cells. Fibroblasts, epithelial cells, granulocytes, macrophages, and other cells are permissive for CMV replication. Virus replication is much slower than for HSV, and CPE may not be seen for 7 to 14 days. This may facilitate the establishment of latent infection in myeloid stem cells, monocytes, lymphocytes, the stromal cells of the bone marrow, or other cells.

PATHOGENESIS AND IMMUNITY

CMV is an excellent parasite and readily establishes persistent and latent infections rather than an extensive lytic infection (Box 43.11). CMV is highly cell associated and is spread throughout the body within infected cells, especially

Clinical Case 43.3 A Role for Cytomegalovirus in Medulloblastoma

CMV is present in a large percentage of medulloblastomas, which is the most common malignant brain tumor in children. In a study of these tumors by Baryawno and associates (*J Clin Invest* 121:4043–4055, 2011), CMV induced inflammation and promoted the production of interleukin 6, vascular endothelial growth factor, and prostaglandin E_2, which promoted the growth of the medulloblastoma cells. Treatment with ganciclovir and a nonsteroidal anti-inflammatory drug stopped the growth of these cells.

CMV, Cytomegalovirus.

lymphocytes and leukocytes. The virus establishes latency in hematopoietic progenitor cells in the bone marrow and monocytes. The virus reactivates on immunosuppression (e.g., corticosteroids, infection with HIV) and possibly by allogeneic stimulation (i.e., the host response to transfused or transplanted cells) and replicates in ductal epithelia to be shed in saliva, urine, breast milk, semen and other body fluids. **CMV is shed sporadically throughout life.**

Cell-mediated immunity is essential for resolving and controlling the outgrowth of CMV infection. However, CMV is an expert at immune evasion and has several means for evading innate and immune responses. The virus prevents antigen presentation to both CD8 cytotoxic T cells and CD4 T cells by preventing the expression of MHC I molecules on the cell surface and by interfering with cytokine-induced expression of MHC II molecules on antigen-presenting cells (including the infected cells). A viral protein also blocks NK-cell attack of CMV-infected cells. Similar to EBV, CMV also encodes an IL-10 analog that would inhibit TH1 protective immune responses.

CMV is a common passenger in many children and adults and may reactivate throughout life to cause transient immune responses and inflammation and influence the health of the individual. CMV has been implicated as a cofactor for medulloblastoma, leukemia, and other diseases (Clinical Case 43.3).

EPIDEMIOLOGY AND CLINICAL SYNDROMES

In most cases, CMV replicates and is shed without causing symptoms (Table 43.5). Activation and replication of CMV in the kidney and secretory glands promote its secretion in urine and bodily secretions. CMV can be isolated from urine, blood, throat washings, saliva, tears, breast milk, semen, stool, amniotic fluid, vaginal and cervical secretions, and tissues obtained for transplantation (Box 43.12 and Table 43.6). Virus can be transmitted to other individuals by means of blood transfusions and organ transplants. The congenital, oral, and sexual routes, blood transfusion, and tissue transplantation are the major means by which CMV is transmitted. CMV disease is an opportunistic disease, rarely causing symptoms in the immunocompetent host but causing serious disease in an immunosuppressed or immunodeficient person, such as a patient with AIDS or a neonate (Fig. 43.16).

TABLE 43.5 Sources of Cytomegalovirus Infection

Age Group	Source
Neonate	Transplacental transmission, intrauterine infections, cervical secretions
Baby or child	Body secretions: breast milk, saliva, tears, urine
Adult	Sexual transmission (semen), blood transfusion, organ graft

BOX 43.12 Epidemiology of Cytomegalovirus Infection

Disease/Viral Factors

Virus causes lifelong infection.
Recurrent disease is source of contagion.
Virus causes asymptomatic shedding.

Transmission

Transmission occurs via blood, organ transplants, and all secretions (urine, saliva, semen, cervical secretions, breast milk, and tears).
Virus is transmitted orally and sexually, in blood transfusions, in tissue transplants, in utero, at birth, and by nursing.

Who Is at Risk?

Babies
  Babies of mothers who experience seroconversion during term are at high risk for congenital defects
Sexually active people
Blood and organ recipients
Burn victims
Immunocompromised people: symptomatic and recurrent disease

Geography/Season

Virus is found worldwide.
There is no seasonal incidence.

Modes of Control

Antiviral drugs are available for serious disease.
Screening potential blood and organ donors for cytomegalovirus reduces transmission of virus.

Congenital Infection

CMV is the most prevalent viral cause of congenital disease. Approximately 15% of stillborn babies are infected with CMV. Almost 1% of all newborns in the United States are infected with CMV before birth, and a large percentage of babies are infected within the first months of life. Of these, 80% may shed virus for long periods with as many as 25% of them having hearing, eyesight, and IQ deficits that develop over time. CMV is the most common infectious cause of congenital hearing loss in the United States, and vision loss and mental retardation are also common consequences of congenital CMV infection. Approximately 1/10,000 live births will be born with **cytomegalic inclusion disease**. Disease signs include small size, thrombocytopenia, microcephaly, intracerebral calcification, jaundice, hepatosplenomegaly, and rash. The risk for serious birth defects is extremely high for infants born to mothers who had primary CMV infections during their pregnancies.

TABLE 43.6 Cytomegalovirus Syndromes

Tissue	Children/Adults	Immunosuppressed Patients
Predominant presentation	Asymptomatic	Disseminated disease, severe disease
Eyes	—	Retinitis
Lungs	—	Pneumonia, pneumonitis
Gastrointestinal tract	—	Esophagitis, colitis
Nervous system	Polyneuritis, myelitis	Meningitis and encephalitis, myelitis
Lymphoid system	Mononucleosis syndrome, posttransfusion syndrome	Leukopenia, lymphocytosis
Major organs	Carditis,[a] hepatitis[a]	Hepatitis
Neonates	Deafness, intracerebral calcification, microcephaly, mental retardation	—

[a]Complication of mononucleosis or posttransfusion syndrome.

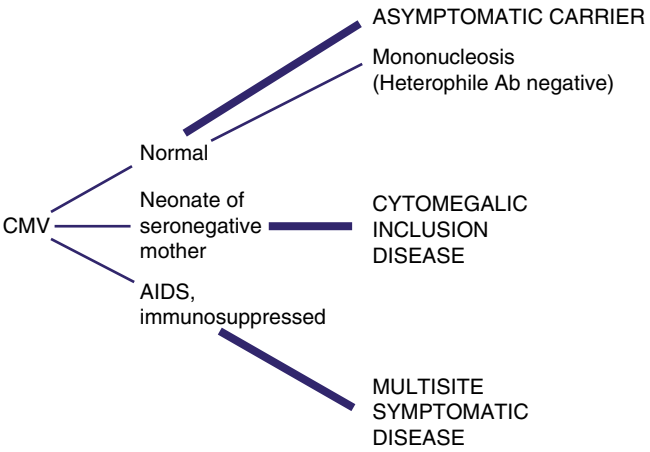

Fig. 43.16 Outcomes of cytomegalovirus *(CMV)* infections. The outcome of CMV infection depends very heavily on the immune status of the patient. *Ab,* Antibody; *AIDS,* acquired immunodeficiency syndrome.

Fetuses are infected by the virus in the mother's blood (primary infection) or by virus ascending from the cervix (after a recurrence). Congenital CMV infection is best documented by isolation of the virus from the infant's urine during the first week of life.

Perinatal Infection

In the United States, approximately 60% of pregnant women are infected with CMV at term and are likely to experience reactivation of the virus during pregnancy. Approximately half the neonates born from an infected mother acquire CMV infection and become excreters of the virus at 3 to 4 weeks of age. Neonates may also acquire CMV from maternal milk or colostrum. Perinatal infection causes no clinically evident disease in healthy full-term infants. Significant clinical infection may occur in premature infants who acquire CMV from transfused blood, usually resulting in pneumonia and hepatitis.

Infection in Children and Adults

Approximately 40% of adolescents are infected with CMV, but this number increases to 50% to 85% of adults in the United States by the age of 40. CMV is more prevalent among people in low socioeconomic brackets living in crowded conditions and in people living in developing countries. CMV is a **sexually transmitted disease,** and 90% to 100% of patients attending sexually transmitted disease clinics are infected**.** The titer of the CMV in semen is the highest of that in any body secretion.

Although most CMV infections acquired in young adulthood are asymptomatic, patients may show a **heterophile-negative mononucleosis syndrome.** The symptoms of CMV disease are similar to those of EBV infection but with less severe pharyngitis and lymphadenopathy (see Fig. 43.16). Although the presence of CMV-infected cells promotes a T-cell outgrowth (atypical lymphocytosis) similar to that seen in EBV infection, heterophile antibody is not present. Because CMV does not infect the B cell, nor does it stimulate or activate the B cell, there is no heterophile antibody. CMV disease should be suspected in a patient who has heterophile-negative mononucleosis or in whom there are signs of hepatitis but results of tests for hepatitis A, B, and C are negative.

Transmission via Transfusion and Transplantation

Transmission of CMV by blood most often results in an asymptomatic infection; if symptoms are present, they typically resemble those of mononucleosis. Fever, splenomegaly, and atypical lymphocytosis usually begin 3 to 5 weeks after transfusion. Pneumonia and mild hepatitis may also occur. CMV may also be transmitted by organ transplantation (e.g., kidneys, bone marrow), and CMV infection is often reactivated in transplant recipients during periods of intense immunosuppression.

Infection in the Immunocompromised Host

CMV is a prominent opportunistic infectious agent. In immunocompromised people, it causes symptomatic primary or recurrent disease (see Table 43.6).

CMV disease of the lung **(pneumonia and pneumonitis)** is a common outcome in immunosuppressed patients and can be fatal if not treated. CMV often causes **retinitis, colitis, or esophagitis** in patients who are severely immunodeficient (e.g., patients with AIDS). Interstitial pneumonia and encephalitis also may be caused by CMV but may be difficult to distinguish from infections caused by other opportunistic agents. CMV esophagitis may mimic candidal esophagitis. A smaller percentage of immunocompromised patients may experience CMV infection of the gastrointestinal tract. Patients with CMV colitis usually have diarrhea, weight loss, anorexia, and fever. Effective anti-HIV therapy has reduced the incidence of these diseases.

CMV is also responsible for the **failure of many kidney transplants.** The graft may succumb to virus replication or cytolytic immune responses to the viral antigens. CMV can also infect the immunosuppressed host.

LABORATORY DIAGNOSIS

Histology

The histologic hallmark of CMV infection is the **cytomegalic cell,** which is an **enlarged cell** (25 to 35 mm in

diameter) that contains a dense, **central**, **"owl's eye," basophilic intranuclear inclusion body** (Fig. 43.17 and Table 43.7). Such infected cells may be found in any tissue of the body and in urine and are thought to be epithelial in origin. The inclusions are readily seen with Papanicolaou or hematoxylin-eosin staining.

Antigen and Genome Detection

A rapid, sensitive diagnosis can be obtained by detection of viral antigen, using immunofluorescence or an ELISA, or the viral genome, using PCR and related techniques in cells of a biopsy, blood, bronchoalveolar lavage, or urine sample (see Chapter 5). Distinction of active CMV from latent CMV requires detection of CMV mRNA or large amounts of DNA in blood.

Culture

CMV is grown in diploid fibroblast cell cultures and normally must be maintained for at least 4 to 6 weeks because the characteristic CPE develops very slowly in specimens with very low titers of the virus. Isolation of CMV is especially reliable in immunocompromised patients, who often have high titers of virus in their secretions. For example, in the semen of patients with AIDS, titers of viable virus may be greater than 10^6.

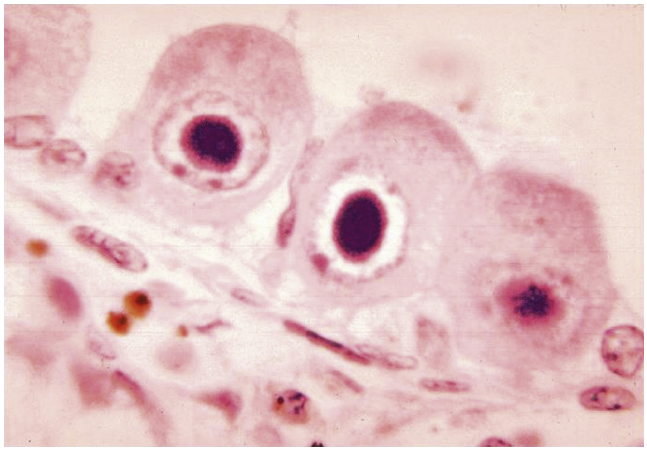

Fig. 43.17 Cytomegalovirus-infected cell with basophilic nuclear inclusion body.

TABLE 43.7 Laboratory Tests for Diagnosing Cytomegalovirus Infection

Test	Finding
Cytology and histology[a]	"Owl's-eye" basophilic nuclear inclusion body Antigen detection In situ DNA probe hybridization **PCR**[b]
Cell culture	Cytologic effect in human diploid fibroblasts (slow) Immunofluorescence detection of early antigens (faster) **PCR (fastest)**
Serology	Only for primary infection

[a]Samples taken for analysis include urine, saliva, blood, bronchoalveolar lavage specimens, and tissue biopsy specimens.
[b]most accepted approach.
PCR, Polymerase chain reaction.

More rapid results are achieved by centrifuging a patient's sample onto cells grown on a coverslip within a shell vial. Specimens are examined after 1 to 2 days of incubation by indirect immunofluorescence for the presence of one or more of the immediate early viral antigens.

Serology

Seroconversion is usually an excellent marker for primary CMV infection. Titers of CMV-specific IgM antibody may be very high in patients with AIDS. However, CMV-specific IgM antibody may also develop during the reactivation of CMV; therefore it is not a dependable indicator of primary infection.

TREATMENT, PREVENTION, AND CONTROL

Ganciclovir (dihydroxypropoxymethyl guanine), **valganciclovir** (valyl ester of ganciclovir), **cidofovir**, and **foscarnet** (phosphonoformic acid) have been approved by the U.S. Food and Drug Administration (FDA) for the treatment of specific diseases resulting from CMV infections of immunosuppressed patients (see Box 43.5). Ganciclovir is structurally similar to ACV; it is phosphorylated and activated by a CMV-encoded protein kinase, inhibits the viral DNA polymerase, and causes DNA termination (see Chapter 40). Ganciclovir is more toxic than ACV. Ganciclovir can be used to treat severe CMV infections in immunocompromised patients. Valganciclovir is a prodrug of ganciclovir that can be taken orally, is converted to ganciclovir in the liver, and has better bioavailability than ganciclovir. Cidofovir is a phosphorylated cytidine nucleoside analog that does not require a viral enzyme for activation. Foscarnet is a simple molecule that inhibits the viral DNA polymerase by mimicking the pyrophosphate portion of nucleotide triphosphates.

CMV spreads mainly by sexual, tissue transplantation, and transfusion routes; and spread by these means is preventable. Semen is a major vector for the sexual spread of CMV to both heterosexual and homosexual contacts. The use of condoms or abstinence would limit viral spread. Transmission of the virus can also be reduced through the screening of potential blood and organ donors for CMV seronegativity. Screening is especially important for donors of blood transfusions to be given to infants. Although congenital and perinatal transmission of CMV cannot effectively be prevented, a seropositive mother is least likely to produce a baby with symptomatic CMV disease. No vaccine for CMV is available.

Human Herpesviruses 6 and 7

The two variants of HHV-6, HHV-6A and HHV-6B, and HHV-7, are members of the genus *Roseolovirus* of the subfamily Betaherpesvirinae. HHV-6 was first isolated from the blood of patients with AIDS and grown in T-cell cultures. It was identified as a herpesvirus because of its characteristic morphology within infected cells. Similar to CMV, HHV-6 is lymphotropic and ubiquitous. At least 45% of the population is seropositive for HHV-6B and HHV-7 by age 2 years, and almost 100% by adulthood. HHV-6B and HHV-7 cause a common disease of children, **exanthem subitum,**

commonly known as **roseola.** HHV-7 was isolated in a similar manner from the T cells of a patient with AIDS who was also infected with HHV-6.

PATHOGENESIS AND IMMUNITY

HHV-6 infection occurs very early in life. The virus replicates in the salivary gland, is shed, and is transmitted in saliva.

HHV-6 primarily infects lymphocytes, especially CD4 T cells. HHV-6 establishes a latent infection in hematopoietic progenitor cells and T cells but may replicate on activation of the cells. Cells in which the virus is replicating appear large and refractile and have occasional intranuclear and intracytoplasmic inclusion bodies. Similar to the replication of CMV, the replication of HHV-6 is controlled by cell-mediated immunity. Similar to CMV, the virus is likely to become activated in patients with AIDS or other lymphoproliferative and immunosuppressive disorders and cause opportunistic disease.

CLINICAL SYNDROMES

Exanthem subitum, or roseola, is caused by either HHV-6B or HHV-7 and is one of the five classic childhood exanthems previously mentioned (Box 43.13 and Fig. 43.18). It is characterized by the rapid onset of high fever of a few days' duration, which is followed by a rash on the trunk and face, and then it spreads and lasts only 24 to 48 hours. The presence of infected T cells or the activation of delayed-type hypersensitivity T cells in the skin may be the cause of the rash. The disease is effectively controlled and resolved by cell-mediated immunity, but the virus establishes a lifelong latent infection of T cells. Although usually benign, HHV-6 is the most common cause of febrile seizures in childhood (aged 6 to 24 months).

HHV-6 may also cause a mononucleosis syndrome and lymphadenopathy in adults and may be a cofactor in the pathogenesis of AIDS. Similar to CMV, HHV-6A and HHV-6B may reactivate in transplant patients and contribute to graft failure. HHV-6A and HHV-6B have also been associated with multiple sclerosis, Alzheimer disease, and chronic fatigue syndrome. HHV-6 infection or reactivation is also associated with the drug reaction with eosinophilia and systemic symptoms (DRESS) syndrome.

In approximately 1% of individuals in the United States and the United Kingdom, HHV-6 is integrated into the telomeres of every chromosome and can be genetically transmitted to offspring. The virus may be reactivated by certain drugs (including antibiotics and steroids), produce virus, and may cause fatigue, cognitive dysfunction, and other problems.

BOX 43.13 Clinical Summaries

Herpes Simplex Virus

Primary oral herpes: A 5-year-old boy has an ulcerative rash with vesicles around the mouth. Vesicles and ulcers are also present within the mouth. Results of a Tzanck smear show multinucleated giant cells (syncytia) and Cowdry type A inclusion bodies. The lesions resolve after 18 days.

Recurrent oral HSV: A 22-year-old medical student studying for examinations feels a twinge at the crimson border of his lip and 24 hours later has a single vesicular lesion at the site.

Recurrent genital HSV: A sexually active 32-year-old woman has a recurrence of ulcerative vaginal lesions with pain, itching, dysuria, and systemic symptoms 48 hours after being exposed to ultraviolet B light while skiing. The lesions resolve within 8 days. Results of a Papanicolaou smear show multinucleated giant cells (syncytia) and Cowdry type A inclusion bodies.

Encephalitis HSV: A patient has focal neurologic symptoms and seizures. Magnetic resonance imaging results show destruction of a temporal lobe. Erythrocytes are present in the cerebrospinal fluid, and polymerase chain reaction is positive for viral DNA.

Varicella-Zoster Virus

Varicella (chickenpox): A 5-year-old boy develops a fever and a maculopapular rash on his abdomen 14 days after meeting with his cousin, who also developed the rash. Successive crops of lesions appear for 3 to 5 days, and the rash spreads peripherally.

Zoster (shingles): A 65-year-old woman has a belt of vesicles along the thoracic dermatome and experiences severe pain localized to the region.

Epstein-Barr Virus

Infectious mononucleosis: A 23-year-old college student develops malaise, fatigue, fever, swollen glands, and pharyngitis. After empirical treatment with ampicillin for a sore throat, a rash appears. Heterophile antibody and atypical lymphocytes are detected from blood.

Cytomegalovirus

Congenital CMV disease: A neonate exhibits microcephaly, hepatosplenomegaly, and rash. Intracerebral calcification is noted on a radiograph. The mother had symptoms similar to mononucleosis during the third trimester of her pregnancy.

Human Herpesvirus 6

Roseola (exanthem subitum): A 4-year-old child experiences a rapid onset of high fever that lasts for 3 days and then suddenly returns to normal. Two days later, a maculopapular rash appears on the trunk and spreads to other parts of the body.

CMV, Cytomegalovirus; *HSV,* herpes simplex virus.

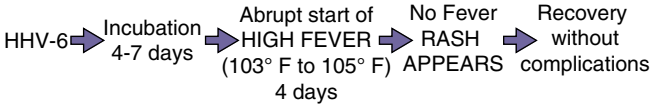

Fig. 43.18 Time course of symptoms of exanthem subitum (roseola) caused by human herpesvirus 6 *(HHV-6).* Compare these symptoms and this time course with those of fifth disease, which is caused by parvovirus B19 (see Chapter 45).

Other Human Herpesviruses

HUMAN HERPESVIRUS 8 (KAPOSI SARCOMA–ASSOCIATED HERPESVIRUS)

HHV-8 DNA sequences were discovered in biopsy specimens of **Kaposi sarcoma, primary effusion lymphoma** (a rare type of B-cell lymphoma), **and multicentric**

Castleman disease through the use of PCR analysis. Kaposi sarcoma is one of the characteristic opportunistic diseases associated with AIDS. Genome sequence analysis showed that the virus was unique and a member of the subfamily Gammaherpesvirinae. Similar to EBV, the B cell is the primary target cell for HHV-8, but the virus also infects a limited number of endothelial cells, monocytes, and epithelial and sensory nerve cells. Within the Kaposi sarcoma tumors, endothelial spindle cells contain the virus.

HHV-8 encodes several proteins that resemble human proteins and promote the growth and prevent apoptosis of the infected and surrounding cells. These proteins include an IL-6 homolog (growth and antiapoptosis), a Bcl-2 analog (antiapoptosis), chemokines, and a chemokine receptor. These proteins can promote growth and development of polyclonal Kaposi sarcoma cells in AIDS patients and others. HHV-8 DNA is present and is associated with peripheral blood lymphocytes, most likely B cells, in approximately 10% of immunocompetent people. HHV-8 is more prevalent in certain geographic areas (Italy, Greece, Africa) and in patients with AIDS. Kaposi sarcoma is the most common cancer in sub-Saharan Africa. The virus is most likely a sexually transmitted disease but may be spread by other means.

Herpesvirus simiae (B virus) (subfamily Alphaherpesvirinae, the simian counterpart of HSV) is indigenous to Asian monkeys. The virus is transmitted to humans by monkey bites or saliva, or even by tissues and cells widely used in virology laboratories. Once infected, a human may have pain, localized redness, and vesicles at the site where the virus entered. An encephalopathy develops and is often fatal; most people who survive have serious brain damage. PCR or serologic tests can be used to establish the diagnosis of B-virus infections. Virus isolation requires special facilities.

Case Studies and Questions

A 2-year-old child with fever for 2 days has not been eating and has been crying often. On examination, the physician notes that the mucous membranes of the mouth are covered with numerous shallow, pale ulcerations. A few red papules and blisters are also observed around the border of the lips. The symptoms worsen over the next 5 days and then slowly resolve, with complete healing after 2 weeks.

1. The physician suspects that this is an HSV infection. How would the diagnosis be confirmed?

2. How could you determine whether this infection was caused by HSV-1 or HSV-2?

3. What immune responses were most helpful in resolving this infection, and when were they activated?

4. HSV escapes complete immune resolution by causing latent and recurrent infections. What was the site of latency in this child, and what might promote future recurrences?

5. What were the most probable means by which the child was infected with HSV?

6. Which antiviral drugs are available for the treatment of HSV infections? What are their targets? Were they indicated for this child? Why or why not?

A 17-year-old high school student has had low-grade fever and malaise for several days, followed by sore throat, swollen cervical lymph nodes, and increasing fatigue. The patient also notes some discomfort in the left upper quadrant of the abdomen. The sore throat, lymphadenopathy, and fever gradually resolve over the next 2 weeks, but the patient's full energy level does not return for another 6 weeks.

7. What laboratory tests would confirm the diagnosis of EBV-induced infectious mononucleosis and distinguish it from CMV infection?

8. To what characteristic diagnostic feature of the disease does mononucleosis refer?

9. What causes the swollen glands and fatigue?

10. Who is at greatest risk for a serious outcome of an EBV infection? What is the outcome? Why?

Thought Question: The herpesviruses are ubiquitous and establish lifelong latent-recurrent infections. Immune responses are continuously activated to prevent recurrence. The viruses recur with different frequency depending on the person, and although the recurrence may be asymptomatic, it will elicit immune and inflammatory responses. Consider for a moment how this can influence the health of the individual over his or her lifetime. The immune stimulation may be helpful, harmful, or have no consequence. The presence of the virus within cells during latency may have no effect or may alter the growth or function of the cell.

44 Poxviruses

A goat herder has a large vesicular lesion on his index finger.

1. How does the orf virus infecting this individual resemble smallpox?
2. What was the source, and how was it acquired?
3. How is replication of this virus different from other DNA viruses?
4. Why was it possible to eradicate wild-type smallpox virus?

A 57-year-old woman who has rheumatoid arthritis and treated with a tumor necrosis factor (TNF) antagonist notices a large number of umbilicated papules on the skin of her upper thighs.

5. How does the molluscum contagiosum virus (MCV) resemble and differ from other poxviruses?
6. What was the source, and how was it acquired?
7. What other conditions increase susceptibility to this infection and presentation?

Answers to these questions are available on Student Consult.com.

Summaries Clinically Significant Organisms

POXVIRUSES

Trigger Words

Molluscum, smallpox, zoonosis, vaccinia vaccine, cytoplasmic replication

Biology, Virulence, and Disease

- Very large, enveloped with complex morphology, linear DNA genome fused at ends, virus encodes DNA-dependent RNA and DNA-dependent DNA polymerases
- Cell-mediated immunity essential for control
- Molluscum contagiosum stimulates cell growth to cause wartlike growth; only infects humans
- Smallpox: lytic, only infects humans, vesicles appear all at once, bioterror agent
- Vaccinia, orf: lytic viruses, zoonotic

Epidemiology

- Smallpox transmitted by aerosols, direct contact; all others only by contact

Diagnosis

- Polymerase chain reaction genome analysis of lesion fluid

Treatment, Prevention, and Control

- Vaccinia virus as vaccine for smallpox
- Quarantine

The poxviruses include the human viruses **variola (smallpox)** (genus *Orthopoxvirus*) and **molluscum contagiosum** (genus *Molluscipoxvirus*) and some viruses that naturally infect animals but can cause incidental infection in humans **(zoonoses).** Many of these viruses share antigenic determinants with smallpox, allowing the use of an animal poxvirus for a human vaccine.

In 18th century England, smallpox accounted for 7% to 12% of all deaths and the deaths of one-third of children. However, the development of the first live vaccine in 1796 and the later worldwide distribution of this vaccine led to eradication of smallpox by 1980. As a result, reference stocks of smallpox virus in two World Health Organization (WHO) laboratories were destroyed in 1996 after an international agreement to do so was reached. Unfortunately, smallpox did not disappear. Stocks of the virus still exist in the United States and Russia. While the world was successfully eliminating natural smallpox, the former Union of Soviet Socialist Republics (USSR) was stockpiling immense amounts of weaponized smallpox virus for biowarfare. Smallpox is considered a *category A agent* by the U.S. Centers for Disease Control and Prevention (CDC), along with anthrax, plague, botulism, tularemia, and viral hemorrhagic fevers because of their great potential as bioterrorism-biowarfare agents capable of large-scale dissemination and serious disease. The potential for these stocks of smallpox to be acquired and used by a terrorist has been the impetus to renew interest in developing new smallpox vaccine programs and antiviral drugs.

On a positive note, the vaccinia and canarypox viruses have found a beneficial use as gene delivery vectors and for the development of hybrid vaccines. These hybrid viruses contain and express the genes of other infectious agents, and infection results in immunization against both agents.

Structure and Replication

Poxviruses are the largest viruses and are almost visible on light microscopy (Box 44.1). They measure 230 × 300 nm and are ovoid to brick shaped with a complex morphology. The poxvirus virion particle must carry many enzymes, including a deoxyribonucleic acid (DNA)-dependent ribonucleic acid (RNA) polymerase, to allow viral messenger RNA (mRNA) synthesis to occur in the cytoplasm. The viral genome consists of a large, double-stranded, linear DNA that is fused at both ends. The structure and replication of vaccinia virus is representative of the other poxviruses (Fig. 44.1). The genome of vaccinia virus consists of approximately 189,000 base pairs.

The replication of poxviruses is unique among the DNA-containing viruses in that the entire multiplication cycle

takes place within the host cell cytoplasm (Fig. 44.2). Thus poxviruses must encode the enzymes required for mRNA and DNA synthesis and activities other DNA viruses normally obtain from the host cell.

After binding to a cell-surface receptor, the poxvirus outer envelope fuses with cellular membranes, either at the cell surface or within the cell. Early gene transcription is initiated on removal of the outer membrane. The virion core contains a specific transcriptional activator and all the enzymes necessary for transcription, including a multisubunit RNA polymerase, as well as enzymes for polyadenylate addition and capping mRNA. Among the early proteins produced is an uncoating protein (uncoatase) that removes the core membrane, liberating viral DNA into the cell cytoplasm. Viral DNA then replicates in electron-dense cytoplasmic inclusions (Guarnieri inclusion bodies), referred to as **factories.** Late viral mRNA for structural, virion, and other proteins is produced after DNA replication. In poxviruses, unlike other viruses, the membranes assemble around the core factories. Approximately 10,000 viral particles are produced per infected cell. Different forms of viruses are released by exocytosis or on cell lysis, but both are infectious.

MCV infection proceeds similarly to the other poxviruses but is restricted to keratinocytes, stimulates the growth of the cell, prevents apoptosis, inhibits inflammation, and is not cytolytic. Like human papillomaviruses, the virus is released when the keratinocyte matures and senesces.

BOX 44.1 Unique Properties of Poxviruses

Largest, most complex viruses.
Have complex, oval- to brick-shaped morphology with internal structure.
Have a linear, double-stranded DNA genome with fused ends.
DNA viruses that replicate in the cytoplasm.
Encodes and carries all proteins necessary for mRNA synthesis.
Also encodes proteins for functions such as DNA synthesis, nucleotide scavenging, and immune escape mechanisms.
Assembled in inclusion bodies (Guarnieri bodies; factories), where it acquires its outer membranes.

Pathogenesis and Immunity

After being inhaled, smallpox virus replicates in the upper respiratory tract (Fig. 44.3). Dissemination occurs via lymphatic and cell-associated viremic spread. Internal and dermal tissues are inoculated after a second, more intense viremia, causing simultaneous eruption of the characteristic "pocks." Molluscum contagiosum and the other poxviruses, however, are acquired through direct contact with lesions and do not spread extensively. Molluscum contagiosum stimulates cell growth and causes a wartlike lesion rather than a lytic infection.

The poxviruses encode many proteins that facilitate their replication and pathogenesis in the host. They include proteins that initially stimulate host cell growth and then lead to cell lysis and viral spread.

Cell-mediated immunity is essential for resolving a poxvirus infection. However, up to 30% of the genome of poxviruses is devoted to activities that help the virus evade immune control, including proteins that impede the interferon, complement, inflammatory, antibody, and cell-mediated protective responses. In addition, these viruses can spread cell to cell and avoid antibody. The disease mechanisms of poxviruses are summarized in Box 44.2.

Epidemiology

Smallpox and molluscum contagiosum are strictly human viruses. Smallpox is transmitted by aerosols and by contact with lesion material or by a fomite. Molluscum contagiosum is spread by direct contact (e.g., sexual contact, wrestling, self-inoculation) or by fomites (e.g., towels). In contrast, the natural hosts for the other poxviruses are vertebrates other than humans (e.g., cow, sheep, goats), and they infect humans only through accidental or occupational exposure (zoonosis). A recent outbreak of monkeypox in the United States is such an example. The infected individuals had purchased prairie dog pets that had been in contact with Gambian giant rats, which were the probable source of the virus. The revival of smallpox vaccination of military personnel has brought with it incidences of vaccine-mediated (vaccinia) disease in contacts.

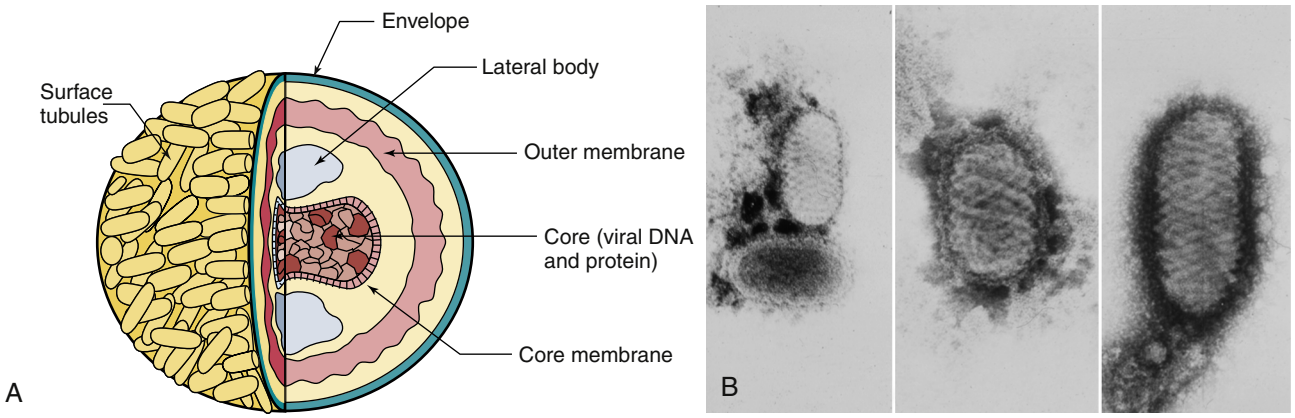

Fig. 44.1 (A) Structure of the vaccinia virus. Within the virion, the core assumes the shape of a dumbbell because of the large lateral bodies. Virions have a double membrane; the "outer membrane" assembles around the core in the cytoplasm, and the virus leaves the cell by exocytosis or on cell lysis. (B) Electron micrographs of orf virus. Note its complex structure.

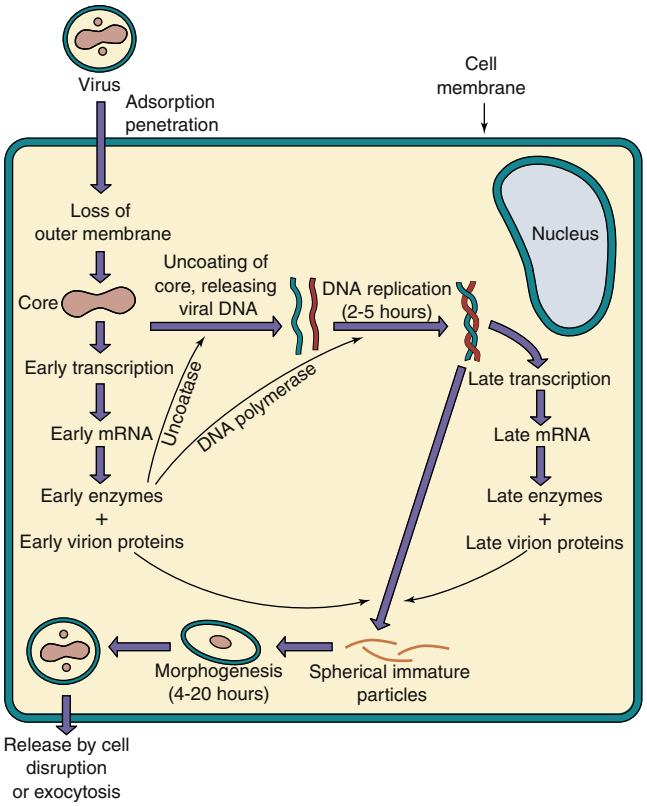

Fig. 44.2 Replication of vaccinia virus. The core is released into the cytoplasm, where virion enzymes initiate transcription of early genes. A viral-encoded "uncoatase" enzyme then causes the release of DNA. Viral polymerase replicates the genome, and late transcription occurs. DNA and protein are assembled into cores within the core membrane. An outer membrane shrouds the core containing the lateral bodies and the enzymes required for infectivity. The virion is exocytosed or is released by cell lysis.

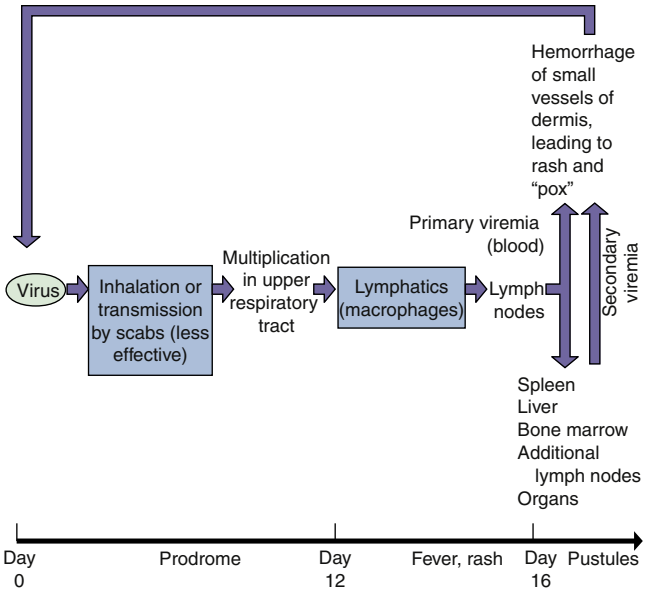

Fig. 44.3 Spread of smallpox within the body. The virus enters and replicates in the respiratory tract without causing symptoms. The virus infects macrophages, which enter the lymphatic system and carry the virus to regional lymph nodes. The virus then replicates and initiates a viremia, causing the infection to spread to the spleen, bone marrow, lymph nodes, liver, and all organs, followed by the skin (rash). A secondary viremia causes the development of additional lesions throughout the host, followed by death or recovery with or without sequelae. Recovery from smallpox was associated with prolonged immunity and lifelong protection.

Smallpox (variola) was very contagious and, as just noted, was spread primarily by the respiratory route. It was also spread less efficiently through close contact with dried virus on clothes or other materials. Despite the severity of the disease and its tendency to spread, several factors contributed to its elimination, as listed in Box 44.3.

Clinical Syndromes

The diseases associated with poxviruses are listed in Table 44.1.

SMALLPOX

The two variants of smallpox disease were variola major, which was associated with a mortality rate of 15% to 40%, and variola minor, which was associated with a mortality rate of 1%. Smallpox was usually initiated by infection of the respiratory tract, with subsequent involvement of local lymph glands, which in turn led to viremia.

The symptoms and course of the disease are presented in Fig. 44.3, and the characteristic rash is shown in Fig. 44.4. After a 5- to 17-day incubation period, the infected person experienced high fever, fatigue, severe headache, backache, and malaise, followed by the vesicular rash in the mouth

BOX 44.2 Disease Mechanisms of Poxvirus

Smallpox is initiated by respiratory tract infection and is spread mainly by the lymphatic system and cell-associated viremia.
Molluscum contagiosum and other poxviruses are transmitted by contact.
Virus may cause initial stimulation of cell growth and then cell lysis.
Virus encodes immune evasion mechanisms.
Cell-mediated immunity and humoral immunity are important for resolution.
Most poxviruses share antigenic determinants, allowing preparation of "safe" live vaccines from animal poxviruses.

BOX 44.3 Properties of Natural Smallpox That Led to Its Eradication

Viral Characteristics

Exclusive human host range (no animal reservoirs or vectors)
Single serotype (immunization protected against all infections)
Shares antigenic determinants with other pox viruses.

Disease Characteristics

Consistent disease presentation with visible pustules (identification of sources of contagion allowed quarantine and vaccination of contacts)

Vaccine

Immunization with animal poxviruses protects against smallpox
Stable, inexpensive, and easy-to-administer vaccine
Presence of scar, indicating successful vaccination

Public Health Service

Successful worldwide World Health Organization program combining vaccination and quarantine

TABLE 44.1 Diseases Associated with Poxviruses

Virus	Disease	Source	Location
Variola	Smallpox (now extinct)	Humans	Extinct
Vaccinia	Used for smallpox vaccination	Laboratory product	—
Orf	Localized lesion	Zoonosis: sheep, goats	Worldwide
Cowpox	Localized lesion	Zoonosis: rodents, cats, cows	Europe
Pseudocowpox	Milker nodule	Zoonosis: dairy cows	Worldwide
Monkeypox	Generalized disease	Zoonosis: monkeys, squirrels	Africa
Bovine papular stomatitis virus	Localized lesion	Zoonosis: calves, beef cattle	Worldwide
Tanapox	Localized lesion	Rare zoonosis: monkeys	Africa
Yabapox	Localized lesion	Rare zoonosis: monkeys, baboons	Africa
Molluscum contagiosum	Many skin lesions	Humans	Worldwide

Modified from Balows, A., Hausler, W.J., Lennette, E.H. (Eds.), 1988. Laboratory Diagnosis of Infectious Diseases: Principles and Practice, vol. 2. Springer-Verlag, New York, NY.

Fig. 44.4 Child with smallpox. Note the characteristic rash.

and soon after on the body. Vomiting, diarrhea, and excessive bleeding would quickly follow. The simultaneous outbreak of the vesicular rash distinguishes smallpox from the vesicles of varicella-zoster, which erupt in successive crops.

Smallpox was the first disease to be controlled by immunization, and its eradication is one of the greatest triumphs of public health. Eradication resulted from a massive WHO campaign to vaccinate all susceptible people, especially those exposed to anyone with the disease, interrupting the chain of human-to-human transmission. The campaign began in 1967 and succeeded. The last case of naturally acquired infection was reported in 1977, and eradication of the disease was acknowledged in 1980.

Variolation, an early approach to immunization, involved inoculation of susceptible people with the virulent smallpox pus. It was first performed in the Far East and later in England. Cotton Mather introduced the practice to America. Variolation was associated with a fatality rate of approximately 1%, which is a better risk than that associated with smallpox itself. In 1796, Jenner developed and then popularized a vaccine using the less virulent cowpox virus, which shares antigenic determinants with smallpox.

Renewed interest is being paid to antiviral drugs that are effective against smallpox and other poxviruses. Cidofovir, a nucleotide analog capable of inhibiting the viral DNA polymerase, is effective and approved for treatment of poxvirus infections. Newer, safer vaccines are being stockpiled in response to concerns regarding the use of smallpox in biowarfare.

Clinical Case 44.1 **Vaccinia Infection in Vaccinated Contacts**

The Centers for Disease Control and Prevention (CDC) (*MMWR* 56:417–419, 2007) described the case of a woman who visited the public health clinic in Alaska because the pain from vaginal tears had increased over the course of 10 days. There was no fever, itching, or dysuria. Clinical examination showed two shallow ulcers, redness, and vaginal discharge. There was no inguinal lymphadenopathy. A viral specimen from the lesion was identified by the CDC as the vaccine strain of vaccinia virus. Presence of the virus was identified by a variation of a polymerase chain reaction test, which produces characteristic vaccinia DNA fragments from the genome. Although the woman routinely insisted on using condoms during sex, a condom broke during vaginal intercourse with a new male sex partner. The male partner was in the U.S. military and had been vaccinated for smallpox 3 days before initiating his relationship with the woman. Virus from the lesion was placed on the condom or into the site. Military and other personnel are receiving vaccinia immunization for protection against weaponized smallpox. This increases the potential for unintentional transmission of the vaccinia vaccine virus. Other cases of vaccine-related vaccinia infection have included infants and individuals with atopic dermatitis, who had more severe consequences.

VACCINIA AND VACCINE-RELATED DISEASE

Vaccinia is the virus used for the smallpox vaccine (Clinical Case 44.1). Although thought to be derived from cowpox, it may be a hybrid or other poxvirus. The vaccination procedure consists of scratching live virus into the patient's skin with a bifurcated needle and then observing for the development of vesicles and pustules to confirm a "take." As the incidence of smallpox waned, however, it became apparent that there were more complications related to vaccination

Fig. 44.5 Orf lesion on the finger of a taxidermist. (Courtesy Joe Meyers, MD, Akron, Ohio.)

than cases of smallpox. Several of these complications were severe and even fatal. Therefore routine smallpox vaccination began to be discontinued in the 1970s and was totally discontinued after 1980, but it has been reintroduced for military personnel and first responders in case of biowarfare.

Complications from vaccination included encephalitis and progressive infection (vaccinia necrosum), the latter occurring occasionally in immunocompromised patients who were inadvertently vaccinated. Recent cases of vaccine-related disease have been noted in family members and contacts of immunized military personnel (see Clinical Case 44.1). The virus was transmitted to these individuals by contact with vesicular fluid. They can be treated with vaccinia immune globulin and antiviral drugs.

ORF, COWPOX, AND MONKEYPOX

Human infection with the orf (poxvirus of sheep and goat) or cowpox (vaccinia) virus is usually an occupational hazard resulting from direct contact with lesions on the animal. A single nodular lesion usually forms on the point of contact, such as the fingers, hand, or forearm, and is hemorrhagic (cowpox) or granulomatous (orf or pseudocowpox) (Fig. 44.5). Vesicular lesions frequently develop and then regress in 25 to 35 days, generally without scar formation. The lesions may be mistaken for anthrax. The virus can be grown in culture or seen directly with electron microscopy, but it is usually diagnosed from the symptoms and patient history.

The more than 100 cases of illnesses resembling smallpox have been attributed to the monkeypox virus. Except for the outbreak in Illinois, Indiana, and Wisconsin in 2003, they all have occurred in western and central Africa, especially in Zaire. Monkeypox causes a milder version of smallpox disease, including the pocklike rash.

MOLLUSCUM CONTAGIOSUM

Molluscum contagiosum is a common disease affecting 3% to 20% of the population (Box 44.4). The lesions of

BOX 44.4 Clinical Summary

Molluscum contagiosum: A 5-year-old girl has a group of wartlike growths on her arm that exude white material on squeezing.

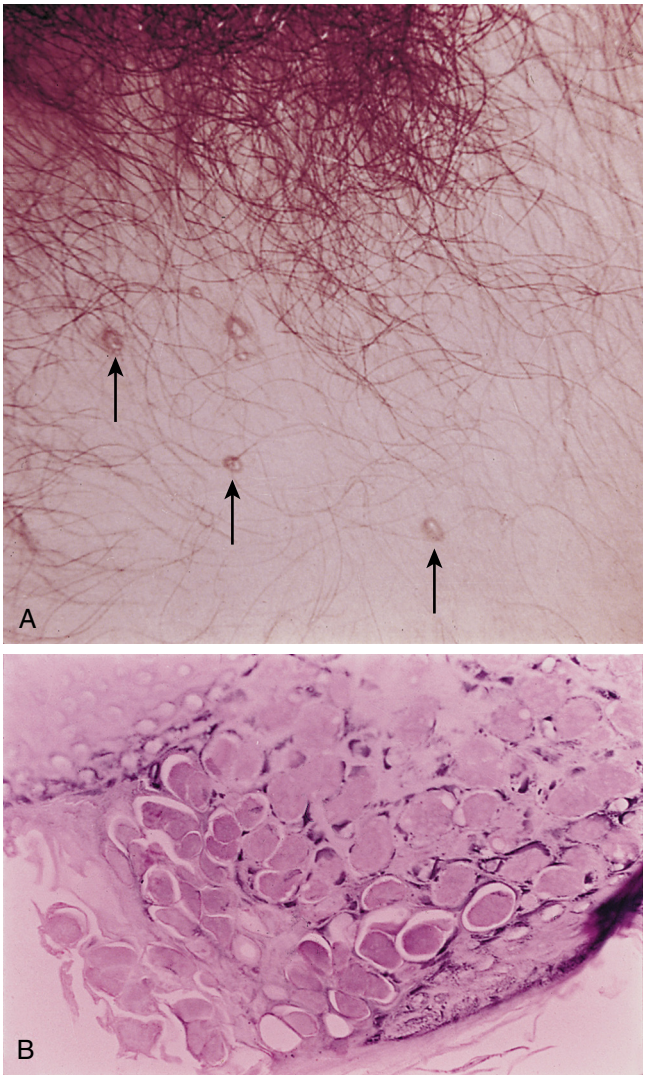

Fig. 44.6 Molluscum contagiosum. (A) Skin lesions *(arrows)*. (B) Microscopic view; epidermis is filled with molluscum bodies (magnification 100×).

molluscum contagiosum differ significantly from other pox lesions because they are nodular to wartlike (Fig. 44.6A). They begin as papules and then become pearl-like umbilicated nodules that are 2 to 10 mm in diameter and have a central caseous plug that can be squeezed out. They are most common on the trunk, genitalia, and proximal extremities and usually occur in a cluster of 5 to 20 nodules. The incubation period for molluscum contagiosum is 2 to 8 weeks. The disease is more common in children than adults, but its incidence is increasing in sexually active and immunocompromised individuals.

The diagnosis of molluscum contagiosum is confirmed histologically by the finding of characteristic large, eosinophilic, cytoplasmic inclusions (molluscum bodies) in

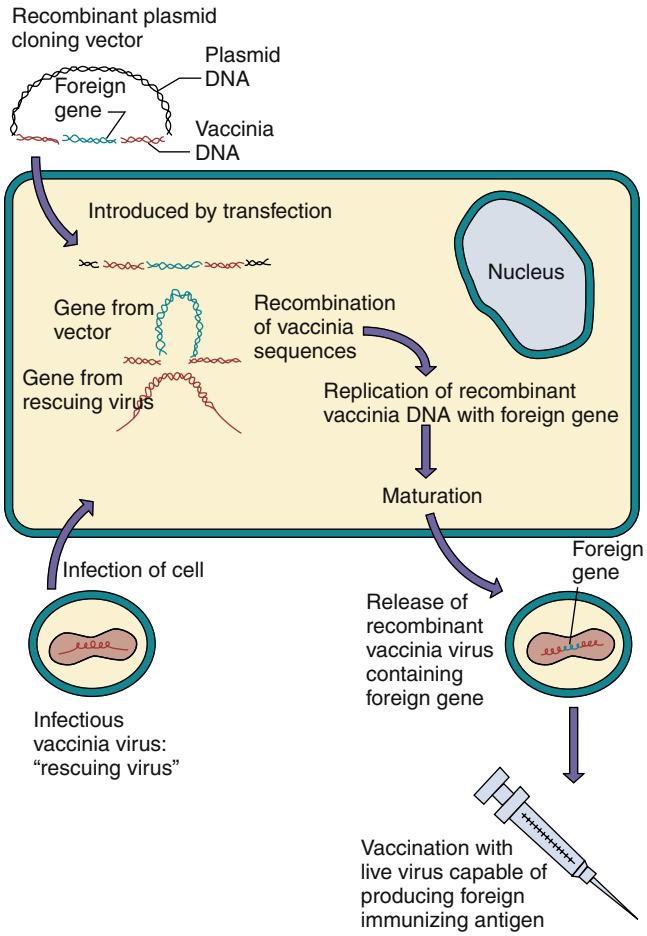

Fig. 44.7 Vaccinia virus as an expression vector for the production of live recombinant vaccines. (Modified from Piccini, A., Paoletti, E., 1988. Vaccinia: virus, vector, vaccine. Adv. Virus Res. 34, 43–64.)

epithelial cells (see Fig. 44.6B). These bodies can be seen in biopsy specimens or in the expressed caseous core of a nodule. MCV cannot be grown in tissue culture or animal models.

Lesions of molluscum contagiosum usually disappear within 2 to 12 months, presumably as a result of immune responses. The nodules can be removed by curettage (scraping) or by the application of liquid nitrogen or iodine solutions.

HYBRID POXVIRUSES FOR GENE DELIVERY AND VACCINES

The vaccinia and canarypox viruses are used as expression vectors to produce live recombinant/hybrid vaccines for more virulent infectious agents (Fig. 44.7). Immunization with the recombinant poxvirus results from expression of the foreign gene and its presentation to the immune response, almost as if by infection with the other agent. A vaccinia hybrid virus containing the G-protein of rabies virus soaked onto a bait food and dropped into forests has been used successfully to immunize raccoons, foxes, and other mammals. Experimental vaccines for human immunodeficiency virus (HIV), hepatitis B, influenza, and other viruses have also been prepared using these techniques. The potential for producing other vaccines in this manner is unlimited.

Hybrid vaccinia viruses are also being used for oncolytic agents to selectively kill tumors and for gene replacement therapy.

Questions

1. The structure of poxviruses is more complex than that of most other viruses. What problems does this complexity create for viral replication?

2. Poxviruses replicate in the cytoplasm. What problems does this feature create for viral replication?

3. How does the immune response to smallpox infection in an immunologically naive person differ from that in a vaccinated person? When is antibody present in each case? What stage or stages of viral dissemination are blocked in each case?

4. What characteristics of smallpox facilitated its elimination?

5. Vaccinia virus is being used as a vector for the development of hybrid vaccines. Why is vaccinia virus well suited to this task? Which infectious agents would be appropriate for a vaccinia hybrid vaccine, and why?

6. How does molluscum contagiosum infection resemble that of human papillomavirus?

(see https://www.clinicalkey.com/#!/content/journal/1-s2.0-S0264410X13008839).

45 Parvoviruses

A 6-year-old girl had a viral respiratory infection and then became very pale, weak, tired, and severely anemic because of a transient aplastic crisis.

1. What predisposing condition exacerbated the relatively benign disease in this child?
2. What cell type is the host for this virus, and what determines this tropism?
3. What disease signs occur after infection of an adult? Of a fetus?

Answers to these questions are available on Student Consult.com.

Summaries Clinically Significant Organisms

PARVOVIRUSES

Trigger Words

B19, fifth disease, slapped cheeks, aplastic crisis, sickle crisis, spontaneous abortions

Biology, Virulence, and Disease

- Small, icosahedral capsid, single-strand DNA genome
- Must replicate in growing cell: erythroid precursor cells

- Children: erythema infectiosum (fifth disease); high fever during viremia followed later by rash
- Individuals with chronic anemia: aplastic crisis
- Adults: arthralgia and arthritis
- Fetus: anemia-related disease and death (hydrops fetalis)

Epidemiology

- Transmitted by aerosols, direct contact

Diagnosis

- Symptomatology, confirmation by polymerase chain reaction genome analysis of blood

Treatment, Prevention, and Control

- No modes of control or treatment

The Parvoviridae are the smallest of the deoxyribonucleic acid (DNA) viruses. Their small size and limited genetic repertoire make them more dependent than any other DNA virus on the host cell, or they require the presence of a helper virus to replicate. **B19** and **bocavirus** cause human disease, and adeno-associated viruses (AAVs) are used for gene replacement therapy.

B19 normally causes **erythema infectiosum,** or **fifth disease,** which is a mild febrile exanthematous disease that occurs in children. It goes by the latter name because it was counted as one of five classic childhood exanthems (the first four being varicella, rubella, roseola, and measles). B19 is also responsible for episodes of **aplastic crisis in patients with chronic hemolytic anemia** and is associated with **acute polyarthritis** in adults. Infection of the fetus during pregnancy can result in hydrops fetalis and abortion. **Bocavirus** is a recently discovered virus that can cause acute respiratory disease, which may become severe in young children.

Other parvoviruses, such as RA-1 (isolated from a person with rheumatoid arthritis), fecal parvoviruses, and PARV4 may cause nonspecific viral symptoms and will not be discussed further. Feline and canine parvoviruses do not cause human disease and are preventable with vaccination of the pet.

AAVs are members of the genus *Dependovirus*. They commonly infect humans but replicate only in association with a second "helper" virus, which is usually an adenovirus. Dependoviruses neither cause illness nor modify infection by their helper viruses. These properties and the propensity of AAVs to integrate into the host chromosome have made genetically modified AAVs excellent candidates for use in **gene-replacement therapy.**

Structure and Replication

The parvoviruses are extremely small (18 to 26 nm in diameter) and have a nonenveloped icosahedral capsid (Fig. 45.1 and Box 45.1). The B19 virus genome contains one linear, single-stranded DNA molecule with a molecular mass of 1.5 to 1.8 × 10^6 Da (5500 bases in length) (Box 45.2). Plus or minus DNA strands are packaged separately into virions. The genome encodes three structural and two major nonstructural proteins. Unlike larger DNA viruses, the parvoviruses must infect mitotically active cells because they do not encode the means to stimulate cell growth or a polymerase. Only one serotype of B19 is known to exist.

B19 virus replicates in mitotically active cells and prefers cells of the erythroid lineage, such as fresh human bone marrow cells, erythroid cells from fetal liver, and erythroid leukemia cells (Fig. 45.2). After binding to the erythrocyte blood group P antigen (globoside) and its internalization, the virion is uncoated, and the single-stranded DNA genome is delivered to the nucleus. Factors available only during the S phase of the cell's growth cycle and cellular DNA polymerases are required to generate a complementary DNA strand.

The single-stranded DNA virion genome is converted to a double-stranded DNA version, which is required for transcription and replication. Inverted repeat sequences of DNA at both ends of the genome fold back and hybridize with the genome to create a primer for the cell's DNA polymerase. This creates the complementary strand and replicates the genome. The two major nonstructural proteins and the VP1 and VP2 structural capsid proteins are synthesized in the

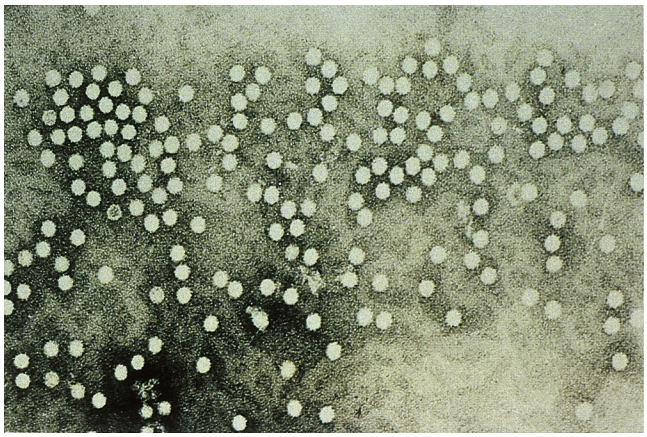

Fig. 45.1 Electron micrograph of parvovirus. Parvoviruses are small (18 to 26 nm), nonenveloped viruses with single-stranded DNA. (Courtesy Centers for Disease Control and Prevention, Atlanta, Georgia.)

BOX 45.1 Unique Properties of Parvoviruses

Smallest DNA virus
Naked icosahedral capsid
Single-stranded (+ or – sense) DNA genome
Requirement of growing cells (B19) or helper virus (dependovirus) for replication

BOX 45.2 Parvovirus Genome

Single-stranded linear DNA genome.
Approximately 5.5 kilobases in length.
Plus and minus strands packaged into separate B19 virions.
Ends of the genome have inverted repeats that hybridize to form hairpin loops and a primer for DNA synthesis.
Separate coding regions for nonstructural and structural proteins.

cytoplasm, and the structural proteins go to the nucleus, in which the virion is assembled. The VP2 protein is cleaved later to produce VP3. The nuclear and cytoplasmic membrane degenerates, and the virus is released on cell lysis.

Pathogenesis and Immunity

B19 targets and is cytolytic for erythroid precursor cells (Box 45.3). B19 disease is determined by the direct killing of these cells and the subsequent immune response to the infection (rash and arthralgia). The immunopathogenesis for B19 and rubella are similar; both are caused by immune complexes with virions, hence both cause rash and arthralgia in adults.

Studies performed in volunteers suggest that B19 virus first replicates in the nasopharynx or upper respiratory tract and then spreads by viremia to the bone marrow and elsewhere, where it replicates and kills erythroid precursor cells (Fig. 45.3). Bocavirus also initiates infection in the respiratory tract, replicates in the respiratory epithelium, and causes disease.

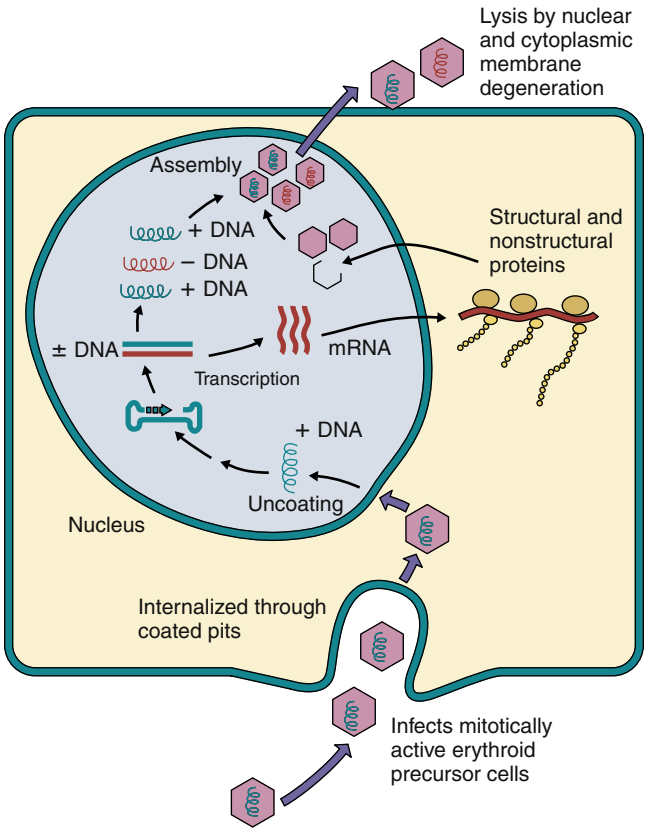

Fig. 45.2 Postulated replication of parvovirus (B19) based on information from related viruses (minute virus of mice). The internalized parvovirus delivers its genome to the nucleus, in which the single-stranded (plus or minus) DNA is converted to double-stranded DNA by host factors, and DNA polymerases present only in growing cells. Transcription, replication, and assembly occur in the nucleus. Virus is released by cell lysis.

BOX 45.3 Disease Mechanisms of B19 Parvovirus

Spreads by **respiratory** and **oral** secretions.
Infects mitotically active erythroid precursor cells in bone marrow and establishes lytic infection.
Establishes large **viremia** and can **cross the placenta.**
Antibody is important for resolution and prophylaxis.
Causes biphasic disease.
  Initial phase is related to viremia:
    Flulike symptoms and viral shedding
  Later phase is related to immune response:
    Circulating immune complexes of antibody and virions that do not fix complement
    Erythematous maculopapular rash, arthralgia, and arthritis
Depletion of erythroid precursor cells and destabilization of erythrocytes initiate **aplastic crisis in persons with chronic anemia and cause hydrops fetalis in a fetus.**

B19 viral disease has a **biphasic course.** The *initial febrile stage is the infectious stage*. During this time, erythrocyte production is stopped for approximately 1 week because of the viral killing of erythroid precursor cells. A large viremia occurs within 8 days of infection and is accompanied by nonspecific flulike symptoms. Large numbers of viruses are

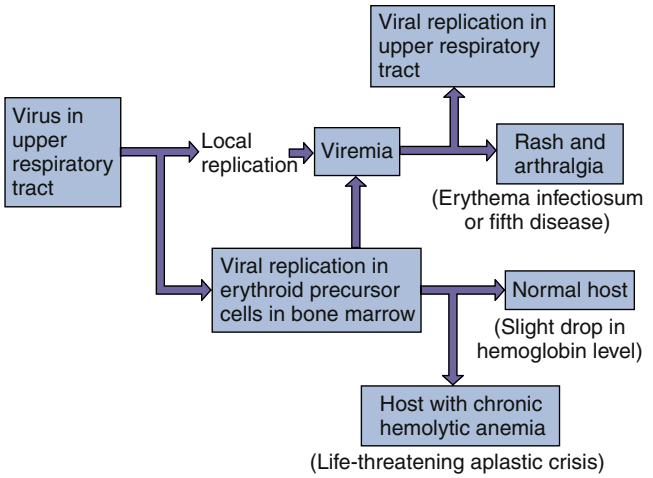

Fig. 45.3 Mechanism of spread of parvovirus within the body.

also released into oral and respiratory secretions. Antibody stops the viremia and is important for resolution of the disease but contributes to the symptoms.

The *second, symptomatic, stage is immune mediated.* The rash and arthralgia seen in this stage coincide with the appearance of virus-specific antibody, the disappearance of detectable B19 virus, and the formation of immune complexes.

Hosts with chronic hemolytic anemia (e.g., sickle cell anemia) who are infected with B19 are at risk for a life-threatening reticulocytopenia, which is referred to as **aplastic crisis.** The reticulocytopenia results from the combination of B19 depletion of red blood cell precursors and the shortened life span of erythrocytes caused by the underlying anemia.

Epidemiology

Approximately 65% of the adult population has been infected with B19 by age 40 (Box 45.4). Erythema infectiosum is most common in children and adolescents aged 4 to 15 years, who are a source of contagion. Arthralgia and arthritis are likely to occur in adults.

Respiratory droplets and oral secretions transmit the virus before the onset of the rash. Disease usually occurs in late winter and spring. Parenteral transmission of the virus by a blood clotting–factor concentrate has also been described.

Bocavirus is found worldwide and causes disease in children younger than 2 years. The virus is transmitted in respiratory secretions but also can be isolated from stool.

Clinical Syndromes

B19 virus, as stated earlier, is the cause of erythema infectiosum (fifth disease) (Box 45.5). Infection starts with an unremarkable prodromal period of 7 to 10 days during which the person is contagious. Infection of a normal host may cause either no noticeable symptoms or fever and nonspecific symptoms (e.g., fever, runny nose, sore throat, chills, malaise, myalgia, headache), as well as a slight decrease in hemoglobin levels (Fig. 45.4). This period is followed by a

BOX 45.4 Epidemiology of B19 Parvovirus Infection

Disease/Viral Factors

Capsid virus resistant to inactivation
Contagious period precedes symptoms
Virus crosses placenta and infects fetus

Transmission

Transmitted via respiratory droplets

Who Is at Risk?

Children, especially those in elementary school: erythema infectiosum (fifth disease)
Parents of children with B19 infection
Pregnant women: fetal infection and disease
Persons with chronic anemia: aplastic crisis

Geography/Season

Virus found worldwide
Fifth disease more common in late winter and spring

Modes of Control

No modes of control

BOX 45.5 Clinical Consequences of Parvovirus (B19) Infection

Mild flulike illness (fever, headache, chills, myalgia, malaise)
Erythema infectiosum (fifth disease)
Aplastic crisis in persons with chronic anemia
Arthropathy (polyarthritis: symptoms in many joints)
Risk of fetal loss (**hydrops fetalis**) as a result of B19 virus crossing the placenta, causing anemia-related disease but not congenital anomalies

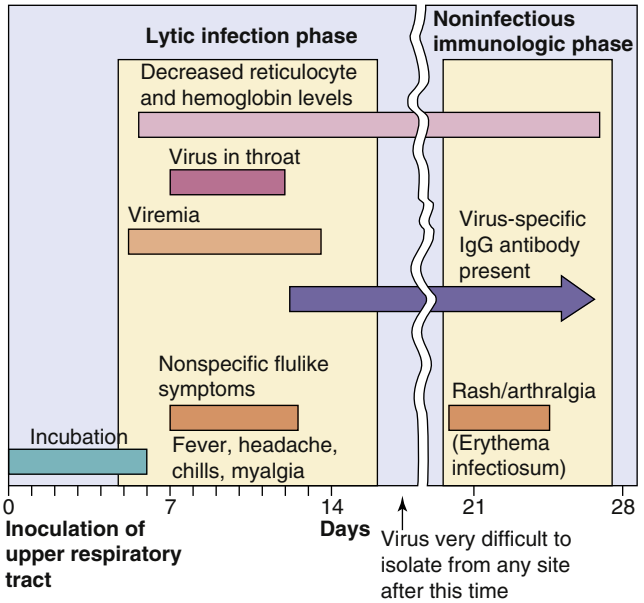

Fig. 45.4 Time course of parvovirus (B19) infection. B19 causes biphasic disease: first, an initial lytic infection phase characterized by febrile flulike symptoms, and then a noninfectious immunologic phase characterized by a rash and arthralgia. *IgG,* Immunoglobulin G.

Fig. 45.5 A "slapped-cheek" appearance is typical of the rash for erythema infectiosum. (From Hart, C.A., Broadhead, R.L., 1992. A Color Atlas of Pediatric Infectious Diseases. Wolfe, London, UK.)

Clinical Case 45.1 **B19 Infection of a Transplant Recipient**

Persistent, rather than transient, anemia occurs on human parvovirus B19 infection of immunosuppressed individuals. One such case was reported by Pamidi and associates (*Transplantation* 69:2666–2669, 2000). After 1 year of immunosuppressive therapy (mycophenolate mofetil, prednisone, and tacrolimus) after a kidney transplant, a 46-year-old man complained of dyspnea, lightheadedness, and fatigue on exercise. Laboratory tests confirmed a diagnosis of anemia. Bone marrow analysis indicated erythroid hyperplasia with a predominance of immature erythroblasts. Proerythroblasts could be found, with deep basophilic cytoplasm and intranuclear inclusions that immunohistologically stained for B19 antigen. The patient received 16 units of packed red blood cells over 6 weeks, with continued anemia. Serology indicated the presence of IgM (1:10) but insignificant IgG anti-B19 antibody. Treatment with intravenous IgG for 5 days resulted in a dramatic improvement. Immunosuppressive therapy of this patient prevented class switch to an IgG antibody response and expansion because of the lack of helper T cells. Resolution of the encapsidated parvovirus is dependent on a robust antibody response, and in its absence, the normal transient anemia resulting from virus replication in erythroid precursors cannot be resolved.

distinctive rash on the cheeks, which appear to have been slapped. The rash then usually spreads, especially to exposed skin such as the arms and legs (Fig. 45.5), and then subsides over 1 to 2 weeks (Clinical Case 45.1).

B19 infection in adults causes polyarthritis (with or without a rash) that can last for weeks, months, or longer. Arthritis of the hands, wrists, knees, and ankles predominates. The rash may precede the arthritis but often does not occur. B19 infection of immunocompromised people may result in chronic disease.

The most serious complication of parvovirus infection is the aplastic crisis that occurs in patients with chronic hemolytic anemia (e.g., sickle cell anemia). Infection in these people causes a transient reduction in erythropoiesis in the bone marrow. The reduction results in a transient reticulocytopenia that lasts 7 to 10 days and a decrease in hemoglobin level. An aplastic crisis is accompanied by fever and nonspecific symptoms such as malaise, myalgia, chills, and itching. A maculopapular rash with arthralgia and some joint swelling may also be present.

BOX 45.6 **Clinical Summary**

A 10-year-old patient has a 5-day history of a flulike illness (headache, fever, muscle pain, feels tired) and then a week later develops an intensely red rash over the cheeks and a fainter "lacy" rash over the trunk and extremities.

B19 infection of a seronegative mother increases the risk for fetal death. The virus can infect the fetus and kill erythrocyte precursors, causing anemia, edema, hypoxia, and congestive heart failure **(hydrops fetalis).** Infection of seropositive pregnant women often has no adverse effect on the fetus. There is no evidence that B19 causes congenital abnormalities (Box 45.6; see Box 45.5).

Bocavirus may cause mild or severe acute respiratory disease. The more severe disease occurs in children younger than age 2, who may have bronchiolitis with wheezing and a viremia that extends long beyond the disease. A fatal case of bocavirus bronchiolitis has been reported.

Laboratory Diagnosis

The diagnosis of erythema infectiosum is usually based on the clinical presentation. For B19 disease to be definitively diagnosed; however, specific immunoglobulin (Ig)M or viral DNA must be detected (i.e., to distinguish the rash of B19 from that of rubella in a pregnant woman). Enzyme-linked immunosorbent assays for B19 IgM and IgG are available. The polymerase chain reaction test is a very sensitive method for detecting the B19 and bocavirus genomes in clinical samples. Virus isolation is not performed.

Treatment, Prevention, and Control

No specific antiviral treatment or means of control are available. Vaccines are available for dog and cat parvoviruses.

Case Study and Questions

Mrs. Doe brought her daughter to the pediatrician with the complaint of a rash. The daughter's face appeared as if it had been slapped, but she had no fever or other notable symptoms. On questioning, Mrs. Doe reported that her daughter had had a mild cold within the previous 2 weeks and that she herself was currently having more joint pain than usual and felt very tired.

1. What features of this history indicate a parvovirus B19 etiology?

2. Was the child infectious at presentation? If not, when was she contagious?

3. What caused the symptoms?

4. Were the symptoms of the mother and daughter related?

5. What underlying condition would put the daughter at increased risk for serious disease after B19 infection? The mother?

6. Why is quarantine a poor means of limiting the spread of B19 parvovirus?

46 Picornaviruses

A 9-day-old infant with a fever and who appeared to be septic progressed to multisystem organ dysfunction syndrome with a combination of hepatitis, meningoencephalitis, myocarditis, and pneumonia. The cerebrospinal fluid (CSF) had normal glucose levels and lacked neutrophil infiltrate. The infant was started on acyclovir therapy for a suspected congenital herpes simplex virus (HSV) infection. Genome analysis (polymerase chain reaction [PCR] and reverse transcriptase [RT]-PCR) of the CSF did not detect HSV but did detect an enterovirus that was subsequently identified as echovirus 11. Several days earlier, the mother had had a slight fever and a cold.

1. How did the baby become infected?
2. How does the viral structure facilitate virus spread in the body and transmission to others?
3. What type of immunity is protective for this virus, and why was the baby not protected?

Answers to these questions are available on Student Consult.com.

Summaries Clinically Significant Organisms

PICORNAVIRUSES

Trigger Words

Polio: flaccid paralysis, major and minor disease, fecal-oral
Coxsackievirus A: vesicular diseases, meningitis; coxsackievirus B (body): pleurodynia, myocarditis
Other echovirus and enteroviruses: like coxsackievirus and hepatitis A virus
Rhinoviruses: common cold, acid labile, does not replicate above 33° C

Biology, Virulence, and Disease

- Small size, icosahedral capsid, positive RNA genome with terminal protein
- Genome is sufficient for infection
- Encodes RNA-dependent RNA polymerase, replicates in cytoplasm

ENTEROVIRUSES

- Disease caused by lytic infection of important target tissue
- Capsid virus resistant to inactivation
- Initial replication may be in the respiratory tract, oropharynx, or gastrointestinal tract but does not cause enteric disease.
- Polio: cytolytic infection of motor neurons of anterior horn and brainstem, paralysis
- Coxsackievirus A: herpangina, hand-foot-and-mouth disease, common cold, meningitis
- Coxsackievirus B: pleurodynia, neonatal myocarditis, type 1 diabetes
- Echoviruses: like coxsackievirus
- Parechoviruses: like coxsackie and major cause of neonatal viral sepsis and meningitis

HEPATOVIRUS: Hepatitis A virus[a]

- Properties like enterovirus
- Human virus
- Liver disease caused by immune response

RHINOVIRUSES

- Acid labile and cannot replicate at body temperature
- Restricted to upper respiratory tract
- Common cold

Epidemiology

- Enteroviruses transmitted by fecal-oral route and aerosols
- Rhinoviruses transmitted by aerosols and contact

Diagnosis

- Immune assays (ELISA) or RT-PCR genome analysis of blood, CSF, or other relevant sample

Treatment, Prevention, and Control

- OPV and IPV polio vaccines

[a]Hepatitis A virus is discussed in Chapter 55.
CSF, Cerebrospinal fluid; *ELISA,* enzyme-linked immunosorbent assay; *IPV,* inactivated polio vaccine; *OPV,* oral polio vaccine; *RT-PCR,* reverse transcriptase polymerase chain reaction.

Picornaviridae is one of the largest families of viruses and includes some of the most important human and animal viruses (Box 46.1). As the name indicates, these viruses are **small *(pico)*** ribonucleic acid **(RNA)** viruses that have a **naked capsid** structure. The family has more than 230 members divided into nine genera, including *Enterovirus, Rhinovirus*, *Hepatovirus* (hepatitis A virus; discussed in Chapter 55), *Cardiovirus*, and *Aphthovirus*. The enteroviruses are distinguished from the rhinoviruses by the stability of the capsid at pH 3, the optimum temperature for growth, the mode of transmission, and their diseases (Box 46.2).

At least 90 serotypes of human enteroviruses exist and are classified as polioviruses, coxsackieviruses A and B, echoviruses, parechoviruses or for the more recently discovered viruses, as numbered enteroviruses (e.g., enterovirus D68). Several different disease syndromes may be caused by a specific serotype of enterovirus. Likewise, several different serotypes may cause the same disease, depending on the target tissue affected.

The capsids of enteroviruses are *very resistant to harsh environmental conditions* (sewage systems) and the conditions in the gastrointestinal tract, which facilitates their transmission by the fecal-oral route. Although they may initiate infection in the gastrointestinal tract, the enteroviruses rarely cause enteric disease. In fact, most infections are usually asymptomatic. The best-known and most-studied picornavirus is poliovirus, of which there are three serotypes.

Coxsackieviruses are named after the town of Coxsackie, New York, in which they were first isolated. They are divided into two groups, A and B, on the basis of certain biological and antigenic differences and are further subdivided into numeric serotypes on the basis of additional antigenic differences.

BOX 46.1 Picornaviridae

Enterovirus
- Poliovirus types 1, 2, and 3
- Coxsackievirus A 24 types
- Coxsackievirus B 6 types
- Echovirus[a] 34 types
- Parechovirus 16 types
- Enterovirus 4

Hepatovirus
- Hepatitis A virus

Rhinovirus: >100 types+
Cardiovirus
Aphthovirus

[a]*E*nteric, *c*ytopathic, *h*uman, *o*rphan + virus.

BOX 46.2 Unique Properties of Human Picornaviruses

Virion is a **naked, small** (25 to 30 nm), **icosahedral** capsid enclosing a single-stranded positive RNA genome.
Enteroviruses are resistant to pH 3 to pH 9, detergents, mild sewage treatment, and heat.
Rhinoviruses are labile at acidic pH; optimum growth temperature is 33° C.
Genome is an mRNA.
Naked genome is sufficient for infection.
Virus replicates in cytoplasm.
Viral RNA is translated into **polyprotein,** which is then cleaved into enzymatic and structural proteins.
Most viruses are **cytolytic.**

mRNA, Messenger ribonucleic acid.

The name **echovirus** is derived from ***e***nteric ***c***ytopathic ***h***uman ***o***rphan because the disease associated with these agents was not initially known. Parechoviruses were thought to be echoviruses. Since 1967, newly isolated enteroviruses have been distinguished numerically.

The human **rhinoviruses** consist of at least 100 serotypes and are the major cause of the common cold. They are *sensitive to acidic pH and replicate poorly at temperatures above 33° C*. These properties usually limit rhinoviruses to causing upper respiratory tract infections.

Structure

The plus-strand RNA of the picornaviruses is surrounded by an **icosahedral capsid** that is approximately 30 nm in diameter. The icosahedral capsid has 12 pentameric vertices, each of which is composed of five protomeric units of proteins. The protomers are made of four virion polypeptides (VP1 to VP4). VP2 and VP4 are generated by the cleavage of a precursor, VP0. VP4 in the virion solidifies the structure, but it is not generated until the genome is incorporated into the capsid. This protein is released on binding of the virus to the cellular receptor. The capsids are stable in the presence of heat, acid, and detergent, with the exception of the rhinoviruses, which are labile to acid. The capsid structure is so regular that paracrystals of virions often form in infected cells (Figs. 46.1 and 46.2).

The **genome of the picornaviruses resembles a messenger RNA (mRNA)** (Fig. 46.3). It is a single strand of plus-sense RNA of approximately 7200 to 8450 bases. The genome has a polyA (polyadenosine) sequence at the 3′ end and a small protein, VPg (viral protein genome-linked; 22 to 24 amino acids), attached to the 5′ end. The polyA sequence enhances the infectivity of the RNA, and the VPg is important in packaging the genome into the capsid and initiating viral RNA synthesis. *The naked picornavirus genome is sufficient for infection if microinjected into a cell.*

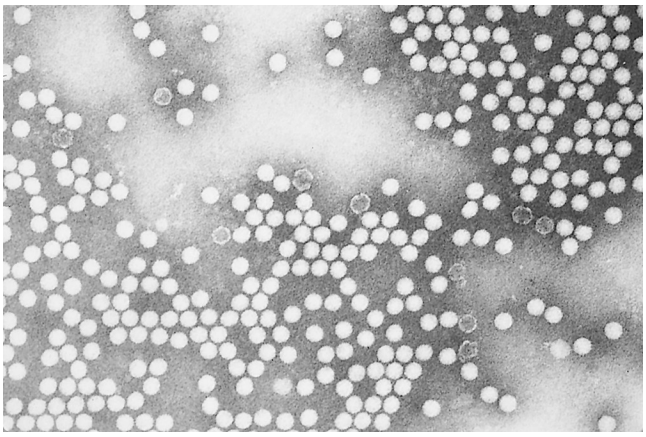

Fig. 46.1 Electron micrograph of poliovirus. (Courtesy Centers for Disease Control and Prevention, Atlanta, Georgia.)

Replication

The specificity of the picornavirus interaction for cellular receptors is the major determinant of the target tissue tropism and disease (see Fig. 36.12). The VP1 proteins at the vertices of the virion contain a canyon structure to which the receptor binds. Pleconaril and related antiviral compounds contain a 3-methylisoxazole group that binds to the floor of this canyon and alters its conformation to prevent the uncoating of the virus.

The picornaviruses can be categorized according to their cell-surface receptor specificity. The receptors for polioviruses, some coxsackieviruses, and rhinoviruses are members of the immunoglobulin superfamily of proteins. At least 80% of the rhinoviruses and several serotypes of coxsackievirus bind to the intercellular adhesion molecule-1 (ICAM-1) expressed on epithelial cells, fibroblasts, and endothelial cells. Several coxsackieviruses, echoviruses, and other enteroviruses bind to decay accelerating factor (CD55), and coxsackievirus B shares a receptor with adenovirus. Poliovirus binds to a different molecule (PVR/CD155) that is similar to the receptor for HSV. The poliovirus receptor is present on many different human cells, but not all of these cells will replicate the virus.

On binding to the receptor, the VP4 is released and the capsid is weakened. The genome is then injected directly across the membrane through a channel created by the VP1 protein at one of the vertices of the virion. The genome binds directly to ribosomes, despite the lack of a 5′-cap structure. The ribosomes recognize a unique internal RNA loop (internal ribosome entry site [IRES]) in the genome that is also present in some cellular mRNAs. A **polyprotein** containing all the viral protein sequences is synthesized within 10 to 15 minutes of infection. This polyprotein is cleaved by viral proteases encoded in it. Viral proteins tether the

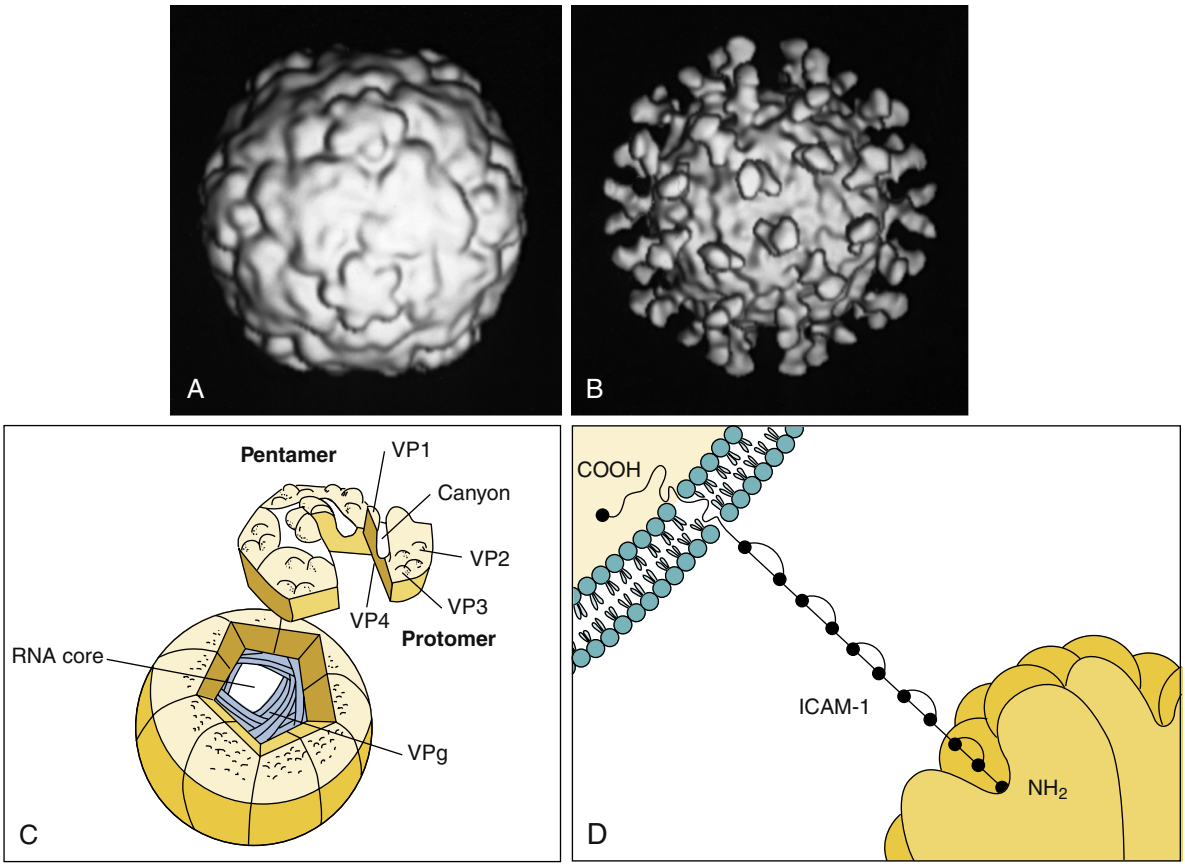

Fig. 46.2 (A) Cryoelectron microscopy computer-generated reconstruction of human rhinovirus 16. Fig. 46.3 Structure of the picornavirus genome. The genome (7200 to 8400 bases) is translated as a polyprotein that is cleaved by viral-encoded proteases into individual proteins. *Viral genes*: *VP1, 2, 3, 4,* capsid proteins 1, 2, 3, 4; *2A* cleaves eIF4g to inhibit host protein synthesis; *2B, 2C, 3A, 3B* generate membrane-binding, vesicle-forming proteins that facilitate replication; *3B* also encodes VPg genome-binding protein; *3Cpro,* protease; *RdRp,* RNA-dependent RNA polymerase. (Redrawn from Whitton, J.L., Cornell, C.T., Feuer, R., 2005. Host and virus determinants of picornavirus pathogenesis and tropism. Nat. Rev. Microbiol. 3, 765–776.)

genome to endoplasmic reticulum membranes, and the machinery for replication of the genome is collected into a vesicle. The viral RNA-dependent RNA polymerase generates a negative-strand RNA template from which the new mRNA/genome can be synthesized. The amount of viral mRNA increases rapidly in the cell, with the number of viral RNA molecules reaching as many as 400,000 per cell.

The genome encodes a polyprotein that is proteolytically cleaved by viral-encoded proteases to produce the enzymatic and structural proteins of the virus (see Fig. 46.3). In addition to the capsid proteins and VPg, the picornaviruses encode at least two proteases and an RNA-dependent RNA polymerase.

Most picornaviruses inhibit cellular RNA and protein synthesis during infection. For example, cleavage of the cell's cap-binding protein (eIF4-G) of the ribosome by a poliovirus protease prevents most cellular mRNA from binding to the ribosome. Inhibition of transcription factors decreases cellular mRNA synthesis, and permeability changes induced by picornaviruses reduce the ability of cellular mRNA to bind to the ribosome. In addition, viral mRNA can outcompete cellular mRNA for the factors required in protein synthesis. These activities contribute to the cytopathologic effect of the virus on the target cell.

As the viral genome is being replicated and translated, the structural proteins VP0, VP1, and VP3 are cleaved from the polyprotein by viral-encoded proteases and assembled into subunits. Five **subunits** associate into **pentamers,** and 12 **pentamers** associate to form the **procapsid.** After insertion of the genome, VP0 is cleaved into VP2 and VP4

to complete the **capsid.** As many as 100,000 virions per cell may be produced and released on cell lysis. The entire replication cycle may be as short as 3 to 4 hours.

Enteroviruses

PATHOGENESIS AND IMMUNITY

Contrary to their name, enteroviruses do not usually cause enteric disease, but they do replicate within and are transmitted by the fecal-oral route. The diseases produced by the enteroviruses are determined mainly by differences in tissue tropism and the cytolytic capacity of the virus (Fig. 46.4; Box 46.3). The virions are impervious to stomach acid, proteases, and bile. Enteroviruses are acquired through the upper respiratory tract and mouth. Viral replication is initiated in the mucosa and lymphoid tissue of the tonsils and pharynx, and the virus later infects M cells and lymphocytes of the Peyer patches and enterocytes in the intestinal mucosa. Primary viremia spreads the virus to receptor-bearing target tissues, including the reticuloendothelial cells of the lymph nodes, spleen, and liver, to initiate a second phase of viral replication, resulting in a secondary viremia and symptoms.

Most enteroviruses are cytolytic, replicating rapidly and causing direct damage to the target cell.

In the case of poliovirus, the virus gains access to the brain by infecting skeletal muscle and traveling up the innervating nerves to the brain, similar to the rabies virus (see Chapter 50). The virus is cytolytic for the motor neurons of the anterior horn and brainstem. The location and number of nerve cells destroyed by the virus govern the extent of paralysis and whether and when other neurons can reinnervate the muscle and restore activity. The combined loss of neurons to polio and to old age may result in paralysis later in life; this is termed **postpolio syndrome.**

Viral shedding from the oropharynx blood or the cerebral spinal fluid can be detected for a short time before and during symptoms, whereas viral production and shedding from the intestine may last for 30 days or longer, even in the presence of a humoral immune response.

Antibody is the major protective immune response to the enteroviruses. Secretory antibody can prevent the initial establishment of infection in the oropharynx and gastrointestinal tract, and serum antibody prevents viremic spread to the target tissue and therefore prevents disease. The time course for antibody development after infection with a live vaccine is presented in Fig. 46.10. Cell-mediated immunity is not usually involved in protection but may play a role in resolution and pathogenesis.

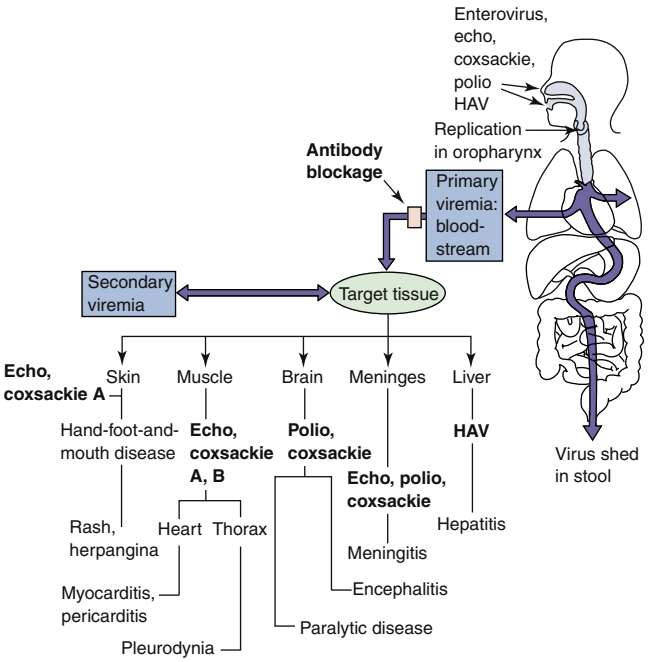

Fig. 46.4 Pathogenesis of enterovirus infection. The target tissue infected by the enterovirus determines the predominant disease caused by the virus. *Coxsackie,* Coxsackievirus; *echo,* echovirus; *HAV,* hepatitis A virus; *polio,* poliovirus.

EPIDEMIOLOGY

The enteroviruses are exclusively human pathogens (Box 46.4). As the name implies, these viruses primarily spread via the **fecal-oral** route. **Asymptomatic shedding** can occur for up to a month, putting virus into the environment. Poor sanitation and crowded living conditions foster transmission of the viruses (Fig. 46.5). Sewage contamination of water supplies can result in enterovirus epidemics. Outbreaks of enterovirus disease are seen in schools and day-care settings, and summer is the major season for such disease. The coxsackieviruses and echoviruses may also be spread in aerosol droplets and cause respiratory tract infections.

With the success of the polio vaccines, the wild-type poliovirus has been eliminated from the Western Hemisphere (Fig. 46.6) and most, but not all, of the world. Paralytic polio was never eliminated from Nigeria, Afghanistan, and Pakistan, and the viruses have spread from these countries to others. A small but significant number of vaccine-related cases of polio result from mutation in the VP1 gene of one of the three strains that reestablishes neurovirulence (circulating vaccine-derived poliovirus [cVDPV] 2) in the live vaccine virus. Infectious poliovirus is feared to remain in sewage for very long periods because of the hardy nature

BOX 46.3 Disease Mechanisms of Picornaviruses

Enteroviruses enter via the oropharynx, intestinal mucosa, or upper respiratory tract and infect the underlying lymphatic tissue; rhinoviruses are restricted to the upper respiratory tract.
In the absence of serum antibody, enterovirus spreads by viremia to cells of a receptor-bearing target tissue.
Different picornaviruses bind to different receptors, many of which are members of the immunoglobulin superfamily (i.e., intercellular adhesion molecule-1).
The infected target tissue determines the subsequent disease.
Viral, rather than immune, pathologic effects are usually responsible for causing disease.
The secretory antibody response is transitory but can prevent the initiation of infection.
Serum antibody blocks viremic spread to target tissue, preventing disease.
Enterovirus is shed in feces for long periods.
Infection is often asymptomatic or causes mild, flulike, or upper respiratory tract disease.

of the virions, extending the risk of contact and the need for vaccination programs.

Polioviruses are spread most often during the summer and autumn. Paralytic polio was once considered a middle class disease because good hygiene would delay exposure of a person to the virus until late childhood, the adolescent years, or adulthood, when infection would produce the most severe symptoms. Infection during early childhood is more likely to be asymptomatic or cause very mild disease.

BOX 46.4 Epidemiology of Enterovirus Infections

Disease/Viral Factors

Nature of disease correlates with specific enterovirus
Severity of disease correlates with age of person
Infection often asymptomatic, with viral shedding
Virion resistant to environmental conditions (detergents, acid, drying, mild sewage treatment, and heat)

Transmission

Fecal-oral route: poor hygiene, dirty diapers (especially in day-care settings)
Ingestion via contaminated food and water
Contact with infected hands and fomites
Inhalation of infectious aerosols

Who Is at Risk?

Young children: at risk for polio (asymptomatic or mild disease)
Older children and adults: at risk for polio (asymptomatic to paralytic disease)
Newborns and neonates: at highest risk for serious coxsackievirus, echovirus, and enterovirus disease

Geography/Season

Viruses have worldwide distribution; wild-type polio virtually eradicated in most countries because of vaccination programs
Disease more common in summer

Modes of Control

For polio, live oral polio vaccine (trivalent OPV) or inactivated trivalent polio vaccine (IPV) is administered
For other enteroviruses, no vaccine; good hygiene limits spread

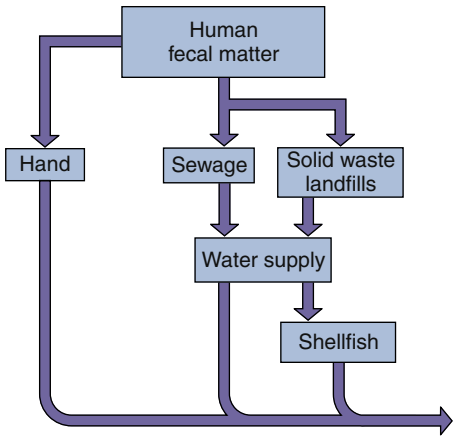

Fig. 46.5 Transmission of enteroviruses. The capsid structure is resistant to mild sewage treatment, salt water, detergents, and temperature changes, allowing these viruses to be transmitted by fecal-oral routes, by fomites, and on hands.

Similar to poliovirus infection, coxsackievirus A disease is generally more severe in adults than in children. Coxsackievirus B and some of the echoviruses (especially echovirus 11) can be particularly harmful to infants. Specific enteroviruses are attributed to causing an increased incidence of acute flaccid myelitis, resembling polio disease, in 2018.

CLINICAL SYNDROMES

The clinical syndromes produced by the enteroviruses are determined by several factors including (1) viral serotype; (2) infecting dose; (3) tissue tropism; (4) portal of entry; (5) patient's age, gender, and state of health; and (6) pregnancy (Table 46.1). The incubation period for enterovirus disease varies from 1 to 35 days, depending on the virus, the target tissue, and the person's age. Viruses that affect oral and respiratory sites have the shortest incubation periods.

Poliovirus Infections

There are three poliovirus types, with 85% of the cases of paralytic polio caused by type 1. Reversion of the attenuated vaccine virus type 2 to virulence can cause vaccine-associated disease. Wild-type polio infections are rare because of the success of polio vaccines (see Fig. 46.6). As noted earlier, however, vaccine-associated cases of polio do occur, and some populations remain unvaccinated, putting them at risk for infection. Poliovirus may cause one of the following four outcomes in unvaccinated people, depending on the progression of the infection (Fig. 46.7):

1. **Asymptomatic illness** results if the viral infection is limited to the oropharynx and the gut. At least 90% of poliovirus infections are asymptomatic.
2. **Abortive poliomyelitis, the minor illness,** is a nonspecific febrile illness occurring in approximately 5% of infected people. Fever, headache, malaise, sore throat, and vomiting occur in such persons within 3 to 4 days of exposure.
3. **Nonparalytic poliomyelitis or aseptic meningitis** occurs in 1% to 2% of patients with poliovirus infections. In this disease, the virus progresses into the central ner-

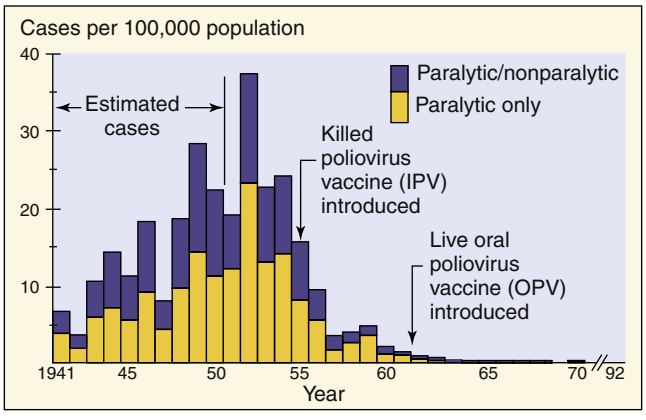

Fig. 46.6 Incidence of polio in the United States. Killed (inactivated) polio vaccine (IPV) was introduced in 1955, and live oral polio vaccine (OPV) was introduced in 1961 and 1962. Wild-type polio has been eradicated in the United States. (Courtesy Centers for Disease Control and Prevention, 1973. Against Disease: 1972. U.S. Government Printing Office, Washington, DC.)

TABLE 46.1 Summary of Clinical Syndromes Associated with Major Enterovirus Groups[a]

Syndrome	Occurrence	Polioviruses	Coxsackievirus A	Coxsackievirus B	Echo-/Enteroviruses[b]
Asymptomatic	Frequent	+	+	+	+
Paralytic disease	Sporadic	+	+	+	+ (enteroD68)
Encephalitis, meningitis	Outbreaks	+	+	+	+
Carditis	Sporadic	—	+	+	+
Neonatal disease	Outbreaks	—	—	+	+
Pleurodynia	Outbreaks	—	—	+	—
Herpangina	Common	—	+	—	—
Hand-foot-and-mouth disease	Common	—	+	—	—
Rash disease	Common	—	+	+	+
Acute hemorrhagic conjunctivitis	Epidemics	—	+		+ (entero70)
Respiratory tract infections	Common	+	+	+	+
Undifferentiated fever	Common	+	+	+	+
Diarrhea, gastrointestinal disease	Uncommon	—	—	—	+
Diabetes, pancreatitis	Uncommon	—	—	+	—
Orchitis	Uncommon	—	—	+	—

[b]Enteroviruses 68 to 71+.

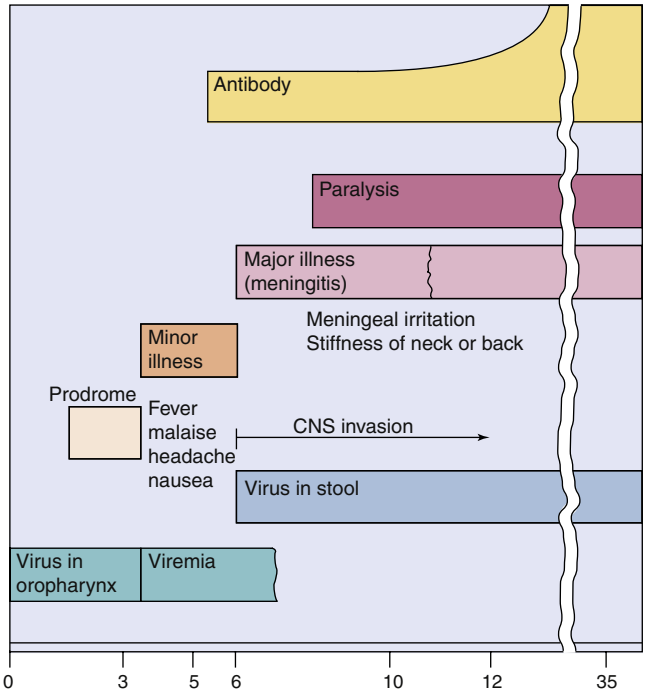

Fig. 46.7 Progression of poliovirus infection. Infection may be asymptomatic or may progress to minor or major disease. *CNS,* Central nervous system.

vous system and the meninges, causing back pain and muscle spasms in addition to the symptoms of the minor illness.

4. **Paralytic polio, the major illness,** occurs in 0.1% to 2.0% of persons with poliovirus infections and is the most severe outcome. It appears 3 to 4 days after the minor illness has subsided, producing a biphasic illness. In this disease, the virus spreads from the blood to the anterior horn cells of the spinal cord and to the motor cortex of the brain. The severity of paralysis is determined by the extent of the neuronal infection and by which neurons are affected. **Paralytic poliomyelitis** is characterized by an asymmetric flaccid paralysis with no sensory loss. The degree of paralysis varies in that it may involve only a few muscle groups (e.g., one leg) or there may be complete flaccid paralysis of all four extremities. The paralysis may then progress over the first few days and may result in complete recovery, residual paralysis, or death. Most recoveries occur within 6 months, but as long as 2 years may be required for complete remission.

Bulbar poliomyelitis can be more severe, may involve the muscles of the pharynx, vocal cords, and respiration, and may result in death in 75% of patients. Iron lungs, chambers that provided external respiratory compression, were used during the 1950s to assist the breathing of patients with such polio disease. Before vaccination programs, iron lungs filled the wards of children's hospitals.

Postpolio syndrome is a sequela of poliomyelitis that may occur much later in life (30 to 40 years later) in 29% of the original victims. Affected persons suffer a deterioration of the originally affected muscles. Poliovirus is not present, but the syndrome is believed to result from a loss of neurons in the initially affected nerves.

Coxsackievirus and Echovirus Infections

Several clinical syndromes may be caused by either a coxsackievirus or an echovirus (e.g., aseptic meningitis), but certain illnesses are specifically associated with coxsackieviruses. Coxsackievirus A is associated with diseases involving vesicular lesions (e.g., herpangina), whereas coxsackievirus B ***(B for body)*** is most frequently associated with myocarditis and pleurodynia. Coxsackieviruses,

Clinical Case 46.1 **Polio-like Disease Caused by Coxsackievirus A**

In a case reported by Yoshimura and Kurashige (*Brain Dev* 20:540–542, 1998), a 4-year-old child's onset of abdominal pain, distended abdomen, inability to urinate, and inability to walk prompted admission to the hospital. All abdominal reflexes were gone, accompanied by bladder and rectal dysfunction. Pain and temperature sense was normal. CSF showed an increase in cell count, with 393 cells/mm^3 and with 95% neutrophils and 5% lymphocytes. CSF protein and glucose were within normal values. Serologic analysis was negative for poliovirus, echovirus, and coxsackievirus types A4, A7, A9, B1, and B5, viruses reported to cause polio-like paralytic disease. Antibody for coxsackievirus A10 was detected during the acute phase (titer = 32) and after 4 weeks (titer = 128). Three weeks after admission, the child was able to walk again, but mild dysfunction of the bladder and rectum remained, even 3 months after admission. Although routine immunization has eliminated polio-induced paralysis in most parts of the world, polio-like disease can still be caused by other picornaviruses and revertants of the vaccine-related strains of polio.

CSF, Cerebrospinal fluid.

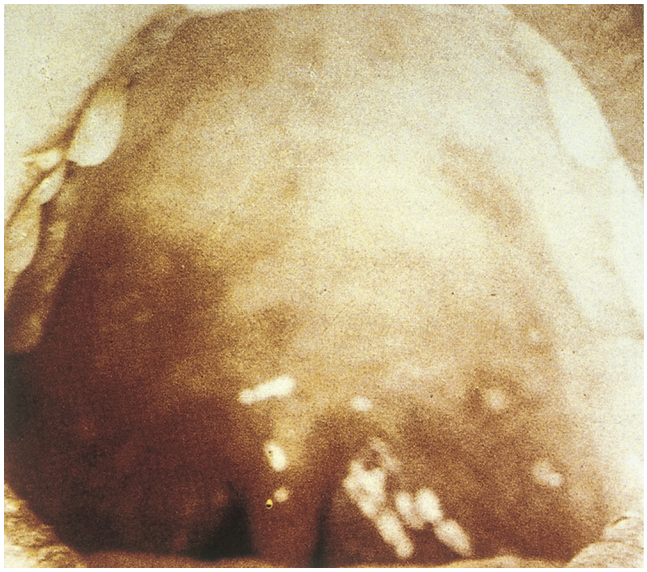

Fig. 46.8 Herpangina. Characteristic discrete vesicles are seen on the anterior tonsillar pillars. (Courtesy Dr. GDW McKendrick; from Lambert, H.P., et al., 1982. Infectious Diseases Illustrated: An integrated text and color atlas. Gower, London.)

enterovirus D68, and other picornaviruses can also cause a polio-like flacid paralytic disease (Clinical Case 46.1). The most common result of infection is lack of symptoms or a mild upper respiratory tract or flulike disease.

Herpangina is caused by several types of coxsackievirus A and is not related to a herpesvirus infection. Fever, sore throat, pain on swallowing, anorexia, and vomiting accompany this disease. The classic finding is vesicular ulcerated lesions around the soft palate and uvula (Fig. 46.8). Less typically, the lesions affect the hard palate.

Fig. 46.9 Hand-foot-and-mouth disease caused by coxsackie A virus (A) Lesions initially appear in the oral cavity and then develop within 1 day on the palms and, as seen here, the soles. (From Habif, T.P., Clinical Dermatology: A Color Guide to Diagnosis and Therapy, third ed. Mosby, St. Louis, MO.)

The virus can be recovered from the lesions or from feces. The disease is self-limited and requires only symptomatic management.

Hand-foot-and-mouth disease is a vesicular exanthem usually caused by coxsackievirus A16. The name is descriptive because the main features of this infection consist of vesicular lesions on the hands, feet, mouth, and tongue (Fig. 46.9). The patient is mildly febrile, and the illness subsides in a few days.

Pleurodynia (Bornholm disease), also known as the **devil's grip,** is an acute illness in which patients have a sudden onset of fever and unilateral low thoracic, pleuritic chest pain that may be excruciating. Abdominal pain and even vomiting may also occur, and muscles on the involved side may be extremely tender. Pleurodynia lasts an average of 4 days but may relapse after the condition has been asymptomatic for several days. Coxsackievirus B is the causative agent.

Myocardial and **pericardial infections** caused by coxsackievirus B occur sporadically in older children and adults but are most threatening in newborns. Neonates with these infections have febrile illnesses and sudden and unexplained onset of heart failure. Cyanosis, tachycardia, cardiomegaly, and hepatomegaly occur. The mortality associated with the infection is high, and autopsy typically reveals involvement of other organ systems, including the brain, liver, and pancreas. Acute benign pericarditis affects young adults but may be seen in older persons. The symptoms resemble those of myocardial infarction with fever.

Viral (aseptic) meningitis is an acute febrile illness accompanied by headache and signs of meningeal irritation, including nuchal rigidity. Petechiae or a rash may occur in patients with enteroviral meningitis. Recovery is usually uneventful unless the illness is associated with encephalitis (meningoencephalitis) or occurs in children younger than 1 year. Outbreaks of picornavirus meningitis (echovirus 11) occur each year during the summer and autumn.

Fever, rash, and common coldlike symptoms may occur in patients infected with echoviruses or coxsackieviruses. The rash is usually maculopapular but may occasionally be petechial or even vesicular. The petechial type of eruption can be confused with the rash of meningococcemia, which is life-threatening and must be treated. Enteroviral disease is usually less intense for the child than meningococcemia. Coxsackieviruses A21 and A24 and echoviruses 11 and 20 can cause rhinovirus-like symptoms resembling the common cold.

Other Enterovirus Diseases

Enterovirus 70 and a variant of coxsackievirus A24 have been associated with an extremely contagious ocular disease, **acute hemorrhagic conjunctivitis.** The infection causes subconjunctival hemorrhages and conjunctivitis. The disease has a 24-hour incubation period and resolves within 1 or 2 weeks. **Parechoviruses** (including HPeV1 and HPeV2, previously named echovirus 22 and 23) are a major cause of viral sepsis-like illness, meningitis, and sudden death in neonates and infants. Coxsackievirus A16, enterovirus-A71, and D68 have been isolated from spinal fluid of children with acute flaccid paralysis. Some strains of coxsackievirus B, echovirus, and parechovirus can be transmitted transplacentally to the fetus. Infection of the fetus or an infant by this or another route may produce severe disseminated disease. Coxsackievirus B infections of the beta cells of the pancreas are a major cause of **type 1 insulin-dependent diabetes** as a result of immune destruction of the islets of Langerhans.

LABORATORY DIAGNOSIS

Clinical Chemistry

CSF from enterovirus aseptic meningitis can be distinguished from bacterial meningitis. The CSF lacks neutrophils, and the glucose level is usually normal or slightly low. The CSF protein level is normal to slightly elevated. The CSF is rarely positive for the virus.

Culture

Polioviruses may be isolated from the patient's pharynx during the first few days of illness, from the feces for as long as 30 days, but only rarely from CSF. The virus grows well in monkey kidney tissue culture. Coxsackieviruses and echoviruses can usually be isolated from the throat and stool during infection and often from CSF in patients with meningitis. Virus is rarely isolated in patients with myocarditis because the symptoms occur several weeks after the initial infection. Coxsackievirus B can be grown on primary monkey or human embryo kidney cells. Many strains of coxsackievirus A do not grow in tissue culture but can be grown in suckling mice.

Genome and Serology Studies

The exact type of enterovirus can be determined through the use of specific antibody and antigen assays (e.g., neutralization, immunofluorescence, enzyme-linked immunosorbent assay) or RT-PCR detection of viral RNA. RT-PCR of clinical samples has become a rapid and routine method to detect the presence of an enterovirus or distinguish a specific enterovirus, depending on the primers used.

Serology can be used to confirm an enterovirus infection through detection of specific IgM or the finding of a fourfold increase in the antibody titer between the time of the acute illness and the period of convalescence. Because of their many serotypes, this approach may not be practical for detection of echovirus and coxsackievirus unless a specific virus is suspected.

TREATMENT, PREVENTION, AND CONTROL

Prevention of paralytic poliomyelitis is one of the triumphs of modern medicine. By 1979, infections with the wild-type poliovirus disappeared from the United States, with the number of cases of polio decreasing from 21,000 per year in the prevaccine era to 18 in unvaccinated patients in 1977. Similar to smallpox, polio has been targeted for elimination. Health care delivery to underdeveloped countries is more difficult, and for this reason, wild-type viral disease still exists in Africa, the Middle East, and Asia. Misinformation, misunderstanding, and political unrest in Africa and other parts of the world have also limited acceptance of polio vaccination. New worldwide vaccination programs have been developed to reach the goal.

The two types of poliovirus vaccine are (1) **inactivated polio vaccine (IPV),** developed by Jonas Salk, and (2) **live attenuated oral polio vaccine (OPV),** developed by Albert Sabin. Both vaccines incorporate the three strains of polio, are stable, are relatively inexpensive, and induce a protective antibody response (Fig. 46.10). The IPV was proven effective in 1955, but the oral vaccine took its place because it is less expensive, easy to administer, limits production of virus and virus transmission, and elicits lifelong and mucosal immunity (Table 46.2). The IPV is now favored based on its safety profile.

The OPV was **attenuated** (i.e., rendered less virulent) by passage in human or monkey cell cultures. Attenuation yielded a virus that can replicate in the oropharynx and intestinal tract but cannot infect neuronal cells. The vaccine elicits IgA and IgG that can stop virus spread in and from the gut as well as spread within the body. A mixed blessing of the live vaccine strain is that it is shed in feces for weeks and may be spread to close contacts. The spread will immunize or reimmunize close contacts, promoting mass immunization. The major drawbacks of the live vaccine are that (1) the vaccine virus may infect an immunologically compromised person, and (2) there is a remote potential for the virus to revert to its virulent form and cause paralytic disease (less than 1 per 4 million doses administered versus 1 in 100 persons infected with the wild-type poliovirus).

In the absence of wild-type poliovirus, IPV has less potential for vaccine-related disease and is the vaccine of choice for routine vaccination. Children should receive the IPV at 2 months, 4 months, and 15 months and then at 4 to 6 years of age. In addition, with the elimination of wild-type polio, the next step is to stop the use of the oral vaccine to eliminate all polio from the world.

There are no vaccines for other enteroviruses. Transmission of these viruses can presumably be reduced by improvements in hygiene and living conditions. Enteroviruses are impervious to most common disinfectants and detergents but can be inactivated by formaldehyde, hypochlorite, and chlorine.

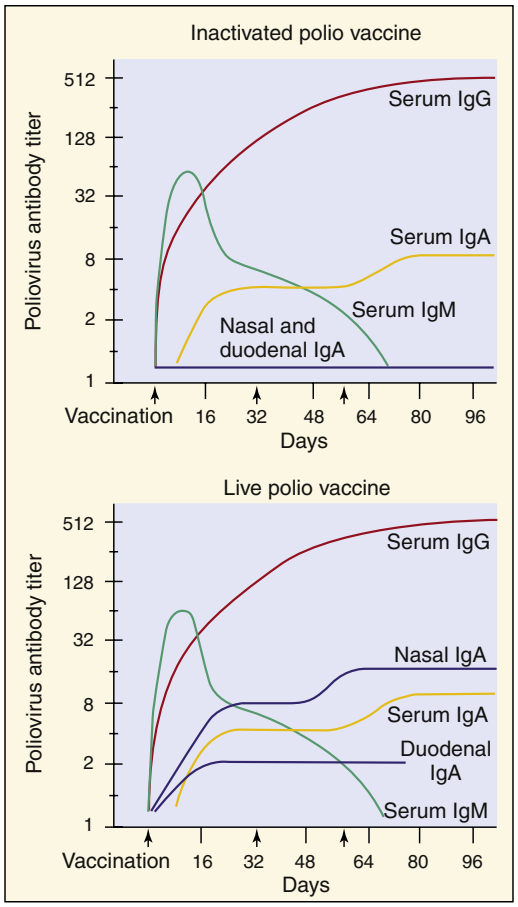

Fig. 46.10 Serum and secretory antibody response to intramuscular inoculation of inactivated polio vaccine (IPV) and to oral live attenuated polio vaccine (OPV). Note the presence of secretory IgA induced by the OPV. *Ig,* Immunoglobulin. (Modified from Ogra, P., Fishaut, M., Gallagher, M.R., 1980. Viral vaccination via the mucosal routes. Reviews of Infectious Diseases 2:352–369. Copyright 1980, University of Chicago Press.)

TABLE 46.2 Advantages and Disadvantages of Polio Vaccines

Vaccine	Advantages	Disadvantages
OPV	Effective Lifelong immunity Induction of secretory antibody response similar to that of natural infection Prevents spread of virus in feces Spread of attenuated virus to contacts promotes indirect immunization Inexpensive and easy to administer No need for repeated booster vaccine Herd immunity	Risk of vaccine-associated poliomyelitis in vaccine recipients or contacts; spread of vaccine to contacts without their consent Not safe for administration to immunodeficient patients
IPV	Effective Good stability during transport and in storage Safe administration in immunodeficient patients No risk of vaccine-related disease	Lack of induction of secretory antibody Booster vaccine needed for lifelong immunity Requires sterile syringes and needles Injection more painful than oral administration Higher community immunization levels needed than with live vaccine Does not prevent replication and spread of virus from gastrointestinal tract

IPV, Inactive polio vaccine; *OPV,* live oral polio vaccine.

Rhinoviruses

Rhinoviruses are the most important cause of the **common cold** and upper respiratory tract infections. Such infections are self-limited, however, and do not cause serious disease. More than 100 serotypes of rhinovirus have been identified. At least 80% of the rhinoviruses have a common receptor that is also used by some of the coxsackieviruses. This receptor has been identified as ICAM-1, which is a member of the immunoglobulin superfamily and is expressed on epithelial, fibroblast, and B-lymphoblastoid cells.

PATHOGENESIS AND IMMUNITY

Unlike the enteroviruses, rhinoviruses are **unable to replicate in the gastrointestinal tract**. The rhinoviruses are **labile to acidic pH.** Also, they **grow best at 33° C,** a feature that contributes to their preference for the cooler environment of the nasal mucosa. Infection can be initiated by as little as one infectious viral particle. During the peak of illness, nasal secretions contain concentrations of 500 to 1000 infectious virions per milliliter. The virus enters through the nose, mouth, or eyes and initiates infection of the upper respiratory tract, including the throat. Most viral replication occurs in the nose, and the onset and severity of the symptoms correlate with the time of viral shedding and quantity (titer) of virus shed. Infected cells release bradykinin and histamine, which cause a "runny nose."

Interferon, which is generated in response to the infection, may limit progression of the infection and contribute to the symptoms. Immunity to rhinoviruses is transient and unlikely to prevent subsequent infection (because of the numerous serotypes of the virus). Both nasal secretory IgA and serum IgG serotype specific antibody are induced by a primary rhinovirus infection and can be detected within a week of infection. The protective secretory IgA response dissipates quickly, and immunity begins to wane approximately 18 months after infection. Cell-mediated immunity is not likely to play an important role in controlling rhinovirus infections.

EPIDEMIOLOGY

Rhinoviruses cause at least half of all upper respiratory tract infections (Box 46.5). Other agents likely to cause the symptoms of the common cold are enteroviruses, coronaviruses, adenoviruses, and parainfluenza viruses. Rhinoviruses can be transmitted by two mechanisms: as aerosols and on fomites (e.g., by hands or on contaminated inanimate objects). Hands appear to be the major vector, and direct person-to-person contact is the predominant mode of spread. These nonenveloped viruses are extremely stable and can survive on such objects for many hours.

BOX 46.5 Epidemiology of Rhinovirus Infections

Disease/Viral Factors

Virion is resistant to drying and detergents
Multiple serotypes preclude prior immunity
Replication occurs at optimum temperature of 33° C and cooler temperatures

Transmission

Direct contact via infected hands and fomites
Inhalation of infectious droplets

Who Is at Risk?

Persons of all ages

Geography/Season

Virus found worldwide
Disease more common in early autumn and late spring

Modes of Control

Washing hands and disinfecting contaminated objects help prevent spread

BOX 46.6 Clinical Summaries

Poliovirus

Polio: A 12-year-old girl from Nigeria has headache, fever, nausea, and stiff neck. Symptoms improve and then recur several days later, with weakness and paralysis of her legs. She has no history of polio immunization.

Coxsackievirus A

Herpangina: Vesicular lesions on the tongue and roof of the mouth of a 7-year-old patient accompany fever, sore throat, and pain on swallowing.

Coxsackievirus B (B for body)

Pleurodynia: A 13-year-old boy has fever and severe chest pain with headache, fatigue, and aching muscles lasting for 4 days.

Coxsackievirus or Echovirus

Aseptic meningitis: A 7-month-old infant with fever and rash appears listless, with a stiff neck. A sample of his cerebrospinal fluid contains lymphocytes but has normal glucose and no bacteria. Full recovery occurs within 1 week.

Rhinovirus

Common cold: A 25-year-old office worker develops a runny nose, mild cough, and malaise with a low-grade fever. A coworker has had similar symptoms for the past few days.

Rhinoviruses produce clinical illness in only half of the persons infected. Asymptomatic persons are also capable of spreading the virus, even though they may produce less of it.

Rhinovirus "colds" occur most often in early autumn and late spring in persons living in temperate climates. This may reflect social patterns (e.g., return to school and day care) rather than any change in the virus itself.

Rates of infection are highest in infants and children. Children younger than 2 years "share" their colds with their families. Secondary infections occur in approximately 50% of family members, especially other children.

Many different rhinovirus serotypes may be found in a given community during a specific cold season, but the predominant strains are usually the newly categorized serotypes. This pattern indicates the existence of a gradual antigenic drift (mutation) similar to that seen for the influenza virus.

CLINICAL SYNDROMES

Common cold symptoms caused by rhinoviruses cannot readily be distinguished from those caused by other viral respiratory pathogens (e.g., enteroviruses, paramyxoviruses, coronaviruses) (Box 46.6). An upper respiratory tract infection usually begins with sneezing, which is soon followed by rhinorrhea (runny nose). The rhinorrhea increases and is then accompanied by symptoms of nasal obstruction. Mild sore throat also occurs, along with headache and malaise but usually without fever. The illness peaks in 3 to 4 days, but the cough and nasal symptoms may persist for 7 to 10 days or longer.

LABORATORY DIAGNOSIS

The clinical syndrome of the common cold is usually so characteristic that laboratory diagnosis is unnecessary. Virus can be obtained from nasal washings. Rhinoviruses are grown in human diploid fibroblast cells (e.g., WI-38) at 33° C. Virus is identified by the typical cytopathologic effect and the demonstration of acid lability. Serotyping is rarely necessary but can be performed with the use of pools of specific neutralizing sera. Identification can also be made by genome analysis by RT-PCR. The performance of serologic testing to document rhinovirus infection is not practical.

TREATMENT, PREVENTION, AND CONTROL

There are many over-the-counter remedies for the common cold. Nasal vasoconstrictors may provide relief, but their use may be followed by rebound congestion and a worsening of symptoms. Inhaling hot, humidified air, and even the steam from hot chicken soup, may actually help by increasing nasal drainage.

No antiviral drugs are available for picornavirus disease. Pleconaril and similar experimental antiviral drugs (e.g., arildone, rhodanine, disoxaril) contain a 3-methylisoxazole group that inserts into the base of the receptor-binding canyon and blocks uncoating of the virus. Enviroxime inhibits the viral RNA-dependent RNA polymerase. Rhinovirus is not a good candidate for a vaccine program. The multiple serotypes and other causes of the common cold, the apparent antigenic drift in rhinoviral antigens, the requirement for secretory IgA production, and the transience of the antibody response pose major problems for vaccine development. In addition, the benefit-to-risk ratio would be very low because rhinoviruses do not cause significant disease.

Handwashing and disinfection of contaminated objects are the best means of preventing viral spread. Virucidal facial tissues impregnated with citric acid may also limit rhinovirus spread.

Case Study and Questions

A 6-year-old girl was brought to the doctor's office at 4:30 p.m. because she had a sore throat, had been unusually tired, and was napping excessively. Her temperature was 39° C. She had a sore throat, enlarged tonsils, and a faint rash on her back. At 10:30 p.m., the patient's mother reported that the child had vomited three times, continued to nap excessively, and complained of a headache when awake. The doctor examined the child at 11:30 p.m. and noted that she was lethargic and aroused only when her head was turned, complaining that her back hurt. Her CSF contained no red blood cells, but there were 28 white blood cells/mm^3, half polymorphonuclear neutrophils and half lymphocytes. The glucose and protein levels in the CSF were normal, and Gram stain of a specimen of CSF showed no bacteria.

1. What were the key signs and symptoms in this case?
2. What was the differential diagnosis?
3. What signs and symptoms suggested an enterovirus infection?
4. How would the diagnosis be confirmed?
5. What were the most likely sources and means of infection?
6. What were the target tissue and mechanism of pathogenesis?

47 Coronaviruses and Noroviruses

A 17-year-old student complains that he has a cold.

1. What are the possible causes?
2. What properties of the virus restrict the infection to the upper respiratory tract?
3. How is it transmitted and acquired?

A day after eating burritos at a fast food restaurant, several medical students complained of serious diarrhea, nausea, vomiting, and a mild fever for 2 days. Other patrons also had gastroenteritis.

4. What are the likely causes of the gastroenteritis? How does the 24-hour incubation period help narrow down the diagnosis?
5. How does this agent cause diarrhea?
6. What is the best means of detecting the agent?

Answers to these questions are available on Student Consult.com.

Summaries Clinically Significant Organisms

CORONAVIRUSES

Trigger Words

Common cold, SARS, MERS

Biology, Virulence, and Disease

- Medium size, enveloped, (+) RNA genome
- Detergent resistant because of glycoprotein corona (exception to the rule for enveloped viruses)
- Encodes RNA-dependent RNA polymerase, replicates in cytoplasm
- Most coronaviruses cannot replicate at body temperature, restricted to upper respiratory tract
- Most coronaviruses cause the common cold
- MERS and SARS can replicate at 37° C and cause severe pneumonias

Epidemiology

- Transmitted by aerosols, direct contact, fecal oral, contaminated swimming pools

Diagnosis

- Symptomatology, RT-PCR genome analysis, or respiratory secretions

Treatment, Prevention, and Control

- Quarantine for SARS, MERS

NOROVIRUSES (CALICIVIRIDAE)

Trigger Words

Outbreaks of diarrhea, cruise ships, watery diarrhea, vomiting

Biology, Virulence, and Disease

- Small size, capsid, (+) RNA genome
- Very resistant to environment, including detergents and other disinfectants
- Encodes RNA-dependent RNA polymerase, replicates in cytoplasm
- Damages intestinal brush border
- Diarrhea with nausea and vomiting

Epidemiology

- Transmitted by fecal-oral route, in contaminated foods and water; very resistant to inactivation

Diagnosis

- Symptomatology, RT-PCR genome analysis

Treatment, Prevention, and Control

- Supportive care

MERS, Middle East respiratory syndrome; *RT-PCR,* reverse transcriptase-polymerase chain reaction; *SARS,* severe acute respiratory syndrome.

Coronaviruses

Coronaviruses are named for the solar corona–like appearance (the surface projections) of their virions when viewed with an electron microscope (Fig. 47.1). Coronaviruses are the second most prevalent cause of the **common cold** (rhinoviruses are the first). Coronaviruses have caused outbreaks of **severe acute respiratory syndrome coronavirus (SARS-CoV)** in China and the Middle East (Middle East respiratory syndrome coronavirus [**MERS-CoV**]). Electron microscopic findings have also linked coronaviruses to gastroenteritis in children and adults.

STRUCTURE AND REPLICATION

Coronaviruses are **enveloped virions** with the longest **positive (+) ribonucleic acid (RNA)** genome. Virions measure 80 to 160 nm in diameter (Box 47.1). The glycoproteins on the surface of the envelope appear as club-shaped projections that appear as a halo (corona) around the virus. Unlike most enveloped viruses, the "corona" formed by the glycoproteins allows the virus to endure the conditions in the gastrointestinal tract and be spread by the fecal-oral route.

The large plus-stranded RNA genome (27,000 to 30,000 bases) associates with the N protein to form a helical nucleocapsid. Protein synthesis occurs in two phases, similar to that of the togaviruses. On infection, the genome is translated to produce a polyprotein that is cleaved to produce an RNA-dependent RNA polymerase (L [225,000 Da]) and other proteins. Transcription and replication of the genome occurs within membrane vesicles created by viral proteins. The L protein produces and then uses a negative-sense template RNA to replicate new genomes and produce five to seven **individual messenger RNAs (mRNAs)** for the individual viral proteins.

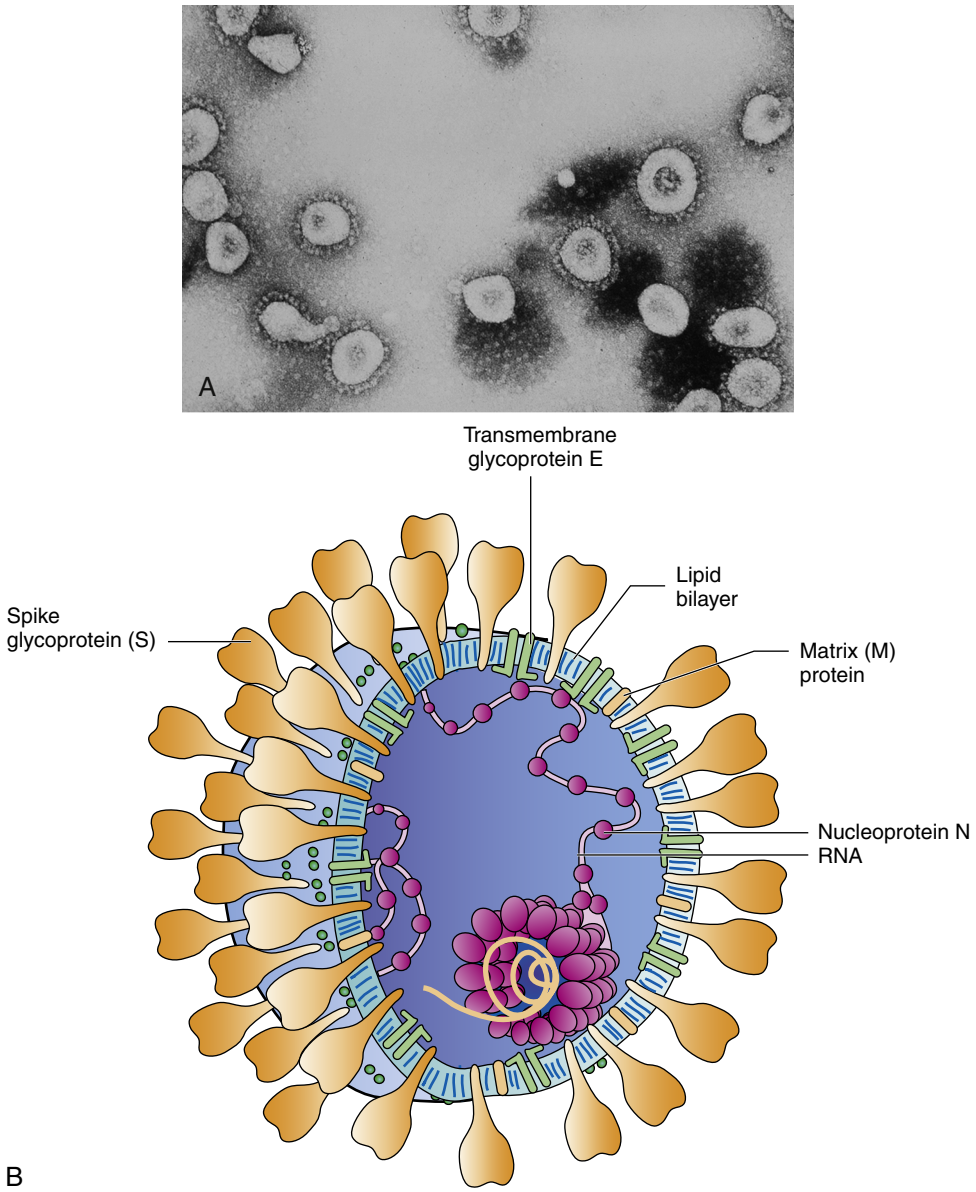

Fig. 47.1 (A) Electron micrograph of the human respiratory coronavirus (magnification 90,000×). (B) Model of a coronavirus. The viral nucleocapsid is a long, flexible helix composed of the positive-strand genomic RNA and many molecules of the phosphorylated nucleocapsid protein N. The viral envelope consists of a lipid bilayer derived from the intracellular membranes of the host cell, two or three viral glycoproteins (Spike [S], E, possibly hemagglutinin-esterase [HE]), and a matrix protein. (A, Courtesy Centers for Disease Control and Prevention, Atlanta, Georgia. B, Modified from Fields, B.F., Knipe, D.M., 1985. Virology. Raven, New York, NY.)

Virions contain the glycoproteins E1 (20,000 to 30,000 Da) and E2 (160,000 to 200,000 Da) and a core nucleoprotein (N [47,000 to 55,000 Da]); some strains also contain a hemagglutinin neuraminidase (E3 [120,000 to 140,000 Da]) (Table 47.1). The E2 glycoprotein is responsible for mediating viral attachment and membrane fusion and is the target of neutralizing antibodies. The E1 glycoprotein is a transmembrane matrix protein. The replication scheme for coronaviruses is shown in Fig. 47.2.

PATHOGENESIS AND CLINICAL SYNDROMES

Most human coronaviruses have an *optimum temperature for viral growth of 33° C to 35° C;* therefore infection remains localized to the upper respiratory tract. Animal coronaviruses, including SARS-CoV and MERS-CoV, can replicate at 37° C and cause systemic disease in humans. Coronaviruses cause cytolytic infections and when inoculated into the respiratory tracts of human volunteers, they infect and disrupt the function of ciliated epithelial cells (Box 47.2).

The virus is most likely spread by aerosols. Most human coronaviruses cause an upper respiratory tract infection, accounting for approximately 10% to 15% of upper respiratory tract infections in humans. The disease is similar to the common cold caused by rhinoviruses but with a longer incubation period (average, 3 days). The infection may exacerbate a preexisting chronic pulmonary disease, such as asthma or bronchitis, and on rare occasions may cause pneumonia.

BOX 47.1 Unique Features of Coronaviruses

Virus has medium-sized virions with a solar corona–like appearance.
Single-stranded, positive-sense RNA genome is enclosed in an envelope containing the E2 viral attachment protein, E1 matrix protein, and N nucleocapsid protein.
Translation of genome occurs in two phases: (1) the early phase produces an RNA polymerase (L), and (2) the late phase, from a negative-sense RNA template, yields structural and nonstructural proteins.
Virus assembles at the rough endoplasmic reticulum.
Virus is difficult to isolate and grow in routine cell culture.

Infections occur mainly in infants and children. Coronavirus disease appears either sporadically or in outbreaks in the winter and spring. Usually, one strain predominates in an outbreak. Antibodies to coronaviruses are uniformly present by adulthood, but reinfections are common, despite the preexisting serum antibodies.

Coronavirus-like particles have also been seen in electron micrographs of stool specimens obtained from adults and children with diarrhea and gastroenteritis and in infants with neonatal necrotizing enterocolitis.

SARS-CoV and MERS-CoV are zoonoses. The outbreaks of these viral diseases have occurred when the animal reservoir has come in contact with man. SARS-CoV and MERS-CoV are cytolytic viruses that can replicate at body temperatures in epithelial cells, lymphocytes, and leukocytes. A combination of viral pathogenesis and immunopathogenesis causes significant lung, kidney, liver, and gastrointestinal tissue damage and depletion of immune cells.

SARS is a form of atypical pneumonia characterized by high fever (>38° C), chills, rigors, headache, dizziness, malaise, myalgia, cough, or breathing difficulty, leading to acute respiratory distress syndrome. Up to 20% of patients will also develop diarrhea. Persons with SARS were exposed within the previous 10 days. Mortality is at least 10% of symptomatic people. Although SARS-CoV is most likely transmitted in respiratory droplets, it is also present in sweat, urine, and feces.

The outbreak of SARS started in November 2002 in South China's Guangdong Province, was brought to Hong Kong by a physician working within the original outbreak, and then was brought to Vietnam, Toronto, and other places by travelers. The virus was shown to be a coronavirus by its electron microscopic morphology and by RT-PCR. The virus apparently jumped to man from animals (masked-palm civets, raccoon dogs, and Chinese ferret badgers) raised for food. A World Health Organization (WHO) global alert prompted containment measures to control the spread of the virus and limited the outbreak to 8000 known diseased individuals, but there were at least 784 deaths. Travel restrictions and public concern resulted in a loss of hundreds of millions of dollars in travel and other business.

MERS-CoV also causes acute respiratory distress syndrome, with a 50% mortality of those identified as infected with MERS. Most of the cases of MERS have occurred in the Arabian Peninsula. Bats and camels are the natural reservoirs of MERS-CoV.

Table 47.1 Major Human Coronavirus Proteins

Proteins	Molecular Weight (kDa)	Location	Functions
E2 (peplomeric glycoprotein)	160-200	Envelope spikes (peplomer)	Binding to host cells; fusion activity
H1 (hemagglutinin protein)	60-66	Peplomer	Hemagglutination
N (nucleoprotein)	47-55	Core	Ribonucleoprotein
E1 (matrix glycoprotein)	20-30	Envelope	Transmembrane protein
L (polymerase)	225	Infected cell	Polymerase activity

Modified from Balows, A., Hausler, W.J., Lennette, E.H., et al., 1998. Laboratory Diagnosis of Infectious Diseases: Principles and Practice. Springer-Verlag, New York, NY.

LABORATORY DIAGNOSIS

Laboratory tests are not routinely performed to diagnose coronavirus infections other than for SARS and MERS. RT-PCR is the method of choice for detection of the viral RNA genome in respiratory and stool samples. Virus isolation of the coronaviruses is difficult and for SARS-CoV and MERS-CoV requires stringent biosafety level 3 (BSL-3) conditions.

TREATMENT, PREVENTION, AND CONTROL

Control of respiratory transmission of the common cold form of coronavirus would be difficult and is probably unnecessary because of the mildness of the infection. Strict quarantine of infected individuals and screening for fever in travelers from a region with an outbreak of SARS-CoV and MERS-CoV limit the spread of these viruses. No vaccine or specific antiviral therapy is available.

Noroviruses

Norovirus is the most common cause of foodborne disease outbreaks in the United States. The noroviruses are members of the Caliciviridae family, which like astroviruses, are small, round gastroenteritis viruses. Norwalk virus, the prototypical norovirus, was discovered during an epidemic of acute gastroenteritis in Norwalk, Ohio, in 1968 on electron microscopic examination of stool samples from adults. Many of the other viruses in this family also bear the names of the geographic locations in which they were identified (Box 47.3).

STRUCTURE AND REPLICATION

Noroviruses resemble and are approximately the same size as the picornaviruses. Their **positive-sense RNA genome** (≈7500 bases) has a VPg protein (viral protein genome-linked) and a 3′ terminal polyadenylate sequence similar to picornaviruses. The genome is contained in a 27-nm **naked capsid** consisting of 60,000-Da capsid proteins. Norwalk virion capsid is icosahedral with a ragged outline.

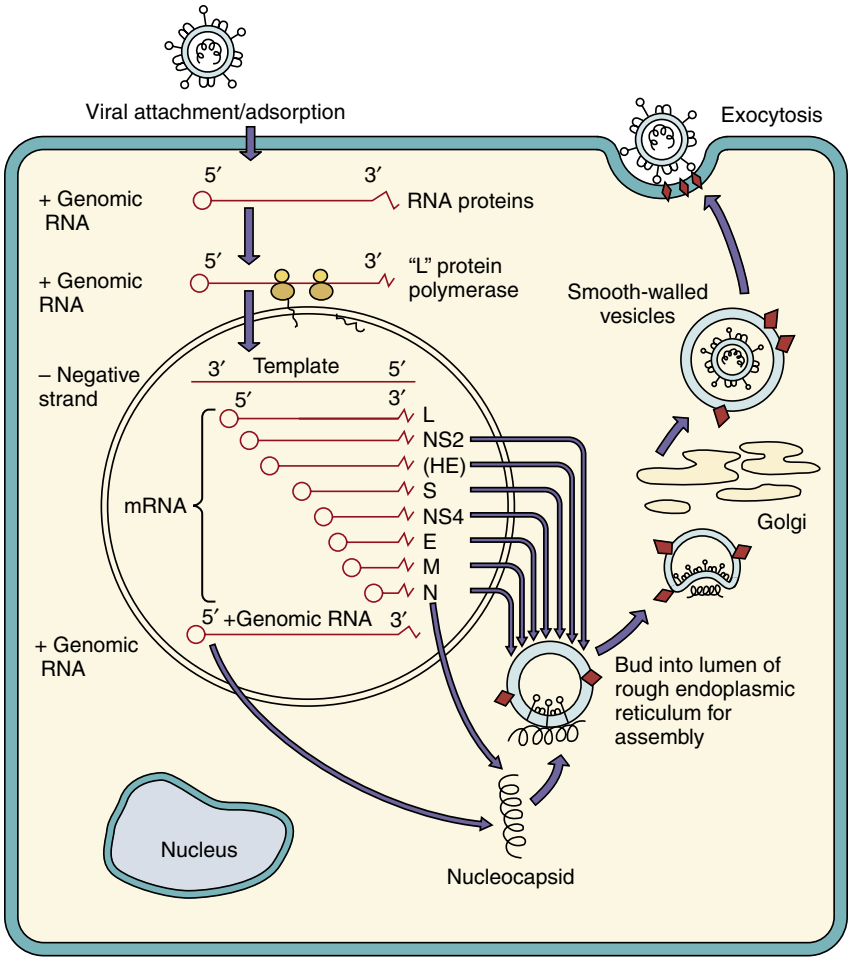

Fig. 47.2 Replication of human coronaviruses. The E2 glycoprotein interacts with receptors on epithelial cells, the virus fuses or is endocytosed into the cell, and the genome is released into the cytoplasm. Protein synthesis is divided into early and late phases, similar to that in the togaviruses. The genome binds to ribosomes, and an RNA-dependent RNA polymerase is translated. This enzyme generates a full-length, negative-sense RNA template for the production of new virion genomes and six individual mRNAs for the other coronavirus proteins. The genome associates with rough endoplasmic reticulum membranes modified by virion proteins and buds into the lumen of the rough endoplasmic reticulum. Vesicles that contain the virus migrate to the cell membrane, and the virus is released by exocytosis. (Modified from Balows, A., Hausler, W.J., Lennette, E.H., et al., 1988. Laboratory Diagnosis of Infectious Diseases: Principles and Practice. Springer-Verlag, New York, NY.)

BOX 47.2 Disease Mechanisms of Human Coronaviruses

Human coronavirus infects and kills epithelial cells of the upper respiratory tract.
Virus replicates best at 33° C to 35° C; therefore it prefers the upper respiratory tract.
Reinfection occurs in the presence of serum antibodies.
The glycoprotein "corona" helps this enveloped virus survive the gastrointestinal tract.
SARS-CoV and MERS-CoV replicate at 37° C, kill cells and initiate inflammatory responses in the lung.

MERS-CoV, Middle East respiratory syndrome coronavirus; *SARS-CoV,* severe acute respiratory syndrome coronavirus.

BOX 47.3 Characteristics of Noroviruses

Viruses are small capsid viruses distinguishable by capsid morphology.
Viruses are resistant to environmental pressure, such as detergents, drying, and acid.
Viruses are transmitted by fecal-oral route in contaminated water, food, vomitus.
Viruses cause outbreaks of gastroenteritis.
Disease resolves after 48 hours, without serious consequences.

The capsomeres of noroviruses, other caliciviruses, and astroviruses differ in conformation. Antibodies from seropositive people can also be used to distinguish these viruses.

Most caliciviruses and astroviruses can be grown in routine cell culture, but the Norwalk viruses cannot. Expression of the structural protein genes of different Norwalk viruses in tissue culture cells produces Norwalk virus–like particles. These particles were used to show that Norwalk viruses bind to the carbohydrate of either the A, B, or O blood group antigen on the cell surface. The noroviruses enter and exit cells similar to the picornaviruses but transcribe an early and late mRNA similar to the togaviruses and coronaviruses. The early mRNA encodes a polyprotein containing the RNA polymerase and other enzymes. The late mRNA encodes the capsid proteins.

PATHOGENESIS

The norovirus strains that infect humans can only infect humans. As few as 10 virions will initiate disease in humans. The virus infects and damages the small intestine, preventing proper absorption of water and nutrients and causing a watery diarrhea. Gastric emptying may be delayed, causing vomiting. Shedding of the virus may continue for 2 weeks after symptoms have ceased. Immunity is generally short-lived at best and may not be protective. The large number of strains and high rate of mutation allow reinfection despite antibodies from a previous exposure.

EPIDEMIOLOGY

Norwalk and related viruses typically cause outbreaks of gastroenteritis from a common source of contamination (e.g., water, shellfish, salad, raspberries, food service). These viruses are transmitted mainly by the fecal-oral route in stool and vomitus. The virus is resistant to drying and heat and can remain on surfaces for long periods. Infected individuals shed the largest amounts of the virus when sick and for 3 days after recovery but continue to shed the virus for up to 4 weeks. During peak shedding, 100 billion virions are released per gram of feces. Up to 30% of infected individuals are asymptomatic but can spread the infection.

Outbreaks in developed countries may occur year-round and have been described in schools, resorts, hospitals, nursing homes, restaurants, and cruise ships. Common-source outbreaks can often be traced to a careless, infected food handler. The Centers for Disease Control and Prevention estimates that nearly 50% (23 million U.S. cases per year) of all foodborne outbreaks of gastroenteritis can be attributed to noroviruses, which is a tribute to the importance of this virus. As many as 70% of children in the United States have antibodies to noroviruses by the age of 7 years.

CLINICAL SYNDROMES

Norwalk and related viruses cause symptoms similar to those caused by the rotaviruses but in adults and children (Clinical Case 47.1; Box 47.4). Infection causes an acute onset of **diarrhea, nausea, vomiting,** and abdominal cramps, especially in children (Fig. 47.3). Bloody stools do not occur. Fever may occur in as many as a third of patients. The incubation period is usually 12 to 48 hours, and the illness usually resolves within 1 to 3 days without problems but can last up to 6 days.

LABORATORY DIAGNOSIS

The use of RT-PCR for detection of the norovirus genome in stool or emesis samples has enhanced the speed and detection of the virus during outbreaks. Immunoelectron microscopy can be used to concentrate and identify the virus from stool. Addition of an antibody directed against the suspected agent causes the virus to aggregate, facilitating recognition. Enzyme-linked immunosorbent assay (ELISA) tests have been developed to detect the virus, viral antigen, and antibody to the virus. The other calicivirus-like agents are more difficult to detect.

Clinical Case 47.1 **Norwalk Virus Outbreak**

Brummer-Korvenkontio and associates (*Epidemiol Infect* 129:335–360, 2002) described an outbreak of gastroenteritis in children who had attended a concert; infection was traced back to contamination of a specific seating area, bathrooms, and other areas visited by one individual. A male concert attendee was ill before attending a concert and then vomited four times in the concert hall: in a waste bin in the corridor, into the toilets, onto the floor of the fire escape, and on a carpeted area in the walkway. His family members showed symptoms within 24 hours. A children's concert for several schools was held the next day. Children sitting in the same section as the incident case and those who traversed the contaminated carpet had the highest incidence of disease, characterized by watery diarrhea and vomiting for approximately 2 days. RT-PCR analysis of fecal samples from two ill children detected Norwalk virus genomic RNA. Infected vomit may have up to a million viruses per milliliter, and only 10 to 100 viruses are required to transmit the disease. Contact with contaminated shoes, hands, clothing, or aerosols may have infected the children. The encapsidated nature of the Norwalk virus makes it resistant to routine cleansers; disinfection usually requires freshly prepared hypochlorite bleach–containing solutions or steam cleaning.

RT-PCR, Reverse transcriptase-polymerase chain reaction.

BOX 47.4 Clinical Summaries

Coronaviruses

Common cold: A 25-year-old office worker develops a runny nose, mild cough, malaise, and a low-grade fever. A coworker has had similar symptoms for the past few days.

SARS: A 45-year-old businessman returned from a 2-week trip to China. Five days after returning home to the United States, he developed a fever of 101.5° F (38.6° C) and cough. Now he observes that it is harder to catch his breath.

Norovirus

Norwalk virus: On the third day of a cruise (incubation period of 24 to 60 hours), a group of 45 passengers on a cruise ship experienced watery diarrhea, nausea, and vomiting for 12 to 60 hours, depending on the individual.

SARS, Severe acute respiratory syndrome.

TREATMENT, PREVENTION, AND CONTROL

There is no specific treatment for the diarrhea caused by caliciviruses or other small, round gastroenteritis viruses other than oral rehydration therapy. Outbreaks may be minimized by handling food carefully and by maintaining the purity of the water supply. Careful hand washing is also important. More resistant to environmental pressures than polioviruses or rotaviruses, the Norwalk virus is resistant to heat (60° C), pH 3, detergent, and even the chlorine levels of drinking water. Contaminated surfaces can be cleaned with a 1:50 to 1:10 dilution of household bleach.

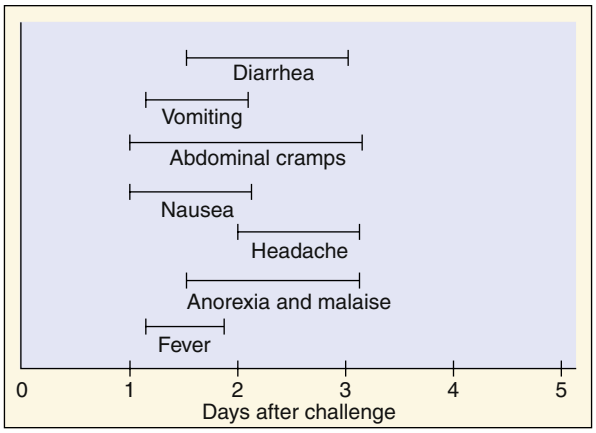

Fig. 47.3 Response to ingestion of Norwalk virus. Symptoms vary in severity.

Case Study and Questions

Several adults complained of serious diarrhea, nausea, vomiting, and a mild fever 2 days after visiting Le Café Grease. The symptoms were too severe to result from food poisoning or a routine gastroenteritis but lasted only 24 hours.

1. What characteristics distinguished this disease from a rotavirus infection?
2. What was the most likely means of viral transmission?
3. What physical characteristics of the virus allowed it to be transmitted by these means?
4. What public health measures could be followed to prevent such outbreaks?

48 Paramyxoviruses

A 10-year-old boy presented with cough, conjunctivitis, and coryza plus fever and lymphadenopathy, which progressed to a rash that spread from the hairline down his face and then his body. Within 10 days, the disease appeared to run its course, but a week after the start of the rash, an abrupt onset of headache, vomiting, and confusion progressed to coma, which is consistent with encephalitis.

1. How does measles replicate?
2. What are the characteristic signs of measles?
3. How is it transmitted?
4. Why was the boy susceptible to measles?
5. What other complications are associated with measles?

Answers to these questions are available on Student Consult.com.

Summaries Clinically Significant Organisms

PARAMYXOVIRUSES

Trigger Words

- Fusion, syncytia, aerosols, envelope
- Measles: cough, conjunctivitis, coryza, photophobia, Koplik spots, rash, fever, SSPE, postmeasles encephalitis
- Mumps: parotitis, orchitis, aseptic meningitis
- Parainfluenza: croup, barking seal, pneumonia
- RSV: infant, pneumonia

Biology, Virulence, and Disease

- Large size, enveloped, (–) RNA genome, fusion protein
- Encodes RNA-dependent RNA polymerase, replicates in cytoplasm
- Parainfluenza and mumps bind to sialic acid and encode neuraminidase activity (HN glycoprotein); measles and RSV glycoprotein bind to proteins
- Fusion protein promotes entry and cell-cell fusion (syncytia)
- Cell-mediated immune response essential for control but causes pathogenesis
- Measles: maculopapular rash, high fever with cough, conjunctivitis, coryza, Koplik spots (small gray lesions in mouth); more severe if vitamin A deficient, giant cell pneumonia if T-cell deficient, postmeasles encephalitis, SSPE 5–7 years later caused by measles variant
- Mumps: parotitis, orchitis, aseptic meningitis
- Parainfluenza: common cold, croup, bronchitis
- RSV: common cold, pneumonia, bronchiolitis, life-threatening for premature infants

Epidemiology

- Transmitted by aerosols

Diagnosis

- Symptomatology, RT-PCR genome analysis of respiratory secretions

Treatment, Prevention, and Control

- Live attenuated vaccine for measles and mumps; RSV: passive immunization for premature infants at high risk; aerosolized ribavirin

RSV, Respiratory syncytial virus; *RT-PCR,* reverse transcriptase-polymerase chain reaction; *SSPE,* subacute sclerosing panencephalitis.

The Paramyxoviridae include the genera *Morbillivirus, Paramyxovirus,* and *Pneumovirus* (Table 48.1; Box 48.1). Human pathogens within the morbilliviruses include the measles virus; within the paramyxoviruses, the **parainfluenza** and **mumps** viruses; and within the pneumoviruses, the **respiratory syncytial virus (RSV)** and **metapneumovirus.** A new group of highly pathogenic paramyxoviruses, including two zoonosis-causing viruses, Nipah virus and Hendra virus, was identified in 1998 after an outbreak of severe encephalitis in Malaysia and Singapore. Their virions have similar morphologies and protein components. Importantly, paramyxoviruses induce **cell-to-cell fusion (syncytia formation and multinucleated giant cells).**

These agents cause some well-known major diseases. The measles virus causes a potentially serious generalized infection characterized by a maculopapular rash **(rubeola).** Parainfluenza and metapneumoviruses cause upper and lower respiratory tract infections, primarily in children, including the common cold, pharyngitis, croup, bronchitis, bronchiolitis, and pneumonia. The mumps virus causes a systemic infection whose most prominent clinical manifestation is parotitis. RSV causes mild upper respiratory tract infections in children and adults but can cause life-threatening pneumonia in infants.

Measles and mumps viruses have only **one serotype,** and protection is provided by effective **live vaccines.** In the United States and other developed countries, successful vaccination programs using the live attenuated measles and mumps vaccines have made measles and mumps rare. The reduction in measles has led to the virtual elimination of the serious sequelae of measles in these countries. Unfortunately, large and serious outbreaks of measles and mumps are now occurring in the United States and Europe because of increased noncompliance with the vaccine programs.

TABLE 48.1 Paramyxoviridae

Genus	Human Pathogen
Morbillivirus	Measles virus
Paramyxovirus	Parainfluenza viruses 1-4
	Mumps virus
Pneumovirus	Respiratory syncytial virus
	Metapneumovirus

BOX 48.1 Unique Features of the Paramyxoviridae

- Large virion consists of a negative-sense RNA genome in a helical nucleocapsid surrounded by an envelope.
- The three genera can be distinguished by the activities of the viral attachment protein: **HN** of parainfluenza virus and mumps virus binds to sialic acid and red blood cells (hemagglutinin and neuraminidase activity), neuraminidase facilitates release from cell; **H** of measles virus binds protein receptors and is also a hemagglutinin; **G** of RSV binds to cells but is not a hemagglutinin.
- Virus replicates in the cytoplasm.
- Virions penetrate the cell by fusion with the plasma membrane and exit by budding from the plasma membrane without killing the cell.
- Viruses induce cell-to-cell fusion, causing multinucleated giant cells **(syncytia).**
- **Cell-mediated immunity** causes many of the symptoms but is essential for control of the infection.
- Paramyxoviridae are transmitted in **respiratory droplets** and initiate infection in the respiratory tract.
- Measles and mumps establish viremia and spread to other body sites.

Structure and Replication

Paramyxoviruses are relatively large viruses with a **negative-sense, single-stranded ribonucleic acid (RNA)** (5 to 8 × 10^6 Da) genome in a helical nucleocapsid surrounded by a pleomorphic **envelope** of approximately 156 to 300 nm (Fig. 48.1). They are similar in many respects to orthomyxoviruses but are larger and do not have the segmented genome of the influenza viruses. Although there are similarities in paramyxovirus genomes, the order of the protein-coding regions differs for each genus. The paramyxovirus proteins are listed in Table 48.2.

The nucleocapsid consists of the negative-sense, single-stranded RNA associated with the nucleoprotein **(N),** polymerase phosphoprotein **(P),** and large **(L)** protein. The L protein is the RNA polymerase, the P protein facilitates RNA synthesis, and the N protein helps maintain genomic structure. The nucleocapsid associates with the matrix **(M)** protein lining the inside of the virion envelope. The envelope contains two glycoproteins, a fusion **(F)** protein, and a viral attachment protein (hemagglutinin-neuraminidase **[HN],** hemagglutinin **[H],** or glycoprotein **[G]** protein) (see Box 48.1). To express membrane-fusing activity, the F protein must be activated by proteolytic cleavage, which produces F_1 and F_2 glycopeptides held together by a disulfide bond. Additional proteins (V and C) result from alternative transcripts of the P gene and facilitate escape from innate host protections.

Replication of the paramyxoviruses is initiated by the binding of the HN, H, or G glycoprotein on the virion envelope to their receptors. The HN of parainfluenza viruses bind to sialic acid on cell-surface glycolipids and glycoproteins. Like influenza, they use the neuraminidase activity to cleave sialic acid on viral and cellular glycoproteins to prevent binding to itself and the infected cell proteins to facilitate exit from the cell. The other paramyxoviruses bind to protein receptors and do not need neuraminidase activity. The F protein promotes fusion of the envelope with the plasma membrane. Paramyxoviruses are also able to induce cell-to-cell fusion, creating multinucleated giant cells (syncytia).

Replication of the genome occurs in a manner similar to that of other negative-strand RNA viruses (i.e., rhabdoviruses). The RNA polymerase is carried into the cell as part of the nucleocapsid. Transcription, protein synthesis, and replication of the genome all occur in the host cell's cytoplasm. The genome is transcribed into individual messenger RNAs (mRNAs) and a full-length positive-sense RNA template. New genomes associate with the L, N, and P proteins to form helical nucleocapsids that associate with the M proteins on viral glycoprotein-modified plasma membranes. The glycoproteins are synthesized and processed like cellular glycoproteins. Mature virions then bud from the host cell plasma membrane and exit without killing the cell. Replication of the paramyxoviruses is represented by the RSV infectious cycle shown in Fig. 48.2.

Measles Virus

Measles, also known as rubeola, is one of the five classic childhood exanthems, along with rubella, roseola, fifth disease, and chickenpox. Historically, measles was one of the most common and unpleasant viral infections, with serious potential sequelae. Before 1960, more than 90% of the population younger than 20 years had experienced the rash, high fever, cough, conjunctivitis, and coryza of measles. Measles is still one of the most prominent causes of disease (>10 million cases per year) and death (120,000 deaths in 2012) worldwide in unvaccinated populations. The development of effective vaccine programs has made measles a rare disease in developed countries, but children remain unvaccinated or do not receive their boosters and outbreaks of measles occur.

PATHOGENESIS AND IMMUNITY

Measles virus can infect many cell types because of the presence of its receptors, CD46 (complement regulatory protein) and nectin 4 poliovirus receptor-like 4 (PVRL4) on epithelial and other cells and CD150 (signaling lymphocyte-activation molecule [SLAM]) on dendritic cells and lymphocytes. Binding to CD150 promotes the viremic spread in dendritic cells, and B and T lymphocytes throughout the body. Measles is known for its propensity to cause cell fusion, leading to the formation of giant cells (Box 48.2) and the ability to

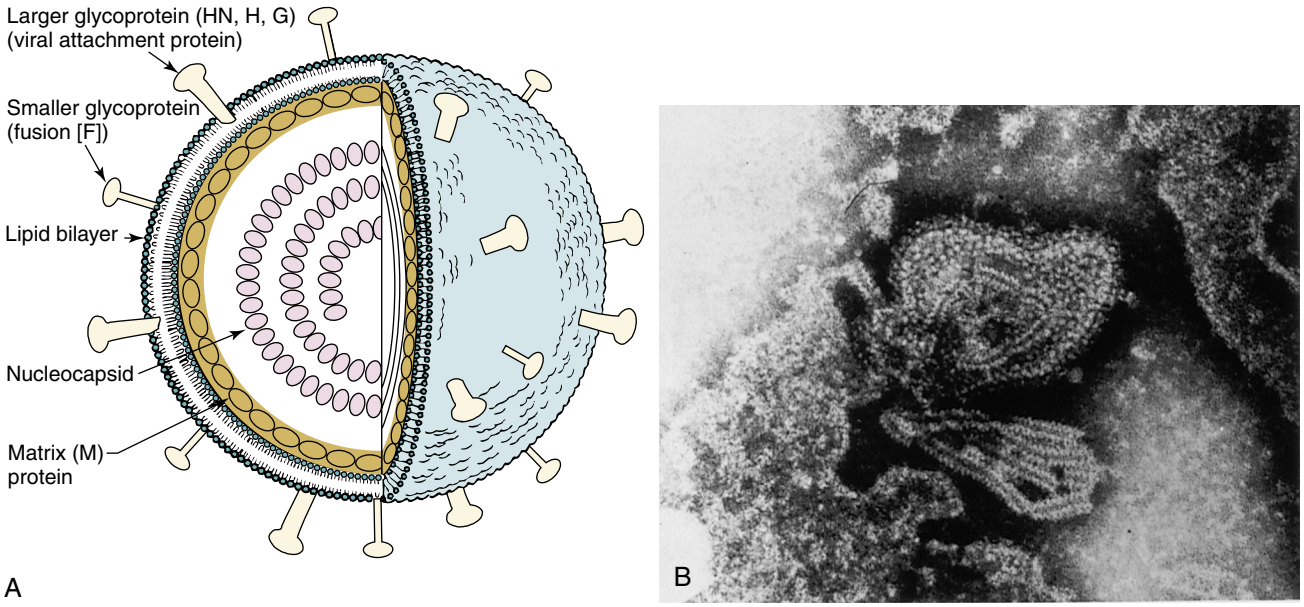

Fig. 48.1 (A) Model of paramyxovirus. The helical nucleocapsid—consisting of negative-sense, single-stranded RNA and the polymerase *(P),* nucleoprotein *(N),* and large protein *(L)*—associates with the matrix *(M)* protein at the envelope membrane surface. The nucleocapsid contains RNA transcriptase activity. The envelope contains the viral attachment glycoprotein (hemagglutinin-neuraminidase *[HN],* hemagglutinin *[H],* or G-protein *[G],* depending on the virus) and the fusion *(F)* protein. (B) Electron micrograph of a disrupted paramyxovirus, showing the helical nucleocapsid. (A, Modified from Jawetz, E., Melnick, J.L., Adelberg, E.A., 1987. Review of Medical Microbiology, 17th ed. Appleton & Lange, Norwalk, CT. B, Courtesy Centers for Disease Control and Prevention, Atlanta, GA.)

TABLE 48.2 Major Viral-Encoded Proteins of Paramyxoviruses

Gene and Proteins[a,b]	Virion Location	Protein Function
N: nucleoprotein	Major internal protein	Protection of viral RNA
P: phosphoprotein and C and V proteins	Association with nucleoprotein	Part of transcription complex; C and V are antagonists of innate responses
M: matrix	Inside virion envelope	Assembly of virions
F: fusion protein	Transmembranous envelope glycoprotein	Protein promotes fusion of cells, hemolysis, and viral entry
G: glycoprotein (HN, H, G)[c]	Transmembranous envelope glycoprotein	Viral attachment protein
L: polymerase (large)	Association with nucleoprotein	Polymerase

[a]In order on the genome.
[b]Pneumoviruses also encode an SH and M2 protein.

pass directly from cell to cell to escape antibody control. Virus production occurs with eventual cell lysis. Persistent infections without lysis can occur in certain cell types (e.g., human brain cells).

Measles is **highly contagious** and is transmitted from person to person by **respiratory droplets** (Fig. 48.3). After local replication of virus in epithelial cells of the respiratory tract, the virus infects monocytes and lymphocytes, and the virus is spread through the lymphatic system and by a cell-associated viremia. The wide dissemination of the virus causes infection of the conjunctiva, respiratory tract, urinary tract, small blood vessels, lymphatic system, and central nervous system. The characteristic **maculopapular** measles rash is caused by the inflammation resulting from immune T cells targeted to measles-infected epithelial cells. Recovery follows the rash in most patients, who then have **lifelong immunity** to the virus. Death caused by pneumonia, diarrhea, or encephalitis can occur. The time course of measles infection is shown in Fig. 48.4.

Measles can cause encephalitis in three ways: (1) direct infection of neurons, (2) a postinfectious encephalitis that is believed to be immune mediated, and (3) subacute sclerosing panencephalitis (SSPE) caused by a defective variant of measles generated during the acute disease. The SSPE virus replicates poorly, stays cell associated, and causes symptoms and cytopathologic effect in neurons many years after acute disease.

Measles and other paramyxoviruses are excellent inducers of interferon (IFN)-α and IFN-β but also have mechanisms to antagonize their action. Cell-mediated immunity is essential for control of the measles infection because a great deal of virus production proceeds before cell death and

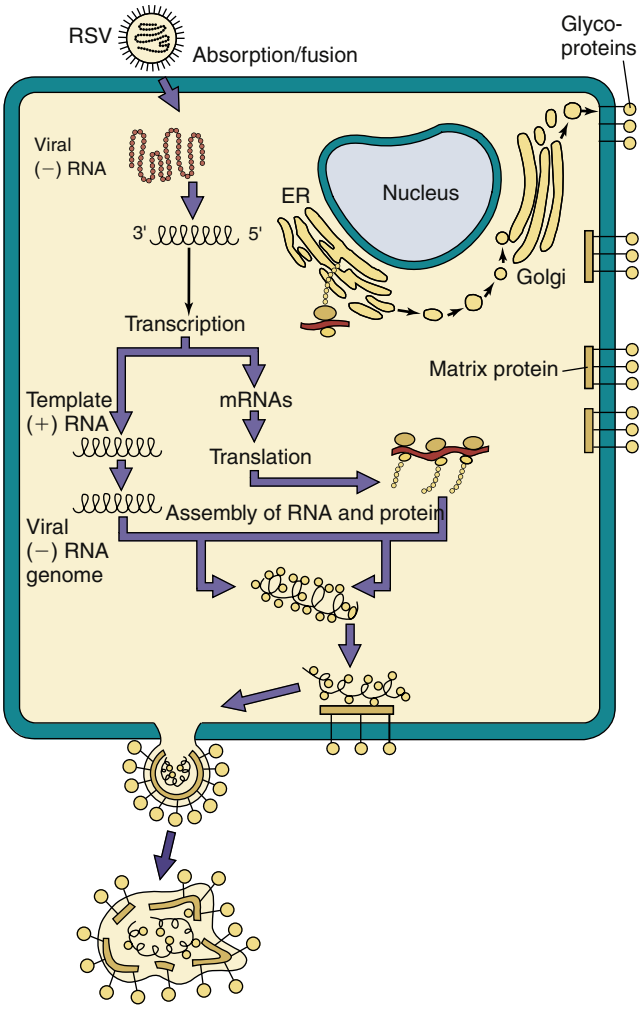

Fig. 48.2 Replication of paramyxoviruses. The virus binds to glycolipids or proteins and fuses with the cell surface. Individual messenger RNAs *(mRNAs)* for each protein and a full-length template are transcribed from the genome. Replication occurs in the cytoplasm. Proteins associate with the new genome, and the nucleocapsid associates with matrix and glycoprotein-modified plasma membranes. The virus leaves the cell by budding. *(−),* Negative sense; *(+),* positive sense; *ER,* endoplasmic reticulum; *RSV,* respiratory syncytial virus. (Modified from Balows, A. et al., 1988. Laboratory Diagnosis of Infectious Diseases: Principles and Practice. Springer-Verlag, New York, NY.)

BOX 48.2 Disease Mechanisms of Measles Virus

Virus infects epithelial cells of respiratory tract.
Virus spreads systemically in lymphocytes by **viremia.**
Virus replicates in cells of conjunctivae, respiratory tract, urinary tract, lymphatic system, blood vessels, and CNS.
Rash is caused by T-cell response to virus-infected epithelial cells.
Virus causes immunosuppression.
Cell-mediated immunity is essential to control infection.
Sequelae in the CNS may result from immunopathogenesis (postinfectious measles encephalitis) or development of defective mutants (subacute sclerosing panencephalitis).

CNS, Central nervous system.

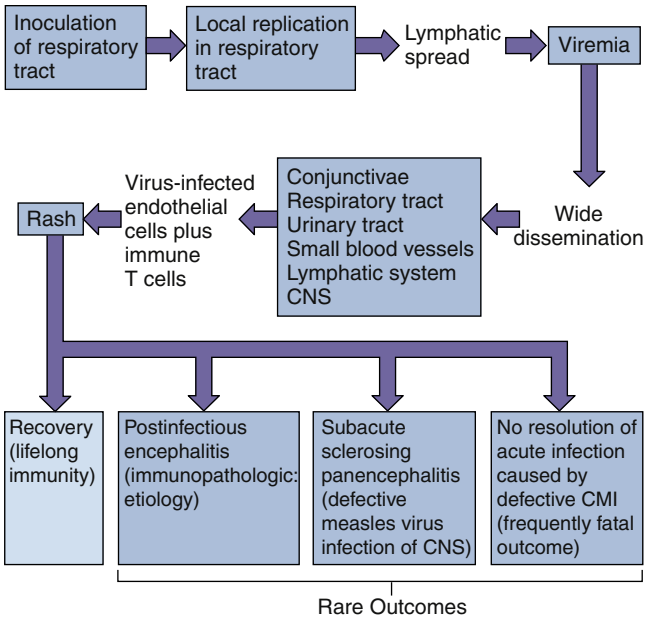

Fig. 48.3 Mechanisms of spread of the measles virus within the body and the pathogenesis of measles. *CMI,* Cell-mediated immunity; *CNS,* central nervous system.

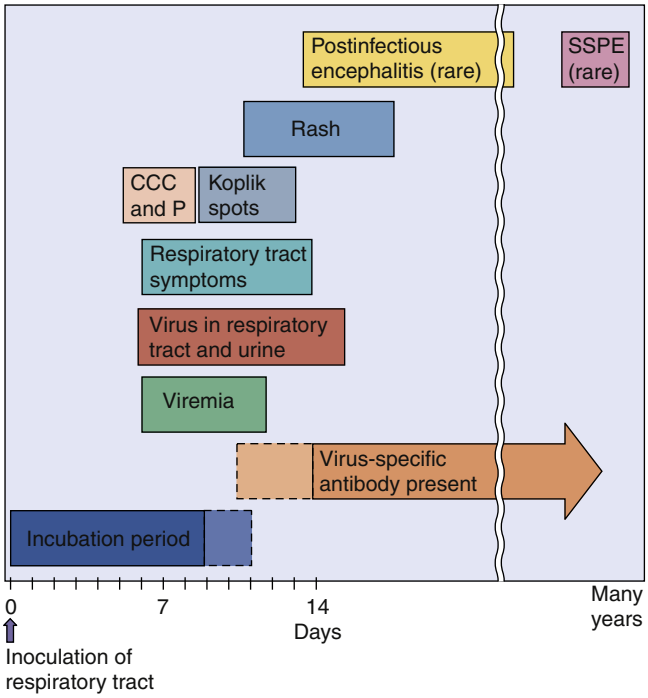

Fig. 48.4 Time course of measles virus infection. Characteristic prodrome symptoms are cough, conjunctivitis, coryza, and photophobia *(CCC and P),* followed by the appearance of Koplik spots and rash. *SSPE,* Subacute sclerosing panencephalitis.

cell–cell transmission by fusion promotes escape from antibody. T-cell–deficient children who are infected with measles have an atypical presentation consisting of **giant cell pneumonia without a rash.** The immune response is also responsible for most of the symptoms of measles. Measles is more severe for people deficient in vitamin A. Vitamin A is important for optimal effector T-cell function and resolution of measles infection. Antibody, including maternal antibody and passive immunization, can block the viremic but not cell-cell spread of the virus to prevent or lessen disease. There is only one serotype of measles, and immune protection from future disease is lifelong.

BOX 48.3 Epidemiology of Measles

Disease/Viral Factors

Virus has large enveloped virion that is easily inactivated by dryness and acid.
Contagion period precedes symptoms.
Very contagious with 95% infectivity rate.
Host range is limited to humans.
Only one serotype exists.
Immunity is lifelong.

Transmission

Inhalation of large-droplet aerosols.

Who Is at Risk?

Unvaccinated people, especially infants <1 year old.
Malnourished people, especially vitamin A deficient, who have more serious outcomes.
Immunocompromised people, who have more serious outcomes.

Geography/Season

Virus found worldwide.
Virus endemic from autumn to spring, possibly because of crowding indoors.

Modes of Control

Live attenuated vaccine (Schwartz or Moraten variants of Edmonston B strain) can be administered.
Immune serum globulin can be administered after exposure.

Measles infection is immunosuppressive. The virus depresses the immune response by (1) directly infecting and killing monocytes and T and B cells and (2) depressing interleukin (IL)-12 production and TH1-type T-cell helper responses. Depression of cell-mediated immune and delayed-type hypersensitivity (DTH) responses increases risk to concurrent opportunistic and other infections. This immunosuppression lasts for weeks or months after the disease.

EPIDEMIOLOGY

Measles is one of the most contagious infections known (Box 48.3). The virus is efficiently spread in respiratory secretions before and after the onset of characteristic symptoms. In a household, approximately 90% of exposed susceptible people become infected, and 95% of these people develop clinical disease.

The measles virus has only one serotype and infects only humans, and infection usually manifests with symptoms. These properties facilitated the development of an effective vaccine program. Once vaccination was introduced, the yearly incidence of measles dropped dramatically in the United States, from 300 to 1.3 per 100,000 (U.S. statistics for 1981 to 1988). This change represented a 99.5% reduction in the incidence of infection from the prevaccination years of 1955 to 1962. Incidences of measles must be reported to state and federal health departments. In areas without a vaccine program, epidemics tend to occur in 1- to 3-year cycles, when a sufficient number of susceptible people have accumulated. Many of these cases occur in preschool-age children who have not been vaccinated and live in large urban areas. The incidence of infection peaks in the winter and spring. Measles is still common in people living in developing countries, especially in individuals who refuse immunization or who have not received a booster in their teenage years. Despite the effectiveness of vaccination programs, poor compliance and the prevaccinated population (children <2 years) continue to provide susceptible individuals. The virus may surface from within the community or can be imported by immigration from areas of the world lacking an effective vaccine program. Once again, outbreaks of measles are occurring more often in the United States, France, and England. In the United States, outbreaks are often initiated by cases imported from other countries and then spread to unvaccinated or unboosted individuals, including infants. An outbreak of measles in a day-care center (10 infants too young to have been vaccinated and two adults) was traced to an infant from the Philippines.

Immunocompromised, malnourished, and vitamin A–deficient people with measles may not be able to resolve the infection, resulting in death. Measles is the most significant cause of death in children age 1 to 5 years in several countries that do not have effective vaccination programs.

TABLE 48.3 Clinical Consequences of Measles Virus Infection

Disorder	Symptoms
Measles	Characteristic maculopapular rash, cough, conjunctivitis, coryza, photophobia, Koplik spots *Complications*: otitis media, croup, pneumonia, blindness, encephalitis
Atypical measles	More intense rash (most prominent in distal areas); possible vesicles, petechiae, purpura, or urticaria
Postmeasles encephalitis	Acute onset of headache, confusion, vomiting, possible coma after rash dissipates
Subacute sclerosing panencephalitis	Central nervous system manifestations (e.g., personality, behavior, and memory changes; myoclonic jerks; spasticity; blindness)

CLINICAL SYNDROMES

Measles is a serious febrile illness (Table 48.3). The incubation period lasts 7 to 13 days, and the prodrome starts with 2 to 4 days of **high fever** and **"CCC and P" (cough, coryza, conjunctivitis**, and **photophobia).** The disease is most infectious during this time.

After 2 days of prodromal illness, the typical mucous membrane lesions known as **Koplik spots** (Fig. 48.5) appear. They are seen most commonly on the buccal mucosa across from the molars, but they may appear on other mucous membranes as well, including the conjunctivae and the vagina. The vesicular lesions, which last 24 to 48 hours, are usually small (1 to 2 mm) and are best described as grains of salt surrounded by a red halo. Their appearance with the other disease signs establishes with certainty the diagnosis of measles.

Within 12 to 24 hours of the appearance of Koplik spots, the **exanthem** of measles starts below the ears and spreads over the body. The **rash is maculopapular** and is usually very extensive, and often the lesions become confluent. The rash, which takes 1 or 2 days to cover the body, fades in the

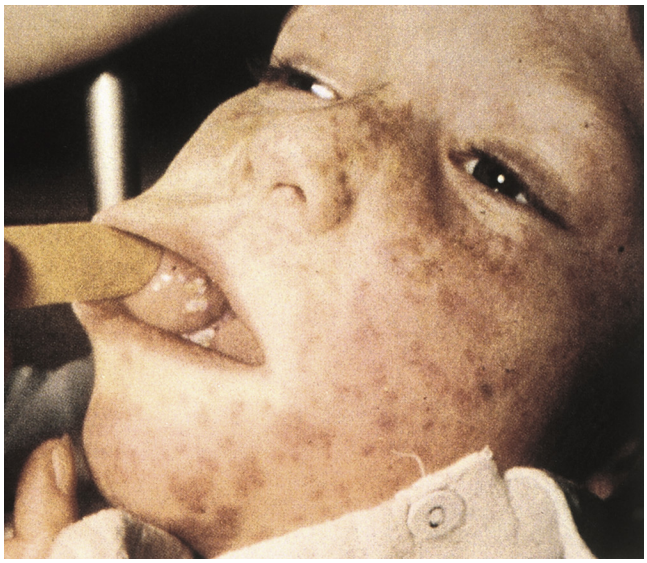

Fig. 48.5 Koplik spots in the mouth and exanthem. Koplik spots usually precede the measles rash and may be seen for the first day or two after the rash appears. (Courtesy Dr. J.I. Pugh, St Albans City Hospital, West Hertfordshire, England. From Emond, R.T.D., Rowland, H.A.K., 1995. A Color Atlas of Infectious Diseases, third ed. Mosby, London, UK.)

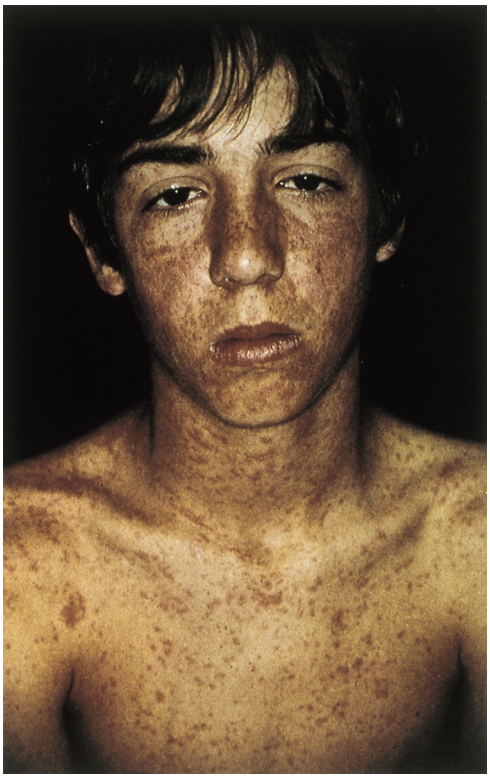

Fig. 48.6 Measles rash. **(A)** A maculopapular rash appears on the face and becomes confluent. **(B)** The rash then appears on the trunk. (From Habif, T.P., 2015. Clinical Dermatology: Color Guide to Diagnosis and Therapy, sixth ed. ©2015, Elsevier.)

same order in which it appeared. The fever is highest and the patient is sickest on the day the rash appears (Fig. 48.6).

Pneumonia, which can also be a serious complication, accounts for 60% of the deaths caused by measles. Similar to the incidence of the other complications associated with measles, the mortality associated with pneumonia is higher in the malnourished and for the extremes of age. **Bacterial superinfection** is common in patients with pneumonia caused by the measles virus.

One of the most feared complications of measles is **encephalitis,** which occurs in as few as 0.5% of those infected but carries a fatality rate of 15%. Encephalitis may rarely occur during acute disease but usually begins 7 to 10 days after the onset of illness. This **postinfectious encephalitis** is caused by immunopathologic reactions, is associated with demyelination of neurons, and occurs more often in older children and adults.

Atypical measles occurred in people who received the older inactivated measles vaccine and were subsequently exposed to the wild-type measles virus. It may also rarely occur in those vaccinated with the attenuated virus vaccine. Prior sensitization with insufficient protection can enhance the immunopathologic response to the challenge by the wild-type measles virus. The illness begins abruptly and is a more intense presentation of measles.

Infections of the immunocompromised and malnourished, especially vitamin A–deficient, child cause the most severe measles disease (Clinical Case 48.1). **Giant cell pneumonia without rash** occurs in children lacking T-cell immunity. Whereas the death rate of measles in the United States is only 0.1%, complications, severe bacterial superinfection, and pneumonia in malnourished children result in up to 60% mortality.

SSPE is an extremely serious, very late neurologic sequela of measles that afflicts approximately 7 of every 1 million patients. The incidence of SSPE has decreased markedly because of measles vaccination programs.

This disease occurs when a defective measles virus persists in the brain, affects multiple loci in the brain (panencephalitis), and acts as a slow virus. The virus can replicate and spread directly from cell to cell but is not released. SSPE is most prevalent in children who were initially infected when younger than 2 years and occurs approximately 7 years after clinical measles. The patient demonstrates changes in personality, behavior, cognition, and memory, followed by myoclonic jerks, blindness, and spasticity, and progresses to coma and death. Unusually high levels of measles antibodies are found in the blood and cerebrospinal fluid of patients with SSPE. Measles antigen and genome can be detected in neurons, as well as Cowdry type A inclusion bodies (these inclusion bodies are usually a marker for herpes simplex virus but also are seen in SSPE).

LABORATORY DIAGNOSIS

The clinical manifestations of measles are usually so characteristic that it is rarely necessary to perform laboratory tests to establish the diagnosis. The measles virus should not be isolated. Respiratory tract secretions, urine, blood, and brain tissue are the recommended specimens. It is best to collect respiratory and blood specimens during the prodromal stage and until 1 to 2 days after the appearance of the rash. Measles antigen can be detected with immunofluorescence in pharyngeal cells or urinary sediment, or the measles genome can be identified by reverse transcriptase-polymerase chain reaction (RT-PCR) in respiratory tract

Clinical Case 48.1 **Measles in the Immunocompromised Child**

The lack of cell-mediated immune responses allows measles infection of immunocompromised individuals to progress to serious outcomes. In a case reported by Pullan and associates (*Br Med J* 1:1562–1565, 1976), within 3 days of exposure to measles, a child on chemotherapy for ALL received pooled immunoglobulin. Despite the IgG therapy, 23 days after exposure, she developed an extensive measles rash that became hemorrhagic. She had a fever of 39.5° C and bronchopneumonia. Measles was grown from nasopharyngeal secretions, and immunohistochemistry identified giant cells (syncytia) containing measles antigen within the secretions. Her chemotherapy was stopped, and she received several massive doses of immunoglobulin. She started to improve 1 month after the onset of the rash.

In another case, during the 2.5 years that a boy was under treatment for ALL, he suffered severe herpes simplex virus infections around the mouth and herpes zoster on his trunk. During the third year on therapy, he was exposed to measles from his sister and received pooled IgG. After 19 days, he developed mild respiratory symptoms but no rash. After 29 days, he refused to go to school and misbehaved; behavioral changes progressed. After 9 weeks, he developed focal motor seizures, increased drowsiness, slurring of speech, and confusion, which progressed to coma and death within 8 days of the onset of seizures. Serology indicated a lack of measles antibody. Autopsy indicated the presence of cytomegalovirus but not measles in the lungs. The brain showed extensive degeneration, but no virus was isolated from the samples. Brain sections indicated large intranuclear and cytoplasmic inclusion bodies with tubular structures that resembled measles nucleocapsids in the cytoplasm. Immunofluorescence with antibody from individuals with **SSPE** or antimeasles antibody indicated the presence of measles antigen. These cases illustrate the excessive pathology measles can cause in the absence of a competent T-cell response. The lack of immune control allowed progression of the virus to the brain, in which it or a variant (SSPE) caused pathology leading to encephalitis.

ALL, Acute lymphoblastic leukemia; *SSPE,* subacute sclerosing panencephalitis.

secretions, urine, blood, and brain tissue. Characteristic cytopathologic effects, including multinucleated giant cells with cytoplasmic inclusion bodies, can be seen in Giemsa-stained cells taken from the upper respiratory tract and urinary sediment.

Antibody, especially immunoglobulin (Ig)M, can be detected when the rash is present.

TREATMENT, PREVENTION, AND CONTROL

As stated previously, a live attenuated measles vaccine, in use in the United States since 1963, has been responsible for significant reduction in the incidence of measles. The Schwartz or Moraten attenuated strains of the original Edmonston B vaccine are currently being used. Live attenuated vaccine is given to all children after 12 months of age when the T-cell immune responses are sufficiently mature and antibodies from the mother have been cleared. The vaccine is given in combination with mumps and rubella **(measles-mumps-rubella [MMR] vaccine)** and the varicella vaccines (Box 48.4). Although early childhood immunization is successful in more than 95% of vaccinees, revaccination before grade school or junior high school is required in many states. Because of the very contagious nature of measles, vaccine-induced herd immunity is very important to prevent spread of the virus in the population. A decrease to 93% immunized within the population creates a risk of a measles outbreak. Complacency or misinformation regarding immunization risks causes many parents to refrain from vaccinating their children, putting them at risk of infection, disease, and becoming sources of contagion to others.

BOX 48.4 **Measles-Mumps-Rubella Vaccine**

Composition: live attenuated viruses
Measles: Schwartz or Moraten substrains of Edmonston B strain
Mumps: Jeryl Lynn strain
Rubella: RA/27-3 strain
Vaccination schedule: after 12 months of age and at age 4 to 6 years or before junior high school (12 years of age)
Efficiency: 95% lifelong immunization with a single dose

Data from https://www.vaccines.gov/diseases/.

Because measles is strictly a human virus with only one serotype, it is a good candidate for eradication, but this is prevented by difficulties in distributing the vaccine to regions that lack proper refrigeration facilities (e.g., Africa) and distribution networks.

Hospitals in areas experiencing endemic measles may wish to vaccinate or check the immune status of their employees to decrease the risk of nosocomial transmission. Pregnant women, immunocompromised individuals, and people with allergies to gelatin or neomycin (components of the vaccine) should not receive the MMR vaccine. Exposed susceptible people who are immunocompromised should be given immunoglobulin to lessen the risk and severity of clinical illness. This product is most effective if given within 6 days of exposure. High-dose vitamin A treatment reduces the risk of measles mortality and is recommended by the World Health Organization. No specific antiviral treatment is available for measles.

Parainfluenza Viruses

Parainfluenza viruses, which were discovered in the late 1950s, are respiratory viruses that usually cause **mild coldlike symptoms** but can also cause **serious respiratory tract disease.** Four serologic types within the parainfluenza genus are human pathogens. Types 1, 2, and 3 are second only to RSV as important causes of severe lower respiratory tract infection in infants and young children. They are especially associated with **laryngotracheobronchitis (croup).** Type 4 causes only mild upper respiratory tract infection in children and adults.

BOX 48.5 Disease Mechanisms of Parainfluenza Viruses

There are four serotypes of parainfluenza viruses.
Infection is **limited to the respiratory tract;** upper respiratory tract disease is most common, but significant disease can occur with lower respiratory tract infection.
Parainfluenza viruses do *not* cause viremia or become systemic.
Diseases include **coldlike** symptoms, **bronchitis** (inflammation of bronchial tubes), and **croup** (laryngotracheobronchitis).
Infection induces protective immunity of short duration.

PATHOGENESIS AND IMMUNITY

Parainfluenza viruses infect epithelial cells of the upper respiratory tract (Box 48.5). The virus replicates more rapidly than measles and mumps viruses and can cause giant cell formation and cell lysis. Unlike measles and mumps viruses, the parainfluenza viruses rarely cause viremia. The viruses generally stay in the upper respiratory tract, causing only coldlike symptoms. In approximately 25% of cases, the virus spreads to the lower respiratory tract, and in 2% to 3%, disease may take the severe form of laryngotracheobronchitis.

The cell-mediated immune response both causes cell damage and confers protection. IgA responses are protective but short-lived. Parainfluenza viruses manipulate cell-mediated immunity to limit development of memory. Multiple serotypes and the short duration of immunity after natural infection make reinfection common, but the reinfection disease is milder, suggesting at least partial immunity.

EPIDEMIOLOGY

Parainfluenza viruses are ubiquitous, and infection is common (Box 48.6). The virus is transmitted by person-to-person contact and respiratory droplets. Primary infections usually occur in infants and children younger than 5 years. Reinfections occur throughout life, indicating short-lived immunity. Infections with parainfluenza viruses 1 and 2, the major causes of croup, tend to occur in the autumn, whereas parainfluenza virus 3 infections occur throughout the year. All these viruses spread readily within hospitals and can cause outbreaks in nurseries and pediatric wards.

CLINICAL SYNDROMES

Parainfluenza viruses 1, 2, and 3 may cause respiratory tract syndromes ranging from a **mild coldlike upper respiratory tract infection** (coryza, pharyngitis, mild bronchitis, wheezing, and fever) to **bronchiolitis** and **pneumonia.** Older children and adults generally experience milder infections than those seen in young children, although pneumonia may occur in the elderly.

A parainfluenza virus infection in infants may be more severe than infections in adults, causing bronchiolitis, pneumonia, and most notably croup (laryngotracheobronchitis). **Croup** results in subglottal swelling that may close the airway. Hoarseness, a "seal bark" cough, tachypnea, tachycardia, and suprasternal retraction develop in infected patients after a 2- to 6-day incubation period. Most children recover within 48 hours. The principal differential diagnosis is epiglottitis caused by *Haemophilus influenzae*.

BOX 48.6 Epidemiology of Parainfluenza Virus Infections

Disease/Viral Factors

Virus has a large enveloped virion that is easily inactivated by dryness and acid.
Contagion period precedes symptoms and may occur in absence of symptoms.
Host range is limited to humans.
Reinfection can occur later in life.

Transmission

Inhalation of large-droplet aerosols.

Who Is at Risk?

Children: at risk for mild disease or croup.
Adults: at risk for reinfection with milder symptoms.

Geography/Season

Virus is ubiquitous and worldwide.
Incidence is seasonal.

Modes of Control

There are no modes of control.

LABORATORY DIAGNOSIS

Rapid RT-PCR techniques are the method of choice to detect and identify parainfluenza viruses from respiratory secretions. Parainfluenza virus is isolated from nasal washings and respiratory secretions and grows well in primary monkey kidney cells. Similar to other paramyxoviruses, the virions are labile during transit to the laboratory and cannot be frozen at −20° C. The presence of virus-infected cells in aspirates or in cell culture is indicated by the finding of syncytia and is identified with immunofluorescence. Similar to the hemagglutinin of the influenza viruses, the hemagglutinin of the parainfluenza viruses promotes hemadsorption and hemagglutination. The serotype of the virus can be determined through the use of specific antibody to block infection (neutralization) and hemadsorption or hemagglutination (hemagglutination inhibition).

TREATMENT, PREVENTION, AND CONTROL

Treatment of croup consists of the administration of nebulized cold or hot steam and careful monitoring of the upper airway. On rare occasions, intubation may become necessary. No specific antiviral agents are available.

Vaccination with killed vaccines is ineffective, possibly because they fail to induce local secretory antibody and appropriate cellular immunity. No live attenuated vaccine is available.

Mumps Virus

Mumps virus is the cause of acute, benign viral **parotitis** (painful swelling of the salivary glands). Mumps is rarely

BOX 48.7 Disease Mechanisms of Mumps Virus

Virus infects epithelial cells of respiratory tract.
Virus spreads systemically by viremia.
Infection of parotid gland, testes, and central nervous system.
Principal symptom is swelling of parotid and other glands caused by inflammation.
Cell-mediated immunity is essential for control of infection and responsible for causing some of the symptoms.
Antibody is not sufficient because of the virus' ability to spread cell to cell.

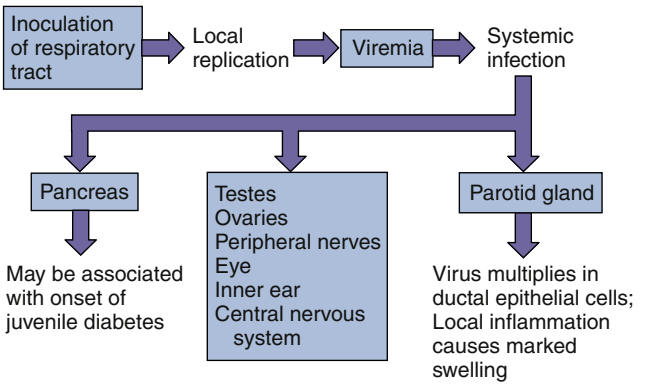

Fig. 48.7 Mechanism of spread of mumps virus within the body.

seen in countries that promote the use of the live vaccine, which is administered with the measles and rubella live vaccines, but outbreaks have occurred recently.

Mumps virus was isolated in embryonated eggs in 1945 and in cell culture in 1955. The virus is most closely related to parainfluenza virus 2, but there is no cross-immunity with the parainfluenza viruses.

PATHOGENESIS AND IMMUNITY

The HN glycoprotein of mumps virus binds to sialic acid and initiates infection of the epithelial cells of the upper respiratory tract. The virus progresses to the parotid gland, either by way of the Stensen duct or by means of a viremia (Box 48.7). Like other paramyxoviruses, mumps causes syncytia formation. The virus is spread by viremia throughout the body to the testes, ovary, pancreas, thyroid, and other organs. Infection of the central nervous system, especially the meninges, occurs in as many as 50% of those infected (Fig. 48.7). T cells are important for resolution but also cause immunopathogenesis. Inflammatory responses cause swelling of glands and are mainly responsible for the symptoms. The time course of human infection is shown in Fig. 48.8. There is only one serotype of mumps, and immunity is lifelong.

EPIDEMIOLOGY

Mumps, like measles, is a very communicable disease with only one serotype, and it infects only humans (Box 48.8). In the absence of vaccination programs, infection occurs in 90% of people by the age of 15 years. The virus spreads by direct person-to-person contact and respiratory droplets.

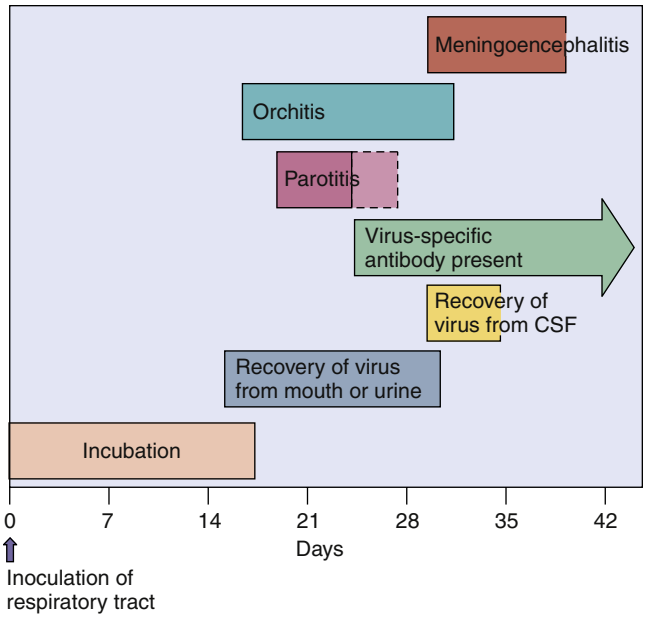

Fig. 48.8 Time course of mumps virus infection. *CSF*, Cerebrospinal fluid.

BOX 48.8 Epidemiology of Mumps Virus

Disease/Viral Factors

Virus has large enveloped virion that is easily inactivated by dryness and acid.
Contagion period precedes symptoms.
Virus may cause asymptomatic shedding.
Host range is limited to humans.
Only one serotype exists.
Immunity is lifelong.

Transmission

Inhalation of large-droplet aerosols.

Who Is at Risk?

Unvaccinated people, especially infants <1 year old.
Immunocompromised people, who have more serious outcomes.

Geography/Season

Virus is found worldwide.
Virus is endemic in late winter and early spring.

Modes of Control

Live attenuated vaccine (Jeryl Lynn strain) is part of measles-mumps-rubella vaccine.

The virus is released in respiratory secretions from patients who are asymptomatic and during the 7-day period before clinical illness, so it is virtually impossible to control the spread of the virus. Living or working in close quarters promotes the spread of the virus, and the incidence of the infection is greatest in the winter and spring.

CLINICAL SYNDROMES

Mumps infections are often asymptomatic. Clinical illness usually manifests as a parotitis that is almost always bilateral and accompanied by fever. Onset is sudden. Oral

examination reveals redness and swelling of the ostium of the Stensen (parotid) duct. The swelling of other glands (epididymoorchitis, oophoritis, mastitis, pancreatitis, and thyroiditis) and meningoencephalitis may occur a few days after the onset of the viral infection but can occur in the absence of parotitis. The swelling that results from mumps orchitis may cause sterility. Mumps virus involves the central nervous system in approximately 50% of patients; 10% of those affected may exhibit mild meningitis, with 5 per 1000 cases of encephalitis.

LABORATORY DIAGNOSIS

The clinical diagnosis of mumps can be confirmed by RT-PCR detection of viral genomes or assay of IgM or antigen by enzyme-linked immunosorbent assay (ELISA). Virus can be recovered from saliva, urine, the pharynx, secretions from the Stensen duct, and cerebrospinal fluid. Virus is present in saliva for approximately 5 days after the onset of symptoms and in urine for as long as 2 weeks. Mumps virus grows well in monkey kidney cells, causing the formation of multinucleated giant cells. Hemadsorption of guinea pig erythrocytes also occurs on virus-infected cells because of the viral hemagglutinin.

TREATMENT, PREVENTION, AND CONTROL

Vaccines provide the only effective means for preventing the spread of mumps infection. Since the introduction of the live attenuated vaccine (Jeryl Lynn vaccine) in the United States in 1967 and its administration as part of the MMR vaccine at 1 year of age, the yearly incidence of the infection has declined from 76 to less than 1 per 100,000, until recently. As with measles, outbreaks caused by increasing numbers of individuals who are unvaccinated or who did not receive a booster immunization have occurred. In 2014, there was an outbreak in Columbus, Ohio, in schools and universities, with more than 230 reported cases. Antiviral agents are not available.

Respiratory Syncytial Virus

RSV, first isolated from a chimpanzee in 1956, is a member of the *Pneumovirus* genus. There are two types and many different strains of RSV causing the same diseases. The glycoprotein of RSV does not bind to sialic acid or red blood cells; therefore the virus does not need or have a neuraminidase. It is the most common cause of **fatal acute respiratory tract infection** in infants and young children. It infects virtually everyone by 2 years of age, and reinfections occur throughout life, even among elderly persons.

PATHOGENESIS AND IMMUNITY

RSV produces an infection that is localized to the respiratory tract (Box 48.9). It binds to many different cell-surface proteins and heparan sulfate proteoglycans. As the name suggests, RSV induces syncytia. The pathologic effect of RSV is mainly caused by immunologically mediated cell injury. Neutrophils play a large role in the inflammation. Necrosis of the bronchi and bronchioles leads to the formation of "plugs" of mucus, fibrin, and necrotic material within smaller airways. The narrow airways of young infants are readily obstructed by such plugs. RSV can exacerbate previous lung disease and asthma. Natural immunity does not prevent reinfection, and vaccination with killed vaccine was ineffective or enhanced the severity of subsequent disease.

BOX 48.9 Disease Mechanisms of Respiratory Syncytial Virus

Virus causes localized infection of respiratory tract.
Virus does not cause viremia or systemic spread.
Pneumonia results from cytopathologic spread of virus (including syncytia).
Bronchiolitis is most likely mediated by the host's immune response.
Narrow airways of young infants are readily obstructed by virus-induced pathologic effects.
Maternal antibody is insufficient to protect infant from infection.
Natural infection does not prevent reinfection.

BOX 48.10 Epidemiology of Respiratory Syncytial Virus

Disease/Viral Factors

Virus has a large enveloped virion that is easily inactivated by dryness and acid.
Contagion period precedes symptoms and may occur in the absence of symptoms.
Host range is limited to humans.

Transmission

Inhalation of large-droplet aerosols.

Who Is at Risk?

Infants: lower respiratory tract infection (bronchiolitis and pneumonia).
Premature neonates: serious disease.
Children: spectrum of disease from mild to pneumonia.
Adults: reinfection with milder symptoms.
Immunocompromised, chronic heart and lung problems: serious disease.

Geography/Season

Virus is ubiquitous and found worldwide.
Incidence is seasonal.

Modes of Control

Immunoglobulin is available for infants at high risk.
Aerosol ribavirin is available for infants with serious disease.

EPIDEMIOLOGY

RSV is very prevalent in young children; almost all children have been infected by 2 years of age (Box 48.10), with global annual infection rates of 64 million and mortality of 160,000. As many as 25% to 40% of these cases involve the lower respiratory tract, and 1% are severe enough to necessitate hospitalization (occurring in as many as 95,000 children in the United States each year).

TABLE 48.4 Clinical Consequences of Respiratory Syncytial Virus Infection

Disorder	Age Group Affected
Bronchiolitis, pneumonia, or both	Fever, cough, dyspnea, and cyanosis in children <1 year Pneumonia in elderly, or those with chronic heart disease, chronic lung disease, or those who are immunocompromised
Febrile rhinitis and pharyngitis	Children
Common cold	Older children and adults

RSV infections almost always occur in the winter. Unlike influenza, which may occasionally skip a year, RSV epidemics occur every year.

The virus is very contagious, with an incubation period of 4 to 5 days. Virus is shed in respiratory secretions for many days after infection, especially by infants. The virus is transmitted in aerosols but also on hands and by fomites.

Introduction of the virus into a nursery, especially into an intensive care nursery, can be devastating. Virtually every infant becomes infected, and the infection is associated with considerable morbidity and occasionally death. Infants born prematurely and children younger than 2 years with complicated congenital heart disease or chronic lung disease are at high risk to serious RSV disease. Outbreaks of serious disease also may occur among the elderly population (e.g., in nursing homes).

CLINICAL SYNDROMES

RSV can cause any respiratory tract illness, from a **common cold** to **pneumonia** (Table 48.4; Box 48.11). Upper respiratory tract infection with prominent rhinorrhea (runny nose) is most common in older children and adults. A more severe lower respiratory tract illness, **bronchiolitis,** may occur in infants. Because of inflammation at the level of the bronchiole, there is air trapping and decreased ventilation. Clinically, the patient usually has low-grade fever, tachypnea, tachycardia, and expiratory wheezes over the lungs. Bronchiolitis is usually self-limited, but it can be a frightening disease to observe in an infant. Reinfection may present as a common cold or exacerbation of asthma. RSV may be fatal in premature infants, persons with underlying lung disease, and immunocompromised people.

LABORATORY DIAGNOSIS

RSV is difficult to isolate in cell culture. Presence of the viral genome in infected cells and nasal washings can be detected by RT-PCR techniques. Enzyme immunoassay can detect viral antigen in washings and immunofluorescence on exfoliated cells.

TREATMENT, PREVENTION, AND CONTROL

In otherwise healthy infants, treatment is supportive, consisting of administration of oxygen, intravenous fluids, and nebulized cold steam. Aerosolized **ribavirin,** a guanosine analog, is approved for treatment of infants with severe disease, but its use is infrequent. **Prophylactic and therapeutic passive immunization** with anti-RSV immunoglobulin or monoclonal antibody (palivizumab) is available for young children at high risk to serious disease.

Infected children must be isolated. Infection-control measures are required for hospital staff caring for infected children to avoid transmitting the virus to uninfected patients. These measures include handwashing and wearing gowns, goggles, and masks.

No vaccine is currently available for RSV prophylaxis. A previously available vaccine containing inactivated RSV caused recipients to have more severe RSV disease when subsequently exposed to the live virus. This development is thought to be the result of a heightened immunologic response at the time of exposure to the wild virus.

BOX 48.11 Clinical Summaries

Measles: An 18-year-old woman had been home for 10 days after a trip to Haiti when she developed a fever, cough, runny nose, and mild redness of her eyes. She now has a red, slightly raised rash over her face, trunk, and extremities. There are several 1-mm white lesions inside her mouth. She was never immunized for measles because of misinformation that an "egg allergy" would be a problem. The vaccine is not produced in eggs.

Mumps: A 30-year-old man returning from a trip to Russia experienced a 1- to 2-day period of headache and decreased appetite, followed by swelling over both sides of his jaw. The swelling extended from the bottom of the jaw to in front of the ear. Five days after the jaw swelling appeared, the patient began complaining of nausea and lower abdominal and testicular pain. He never received a booster immunization with the MMR vaccine.

Croup: An irritable 2-year-old toddler with little appetite has a sore throat, fever, and hoarse voice and coughs with the sound of a barking seal. A high-pitched noise (stridor) is heard on inhalation. Flaring of the nostrils indicates difficulty breathing.

Human Metapneumovirus

Human metapneumovirus is a recently recognized member of the Pneumovirinae subfamily. Use of RT-PCR methods was and remains the means of detecting the pneumoviruses and distinguishing them from other respiratory disease viruses. Its identity was unknown until recently because it is difficult to grow in cell culture. The virus is ubiquitous, and almost all 5-year-old children have experienced a virus infection and are seropositive.

As with its close cousin RSV, infections by human metapneumovirus may be asymptomatic, cause common cold–type disease, or cause serious bronchiolitis and pneumonia. Seronegative children, the elderly, and immunocompromised people are at risk for disease. Human metapneumovirus probably causes 15% of common colds in children, especially those complicated by otitis media. Signs of disease usually include cough, sore throat, runny nose, and high fever. Approximately 10% of patients with metapneumovirus will experience wheezing, dyspnea, pneumonia, bronchitis, or bronchiolitis. As with other common cold agents,

laboratory identification of the virus is not performed routinely but can be performed by RT-PCR. Supportive care is the only therapy available for these infections.

Nipah and Hendra Viruses

A new paramyxovirus, Nipah virus, was isolated from patients after an outbreak of severe encephalitis in Malaysia and Singapore in 1998. Nipah virus is more closely related to the Hendra virus, which was discovered in 1994 in Australia, than to other paramyxoviruses. Both viruses have broad host ranges, including pigs, humans, dogs, horses, cats, and other mammals. For Nipah virus, the reservoir is a fruit bat (flying fox). The virus can be obtained from fruit contaminated by infected bats or amplified in pigs and then spread to humans. The human is an accidental host for these viruses, but the outcome of human infection is severe. Disease signs for Nipah virus include flulike symptoms, seizures, and coma. Of the 269 cases occurring in 1999, 108 were fatal. Another epidemic in Bangladesh in 2004 had a higher mortality rate. More recent outbreaks have occurred in India and neighboring countries.

Case Studies and Questions

An 18-year-old college freshman complained of a cough, runny nose, and conjunctivitis. The physician in the campus health center noticed small white lesions inside the patient's mouth. The next day, a confluent red rash covered his face and neck.

1. What clinical characteristics of this case were diagnostic for measles?
2. Are any laboratory tests readily available to confirm the diagnosis? If so, what are they?
3. Is there a possible treatment for this patient?
4. When was this patient contagious?
5. Why is this disease not common in the United States?
6. Provide several possible reasons for this person's susceptibility to measles at 18 years of age.

A 13-month-old child had a runny nose, mild cough, and low-grade fever for several days. The cough got worse and sounded like "barking." The child made a wheezing sound when agitated. The child appeared well except for the cough. A lateral radiograph of the neck showed a subglottic narrowing.

7. What are the specific and common names for these symptoms?
8. What other agents would cause a similar clinical presentation (differential diagnosis)?
9. Are there readily available laboratory tests to confirm this diagnosis? If so, what are they?
10. Was there a possible treatment for this child?
11. When was this child contagious, and how was the virus transmitted?

49 Orthomyxoviruses

On April 15, 2009, a 33-year-old woman from California at 35 weeks' gestation had a 1-day history of myalgias, dry cough, and low-grade fever when examined by her obstetrician-gynecologist. The patient had not recently traveled to Mexico. Rapid influenza diagnostic testing performed in the physician's office was positive. On April 19, she was examined in a local emergency department, with worsening shortness of breath, fever, and productive cough. She experienced severe respiratory distress and was intubated and placed on mechanical ventilation. An emergency cesarean delivery was performed, resulting in a healthy female infant. On April 21, the patient developed acute respiratory distress syndrome (ARDS). The patient began receiving oseltamivir on April 28 and broad-spectrum antibiotics but died on May 4.[1]

1. How did the woman acquire the infection?
2. What is the normal presentation, and what is abnormal about this presentation of influenza?
3. What put the woman at higher risk and why?
4. How did this strain of influenza evolve?

Answers to these questions are available on Student Consult.com.

Summaries Clinically Significant Organisms

ORTHOMYXOVIRUSES

Trigger Words

Aerosols, envelope, segmented genome/reassortment, hemagglutinin, neuraminidase, antigenic drift (outbreaks), antigenic shift (pandemics), zoonosis

Biology, Virulence, and Disease

- Large size, enveloped, (–) segmented RNA genome
- Encodes RNA-dependent RNA polymerase, replicates in nucleus (exception to the rule)
- Each segment encodes one or two proteins
- Mixed infection results in genetic mixing of segments: reassortment
- Binds to sialic acid (HA glycoprotein) and encodes neuraminidase activity (NA glycoprotein)
- Preexisting antibody can block disease
- Cell-mediated immune response important for control but causes pathogenesis
- Influenza A, not influenza B, is a zoonosis
- Acute flulike symptoms caused by large cytokine release
- Extensive destruction of ciliated epithelium
- Pneumonia by influenza or secondary bacterial infection

Epidemiology

- Transmitted by aerosols
- Annual epidemics caused by mutations, pandemics caused by reassortment of genome segments between human and animal viruses

Diagnosis

- Symptomatology, RT-PCR genome analysis of respiratory secretions, immunology tests (ELISA), hemagglutination and hemagglutination inhibition

Treatment, Prevention, and Control

- Annual vaccine contains two influenza A and one or two influenza B strains: inactivated vaccines contain HA and NA, live attenuated nasal vaccine (for 2 to 49 year olds)
- Neuraminidase, the M2 channel and the cap-dependent endonuclease are targets for antiviral drugs

ELISA, Enzyme-linked immunosorbent assay; *RT-PCR,* reverse transcriptase-polymerase chain reaction.

Influenza A and B viruses are the most important members of the Orthomyxoviridae family. Influenza A is a zoonosis and can be found in many different animals, including birds, pigs, horses, bats, seals, and whales. Influenza C causes only mild respiratory illness, and influenza D infects cattle but is not known to cause human disease. Thogotoviruses are arboviruses, including the tick-borne Bourbon virus. This virus is so named because it caused a lethal infection in Bourbon, Kansas, in 2014. The orthomyxoviruses are **enveloped and have a segmented negative-sense ribonucleic acid (RNA) genome.** The segmented genome of these viruses facilitates the development of new strains through mutation and reassortment of the gene segments among different human and animal (influenza A) strains of virus. This genetic instability is responsible for the annual **epidemics (mutation: drift)** and, for influenza A, **periodic pandemics (reassortment: shift)** of influenza infection worldwide.

Influenza is one of the most prevalent and significant viral infections. Probably the most famous influenza **pandemic (worldwide)** is the Spanish influenza that swept the world from 1918 to 1919, killing 20 to 40 million people. In fact, more people died of influenza during that time than in the battles of World War I. Pandemics caused by novel influenza viruses occurred in 1918, 1947, 1957, 1968, 1977, and 2009. According to the Centers for Disease Control and Prevention (CDC), more than 80,000 deaths from 2017 to 2018 could be attributed to influenza in the United States. Fortunately, prophylaxis with vaccines and antiviral drugs is available.

Influenza viruses cause respiratory symptoms and the classic flulike symptoms of fever, malaise, headache, and

[1]Adapted from Centers for Disease Control and Prevention (CDC): Novel influenza A (H1N1) virus infections in three pregnant women—United States, April–May 2009, *MMWR Morb Mortal Wkly Rep* 58:497–500. www.cdc.gov/mmwr/preview/mmwrhtml/mm58d0512a1.htm.

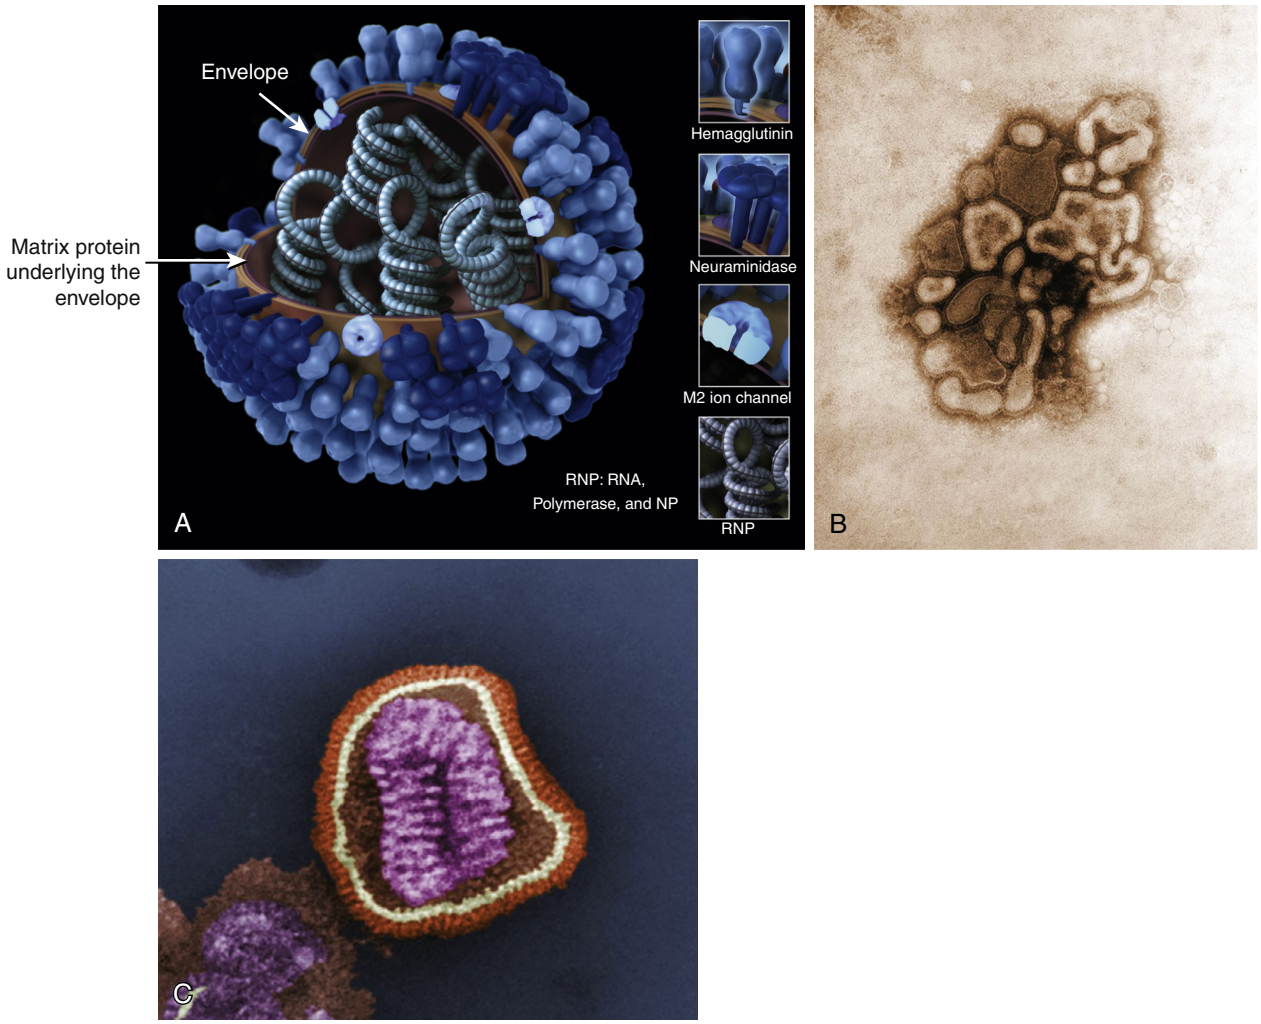

Fig. 49.1 (A) Model of influenza A virus. (B and C) Electron micrographs of influenza A virus. *NP,* Nucleoprotein; *RNA,* ribonucleic acid; *RNP,* ribonucleoprotein complex. (Courtesy Centers for Disease Control and Prevention, Atlanta, GA.)

myalgias (body aches). The term **flu,** however, has been mistakenly used to refer to many other respiratory and viral infections (e.g., "intestinal flu").

Structure and Replication

Influenza virions are pleomorphic, appearing spherical or tubular (Fig. 49.1; Box 49.1) and ranging in diameter from 80 to 120 nm. The genome of the influenza A and B viruses consists of **eight different helical nucleocapsid segments,** each of which contains a negative-sense RNA associated with the **nucleoprotein (NP)** and the **transcriptase (RNA polymerase components: PB1, PB2, PA)** (Table 49.1). Influenza C has only seven genomic segments.

The genomic segments in the influenza A virus range from 890 to 2340 bases. The proteins are encoded on separate segments except for the nonstructural proteins (NS_1 and NS_2) and the M1 and M2 proteins, each of which are transcribed from one segment.

BOX 49.1 Unique Features of the Influenza A and B Viruses

The enveloped virion has a genome of eight unique negative-sense RNA nucleocapsid segments.
Hemagglutinin glycoprotein is the viral attachment protein and fusion protein; it elicits neutralizing, protective antibody responses.
Influenza transcribes and replicates its genome in the target cell nucleus but assembles and buds from the plasma membrane.
The polymerase uses capped cellular mRNA as primers for mRNA synthesis, and this is a target for baloxavir marboxil.
The antiviral drugs amantadine and rimantadine target the M2 (membrane) protein for *influenza A only* to inhibit the uncoating step.
The antiviral drugs zanamivir, oseltamivir, and peramivir inhibit the neuraminidase protein of influenza A and B.
The segmented genome promotes genetic diversity caused by mutation and reassortment of segments on infection with two different strains.
Influenza A infects humans, other mammals, and birds (zoonosis).

TABLE 49.1 Products of Influenza Gene Segments

Segment[a]	Protein	Function
1	PB2	Polymerase component
2	PB1	Polymerase component
3	PA	Polymerase component
4	HA	Hemagglutinin, viral attachment protein, fusion protein, target of neutralizing antibody
5	NP	Nucleocapsid protein
6	NA	Neuraminidase (cleaves sialic acid and promotes virus release)
7[b]	M1	Matrix protein: viral structural protein (interacts with nucleocapsid and envelope, promotes assembly)
	M2	Membrane protein (forms membrane channel and target for amantadine, facilitates uncoating and HA production)
8[b]	NS1	Nonstructural protein (inhibits cellular messenger RNA translation)
	NS2	Nonstructural protein (promotes export of nucleocapsid from nucleus)

[a]Listed in decreasing order of size.
[b]Encodes two messenger RNAs.

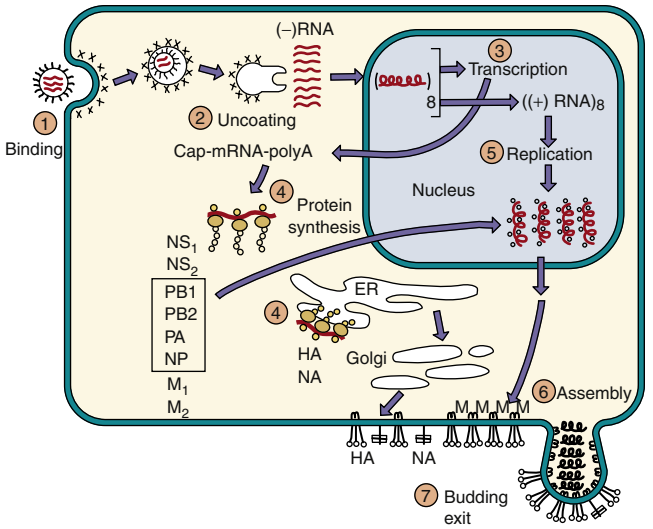

Fig. 49.2 Replication of influenza A virus. After binding *(1)* to sialic acid–containing receptors, influenza is endocytosed and fuses *(2)* with the vesicle membrane. Unlike for most other ribonucleic acid *(RNA)* viruses, transcription *(3)* and replication *(5)* of the genome occur in the nucleus. Viral proteins are synthesized *(4)*, helical ribonucleoprotein complex nucleocapsid segments form and associate *(6)* with the M1 protein–lined membranes containing M2 and the hemagglutinin *(HA)* and neuraminidase *(NA)* glycoproteins. The virus buds *(7)* from the plasma membrane and eventually kills the cell. *(–)*, Negative sense; *(+)*, positive sense; *ER*, endoplasmic reticulum; *NP*, nucleocapsid protein; *NS1, NS2*, nonstructural proteins 1 and 2; *PA, PB1, PB2*, polymerase components; *polyA*, polyadenylate.

The envelope contains two glycoproteins, **hemagglutinin (HA)** and **neuraminidase (NA),** and the **membrane (M2) protein** and is internally lined by the **matrix (M1) protein.** The **HA** forms a spike-shaped trimer; each unit is activated by a protease and is cleaved into two subunits held together by a disulfide bond (see Fig. 36.7). The HA has several functions: it is the viral attachment protein, binding to sialic acid on epithelial cell-surface receptors; it promotes fusion of the envelope to the cell membrane at acidic pH; it hemagglutinates (binds and aggregates) human, chicken, and guinea pig red blood cells; and it elicits the protective neutralizing antibody response. *There are 18 different subtypes of HA designated H1, H2, …, H18.* The HA undergoes minor ("drift") and major ("shift") changes in receptor specificity and antigenicity. ***Shifts occur only with influenza A virus.***

The **NA** glycoprotein forms a tetramer and has enzyme activity. The NA cleaves the sialic acid on glycolipids and glycoproteins, including the cell receptor. Cleavage of the sialic acid on newly synthesized HA and cellular glycoproteins limits binding and prevents clumping of the HA and virions and facilitates the release of virus from infected cells, making NA a target for antiviral drugs, including **zanamivir (Relenza)** and **oseltamivir (Tamiflu).** *The NA of influenza A virus also undergoes antigenic shift, and the different NAs are designated N1, N2, …, N11.*

The M1, M2, and NP proteins are type specific; therefore they are used to differentiate influenza A from B or C viruses. The **M1 proteins** line the inside of the virion and promote assembly. The **M2 protein** forms a proton channel in membranes and promotes uncoating and viral release. The M2 of influenza A is a target for the antiviral drugs **amantadine** and **rimantadine.**

Viral replication begins with the binding of HA to sialic acid on cell-surface glycoproteins (Fig. 49.2). The different HAs bind to different sialic acid structures and, for influenza A (HA1 to H16), this determines the host, human and animal, and site in the lung that can be infected. The virus is then internalized into a coated vesicle and transferred to an endosome. Acidification of the endosome causes the HA to bend over and expose hydrophobic fusion-promoting regions of the protein. The viral envelope then fuses with the endosome membrane. The proton channel formed by the M2 protein promotes acidification of the envelope contents to break the interaction between the M1 protein and the NP, allowing uncoating and delivery of the nucleocapsid into the cytoplasm.

Unlike most RNA viruses, the influenza nucleocapsid travels to the nucleus, where it is transcribed into messenger RNA (mRNA). The transcriptase (PA, PB1, and PB2) uses host cell mRNA as a primer for viral mRNA synthesis. In so doing, it steals the methylated cap region of the RNA, which is the sequence required for efficient binding to ribosomes. This activity of PB2 is a target for **baloxavir marboxil**. All the genomic segments are transcribed into 5′-capped, 3′-polyadenylated (polyA) mRNA for individual proteins except the segments for the M1, M2, and NS1, NS2 proteins, which are each differentially spliced (using cellular enzymes) to produce two different mRNAs. The mRNAs are translated into protein in the cytoplasm. The HA and NA glycoproteins are processed by the endoplasmic reticulum and the Golgi apparatus. The M2 protein inserts into cellular membranes. Its proton channel prevents acidification of Golgi and other vesicles, preventing acid-induced folding and inactivation of the HA within the cell. The HA and NA are then transported to the cell surface, in which the HA protein is activated by cleavage by host proteases.

Positive-sense RNA templates for each segment are produced, and the negative-sense RNA genome is replicated in the nucleus. The genomic segments associate with polymerase and NP proteins to form nucleocapsids, and the NS2 protein facilitates the transport of ribonucleocapsids into the cytoplasm, where they interact with the M1 protein–lined plasma membrane sections containing M2, HA, and NA. The virus buds selectively from the apical (airway) surface of the cell as a result of the preferential insertion of the HA in this membrane. The virus is released approximately 8 hours after infection.

Pathogenesis and Immunity

Influenza initially establishes a local upper respiratory tract infection (Fig. 49.3; Box 49.2). To do so, the virus first targets and kills mucus-secreting, ciliated, and other epithelial cells, causing the loss of this primary defense system. With a lack of ciliated epithelium, swallowed oral and nasal bacteria (e.g., *Staphylococcus aureus*) cannot be expelled and may cause pneumonia. NA facilitates the development of the infection by cleaving sialic acid (neuraminic acid) residues of the mucus, providing access to tissue. Preferential release of the virus at the apical surface of epithelial cells and into the lung promotes cell-to-cell spread and transmission to other hosts. In the lower respiratory tract, the infection can cause severe desquamation (shedding) of bronchial or alveolar epithelium down to a single-cell basal layer or to the basement membrane.

In addition to compromising the mucociliary defenses of the respiratory tract, influenza infection promotes bacterial adhesion to the epithelial cells. Pneumonia may result from a viral pathogenesis or from a secondary bacterial infection. Influenza may also cause a transient or low-level viremia but rarely involves tissues other than the lung.

Influenza infection is an excellent inducer of interferon which is protective. Interferon α and λ promote antiviral activity. The NS1 protein can counteract some of its action. Systemic interferon and cytokine responses peak at 3 to 4 days postinfection. Type I interferon is responsible for the systemic flulike symptoms. This is almost the same time when virus is present in nasal washes. Recovery caused by innate protections often precedes detection of antibody in serum or secretions. T-cell responses are important for effecting recovery and immunopathogenesis, but preexisting antibody, including vaccine-induced antibody, can prevent disease. As for measles, influenza infection depresses macrophage and T-cell function, hindering immune resolution.

Protection against reinfection is primarily associated with the development of neutralizing antibodies to HA, but antibodies to NA are also protective. The antibody response is specific for each strain of influenza, whereas the cell-mediated immune response is more general and is capable of reacting to influenza strains of the same type (influenza A or B virus). Antigenic targets for T-cell responses include peptides from HA and from the nucleocapsid proteins (NP, PB2) and M1 protein. The NP, PB2, and M1 proteins differ considerably for influenza A and B but minimally between strains of these viruses; hence T-cell memory may provide future protection against infection by a strain different from the immunizing strain.

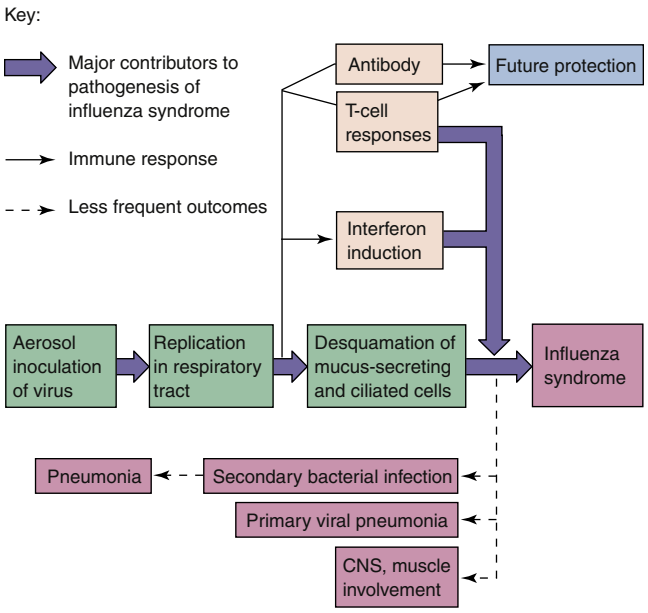

Fig. 49.3 Pathogenesis of influenza A virus. The symptoms of influenza are caused by viral pathologic and immunopathologic effects, but the infection may promote secondary bacterial infection. *CNS,* Central nervous system.

BOX 49.2 Disease Mechanisms of Influenza A and B Viruses

Virus infects the upper and lower respiratory tract.
Systemic symptoms are caused by the interferon and cytokine response to the virus. Local symptoms result from epithelial cell damage, including ciliated and mucus-secreting cells.
Interferon and cell-mediated immune responses (natural killer and T cells) are important for immune resolution and immunopathogenesis.
Infected people are predisposed to bacterial superinfection because of the loss of natural barriers and exposure of binding sites on epithelial cells.
Antibody is important for future protection against infection and is specific for defined epitopes on HA and NA proteins.
The HA and NA of influenza A virus can undergo **major (reassortment: shift)** and **minor (mutation: drift)** antigenic changes to ensure the presence of immunologically naive susceptible people.
Influenza B virus undergoes only minor antigenic changes.

HA, Hemagglutinin; *NA,* neuraminidase.

The symptoms and time course of the disease are determined by the extent of viral and immune killing of epithelial tissue and cytokine action. Influenza is normally a self-limited disease that rarely involves organs other than the lung. The acute onset of *many of the classic flu symptoms (e.g., fever, malaise, headache, and myalgia) is associated with interferon and cytokine induction.* Virus production may be controlled within 4 to 6 days postinfection, but tissue damage caused by innate and immune inflammatory responses continues. Repair of the compromised tissue is initiated within 3 to 5 days of the start of symptoms but may take as long as a month or more, especially for elderly people. The time course of influenza virus infection is illustrated in Fig. 49.4.

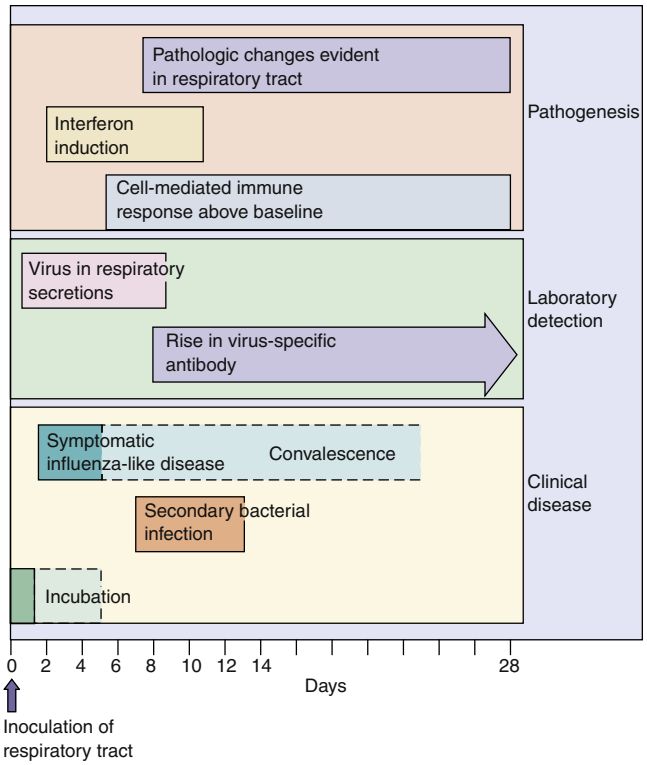

Fig. 49.4 Time course of influenza A virus infection. The classic "flu syndrome" occurs early. Later, pneumonia may result from bacterial pathogenesis, viral pathogenesis, or immunopathogenesis.

Epidemiology

Strains of influenza A virus are classified by the following characteristics:

1. Type (A)
2. Host of origin (chicken, swine, equine), if not human
3. Place of original isolation
4. Strain number
5. Year of original isolation
6. HA and NA type

For example, a current strain of influenza virus might be designated A/duck/Alberta/35/76 (H1N1), meaning that it is an influenza A virus that was first isolated from a duck in Alberta in 1976 and contains HA (H1) and NA (N1) antigens.

Strains of influenza B are designated by (1) type, (2) geography, (3) strain number, and (4) year of isolation (e.g., B/Singapore/3/64) but without specific mention of HA or NA antigens because influenza B does not undergo antigenic shift or pandemics as does influenza A.

Minor antigenic changes resulting from mutation of the HA and NA genes are called **antigenic drift.** This process occurs every 2 to 3 years, causing local outbreaks of influenza A and B infection. **Major antigenic changes (antigenic shift)** result from reassortment of genomes among different strains, including animal strains. *This process occurs only with the influenza A virus*. Such changes are often associated with the occurrence of pandemics. *In contrast to influenza A, influenza B is predominantly a human virus and does not undergo antigenic shift*.

TABLE 49.2 Influenza Pandemics Resulting from Antigenic Shift

Year of Pandemic	Influenza A Subtype
1918	H1N1
1947	H1N1
1957	H2N2; Asian flu strain
1968	H3N2; Hong Kong flu strain
1977	H1N1; Russian
1997, 2003	H5N1: China, avian
2009	H1N1, swine flu

Antigenic shifts occur infrequently, but the pandemics they cause can be devastating (Table 49.2). For example, the prevalent influenza A virus in 1947 was the H1N1 subtype. In 1957, there was a shift in both antigens, resulting in an H2N2 subtype. H3N2 appeared in 1968, and H1N1 reappeared in 1977. The reappearance of H1N1 put the population younger than age 30 years at risk of disease. Prior exposure and an anamnestic antibody response protected members of the population older than 30 years.

The genetic diversity of influenza A is fostered by its segmented genomic structure and ability to infect and replicate in humans and many animal species **(zoonosis),** including birds and pigs. Hybrid viruses are created by coinfection of a cell with different strains of influenza A virus, allowing the genomic segments to randomly associate into new virions. An exchange of the HA glycoproteins may generate a new virus that can infect an immunologically naive human population. Fig. 49.5 depicts the origins of the pandemic A/California/04/2009/H1N1 virus through multiple reassortments of human, avian, and pig influenza viruses, resulting in a virus that was able to infect humans (Clinical Case 49.1).

Influenza infection is spread readily via small airborne droplets expelled during talking, breathing, and coughing. People are most contagious in the first 3 to 4 days of illness, but the period may extend to a week after becoming sick. Low humidity and cool temperatures stabilize the virus, and close proximity during the winter months promotes its spread. The virus can also survive on countertops for as long as a day.

The most susceptible population is children, and school-aged children are most likely to spread the infection. Contagion precedes symptoms and lasts for a long time, especially in children. Children, immunosuppressed people (including pregnant women), the elderly, and people with heart and lung ailments (including smokers) are at highest risk for more serious disease, pneumonia, or other complications of infection. More than 90% of mortalities occur in patients who are older than 65 years, but rapidly progressing lethal bacterial pneumonias secondary to influenza can occur in young healthy individuals.

Influenza A viruses are also spread to humans by aerosols from animals and in the feces of domestic and wild water fowl. Because of its high population density and close proximity of humans, pigs, chickens, and ducks, China is often the breeding ground for new reassortant viruses

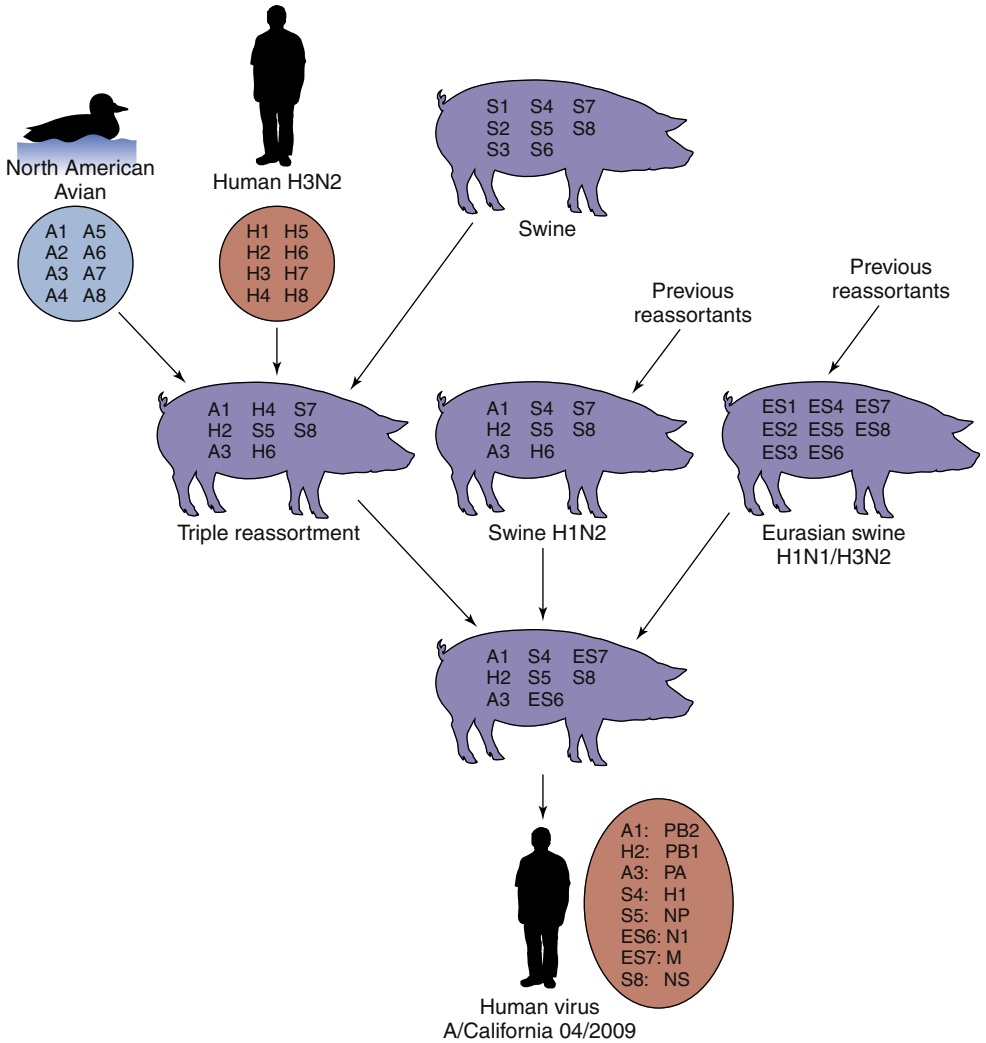

Fig. 49.5 Generation of A/California/04/2009 (H1N1) pandemic swine flu by multiple reassortments of genomic segments of influenza A virus. The pandemic H1N1 virus arose from the mixing of a triple reassortment of avian, human, and swine viruses with two other swine viruses, each of which was also generated by reassortment between swine, human, and other influenza viruses. This new virus emerged in the spring of 2009 (out of season) in Mexico but was first identified in California.

Clinical Case 49.1 **Pandemic Influenza A/California/04/2009 (H1N1)**

In the spring of 2009, a new amantadine- and rimantadine-resistant reassortant H1N1 virus was detected in a 10-year-old patient in California and proceeded to cause a pandemic. As indicated in Fig. 49.5, the virus is a triple-triple reassortant of multiple swine, avian, and human influenza viruses. The virus originated in Mexico and rapidly spread as many cases went unrecognized because of the unseasonal nature of the outbreak. Up to 25,000 deaths occurred worldwide, primarily in people between the ages of 22 months and 57 years. People with chronic medical conditions, especially pregnant women, were at greatest risk to complications, but unlike other outbreaks, this virus had a tendency to affect younger and healthier individuals. Of interest, many people older than 60 years had cross-reactive antibody resulting from prior exposure to an H1N1 influenza virus. Neuraminidase inhibitors were made available for prophylaxis, but detection of resistant strains became a concern. By September, a vaccine had been developed, approved, and manufactured and was available for distribution on a prioritized basis, and then it was administered with the seasonal influenza vaccine. The pandemic was declared over by August 2010, and the H1N1 virus joined H3N2 and influenza B as a seasonal virus.

and the source of many of the pandemic strains of influenza. Inhalation of large amounts of virus (shared living environments) can lead to infection, killing of cells of the lower human lung, and serious disease. In 1997, a highly pathogenic avian influenza virus (HPAIV) (H5N1) strain was isolated from at least 18 humans and caused six deaths in Hong Kong (Clinical Case 49.2). Although primarily a virus of poultry, close contact has caused human infection with H7N9. Outbreaks in 2013 and 2014 of lethal H7N9 disease in China have been traced to chicken-to-human

Clinical Case 49.2 **H5N1 Avian Influenza**

The first case of H5N1 avian influenza in a human was described by Ku and Chan (*J Paediatr Child Health* 35:207–208, 1999). After a 3-year-old boy from China developed a fever of 40° C and abdominal pain, he was given antibiotics and aspirin. On the third day, he was hospitalized with a sore throat, and his chest radiograph demonstrated bronchial inflammation. Blood studies showed a left shift with 9% band forms. On the sixth day, the boy was still febrile and fully conscious, but on the seventh day, his fever increased, he was hyperventilating, and his blood oxygen levels decreased. A chest radiograph indicated severe pneumonia. The patient was intubated. On the eighth day, the boy was diagnosed with fulminant sepsis and ARDS. Therapy for ARDS and other attempts to improve oxygen uptake were unsuccessful. He was treated empirically for sepsis, herpes simplex virus infection (acyclovir), methicillin-resistant *Staphylococcus aureus* (vancomycin), and fungal infection (amphotericin B), but his condition deteriorated further, with disseminated intravascular coagulation and liver and renal failure. He died on the 11th day. Laboratory results indicated elevated influenza A antibody on the eighth day, and influenza A was isolated from a tracheal isolate taken on the ninth day. The isolate was sent to the Centers for Disease Control and Prevention and elsewhere, in which it was typed as H5N1 avian influenza and named *A/Hong Kong/156/97 (H5N1)*. The child may have contracted the virus while playing with pet ducklings and chickens at his kindergarten. Although the H5N1 virus still has difficulty infecting humans, this case demonstrates the speed and severity of the respiratory and systemic manifestations of avian influenza H5N1 disease.

ARDS, Acute respiratory distress syndrome

BOX 49.3 **Epidemiology of Influenza A and B Viruses**

Disease/Viral Factors

Virus has a large, enveloped virion that is easily inactivated by dryness, acid, and detergents.
Segmented genome facilitates major genetic changes, especially on hemagglutinin and neuraminidase proteins.
Influenza A infects many vertebrate species, including other mammals and birds.
Coinfection with animal and human strains of influenza A can generate very different virus strains by genetic reassortment.
Transmission of virus often precedes symptoms.

Transmission

Virus is spread by inhalation of small aerosol droplets expelled during talking, breathing, and coughing.
Virus likes a cool, less humid atmosphere (e.g., winter heating season).
Virus is extensively spread by schoolchildren.

Who Is at Risk?

Seronegative people
Adults: classic flu syndrome.
Children: asymptomatic to severe respiratory tract infections.
High-risk groups: elderly and immunocompromised people, people in nursing homes or with underlying cardiac or respiratory problems (including asthma sufferers and smokers).

Geography/Season

Worldwide occurrence. Epidemics are local; pandemics are worldwide.
Disease is more common in winter.

Modes of Control

Antiviral drugs have been approved for prophylaxis or early treatment.
Killed and live vaccines contain predicted yearly strains of influenza A and B viruses.

transmission in live poultry markets. Outbreaks of avian influenza require destruction of all potentially infected birds, such as the 1.6 million chickens in Hong Kong, to destroy the potential source of the virus.

The changing antigenic nature of influenza ensures a large proportion of immunologically naive susceptible people (especially children) in the population each year (Box 49.3). An influenza outbreak can be readily detected from increased absenteeism in schools and at work and the number of emergency department visits. The influenza season for the Northern Hemisphere is usually from late fall to early spring.

Extensive surveillance of influenza A and B outbreaks is conducted to identify new strains that should be incorporated into new vaccines. The prevalence of a particular strain of influenza A or B virus changes each year and reflects the particular immunologic naïveté of the population at that time. In 2018, influenza A (H3N2) was the predominant strain and caused severe illness, particularly in children and elderly individuals (≥65 years). Surveillance also extends into the animal populations because of the possible presence of recombinant animal influenza A strains that can cause human pandemics.

Clinical Syndromes

Depending on the degree of immunity to the infecting strain of virus and other factors, disease may range from asymptomatic to severe (Box 49.4). Patients with underlying cardiorespiratory disease, people with immune deficiency (even that associated with pregnancy), the elderly, and smokers are more prone to have a severe case.

After an incubation period of 1 to 4 days, the "flu syndrome" begins with a brief prodrome of malaise and headache lasting a few hours. The prodrome is followed by the **abrupt and intense** onset of a high fever, chills, severe myalgias, loss of appetite, weakness and fatigue, sore throat, runny or stuffy nose, and usually a nonproductive cough. The fever persists for 3 to 8 days, and unless a complication occurs, recovery is complete within 7 to 10 days. Influenza in young children (<3 years) resembles other severe respiratory tract infections, potentially causing bronchiolitis, croup, otitis media, vomiting, and abdominal pain, accompanied rarely by febrile convulsions (Table 49.3). Influenza B disease is similar to influenza A disease.

Influenza may directly cause pneumonia, but it more commonly promotes a secondary bacterial superinfection that leads to bronchitis or a rapidly progressing and potentially lethal pneumonia. The tissue damage caused by progressive influenza virus infection of alveoli can be extensive, leading to hypoxia and bilateral pneumonia. Secondary bacterial infection usually involves *Streptococcus pneumoniae, Haemophilus influenzae,* or *S. aureus.* In these infections, sputum usually is produced and becomes purulent.

The inflammatory responses initiated by influenza disease may cause myocarditis, myositis (inflammation of muscle), encephalopathy, postinfluenza encephalitis, multiorgan failure, and Reye syndrome. The inflammatory response can trigger sepsis and exacerbate asthma and chronic heart disease. Reye syndrome is an acute encephalitis that affects children and occurs after a variety of acute febrile viral infections, including varicella and influenza B and A diseases. Children given salicylates (aspirin) are at increased risk for this syndrome. In addition to encephalopathy, hepatic dysfunction is present. The mortality rate may be as high as 40%.

BOX 49.4 Clinical Summary

Influenza A: A 70-year-old woman has rapid onset of fever with headache, myalgia, sore throat, and nonproductive cough. The disease progresses to pneumonia with bacterial involvement. There is no history of recent immunization with influenza A vaccine. Her husband is treated with amantadine or a neuraminidase inhibitor.

TABLE 49.3 Diseases Associated With Influenza Virus Infection

Disorder	Symptoms
Acute influenza infection in adults	Rapid onset of fever, malaise, myalgia, sore throat, and nonproductive cough
Acute influenza infection in children	Acute disease similar to that in adults but with higher fever, gastrointestinal tract symptoms (abdominal pain, vomiting), otitis media, myositis, and more frequent croup
Complications of influenza virus infection	Primary viral pneumonia Secondary bacterial pneumonia Myositis and cardiac involvement Neurologic syndromes: Guillain-Barré syndrome Encephalopathy Encephalitis Reye syndrome

Laboratory Diagnosis

The diagnosis of influenza is usually based on the characteristic symptoms, the season, and the presence of the virus in the community. Influenza viruses are obtained from respiratory secretions taken early in the illness. Rapid techniques detect and identify the influenza genome or antigens of the virus (Table 49.4). Rapid antigen assays (<30 minutes) can detect and distinguish influenza A and B. Reverse transcriptase-polymerase chain reaction (RT-PCR) and multiplex RT-PCR assays can detect and distinguish influenza A and B, different strains (e.g., H5N1), other respiratory viruses, and bacteria. Enzyme immunoassay or immunofluorescence can be used to detect viral antigen in exfoliated cells, respiratory secretions, or cell culture. Immunofluorescence or inhibition of hemadsorption or hemagglutination (hemagglutination inhibition) with specific antibody (see Fig. 39.6) can also detect and distinguish different influenza strains.

The virus can be isolated in primary monkey kidney cell cultures or the Madin-Darby canine kidney cell line. Although cytolytic, the cytopathologic effects of the virus are often difficult to distinguish but may be noted within as few as 2 days (average, 4 days). Before the cytopathologic effects develop, the addition of guinea pig erythrocytes may reveal **hemadsorption** (adherence of these erythrocytes to HA-expressing infected cells) (see Fig. 39.5). Addition of influenza virus–containing fluids to erythrocytes promotes formation of a gel-like aggregate resulting from **hemagglutination.** Hemagglutination and hemadsorption are not specific to influenza viruses; parainfluenza and other viruses also exhibit these properties.

TABLE 49.4 Laboratory Diagnosis of Influenza Virus Infection

Test	Detects
Cell culture in primary monkey kidney or Madin-Darby canine kidney cells	Presence of virus; limited cytopathologic effects
Hemadsorption to infected cells	Presence of hemagglutinin protein on cell surface
Hemagglutination	Presence of virus in secretions
Hemagglutination inhibition	Type and strain of influenza virus or specificity of antibody
Antibody inhibition of hemadsorption	Identification of influenza type and strain
Immunofluorescence, ELISA	Influenza virus and antigens in respiratory secretions or tissue culture
Serology: hemagglutination inhibition, hemadsorption inhibition, ELISA, immunofluorescence, complement fixation	Seroepidemiology
Genomics: rapid viral RNA detection assays, RT-PCR, multiplex RT-PCR, sequence analysis	Detection and identification of influenza type and strain

ELISA, Enzyme-linked immunosorbent assay; *RT-PCR,* reverse transcriptase-polymerase chain reaction.

Treatment, Prevention, and Control

Hundreds of millions of dollars are spent on acetaminophen, antihistamines, and similar drugs to relieve the symptoms of influenza. The antiviral drug **amantadine** and its analog **rimantadine** target the M2 protein and inhibit an uncoating step of the influenza A virus but do not affect the influenza B and C viruses. These drugs are no longer recommended in the United States due to extensive resistance. **Zanamivir, oseltamivir,** and **peramivir** inhibit both influenza A and B as enzyme inhibitors of NA. Without NA, the HA of the virus binds to sialic acid on other glycoproteins and viral particles to form clumps or stick to the cell surface, preventing virus release. Zanamivir is inhaled, whereas oseltamivir is taken orally as a pill. These drugs are effective for prophylaxis and for treatment during the first 24 to 48 hours after the onset of influenza illness. Treatment cannot prevent the later host-induced immunopathogenic stages of the disease. Naturally resistant or mutant strains are selected when antiviral prophylaxis is used and are becoming more prevalent. Stockpiles of oseltamivir have been developed in many countries as a rapid response to an outbreak and an alternative to vaccines. **Baloxavir marboxil** is a new Food and Drug Administration (FDA) approved antiinfluenza drug that targets the activity of the viral polymerase (PB2) that snatches the 5′ cap of cellular mRNAs and uses it as a primer for transcription of viral mRNAs.

The airborne spread of influenza is almost impossible to limit. However, the best way to control the virus is through immunization. Natural immunization, which results from prior exposure, is protective for long periods. Vaccines representing the "strains of the year" and antiviral drug prophylaxis can also prevent infection.

The inactivated subunit influenza vaccines are a mixture of extracts or purified HA and NA proteins from three or four different strains of virus. HA and NA are purified from virus grown in embryonated eggs, from infected tissue culture cells, or by recombinant gene technology. Killed (formalin-inactivated) virion preparations are also used. High-dose and adjuvanted influenza vaccines are available to boost the immunogenicity for older individuals.

The trivalent vaccine incorporates antigens of an influenza A (H1N1) virus, an influenza A (H3N2) virus, and one influenza B virus predicted to be prevalent in the community during the upcoming winter. The quadrivalent vaccine contains an additional influenza B virus. For instance, the 2018–2019 vaccine contained A/Michigan/45/2015 A(H1N1) pdm09-like virus, an A/Singapore/INFIMH-16–0019/2016 A(H3N2)-like virus, and a B/Colorado/06/2017-like (B/Victoria lineage) virus, whereas the quadrivalent vaccine added a B/Phuket/3073/2013-like (B/Yamagata lineage) virus.

A live attenuated influenza vaccine (LAIV) is also available for administration as a nasal spray instead of a "flu shot." The trivalent vaccine consists of reassortant viruses that contain the HA and NA gene segments of the desired influenza strains within a master donor virus that is cold adapted for optimum growth at 25° C. This vaccine is restricted to infecting the nasopharynx and will elicit a more natural protection, including cell-mediated immunity, serum antibody, and mucosal-secretory immunoglobulin (Ig)A antibody. The vaccine is only recommended for people aged 2 to 50 years.

Vaccination is routinely recommended for all individuals and especially persons older than 50 years, health care workers, pregnant women who will be in their second or third trimester during flu season, people living in a nursing home, people with chronic pulmonary heart disease, and others at high risk. Pain at the injection site may result from an Arthus reaction to an annual immunization. Many health care facilities require their personnel to be vaccinated. Persons with serious allergies to eggs can get the recombinant or tissue culture–generated vaccines or the live vaccine.

Although the efficacy of the influenza vaccines may not be 100% for all the viruses, they still reduce the incidence and risk for severe disease. According to the CDC, more than 5 million flu illnesses and 85,000 hospitalizations were prevented in the United States in the 2016–2017 season because of vaccination.

Newer approaches to influenza vaccines include RNA and DNA vaccines and universal influenza A vaccines. RNA and DNA vaccines can be generated from genome sequences within weeks of an outbreak and from smaller and possibly mobile facilities. Molecular regions of the HA protein involved in fusion are being investigated for universal influenza A vaccines.

THOGOTOVIRUSES

Thogotoviruses have six or seven genomic segments and are arboviruses capable of infecting humans and other vertebrates. They are spread primarily by ticks but also possibly by mosquitoes. In 2014, a previously healthy man died of a tick-borne disease that resembled Rocky Mountain spotted fever. It is named the Bourbon virus after Bourbon, Kansas, in which it was isolated.

Case Study and Questions

In late December, a 22-year-old man suddenly experienced headache, myalgia, malaise, dry cough, and fever. He basically felt lousy. After a couple of days, he had a sore throat, his cough had worsened, he started to feel nauseated, and he began vomiting. Several of his family members had experienced similar symptoms during the previous 2 weeks.

1. In addition to influenza, what other agents could cause similar symptoms (differential diagnosis)?

2. How would the diagnosis of influenza be confirmed?

3. Oseltamivir is effective against influenza. What is its mechanism of action? Will it be effective for this patient? For uninfected family members or contacts?

4. When was the patient contagious, and how was the virus transmitted?

5. Which types of family members were at greatest risk for serious disease and why?

6. Why is influenza so difficult to control, even when there is a national vaccination program?

50 Rhabdoviruses, Filoviruses, and Bornaviruses

A 15-year-old girl picked up a bat and was bitten on her hand. One month later, she developed double vision, nausea, and vomiting. Over the course of 4 days, her neurologic disease developed, and she had a fever of 38.9° C. Rabies was suspected, and rabies virus–specific antibodies were detected in the patient's serum and cerebrospinal fluid (1:32 titer). The patient was put into a drug-induced coma with ventilator support and treated with intravenous ribavirin for 7 days, when cerebrospinal fluid antibody titers rose to 1:2048. After 3 months, she was able to walk with assistance, ride a stationary cycle for 8 minutes, feed herself a soft solid diet, solve math puzzles, use sign language, and was regaining the ability to speak. This is the only example of a patient surviving without having received timely postexposure rabies immunization[1]*

1. How is rabies infection confirmed?
2. What is the usual disease progression after a bite from a rabid animal?
3. When is antirabies antibody detected in a normal rabies disease presentation?
4. What is postexposure rabies immunization, and why does it work?
5. How does ribavirin inhibit the replication of rabies and other viruses?

Answers to these questions are available on Student Consult.com.

Summaries Clinically Significant Organisms

RHABDOVIRUSES

Trigger Words

Mad dog, hydrophobia, salivation, bullet-shaped virion, Negri bodies

Biology, Virulence, and Disease

- Medium size, bullet shaped, enveloped, (–) RNA genome
- Encodes RNA-dependent RNA polymerase, replicates in cytoplasm
- Antibody can block disease
- Virus spreads along neurons to salivary glands and brain
- Antibody produced after virus reaches brain
- Incubation period depends on proximity of bite to CNS and infectious dose

Epidemiology

- Zoonosis
- Reservoir in skunks, raccoons, foxes, badgers, bats (aerosols)

Diagnosis

- RT-PCR, antigen detection in biopsy, presence of Negri bodies in infected cells

Treatment, Prevention, and Control

- Immunization with killed vaccine *after* bite and antirabies immunoglobulin
- Prophylaxis if job-related risk
- Inactivated vaccine for pets
- Vaccinia virus hybrid vaccine for wild animals

CNS, Central nervous system; *RT-PCR,* reverse transcriptase-polymerase chain reaction.

Rhabdoviruses

Members of the family Rhabdoviridae (from the Greek word **rhabdos,** meaning "rod") include pathogens for a variety of mammals, fish, birds, and plants. The family contains *Vesiculovirus* (vesicular stomatitis viruses [VSVs]), *Lyssavirus* (Greek for "frenzy") (rabies and rabies-like viruses), and many other rhabdoviruses of plants, mammals, birds, fish, and arthropods.

Rabies virus is the most significant pathogen of the rhabdoviruses. Until Louis Pasteur developed the killed-rabies vaccine, a bite from a "mad" dog always led to the characteristic symptoms of **hydrophobia** and certain death.

PHYSIOLOGY, STRUCTURE, AND REPLICATION

Rhabdoviruses are simple viruses, encoding only five proteins and appearing as **bullet-shaped enveloped virions** with a diameter of 50 to 95 nm and length of 130 to 380 nm (Fig. 50.1; Box 50.1). Spikes composed of a trimer of the glycoprotein (G) cover the surface of the virus. The viral attachment protein, G-protein, generates neutralizing antibodies. The G-protein of the VSV is a simple glycoprotein with N-linked glycan. This G-protein was used as the prototype for studying eukaryotic glycoprotein processing.

Within the envelope, the **helical nucleocapsid** is coiled symmetrically into a cylindrical structure, giving it the appearance of striations (see Fig. 50.1). The nucleocapsid is composed of one molecule of **single-stranded, negative-sense ribonucleic acid (RNA)** of approximately 12,000 bases and the nucleoprotein (N), large (L), and nonstructural (NS) proteins. The L and NS proteins constitute the RNA-dependent RNA polymerase. The N protein is the major structural protein of the virus. It protects the RNA from ribonuclease digestion and maintains the RNA in a configuration acceptable for transcription. The matrix (M) protein lies between the envelope and the nucleocapsid.

The replicative cycle of VSV is the prototype for the rhabdoviruses and other negative-strand RNA viruses

Prototype for replication of negative-strand enveloped viruses.
Replication in cytoplasm.

(see Fig. 36.13). The viral G-protein attaches to the host cell and virions are internalized by endocytosis. Rabies virus binds to either the nicotinic acetylcholine receptor (AChR), neural cell adhesion molecule (NCAM), or other molecules. The viral envelope then fuses with the membrane of the endosome on acidification of the vesicle. This uncoats the nucleocapsid, releasing it into the cytoplasm, where replication takes place. In neurons, Endosomal vesicles may deliver whole rabies virions along the axon to neuronal cell to facilitate neuronal spread.

The RNA-dependent RNA polymerase associated with the nucleocapsid transcribes the viral genomic RNA, producing five individual messenger RNAs (mRNAs). For rabies virus, this occurs in the Negri bodies. These mRNAs are then translated into the five viral proteins. The viral genomic RNA is also transcribed into a full-length, positive-sense RNA template that is used to generate new genomes. The G-protein is synthesized by membrane-bound ribosomes, processed by the Golgi apparatus, and delivered to the cell surface in membrane vesicles. The M protein associates with the G-protein–modified membranes.

Assembly of the virion occurs in two phases: (1) assembly of the nucleocapsid in the cytoplasm and (2) envelopment and release at cytoplasmic or plasma membranes. The genome associates with the N protein and then with the polymerase proteins L and NS to form the nucleocapsid. Association of the nucleocapsid with the M protein induces coiling into its condensed form and the characteristic bullet shape of the virion. In most cells, the virus buds from intracytoplasmic membranes and release is inefficient. The exception is the salivary gland, in which the virus buds efficiently from the plasma membrane and is released when the entire nucleocapsid is enveloped. The time for a single cycle of replication depends on the cell type and the inoculum size.

BOX 50.2 Disease Mechanisms of Rabies Virus

Rabies is usually transmitted in saliva and acquired from the bite of a rabid animal.
Rabies virus is **not very cytolytic** and seems to remain cell associated except in salivary gland.
Virus replicates in the muscle at the site of the bite, with minimal or no symptoms **(incubation phase).**
The length of the incubation phase is determined by the infectious dose and the proximity of the infection site to the CNS and brain.
After weeks to months, the virus infects the peripheral nerves and travels up the CNS to the brain **(prodrome phase).**
Infection of the brain causes classic symptoms, coma, and death **(neurologic phase).**
During the neurologic phase, the virus spreads to the glands, skin, and other body parts, including the salivary glands.
Rabies infection does not elicit an antibody response until the late stages of the disease, when the virus has spread from the CNS to other sites.
Salivary glands produce and release large amounts of virus and is the major source of contagion.
Administration of antibody can block progression of the virus and disease if given early enough.
The long incubation period allows active immunization as a post-exposure treatment.

CNS, Central nervous sy stem.

PATHOGENESIS AND IMMUNITY

Rabies infection usually results from the bite of a rabid animal (Box 50.2). Rabies infection of the animal causes secretion of the virus in the animal's saliva and promotes aggressive behavior and biting (mad dog), which in turn promotes transmission of the virus. The virus can also be transmitted through inhalation of aerosolized virus (as may be found in bat caves), in transplanted infected tissue (e.g., cornea), and by inoculation through intact mucosal membranes.

The virus replicates quietly at the site of infection for days to months (Fig. 50.2) before progressing to the peripheral nervous system and then the central nervous system (CNS). Rabies virus travels by retrograde axoplasmic transport to the dorsal root ganglia and the spinal cord. Once the virus gains access to the spinal cord, the brain becomes rapidly infected and virus production increases. The affected areas are the hippocampus, brainstem, ganglionic cells of the pontine nuclei, and Purkinje cells of the cerebellum. The virus then disseminates from the CNS via afferent neurons to highly innervated sites such as the skin of the head and neck, **salivary glands,** retina, cornea, nasal mucosa, adrenal medulla, renal parenchyma, and pancreatic acinar cells. Virus is released efficiently from the salivary gland to promote contagion from infected animals. After the virus invades the brain and spinal cord, encephalitis develops and neurons degenerate. Despite extensive CNS involvement and impairment of CNS function, little histopathologic change can be observed in the affected tissue, other than the presence of Negri bodies (see section on Laboratory Diagnosis for rhabies).

Rabies is fatal once the clinical disease is apparent. The length of the incubation period is determined by the

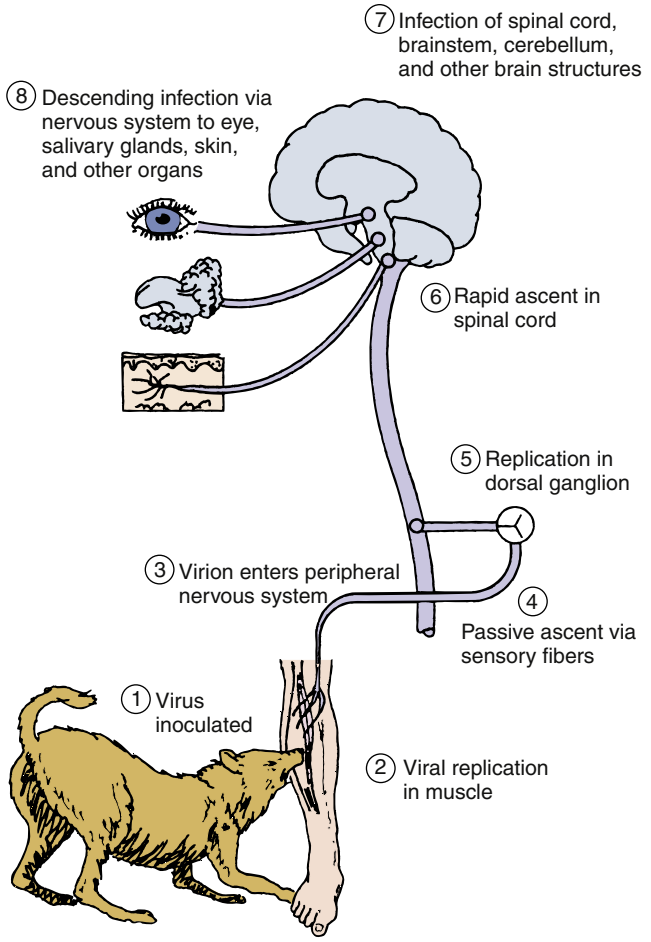

Fig. 50.2 Pathogenesis of rabies virus infection. Numbered steps describe the sequence of events. (Modified from Belshe, R.B., 1991. Textbook of Human Virology, second ed. Mosby, St Louis, MO.)

(1) concentration of the virus in the inoculum, (2) proximity of the wound to the brain, (3) severity of the wound, (4) host's age, and (5) host's immune status.

In contrast to other viral encephalitis syndromes, rabies is minimally cytolytic and rarely causes inflammatory lesions. Viral proteins inhibit apoptosis and aspects of interferon action. Little antigen is released, and the infection probably remains hidden from the immune response. Neutralizing antibodies are not apparent until after the clinical disease is well established. Cell-mediated immunity appears to play little or no role in protection against rabies virus infection.

Antibody can block the spread of virus to the CNS and brain if administered or generated by vaccination during the incubation period. The incubation period is usually long enough to allow generation of a therapeutic protective antibody response after active immunization with the killed rabies vaccine.

EPIDEMIOLOGY

Rabies is the **classic zoonotic infection** spread from animals to humans (Box 50.3). Rabies occurs in most parts of the world but is rarely seen in Japan, Australia, New Zealand, United Kingdom, and certain island states. Rabies is maintained and spread in three ways. In urban rabies, dogs are the primary transmitter, in sylvatic (forest) rabies, many species of wildlife can serve as transmitters, and then there is bat rabies. Virus-containing aerosols, bites, and scratches from infected bats also spread the disease. In the United States, rabies is more prevalent in cats because they are not vaccinated. The principal reservoir for rabies in most of the world, however, is the dog. In Latin America and Asia, this feature is a problem because of the existence of many stray unvaccinated dogs and the absence of rabies-control programs. Although rare, there are cases of rabies transmission via corneal and organ transplants.

Because of the excellent dog vaccination program in the United States, sylvatic and bat exposure accounts for most of the cases of animal rabies in this country. Statistics for animal rabies are collected by the Centers for Disease Control and Prevention, which in 1999 recorded more than 8000 documented cases of rabies in raccoons, skunks, bats, and farm animals, in addition to dogs and cats (Fig. 50.3). Badgers and foxes are also major carriers of rabies in Western Europe. In South America, vampire bats transmit rabies to cattle, resulting in losses of millions of dollars each year.

Although underreported, it is estimated that rabies accounts for 40,000 to 100,000 deaths (mostly children) annually worldwide, with at least 20,000 deaths in India, in which the virus is transmitted by dogs in 96% of cases. In Latin America, cases of human rabies primarily result from contact with rabid dogs in urban areas. In Indonesia, an outbreak of more than 200 human cases of rabies in

BOX 50.3 Epidemiology of Rabies Virus

Disease/Viral Factors

Virus-induced aggressive behavior in animals promotes virus spread.
Production of virus by salivary gland transmits virus in bite.
Disease has long, asymptomatic incubation period.

Transmission

Zoonosis
- Reservoir: wild animals.
- Vector: wild animals and unvaccinated dogs and cats.

Source of virus
- Major: saliva in bite of rabid animal (including bats).
- Minor: aerosols in bat caves containing rabid bats.
- Rare: transplant of contaminated cornea or organ.

Who Is at Risk?

Veterinarians and animal handlers.
Person bitten by a rabid animal.
Inhabitants of countries with no pet vaccination program.

Geography/Season

Virus found worldwide, except in some island nations.
No seasonal incidence.

Modes of Control

Vaccination program is available for pets.
Vaccination is available for at-risk personnel.
Vaccination programs have been implemented to control rabies in forest mammals.

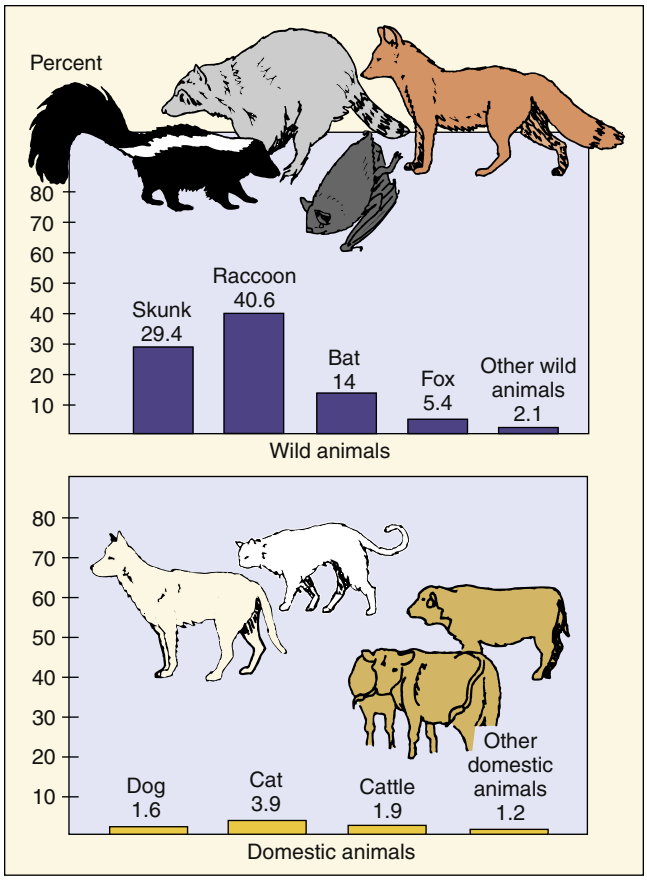

Fig. 50.3 Distribution of animal rabies in the United States, 1999. Percentages relate to the total number of cases of animal rabies. (Data from Krebs, J.W., Rupprecht, C.E., Childs, J.E., 2000. Rabies surveillance in the United States during 1999. Am. Veter. Med. Assoc. 217, 1799–1811.)

1999 prompted the killing of more than 40,000 dogs on the islands. The incidence of human rabies in the United States is approximately one case per year, due in large part to effective dog vaccination programs and limited human contact with skunks, raccoons, and bats. Since 1990, human cases of rabies in the United States are acquired elsewhere or caused primarily by bat variants of the virus. The World Health Organization estimates that 10 million people per year receive treatment after exposure to animals suspected of being rabid.

CLINICAL SYNDROMES

Rabies is virtually always fatal unless treated by vaccination. After a long but highly variable incubation period, the prodrome phase of rabies ensues (Box 50.4; Table 50.1). The patient has symptoms such as fever, malaise, headache, pain or paresthesia (itching) at the site of the bite, gastrointestinal symptoms, fatigue, and anorexia. The prodrome usually lasts 2 to 10 days, after which the neurologic symptoms specific to rabies appear. **Hydrophobia** (fear of water), the most characteristic symptom of rabies, occurs in 20% to 50% of patients. It is triggered by the pain associated with the patient's attempts to swallow water. Focal and generalized seizures, disorientation, and hallucinations are also common during the neurologic phase. Paralysis (15% to 60% of patients) may be the only manifestation of rabies and may lead to respiratory failure.

The patient becomes comatose after the neurologic phase, which lasts from 2 to 10 days. This phase almost universally leads to death resulting from neurologic and pulmonary complications.

BOX 50.4 Clinical Summary

Rabies: A 3-year-old girl was found to have a bat flying in her bedroom. The bat apparently was there all night. There was no evidence of any bite wound or contact, and the bat was caught and released. Three weeks later, the child developed a change in behavior, becoming irritable and agitated. This state quickly progressed to confusion, uncontrollable thrashing about, and inability to handle her secretions. She eventually became comatose and died from respiratory arrest.

LABORATORY DIAGNOSIS

The occurrence of neurologic symptoms in a person who has been bitten by an animal generally establishes the diagnosis of rabies. Unfortunately, *evidence of infection, including symptoms and the detection of antibody, does not occur until it is too late for intervention*. Laboratory tests are usually performed to confirm the diagnosis (too late for treatment) and determine whether a suspected animal is rabid (postmortem).

Antigen detection using direct immunofluorescence or genome detection using reverse transcriptase polymerase chain reaction (RT-PCR) are relatively quick and sensitive assays, and they are the preferred methods for diagnosing rabies. Samples of saliva are easy to test, but serum, spinal fluid, skin biopsy material from the nape of the neck, brain biopsy or autopsy material, and impression smears of corneal epithelial cells can also be examined.

Infected cells will have intracytoplasmic inclusions consisting of aggregates of viral nucleocapsids **(Negri bodies)** in affected neurons (see Fig. 39.3). Although their finding is diagnostic of rabies, Negri bodies are seen in only 70% to 90% of brain tissue from infected humans.

Antibody is not detectable until late in the disease but can be assayed from serum and cerebrospinal fluid by enzyme-linked immunosorbent assay (ELISA).

TREATMENT AND PROPHYLAXIS

Clinical rabies is almost always fatal unless treated early with postrabies immunization. Once the symptoms have appeared, little other than supportive care can be given. There is one case of successful cessation of disease progression by postexposure ribavirin treatment (see introductory case study).

Postexposure prophylaxis is the only hope for preventing overt clinical illness in the affected person. Although human cases of rabies are rare, approximately 20,000 people receive rabies prophylaxis each year in the United States alone. Prophylaxis should be initiated for anyone exposed by bite or by contamination of an open wound or mucous membrane to the saliva or brain tissue of an animal suspected to be infected with the virus, unless the animal is tested and shown not to be rabid.

TABLE 50.1 Progression of Rabies Disease

Disease Phase	Symptoms	Time (Days)	Viral Status	Immunologic Status
Incubation phase	Asymptomatic	60–365 after bite	Low titer, virus in muscle	—
Prodrome phase	Fever, nausea, vomiting, loss of appetite, headache, lethargy, pain at site of bite	2–10	Low titer, virus in CNS and brain	—
Neurologic phase	Hydrophobia, pharyngeal spasms, hyperactivity, anxiety, depression CNS symptoms: loss of coordination, paralysis, confusion, delirium	2–7	High titer, virus in brain and other sites	Detectable antibody in serum and CNS
Coma	Coma, hypotension, hypoventilation, secondary infections, cardiac arrest	0–14	High titer, virus in brain and other sites	—
Death	—	—	—	—

CNS, Central nervous system.

The first protective measure is local treatment of the wound. The wound should be washed immediately with soap and water or another substance that inactivates the virus. Antirabies immunoglobulin is injected near the wound.

Subsequently, four immunizations with rabies vaccine are administered within 2 weeks, with one initial dose of human rabies immunoglobulin (HRIG) or equine antirabies serum. Passive immunization with HRIG provides antibody until the patient produces antibody in response to the vaccine. The slow course of rabies disease allows active immunity to be generated in time to afford protection.

The rabies vaccine is a killed-virus vaccine prepared through chemical inactivation of rabies infected–tissue culture human diploid cells (HDCV) or chick embryo cells. These vaccines cause fewer negative reactions than the older vaccines (Semple and Fermi), which were prepared in the brains of adult or suckling animals. Serum monitoring and preexposure vaccination should be performed on animal workers, laboratory workers who handle potentially infected tissue, and people traveling to areas in which rabies is endemic. HDCV is administered intramuscularly to these individuals and provides 2 years of protection.

Ultimately, the prevention of human rabies hinges on effective control of rabies in domestic and wild animals. Its control in domestic animals depends on removal of stray and unwanted animals and vaccination of all dogs and cats. A variety of attenuated oral vaccines have also been used successfully to immunize foxes. A live recombinant vaccinia virus vaccine expressing the rabies virus G-protein is in use in the United States. This vaccine, which is injected into bait and parachuted into the forest, successfully immunizes raccoons, foxes, and other animals. Accidental injection of a woman with this vaccinia-rabies hybrid vaccine resulted in immunization against both smallpox and rabies viruses (see Bibliography).

Filoviruses

The **Marburg** and **Ebola** viruses (Fig. 50.4) were classified as members of the family Rhabdoviridae but are now classified as **filoviruses (Filoviridae).** They are **filamentous, enveloped, negative-strand RNA viruses.** These agents cause **severe or fatal hemorrhagic fevers** and are **endemic in Africa.** Awareness of the Ebola virus increased after an outbreak of the disease in Zaire in 1995,

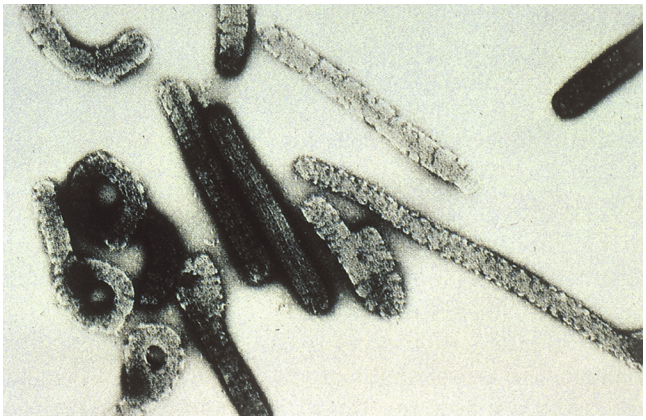

Fig. 50.4 Electron micrograph of Ebola virus. (Courtesy Centers for Disease Control and Prevention, Atlanta, GA.)

in Gabon in 1996, and also after the release of the movie *Outbreak,* based on the book by Robin Cook, and the book *The Hot Zone* by Richard Preston. In 2014, an epidemic of Ebola killed many thousands, mostly in the West African countries of Liberia, Sierra Leone, and Guinea, and more recent outbreaks (2018- ongoing as of printing) have been in the Democratic Republic of Congo.

STRUCTURE AND REPLICATION

Filoviruses have a single-stranded RNA genome (4.5×10^6 Da) that encodes seven proteins. The virions form long enveloped filaments with a diameter of 80 nm but may also assume other shapes. They vary in length from 800 nm to as long as 1400 nm and may contain none, one, or multiple genomes. The nucleocapsid is helical and enclosed in an envelope containing one glycoprotein. The glycoprotein is cleaved into two components, and a shorter version is secreted. The Ebola virus binds to Niemann-Pick C1 (NPC1), which is a cholesterol transfer protein, and T-cell immunoglobulin and mucin domain 1 (TIM-1), which is also the hepatitis A virus receptor. The virus enters the cell and replicates in the cytoplasm like the rhabdoviruses.

PATHOGENESIS

The filoviruses replicate efficiently, producing large amounts of virus in endothelial cells, monocytes, macrophage,

dendritic cells, and other cells. Replication in macrophages, monocytes, and dendritic cells elicits a cytokine storm of proinflammatory cytokines similar to a superantigen-induced cytokine storm promoting sepsis-like symptoms. Viral cytopathogenesis causes extensive tissue necrosis in parenchymal cells of the liver, spleen, lymph nodes, and lungs. Infection of endothelial cells prevents production of cell adhesion proteins and causes cytolysis leading to vascular injury and leakage. Strains with mutations in the glycoprotein gene lack the hemorrhagic component of disease. The widespread hemorrhage that occurs in affected patients causes edema, hypovolemic shock, and disseminated intravascular coagulopathy (DIC). The virus also can evade host innate, including interferon, and immune responses.

EPIDEMIOLOGY

Marburg virus infection was first detected among laboratory workers in Marburg, Germany, who had been exposed to tissues from apparently healthy African green monkeys. Rare cases of Marburg virus infection have been seen in Zimbabwe and Kenya.

Ebola virus was named for the river in the Democratic Republic of Congo (formerly Zaire) in which it was discovered. Outbreaks of Ebola virus disease have occurred in the Democratic Republic of Congo, Sudan, and, most recently, Liberia, Sierra Leone, and Guinea. During an outbreak, the Ebola virus is so lethal it can eliminate the susceptible population before it can be spread from the region. In urban areas, spread of the virus is more difficult to control. In rural areas of central Africa, as much as 18% of the population has antibody to this virus, indicating that subclinical infections do occur.

These viruses may be endemic in bats or wild monkeys and can be spread to humans and between humans. Contact with the animal reservoir or direct contact with infected blood or secretions can spread the disease. These viruses have been transmitted by accidental injection and through the use of contaminated syringes. Health care workers tending to the sick, funeral workers, and monkey handlers may be at risk. In response to the 2014 epidemic, screening similar to that for severe acute respiratory syndrome (SARS) coronavirus was initiated at major airports, and all patients in the United States with flulike symptoms were asked for their travel history.

CLINICAL SYNDROMES

Marburg and Ebola viruses (Clinical Case 50.1) are the most severe causes of viral hemorrhagic fevers. The illness usually begins with flulike symptoms such as headache and myalgia. Nausea, vomiting, and diarrhea occur within a few days; a rash also may develop. Subsequently, hemorrhage from multiple sites (especially the gastrointestinal tract) and death occur in as many as 90% of patients with clinically evident disease.

LABORATORY DIAGNOSIS

All specimens from patients with a suspected filovirus infection must be handled with extreme care to prevent accidental infection. Handling of these viruses requires **level 4 isolation** procedures that are not routinely available. Viral antigens can be detected in tissue by direct immunofluorescence analysis and in fluids by ELISA. RT-PCR amplification of the viral genome in secretions can be used to confirm the diagnosis and minimize handling of samples.

TREATMENT, PREVENTION, AND CONTROL

Antibody-containing serum, artificially produced antibody (ZMAPP), and interferon and ribavirin therapies have been tried in patients with filovirus infections. Infected patients should be quarantined, and contaminated animals should be sacrificed. Handling of the viruses, infected individuals, dead bodies, and contaminated materials requires very stringent (level 4) isolation procedures. Several approaches have been used to develop a vaccine. In the 2018 outbreak in the Democratic Republic of Congo, the rVSV-ZEBOV, a recombinant vaccine in which VSV expresses the Ebola glycoprotein instead of its own, was used. Health care workers and individuals in areas surrounding the outbreak of Ebola who are most likely to be infected (ring vaccination) had priority to be immunized.

Borna Disease Virus

Borna disease virus (BDV) is the only member of a family of enveloped, negative-strand RNA viruses. BDV was first associated with infection of horses in Germany. The virus has received considerable interest because of its association with specific neuropsychiatric diseases such as schizophrenia.

STRUCTURE AND REPLICATION

The 8910-nucleotide-long genome of BDV encodes five detectable proteins, including a polymerase (L), nucleoprotein (N), phosphoprotein (P), matrix protein (M), and envelope glycoprotein (G). Unlike most negative-strand viruses, BDV replicates in the nucleus. Although this is similar to the orthomyxoviruses, BDV differs in that its genome is unsegmented.

PATHOGENESIS

BDV is highly neurotropic and capable of spreading throughout the CNS. BDV also infects parenchymal cells of different organs and peripheral blood mononuclear cells. The virus is not very cytolytic and establishes a persistent infection in the infected individual. T-cell immune responses are important for controlling BDV infections but also contribute to tissue damage, leading to disease.

CLINICAL SYNDROMES

Although there is limited understanding of the BDV disease in humans, infection of animals can result in subtle losses of learning and memory and in fatal immune-mediated meningoencephalitis. Many of the outcomes of BDV infection of laboratory animals resemble human neuropsychiatric diseases, including depression, bipolar disorder, schizophrenia, and autism. The presence of antibodies to the virus and/or infected peripheral blood mononuclear cells in higher than background numbers of patients with schizophrenia, autism, and other neuropsychiatric diseases suggests that BDV either causes or exacerbates these mental illnesses.

EPIDEMIOLOGY

BDV is capable of infecting many different mammalian species (zoonosis), including horses, sheep, and humans. Most outbreaks of the virus have occurred in Central Europe, but it has also been detected in North America and Asia. Neither the reservoir nor the mode of transmission of BDV is known. Higher levels of infection of humans are present where outbreaks in horses have been observed.

LABORATORY DIAGNOSIS

Infection can be detected by direct analysis for the viral genome and mRNA in peripheral blood mononuclear cells using RT-PCR. Serologic analysis of antibody to the viral proteins continues to be used to identify an association of BDV with human diseases.

TREATMENT

Similar to many other RNA viruses, BDV is sensitive to ribavirin treatment. Ribavirin treatment may be a reasonable treatment approach for some psychoneurologic disorders if BDV is demonstrated as a cofactor.

Clinical Case 50.1 **Ebola**

Emond and associates described the following case of Ebola infection (*Br Med J* 2:541–544, 1977). Within 6 days of a needle-stick accident while handling animal liver infected with Ebola virus, a scientist complained of abdominal pain and nausea. He was transferred to a high-security infectious disease unit and placed in an isolation room. At admission (day 1), he was experiencing fatigue, anorexia, nausea, and abdominal pain and had a fever of 38° C. Interferon was administered twice a day, and it appeared to have worked, except that the next morning his fever returned (39° C). He was given heat-inactivated convalescent serum with no immediate effect. On day 4, he sweated profusely, and his temperature dropped to normal, but he had a new rash on his chest. At midday of day 4, he experienced sudden violent shivering, fever of 40° C, nausea, vomiting, and diarrhea. These symptoms continued for 3 days, with spread of the rash across his body. On day 6, more convalescent serum and rehydration treatment were administered. The patient made a slow recovery over the next 10 weeks. Virus (detected by electron microscopy and inoculation of guinea pigs) was present in his blood from the first day of symptoms. (Currently, the analysis would be performed by reverse transcriptase-polymerase chain reaction, with less risk to laboratory personnel.) Virus titers dropped by 1000-fold after interferon treatment and were undetectable by day 9. Treatment of the patient and handling of samples were performed under the strictest isolation conditions available at the time. Even though the scientist took precautions and soaked his hand in bleach as soon as possible, his fate was already sealed. Luckily, interferon therapy and convalescent serum were available to limit the extent of disease progression. In their absence, he would have died from a rapidly progressing hemorrhagic disease

Case Study and Questions

An 11-year-old boy was brought to a hospital in California after falling; his bruises were treated, and he was released. The next day, he refused to drink water with his medicine, and he became more anxious. That night he began to act up and hallucinate. He also was salivating and had difficulty breathing. Two days later, he had a fever of 40.8° C (105.4° F) and experienced two episodes of cardiac arrest. Although rabies was suspected, no remarkable data were obtained from a computed tomographic image of the brain or cerebrospinal fluid analysis. A skin biopsy from the nape of the neck was negative for viral antigen on day 3 but positive for rabies on day 7. The patient's condition continued to deteriorate, and he died 11 days later. When the parents were questioned, it was learned that 6 months earlier the boy had been bitten on the finger by a dog while on a trip to India.

1. What clinical features of this case suggested rabies?

2. Why does rabies have such a long incubation period?

3. What treatment should have been given immediately after the dog bite? What treatment should have been given as soon as the diagnosis was suspected?

4. How do the clinical aspects of rabies differ from those of other neurologic viral diseases?

51 Reoviruses

In January, a 6-month-old boy was seen in the emergency department after 2 days of persistent watery diarrhea and vomiting accompanied by a low-grade fever and mild cough. The infant appeared dehydrated and required hospitalization. The patient attended a day-care center.

1. In addition to rotavirus, what other viral agents must be considered in the differential diagnosis of this infant's disease? What agents would need consideration if the patient were a teenager or an adult?
2. How would the diagnosis of rotavirus have been confirmed?
3. How was the virus transmitted? How long was the patient contagious?
4. Who was at risk for serious disease?

Answers to these questions are available on Student Consult.com.

Summaries Clinically Significant Organisms

REOVIRUSES

Trigger Words

Fecal-oral, infantile diarrhea, double-double (capsid and double-stranded segmented RNA genome), oral vaccine

Biology, Virulence, and Disease

- Medium size, double capsid, double-stranded segmented RNA genome
- Capsid resistant to inactivation
- Encodes RNA-dependent RNA polymerase, replicates in cytoplasm
- Each segment encodes one or two proteins
- Mixed infection results in genetic mixing of segments: reassortment
- Rotavirus induces cholera-type diarrhea
- One of the most serious causes of diarrhea in young children
- Colorado tick fever, zoonosis, dengue-like disease with rash

Epidemiology

- Rotavirus
- Worldwide and ubiquitous, occurs year round
- Fecal-oral spread, very contagious, infants at risk for serious disease

Diagnosis

- ELISA for virus in stool

Treatment, Prevention, and Control

- Treatment: supportive rehydration
- Prevention: oral live vaccines administered at 2, 4, and 6 months of age
- Control: handwashing and good hygiene

The **Reoviridae** consist of the orthoreoviruses, rotaviruses, orbiviruses, and coltiviruses (Table 51.1). The name reovirus was proposed in 1959 by Albert Sabin for a group of respiratory and enteric viruses that were not associated with any known disease **(*r*espiratory, *e*nteric, *o*rphan).** The Reoviridae are nonenveloped viruses with **double-layered protein capsids** containing **10 to 12 segments of the double-stranded ribonucleic acid (dsRNA) genomes.** These viruses are stable in detergents, over wide pH and temperature ranges, and in airborne aerosols. The orbiviruses and coltiviruses are spread by arthropods and are arboviruses.

The **orthoreoviruses,** also referred to as **mammalian reoviruses** or simply reoviruses, were first isolated in the 1950s from the stools of children. They are the prototype of this virus family, and the molecular basis of their pathogenesis has been studied extensively. In general, these viruses cause asymptomatic infections in humans.

Rotaviruses cause **human infantile gastroenteritis,** which is a very common disease. Before the use of the rotavirus vaccines, rotaviruses accounted for approximately 50% of all cases of diarrhea in children requiring hospitalization because of dehydration and in underdeveloped countries, accounted for at least 1 million deaths each year from uncontrolled viral diarrhea in undernourished children. Fortunately, newer vaccines are safer and have lessened the incidence of this disease worldwide.

Structure

Rotaviruses and reoviruses share many structural, replicative, and pathogenic features. Reoviruses and rotaviruses have an icosahedral morphology with a double or triple protein-layered capsid (60 to 80 nm in diameter) (Fig. 51.1; Box 51.1) and a double-stranded segmented genome. The name **rotavirus** is derived from the Latin word **rota,** meaning **"wheel,"** which refers to the triple-layered virion appearance in negative-stained electron micrographs (Fig. 51.2). Proteolytic cleavage of the outer capsid (as occurs in the gastrointestinal tract) activates the virus for infection and produces an **intermediate/infectious subviral particle (ISVP).**

The outer capsid is composed of structural proteins (Figs. 51.3 and 51.4) that surround a nucleocapsid core that includes enzymes for RNA synthesis and 10 (reovirus) or 11 (rotavirus) different dsRNA genomic segments. For rotavirus, the inner capsid consisting of VP2 is surrounded by the intermediate capsid consisting mainly of the major capsid protein (VP6) and an outer layer that contains the viral attachment protein (VP4) and glycoprotein (VP7). Of interest, rotaviruses resemble enveloped viruses in that they (1) have glycoproteins (VP7, NSP4) that are on the outside of the virion, (2) acquire but then lose an envelope during

assembly, and (3) appear to have a fusion protein activity that promotes direct penetration of the target cell membrane.

The genomic segments of rotaviruses and reoviruses encode structural and nonstructural proteins. As for the influenza virus, reassortment of gene segments can occur and thus create hybrid viruses. The genomic segments of rotavirus, the proteins they encode, and their functions are summarized in Table 51.2, and those of the reovirus are summarized in Table 51.3. Core proteins include enzymatic activities required for the transcription of messenger RNA (mRNA). They include a 5′-methyl guanosine mRNA capping enzyme and an RNA polymerase. The σ1 protein (reovirus) and VP4 (rotavirus) are located at the vertices of the capsid and extend from the surface like spike proteins. They have several functions, including viral attachment and hemagglutination, and they elicit neutralizing antibodies. VP4 is activated by protease cleavage into VP5 and VP8 proteins, exposing a structure similar to that of the fusion proteins of paramyxoviruses. Its cleavage facilitates productive entry of the virus into cells.

TABLE 51.1 Reoviridae Responsible for Human Disease

Virus	Disease
Orthoreovirus[a]	Mild upper respiratory tract illness, gastrointestinal tract illness, biliary atresia
Orbivirus/Coltivirus	Febrile illness with headache and myalgia (zoonosis)
Rotavirus	Gastrointestinal tract illness, respiratory tract illness (?)

[a]Reovirus is the common name for the family Reoviridae and for the specific genus *Orthoreovirus*.

Replication

Replication of reoviruses and rotaviruses starts with ingestion of the virus (Fig. 51.5). The virion outer capsid protects the inner nucleocapsid and core from the environment, especially the acidic environment of the gastrointestinal tract. The complete virion is then partially digested in the gastrointestinal tract and activated by protease cleavage and loss of the external capsid proteins (σ3/VP7) and cleavage of the σ1/VP4 protein to produce the ISVP. The σ1/VP4 protein at the vertices of the ISVP binds to sialic acid–containing glycoproteins on epithelial and other cells. Additional receptors include the β-adrenergic receptor for reovirus and integrin molecules for rotavirus. The cleaved VP4 of rotavirus also promotes the direct penetration of the virion through the plasma membrane into the cell. Whole virions of reovirus and rotavirus can also be taken up by receptor-mediated endocytosis.

The ISVP releases the core into the cytoplasm, and the enzymes in the core initiate mRNA production. The **dsRNA always remains in the core.** Transcription of the genome occurs in two phases, early and late. In a manner similar to a negative-sense RNA virus, each of the negative-sense (−) RNA strands is used as a template by virion core enzymes, which synthesize individual mRNAs. Virus-encoded enzymes within the core add a 5′-methyl guanosine cap and a 3′-polyadenylate tail. The 5′-methyl guanosine cap was first discovered for reovirus mRNA and then shown to occur for cellular mRNA. The mRNA then leaves the core and is translated. Later, virion proteins and positive-sense (+) RNA segments associate together into corelike structures within large cytoplasmic inclusions called viroplasms. The (+) RNA segments are copied to produce (−) RNAs in the new cores,

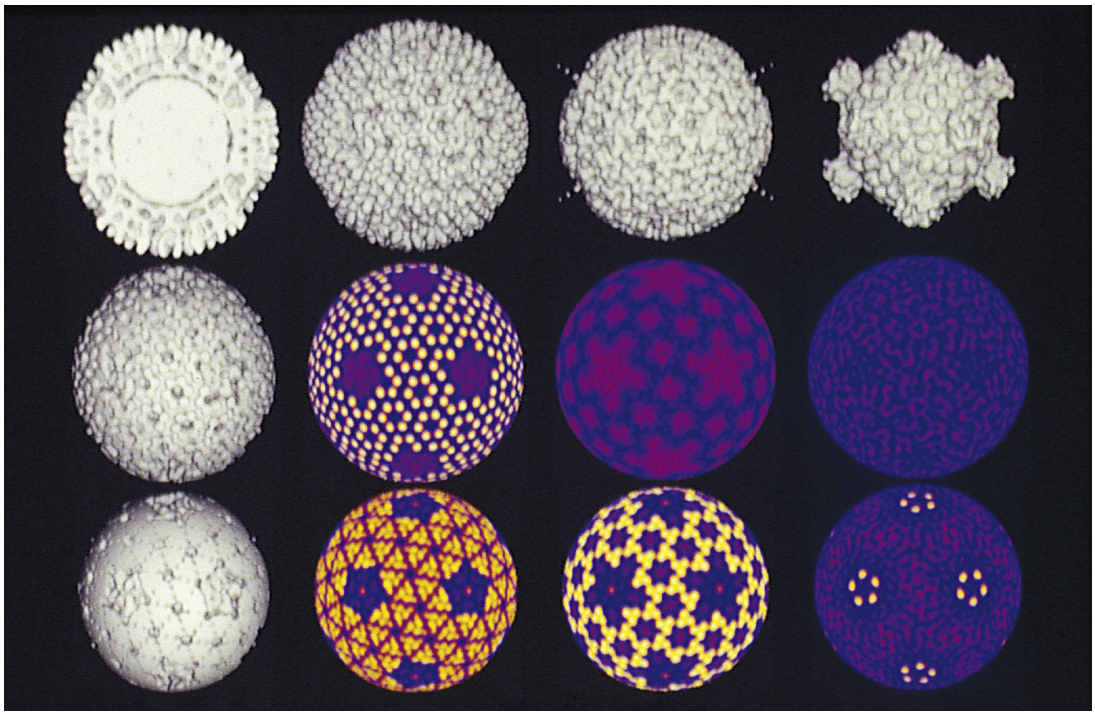

Fig. 51.1 Computer reconstruction of cryoelectron micrographs of human reovirus type 1 (Lang). *Top, left to right:* Cross section of virion, intermediate/infectious subviral particle (ISVP), and core particle. The ISVP and core particles are generated by proteolysis of the virion and play important roles in the replication cycle. *Center and bottom:* Computer-generated images of the virions at different radii after the outer layers of features have been shaved off. The colors help one visualize the symmetry and molecular interactions within the capsid. (Courtesy Tim Baker, Purdue University, West Lafayette, Indiana.)

BOX 51.1 Unique Features of Reoviridae

Double-layered or triple-layered capsid virion (60 to 80 nm) has icosahedral symmetry containing 10 to 12 (depending on the virus) unique **double-stranded genomic segments** *(double:double virus).*

Virion is **resistant** to environmental and gastrointestinal conditions (e.g., detergents, acidic pH, drying).

Rotavirus and orthoreovirus virions are activated by mild proteolysis to intermediate/infectious subviral particles, increasing their infectivity.

Inner capsid contains a complete transcription system, including RNA-dependent RNA polymerase and enzymes for 5′ capping and polyadenylate addition.

Viral replication occurs in the cytoplasm. Double-stranded RNA remains in the inner core.

Inner capsid aggregates around (+) RNA and transcribes (–) RNA in the cytoplasm.

Rotavirus-filled inner capsids bud into the endoplasmic reticulum, acquiring its outer capsid and a membrane, which is then lost.

Virus is released by cell lysis.

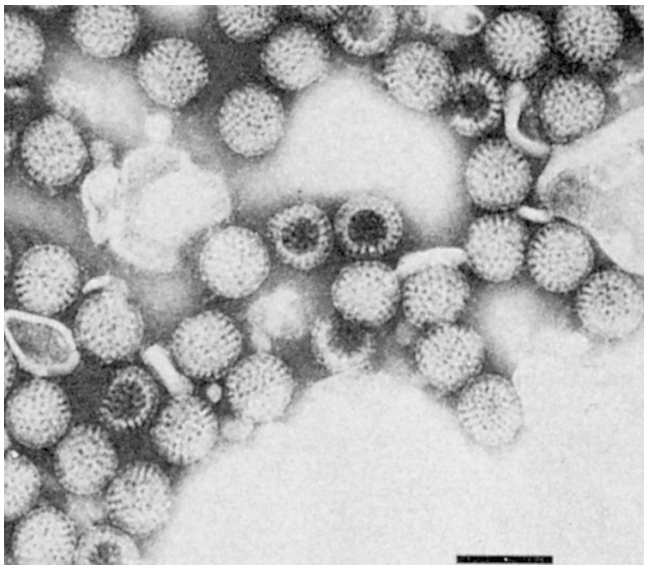

Fig. 51.2 Electron micrograph of rotavirus. Bar = 100 nm. (From Fields, B.N., Knipe, D.M., Chanock, R.M., et al., 1985. Virology. Raven, New York.)

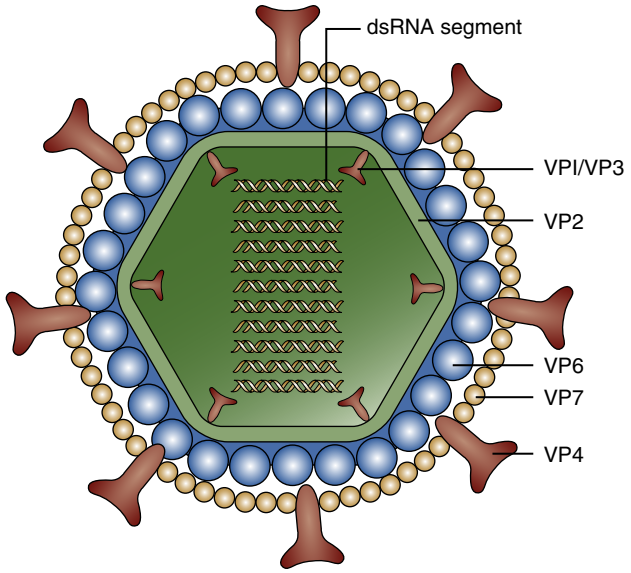

Fig. 51.3 Schematic of rotavirus. See Table 51.2 for descriptions of the viral proteins. *dsRNA,* Double-stranded ribonucleic acid.

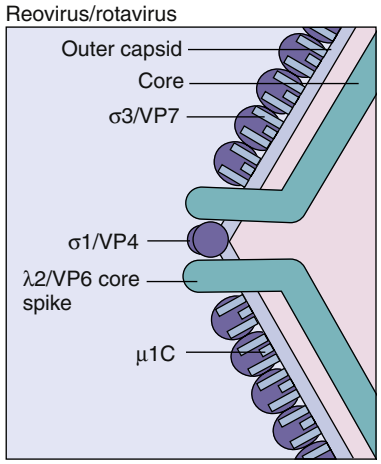

Fig. 51.4 Structure of rotavirus core and outer proteins. See Table 51.2 for descriptions of the viral proteins. (Modified from Sharpe, A.H., Fields, B.N., 1985. Pathogenesis of viral infections. Basic concepts derived from the reovirus model. N. Engl. J. Med. 312, 486–497.)

replicating the double-stranded genome. The new cores either generate more (+) RNA or are assembled into virions.

The assembly processes for reovirus and rotavirus differ. In the assembly of reovirus, the outer capsid proteins associate with the core, and the virion leaves the cell on cell lysis. Assembly of rotavirus resembles that of an enveloped virus in that the rotavirus cores associate with the NSP4 viral protein on the outside of the endoplasmic reticulum (ER); on budding into the ER, they acquire its VP7 outer capsid glycoprotein. The membrane is lost in the ER, and the virus leaves the cell during cell lysis. Cellular macromolecular synthesis is inhibited within 8 hours of infection.

Rotaviruses

Rotaviruses are common agents of infantile diarrhea worldwide. The rotaviruses are a large group of gastroenteritis-causing viruses infecting many different mammals and birds.

Rotavirus virions are stable to environmental abuse, including treatment with detergents, pH extremes of 3.5 to 10, and even repeated freezing and thawing. Within the intestine, proteolytic enzymes such as trypsin enhance infectivity.

Human and animal rotaviruses are divided into serotypes, groups, and subgroups. Serotypes are distinguished primarily by the VP7 (glycoprotein, G) and VP4 (protease-sensitive protein, P) outer capsid proteins. Groups are determined primarily on the basis of the antigenicity of VP6 and the electrophoretic mobility of the genomic segments. Seven groups (A to G) of human and animal rotaviruses have been identified on the basis of the VP6 inner capsid protein. Human disease is caused by group A rotavirus and occasionally group B and C rotaviruses.

TABLE 51.2 Functions of Rotavirus Gene Products

Gene Segment	Protein (Location)	Function
1	VP1 (inner capsid)	Polymerase
2	VP2 (inner capsid)	Transcriptase component
3	VP3 (inner capsid)	mRNA capping
4	VP4 (outer capsid spike protein at vertices of virion)	Activation by protease produces VP5 and VP8 in ISVP, hemagglutinin, viral attachment protein[a]
5	NSP1 (NS53)	RNA binding
6	VP6 (inner capsid)	Major structural protein of inner capsid, binding to NSP4 at ER to promote assembly of outer capsid
7	NSP3 (NS34)	RNA binding
8	NSP2 (NS35)	RNA binding, important for genome replication and packaging
9	VP7 (outer capsid)	Type-specific antigen, major outer capsid component that is glycosylated in ER and facilitates attachment and entry[a]
10	NSP4 (NS28)	Glycosylated protein in ER that promotes inner capsid binding to ER, transient envelopment, and addition of outer capsid; acts as enterotoxin to mobilize calcium and cause diarrhea
11	NSP5 (NS26)	RNA binding
11	NSP6	Binds to NSP5

[a]Target of neutralizing antibody.
ER, Endoplasmic reticulum; *ISVP,* intermediate/infectious subviral particle; *mRNA,* messenger ribonucleic acid.

TABLE 51.3 Functions of Reovirus Gene Products

Genomic Segments (Molecular Weight, Da)	Protein	Function (If Known)
LARGE SEGMENTS (2.8 × 106)		
1	λ3 (inner capsid)	Polymerase
2	λ2 (outer capsid)	Capping enzyme
3	λ1 (inner capsid)	Transcriptase component
MEDIUM SEGMENTS (1.4 × 106)		
1	μ2 (inner capsid)	binds RNA and microtubules
2	μ1C (outer capsid)	Cleaved from μ1, complexes with σ3, promotes entry
3	μNS	Promotes viral assembly[a]
SMALL SEGMENTS (0.7 × 106)		
1	σ1 (outer capsid)	Viral attachment protein, hemagglutinin, determines tissue tropism[b]
2	σ2 (inner capsid)	Facilitates viral RNA synthesis
3	σNS	Facilitates viral RNA synthesis
4	σ3 (outer capsid)	Major component of outer capsid with μ1C

[a]Proteins are not found in the virion.
[b]Target of neutralizing antibodies.
Modified from Fields, B.N., Knipe, D.M., Howley, P.M., 1996. Virology, third ed. Lippincott-Raven, New York.

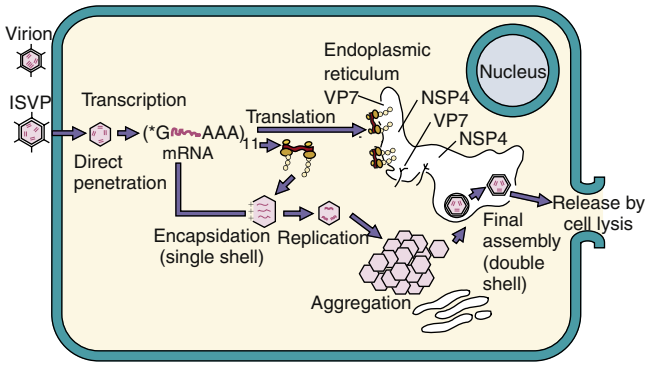

Fig. 51.5 Replication of rotavirus. Rotavirus virions can be activated by protease (e.g., in the gastrointestinal tract) to produce an intermediate/infectious subviral particle *(ISVP)*. The virion or ISVP binds, penetrates the cell, and loses its outer capsid. The inner capsid contains the enzymes for messenger ribonucleic acid *(mRNA)* transcription using the (±) strand as a template. Some mRNA segments are transcribed early, and others are transcribed later. Enzymes in the virion cores attach 5′-methyl capped guanosine ***(*G)*** and 3′-polyadenylate sequence (poly A ***[AAA]***) to mRNA. (+) RNA is mRNA and is also enclosed into inner capsids as a template to replicate the ± segmented genome. VP7 and NSP4 are synthesized as glycoproteins and expressed in the endoplasmic reticulum. The capsids aggregate and "dock" onto the NSP4 protein in the endoplasmic reticulum, acquiring VP7 and its outer capsid and an envelope. The virus loses the envelope and leaves the cell on cell lysis.

PATHOGENESIS AND IMMUNITY

The rotavirus can survive the acidic environment in a buffered stomach or in a stomach after a meal and is converted to the ISVP by proteases (Box 51.2). Clumps of the virus have enhanced infectivity. Viral replication occurs after adsorption of the ISVP to columnar epithelial cells covering the villi of the small intestine. Approximately 8 hours after infection, cytoplasmic inclusions that contain newly synthesized proteins and RNA are seen. As many as 10^{10} viral particles per gram of stool may be released during disease. Studies of the small intestine, either of experimentally infected animals or in biopsy specimens from infants, show shortening and blunting of

BOX 51.2 Disease Mechanisms of Rotavirus

Virus is spread primarily by the **fecal-oral route.**
Cytolytic and toxin-like action on the intestinal epithelium causes loss of electrolytes and prevents reabsorption of water.
Disease can be significant in infants <24 months, but can be asymptomatic in adults.
Large amounts of virus are released during the diarrheal phase.

the microvilli and mononuclear cell infiltration into the lamina propria.

Similar to cholera, rotavirus infection prevents absorption of water, causing a net secretion of water and loss of ions, which together result in a watery diarrhea. The **NSP4 protein** of rotavirus acts in a **toxin-like manner** to promote calcium ion influx into enterocytes, which disrupts the cytoskeleton and the tight junctions to cause leakage and also the release of cytokines and neuronal activators, which alter water absorption. The loss of fluids and electrolytes can lead to severe dehydration and even death if therapy does not include electrolyte replacement. Of interest, the diarrhea also promotes transmission of the virus.

Immunity to infection depends on antibody, primarily immunoglobulin (Ig)A, in the lumen of the gut. Antibodies to the VP7 and VP4 neutralize the virus. Actively or passively acquired antibody (including antibody in colostrum and mother's milk) can lessen the severity of disease but does not consistently prevent reinfection. In the absence of antibody, the inoculation of even small amounts of virus causes infection and diarrhea. Infection in infants and small children is generally symptomatic, whereas in adults it is usually asymptomatic.

EPIDEMIOLOGY

Rotaviruses are ubiquitous worldwide, with 95% of children infected by 3 to 5 years of age (Box 51.3). Rotaviruses are passed from person to person by the **fecal-oral route.** Maximal shedding of the virus occurs 2 to 5 days after the start of diarrhea but can occur without symptoms. The virus survives well on fomites (e.g., furniture and toys) and on hands because it can withstand drying. Outbreaks occur in preschools and day-care centers and among hospitalized infants.

Rotaviruses are **one of the most common causes of serious diarrhea in young children** worldwide. Before the vaccines, 4 of 5 children would get rotavirus diarrhea and 1 of 7 of them required medical help, with 20 to 50 deaths per year in the United States and as many as 500,000 deaths worldwide. In North America, outbreaks occur during the autumn, winter, and spring. More severe disease occurs in severely malnourished children. In developing countries, rotavirus diarrhea is a very contagious and severe life-threatening disease for infants and occurs year round. Several outbreaks of group B rotavirus have occurred in China because of contaminated water supplies that affected millions of people.

CLINICAL SYNDROMES

Rotavirus is a major cause of gastroenteritis (Clinical Case 51.1; Box 51.4). The incubation period for rotavirus diarrheal illness is estimated to be 48 hours. The major clinical findings in hospitalized patients are **vomiting, diarrhea, fever,** and **dehydration.** Neither fecal leukocytes nor blood occurs in stool for this form of diarrhea. Rotavirus gastroenteritis is a self-limited disease, and recovery is generally complete and without sequelae. However, the

BOX 51.3 Epidemiology of Rotavirus

Disease/Viral Factors

Capsid virus is resistant to environmental and gastrointestinal conditions.
Large amounts of virus are released in fecal matter.
Asymptomatic infection can result in release of virus.

Transmission

Virus is transmitted in fecal matter, especially in day-care settings.
Respiratory transmission may be possible.

Who Is at Risk?

Rotavirus Group A

Infants <24 months of age: at risk for infantile gastroenteritis with potential dehydration.
Older children and adults: at risk for mild diarrhea.
Undernourished people in underdeveloped countries: at risk for diarrhea, dehydration, and death.

Rotavirus Group B (Adult Diarrhea Rotavirus)

Infants, older children, and adults in China: at risk for severe gastroenteritis.

Geography/Season

Virus is found worldwide.
Disease is more common in autumn, winter, and spring.

Modes of Control

Handwashing and isolation of known cases are modes of control.
Live vaccines use attenuated human or bovine reassorted rotavirus.

Clinical Case 51.1 Rotavirus Infection of Adults

Mikami and associates (*J Med Virol* 73:460–464, 2004) described an outbreak of acute gastroenteritis that occurred over a 5-day period in 45 of 107 children (aged 11 to 12 years) after a 3-day school trip. The source person for the outbreak was ill at the start of the trip. A case of rotavirus acute gastroenteritis is defined as three or more episodes of diarrhea and/or two or more episodes of vomiting per day. Other symptoms included fever, nausea, fatigue, abdominal pain, and headache. The rotavirus responsible for the outbreak was identified from stool of several individuals as serotype G2 group A rotavirus compared with the genomic ribonucleic acid migration pattern by electrophoresis, by reverse transcriptase-polymerase chain reaction, and by enzyme-linked immunosorbent assay of virus obtained from stool samples. Although rotavirus is the most common cause of infantile diarrhea, this virus, especially the G2 strain, also causes gastroenteritis in adults. This article illustrated the different laboratory methods available for detection of a virus that is difficult to grow in tissue culture.

BOX 51.4 Clinical Summary

Rotavirus: A 1-year-old infant has watery diarrhea, vomiting, and fever for 4 days. Enzyme-linked immunosorbent assay analysis of stool confirms rotavirus. The baby is very dehydrated.

infection may prove fatal in infants who are malnourished and dehydrated before the infection.

LABORATORY DIAGNOSIS

The clinical findings in patients with rotavirus infection resemble those of other viral diarrheas (e.g., Norwalk virus). Most patients have large quantities of virus in stool, making direct detection of viral antigen the method of choice for diagnosis. Enzyme-linked immunoassay and latex agglutination are quick, easy, and relatively inexpensive ways to detect rotavirus in stool. Viral particles in specimens can also be readily detected on electron microscopy or by immunoelectron microscopy. Reverse transcriptase polymerase chain reaction (RT-PCR) is useful to detect and distinguish the genotypes of rotavirus.

Cell culture of rotavirus requires pretreatment of the virus with trypsin to generate the ISVP for infection to occur but is not used for diagnostic purposes.

TREATMENT, PREVENTION, AND CONTROL

Rotaviruses are acquired very early in life. Their ubiquitous nature makes it difficult to limit the spread of the virus and infection. Hospitalized patients with disease must be isolated to limit spread of the infection to other susceptible patients.

No specific antiviral therapy is available for a rotavirus infection. The morbidity and mortality associated with rotavirus diarrhea result from dehydration and electrolyte imbalance. Similar to the therapy for cholera, rehydration therapy is necessary to replace fluids so that blood volume and electrolyte and acid–base imbalances are corrected.

Development of a safe rotavirus vaccine was a high priority for protecting children, especially those in underdeveloped countries, from potentially fatal disease. Animal rotaviruses, such as the rhesus monkey rotavirus and the Nebraska calf diarrhea virus, share antigenic determinants with human rotaviruses and do not cause disease in humans. A human–rhesus monkey reassortant vaccine (RotaShield) was recalled in 1999 because of the incidence of intussusception (misfolding of the bowel possibly resulting from inflammatory reactions) in a small number of infants, more recently shown to be similar to levels in the unvaccinated. Two new safer rotavirus hybrid and live vaccines have since been developed and are approved by the U.S. Food and Drug Administration in the United States and elsewhere. RotaTeq consists of five reassortant bovine rotaviruses containing the VP4 or VP7 of five different human rotaviruses. The Rotarix vaccine is a single-strain attenuated human rotavirus. The **vaccines are administered orally as young as possible,** at 2, 4, and 6 months of age. Oral administration of these vaccines promotes secretory IgA production and good memory responses.

Orthoreoviruses (Mammalian Reoviruses)

The orthoreoviruses are ubiquitous. The virions are very stable and have been detected in sewage and river water. The mammalian reoviruses occur in three serotypes referred to as **reovirus types 1, 2, and 3;** these serotypes are based on neutralization and hemagglutination inhibition tests.

PATHOGENESIS AND IMMUNITY

Orthoreoviruses do not cause significant disease in humans. However, studies of reovirus disease in mice have advanced our understanding of the pathogenesis of viral infections in humans. Depending on the reovirus strain, the virus can be neurotropic or viscerotropic in mice. The functions and virulence properties of the reovirus proteins were identified through comparison of the activities of interstrain hybrid (reassortant) viruses that differ in only one genomic segment (encoding one protein). With this approach, the new activity is attributable to the genomic segment from the other virus strain.

Mice, and presumably humans, mount protective humoral and cellular immune responses to outer capsid proteins. Although orthoreoviruses are normally lytic, they can also establish persistent infection in cell culture.

EPIDEMIOLOGY

The virus is primarily spread by the fecal-oral route and potentially in aerosols. As previously mentioned, the orthoreoviruses have been found worldwide. Most people are infected during childhood.

CLINICAL SYNDROMES

Orthoreoviruses infect people of all ages; linking specific diseases to these agents has been difficult. Most infections are asymptomatic or so mild they go undetected. These viruses have been linked to common coldlike, mild upper respiratory tract illness (low-grade fever, rhinorrhea, and pharyngitis), gastrointestinal tract disease, and biliary atresia.

LABORATORY DIAGNOSIS

Human orthoreovirus infection can be detected through assay of the viral antigen or genomic RNA or virus isolation from throat, nasopharyngeal, and stool specimens, or serologic assays for virus-specific antibody.

TREATMENT, PREVENTION, AND CONTROL

Orthoreovirus disease is mild and self-limited. For this reason, treatment has not been necessary, and prevention and control measures have not been developed.

Coltiviruses and Orbiviruses

The coltiviruses and orbiviruses infect vertebrates and invertebrates. The coltiviruses cause Colorado tick fever and related human disease. The orbiviruses mainly cause disease in animals, including blue tongue disease of sheep, African horse sickness, and epizootic hemorrhagic disease of deer.

Colorado tick fever, an acute disease characterized by fever, headache, and severe myalgia, was originally described in the 19th century and is now believed to be one of the most common tick-borne viral diseases in the United States. Although hundreds of infections occur annually, the exact number is not known, because Colorado tick fever is not a reportable disease.

The structure and physiology of the coltiviruses and orbiviruses are similar to those of the other Reoviridae, with the following major exceptions:

1. The outer capsid of the orbiviruses has no discernible capsomeric structure, even though the inner capsid is icosahedral.
2. The virus causes viremia, infects erythrocyte precursors, and remains in the mature red blood cells, protected from the immune response.
3. The *Orbivirus* life cycle includes vertebrates and invertebrates (insects).
4. Colorado tick fever viruses have 12 ds-RNA genomic segments, and orbiviruses have 10.

PATHOGENESIS

Colorado tick fever virus infects erythroid precursor cells without severely damaging them. The virus remains within the cells even after they mature into red blood cells; this factor protects the virus from clearance. The resulting viremia can persist for weeks or months even after cessation of symptoms. Both of these factors promote transmission of the virus to the tick vector.

Serious hemorrhagic disease can result from infection of vascular endothelial and vascular smooth muscle cells and pericytes, weakening capillary structure. The weakness leads to leakage, hemorrhage, and potentially hypotension and shock. Neuronal infection can lead to meningitis and encephalitis.

EPIDEMIOLOGY

Colorado tick fever occurs in western and northwestern areas of the United States and western Canada at elevations of 4000 to 10,000 feet, which is the habitat of the wood tick *Dermacentor andersoni* (Fig. 51.6). Ticks acquire the virus by feeding on a viremic host and subsequently transmit the virus in saliva when feeding on a new host. Natural hosts of this virus include many mammals, including squirrels, chipmunks, rabbits, and deer. Human disease is observed during the spring, summer, and autumn, seasons when humans are more likely to invade the habitat of the tick.

CLINICAL SYNDROMES

Colorado tick fever virus generally causes mild or subclinical infection. The symptoms of the acute disease resemble those of dengue fever. After a 3- to 6-day incubation period,

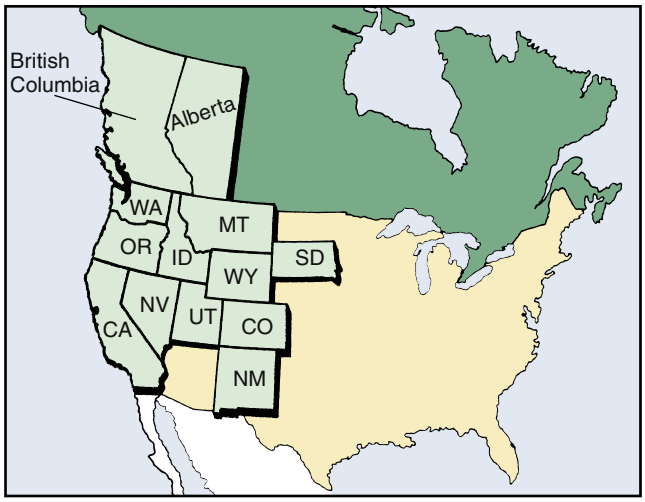

Fig. 51.6 Geographic distribution of Colorado tick fever.

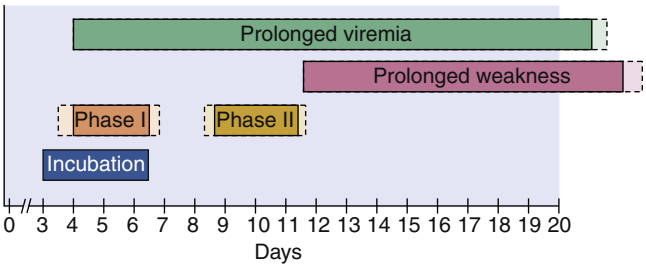

Fig. 51.7 Time course of Colorado tick fever.

symptomatic infections start with the sudden onset of fever, chills, headache, photophobia, myalgia, arthralgia, and lethargy (Fig. 51.7). Characteristics of the infection include a biphasic fever, conjunctivitis, and possibly lymphadenopathy, hepatosplenomegaly, and a maculopapular or petechial rash. A leukopenia involving both neutrophils and lymphocytes is an important hallmark of the disease. Children occasionally have a more severe hemorrhagic disease. Colorado tick fever must be differentiated from Rocky Mountain spotted fever, which is a tick-borne rickettsial infection characterized by a rash, because the latter disease requires antibiotic treatment.

LABORATORY DIAGNOSIS

A diagnosis of Colorado tick fever can be established through direct detection of viral antigens, genome, virus isolation, or serologic tests. Viral antigen can be detected on the surfaces of erythrocytes in a blood smear through the use of immunofluorescence, and viral genomes can be detected with RT-PCR. Laboratory tests may be available through state public health departments or the Centers for Disease Control and Prevention. Serology can be performed for epidemiologic purposes.

TREATMENT, PREVENTION, AND CONTROL

No specific treatment is available for Colorado tick fever. The disease is generally self-limited, indicating that supportive care is sufficient. The viremia is long lasting, implying that

infected patients should not donate blood soon after recovery. Prevention consists of (1) avoiding tick-infested areas, (2) using protective clothing and tick repellents, and (3) removing ticks before they bite. Unlike tick-borne rickettsial disease, in which prolonged feeding is required for the bacteria to be transmitted, the coltivirus from the tick's saliva can enter the bloodstream rapidly and is sufficient to initiate disease.

Case Study and Questions

A 10-month-old Pakistani infant has watery diarrhea, vomiting, and fever for 4 days. The baby becomes very dehydrated and dies.

1. How could a diagnosis of rotavirus be confirmed?
2. How does this agent cause diarrhea?
3. What is the treatment?
4. How can the disease be prevented?
5. Why was this baby at such high risk for mortality?
6. Why is it important to immunize with the rotavirus vaccines so early in life and with a live attenuated oral vaccine?

52 Togaviruses and Flaviviruses

A 5-year-old Indonesian girl died of hemorrhagic shock. The presence of dengue virus serotype 3 in her blood was confirmed by reverse transcriptase-polymerase chain reaction (RT-PCR).

1. How was the child infected with dengue virus?
2. What are the diseases caused by dengue virus?
3. What types of immune responses are protective? Potentially harmful?
4. Where is dengue prevalent? Why?

Answers to these questions are available on Student Consult.com.

Summaries Clinically Significant Organisms

TOGAVIRUSES

Trigger Words

Arboviruses: mosquito, encephalitis
Rubella: German measles, congenital disease, rash, vaccine

Biology, Virulence, and Disease

- Small size, envelope surrounds icosahedral nucleocapsid, (+) RNA genome
- Encodes RNA-dependent RNA polymerase, replicates in cytoplasm
- Early and late mRNA and proteins produced
- Virus spreads in blood to target tissues, including neurons and brain
- Antibody can block viremia and disease
- Prodrome of flulike symptoms caused by interferon and cytokine response
- Arboviruses: equine encephalitis viruses (WEE, EEE, VEE)
- Rubella: benign childhood rash, swollen glands. Adult complications include arthritis, encephalitis. Congenital infection: teratogenic, cataracts, deafness, microcephaly, etc.

Epidemiology

- Arboviruses: zoonosis, reservoir in birds, vectors are *Aedes* and *Culex* mosquitoes
- Rubella: aerosol spread, only infects humans, unvaccinated individuals at risk, fetus at high risk

Diagnosis

- RT-PCR, ELISA

Treatment, Prevention, and Control

- Arboviruses: mosquito control
- Live attenuated rubella vaccine at 1 year of age in MMR; booster at 4 to 6 years

FLAVIVIRUSES

Trigger Words

Arboviruses: mosquito, encephalitis, hemorrhagic diseases
Hepatitis C virus: see Chapter 55

Biology, Virulence, and Disease

- Small size, envelope surrounds icosahedral nucleocapsid, (+) RNA genome
- Encodes RNA-dependent RNA polymerase, replicates in cytoplasm
- Neutralizing antibody can block disease
- Nonneutralizing antibody promotes dengue virus infection
- Cross-reactive antibodies produced against different flaviviruses
- Virus spreads in blood to target tissues: for encephalitis viruses neurons and brain; for hemorrhagic viruses vasculature, liver, organs
- Prodrome of flulike symptoms caused by interferon and cytokine response
- Arboviruses
- Encephalitis viruses: St. Louis, West Nile, Japanese encephalitis viruses
- Hemorrhagic disease:
  Yellow fever: jaundice, black vomit
  Dengue: hemorrhagic fever, breakbone fever, dengue shock syndrome

Epidemiology

- Endemic to habitat of mosquito
- Arboviruses: zoonosis, reservoir in birds, vectors are *Aedes* or *Culex* mosquitoes

Diagnosis

- RT-PCR, ELISA

Treatment, Prevention, and Control

- Arboviruses: mosquito control
- Yellow fever virus: attenuated live vaccine

EEE, Eastern equine encephalitis; *ELISA,* enzyme-linked immunosorbent assay; *MMR,* measles-mumps- rubella; *RT-PCR,* reverse transcriptase-polymerase chain reaction; *VEE,* Venezuelan equine encephalitis; *WEE,* western equine encephalitis.

The members of the Togaviridae and Flaviviridae families are enveloped, positive-sense, single-stranded ribonucleic acid (RNA) viruses (Box 52.1). The *Alphavirus* genus of togaviruses and *Flavivirus* differ in size, morphology, gene sequence, and replication but are discussed together because of similarities in the diseases they cause and in their epidemiology. Most are transmitted by arthropods and are therefore arboviruses (arthropod-borne viruses).

The Togaviridae (togaviruses) that cause human disease are in the *Alphavirus* and *Rubivirus* genera (Table 52.1). **Rubella** virus is the only member of the *Rubivirus* group; it is discussed separately because its disease manifestation **(German measles)** and its means of spread differs from those of the alphaviruses. The Flaviviridae include the flaviviruses, pestiviruses, and hepaciviruses (hepatitis C and G viruses). Hepatitis C and G are discussed in Chapter 55.

Alphaviruses and Flaviviruses

Alphaviruses and flaviviruses are classified as arboviruses because they are spread by arthropod vectors. These viruses

BOX 52.1 Unique Features of Togaviruses and Flaviviruses

Viruses have enveloped, single-stranded, positive-sense RNA.
Togavirus replication includes early (nonstructural) and late (structural) protein synthesis.
Togaviruses replicate in the cytoplasm and bud at plasma membranes.
Flaviviruses replicate in the cytoplasm and bud at intracellular membranes.

TABLE 52.1 Togaviruses and Flaviviruses

Virus Group	Human Pathogens
TOGAVIRUSES	
Alphavirus	Arboviruses
Rubivirus	Rubella virus
Arterivirus	None
FLAVIVIRUSES	Arboviruses
Hepaciviridae	Hepatitis C virus
Pestivirus	None

have a very **broad host range,** including vertebrates (e.g., mammals, birds, amphibians, reptiles) and invertebrates (e.g., mosquitoes, ticks). Diseases spread by animals or with an animal reservoir are called **zoonoses.** Examples of pathogenic alphaviruses and flaviviruses are listed in Table 52.2.

STRUCTURE AND REPLICATION OF ALPHAVIRUSES

The alphaviruses have an **icosahedral capsid** and a positive-sense, single-strand RNA genome that resembles messenger RNA (mRNA). They are slightly larger than picornaviruses (45 to 75 nm in diameter) and are surrounded by an **envelope** (Latin **toga,** "cloak"). The togavirus genome encodes **early** and **late proteins.**

Alphaviruses have two or three glycoproteins that associate to form a single spike. The carboxy (COOH) terminus of the glycoproteins is anchored in the capsid, forcing the envelope to wrap tightly ("shrink-wrap") and take on the shape of the capsid (Fig. 52.1). The capsid proteins of all the alphaviruses are similar in structure and are antigenically cross-reactive. The viruses can be grouped (complexes) and distinguished by different antigenic determinants on their envelope glycoproteins.

The alphaviruses attach to specific receptors expressed on many different cell types from many different species (Fig. 52.2). The host range for these viruses includes vertebrates (e.g., humans, monkeys, horses, birds, reptiles, amphibians) and invertebrates (e.g., mosquitoes, ticks). However, the individual viruses have different tissue tropisms, accounting somewhat for the different disease presentations.

The virus enters the cell by means of receptor-mediated endocytosis (see Fig. 52.2). The viral envelope then fuses with the membrane of the endosome on acidification of the vesicle to deliver the capsid and genome into the cytoplasm. Once released into the cytoplasm, the alphavirus genomes bind to ribosomes as mRNA. The alphavirus genome is translated in early and late phases. The initial two-thirds of the alphavirus RNA is translated into a polyprotein that includes proteases that subsequently cleave the polyprotein into four nonstructural early proteins (NSPs 1 through 4). These early proteins are components of the RNA-dependent RNA polymerase. As for all positive strand RNA viruses, the enzymes for replication of the genome assemble on a membrane scaffold in a vesicle. First, a full-length 42S negative-sense RNA is synthesized as a template for replication of the genome, and then more 42S positive-sense mRNA is produced. In addition, a 26S late mRNA, corresponding to one-third of the genome, is transcribed from the template. The 26S RNA encodes the capsid (C) and envelope (E1 through E3) proteins. Late in the replication cycle, viral mRNA can account for as much as 90% of the mRNA in the infected cell. The abundance of late mRNAs allows production of a large amount of the structural proteins required for packaging the virus.

The structural proteins are produced by protease cleavage of the late polyprotein that was produced from the 26S mRNA. The C protein is translated first and is cleaved from the polyprotein. A signal sequence is then made that associates the nascent polypeptide with the endoplasmic reticulum. Thereafter, envelope glycoproteins are translated, glycosylated, and cleaved from the remaining portion of the polyprotein to produce the E1, E2, and E3 glycoprotein spikes. The E3 is released from most alphavirus glycoprotein spikes. The glycoproteins are processed by the normal cellular machinery in the endoplasmic reticulum and Golgi apparatus and are acetylated and acylated with long-chain fatty acids. Alphavirus glycoproteins are then transferred efficiently to the plasma membrane.

The C proteins associate with the genomic RNA soon after their synthesis and form an icosahedral capsid. Once this step is completed, the capsid associates with portions of the membrane expressing the viral glycoproteins. The alphavirus capsid has binding sites for the C-terminus of the glycoprotein spike, which pulls the envelope tightly around itself in a manner like shrink-wrap (see Figs. 52.1 and 52.2). Alphaviruses are released on budding from the plasma membrane of human cells. They are cytolytic for human but not insect cells.

Of interest, the western equine encephalitis virus (WEEV) was created by recombination of two alphaviruses, the eastern equine encephalitis virus (EEEV) and the Sindbis virus. The beginning of the WEEV genome is almost identical to EEEV, with similar glycoproteins and virulence genes, whereas the end of the genome resembles Sindbis.

STRUCTURE AND REPLICATION OF FLAVIVIRUSES

The flaviviruses also have a positive-strand RNA genome, an icosahedral capsid, and an envelope but are slightly smaller than an alphavirus (40 to 65 nm in diameter). The E viral glycoprotein folds over, pairs up with another E glycoprotein, and lies flat across the surface of the virion to form an outer protein layer (see Fig. 52.1). Most of the

(B) Cross section of alpha-togavirus. The envelope is tightly associated with the capsid. (C) Cross section of flavivirus. The envelope protein surrounds the membrane envelope, which encloses an icosahedral nucleocapsid. *RNA,* Ribonucleic acid. (A, From Fuller, S.D., 1987. The T = 4 envelope of Sindbis virus is organized by interactions with a complementary T = 3 capsid. Cell 48, 923–934.)

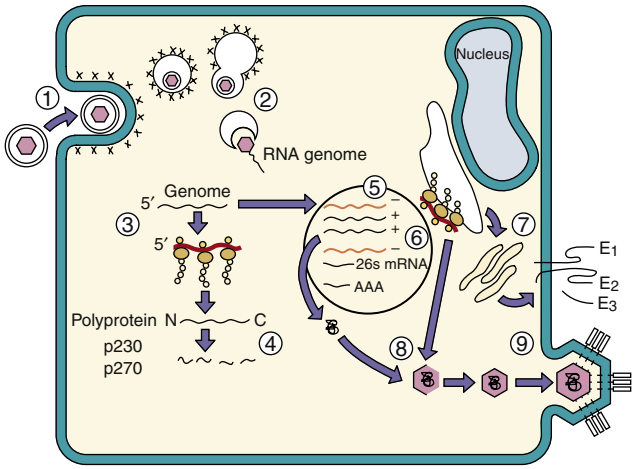

Fig. 52.2 Replication of a togavirus. *1,* Togaviruses bind to cell receptors and are internalized in a coated vesicle. *2,* On acidification of the endosome, the viral envelope fuses with the endosomal membrane to release the nucleocapsid into the cytoplasm. *3,* Ribosomes bind to the positive-sense ribonucleic acid *(RNA)* genome, and the p230 or p270 (full-length) early polyproteins are made. *4,* The polyproteins are cleaved to produce nonstructural proteins 1 to 4 (NSP1 to NSP4), which include a polymerase to transcribe the genome into a negative-sense RNA template. *5,* The replication enzymes assemble onto cellular membrane scaffolds in vesicles, and the template is used to produce a full-length 42S positive-sense mRNA genome and a late 26S mRNA for the structural proteins. *6,* The capsid (C) protein is translated first and cleaved. A signal peptide is exposed, the peptide associates with the endoplasmic reticulum *7,* in which the E glycoproteins are synthesized and glycosylated. They are transferred to the Golgi apparatus and then the plasma membrane. *8,* The capsid proteins assemble on the 42S genomic RNA and then associate with regions of cytoplasmic and plasma membranes containing the E1, E2, and E3 spike proteins. *9,* Budding from the plasma membrane releases the virus. *AAA,* Polyadenylate; *mRNA,* messenger ribonucleic acid.

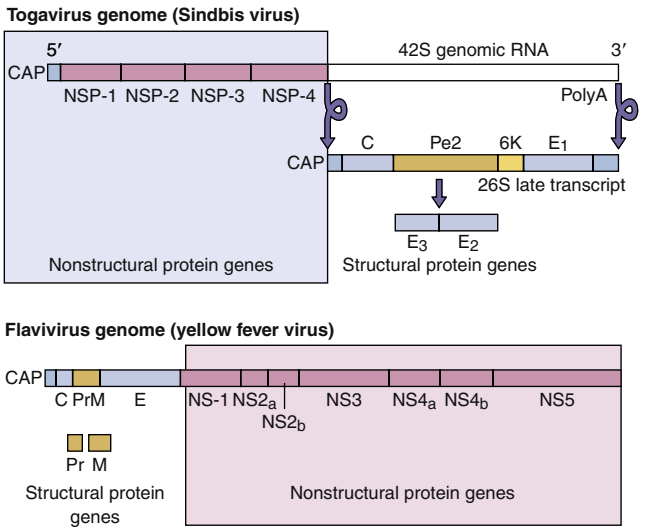

Fig. 52.3 Comparison of the togavirus (alphavirus) and flavivirus genomes. *Alphavirus:* The enzymatic activities are translated from the 5′ end of the input genome, promoting their early rapid translation. The structural proteins are translated later from a smaller messenger ribonucleic acid (mRNA) transcribed from the genomic template. *Flavivirus:* The genes for the structural proteins of the flaviviruses are at the 5′ end of the genome/mRNA, and only one species of polyprotein is made, which represents the entire genome. *PolyA,* Polyadenylate.

flaviviruses are antigenically related, and antibodies to one virus may recognize and neutralize another virus.

Attachment and penetration of the flaviviruses occur in the same way as described for the alphaviruses. Antibody can enhance infectivity and promote viral uptake into macrophages, monocytes, and other cells that have Fc receptors when the virus is coated with antibody. The major differences between alphaviruses and flaviviruses are in the organization of their genomes and their mechanisms of protein synthesis. The entire flavivirus genome is translated into a single polyprotein in a manner more similar to the process for picornaviruses than for alphaviruses (Fig. 52.3). As a result, there is no temporal distinction in the translation of the different viral proteins. The polyprotein produced from the yellow fever genome contains 10 proteins, including a protease and components of the RNA-dependent RNA polymerase, plus the capsid and envelope proteins.

Unlike in the alphavirus genome, the structural genes are at the 5′-end of the flavivirus genome. As a result, the portions of the polyprotein containing the structural (not the catalytic) proteins are synthesized first and with the greatest efficiency and the polymerase (NS5) is last. This arrangement allows production of more structural proteins, but it decreases the efficiency of nonstructural protein synthesis and the initiation of viral replication. The entire flavivirus polyprotein associates with the endoplasmic reticulum membrane and then is cleaved into its components. Unlike the togaviruses, the flaviviruses acquire their envelope by budding into the endoplasmic reticulum rather than at the cell surface. The virus is then released by exocytosis or cell lysis mechanisms. This route is less efficient, and the virus may remain cell associated.

ARBOVIRUS PATHOGENESIS AND IMMUNITY

Because the arboviruses are acquired from the bite of an arthropod such as a mosquito, knowledge of the course of infection in both the vertebrate host and the invertebrate vector is important for an understanding of the diseases. Infections of invertebrates are usually persistent, with continued virus production.

The death of an infected cell results from a combination of virus-induced insults. Increased permeability of the target cell membrane and changes in ion concentrations can alter enzyme activities and favor the translation of viral mRNA over cellular mRNA. The large amount of viral RNA produced on the replication and transcription of the genome blocks cellular mRNA from binding to ribosomes. The displacement of cellular mRNA from the protein synthesis machinery prevents rebuilding and maintenance of the cell and is a major cause of the death of the virus-infected cell.

Female mosquitoes acquire the alphaviruses and flaviviruses by taking a blood meal from a **viremic vertebrate host.** *A sufficient viremia must be maintained in the vertebrate host to allow acquisition of the virus by the mosquito.* The virus then infects the epithelial cells of the midgut of the mosquito, spreads through the basal lamina of the midgut to the circulation, and infects the salivary glands. The virus

BOX 52.2 Disease Mechanisms of Togaviruses and Flaviviruses

Viruses are cytolytic, except for rubella and hepatitis C.
Viruses establish viremia and systemic infection.
Viruses are good inducers of interferon and cytokines, which can account for the flulike symptoms during prodrome.
Viruses, except rubella and hepatitis C, are arboviruses.
Flaviviruses can infect cells of the monocyte-macrophage lineage.
Nonneutralizing antibody can enhance flavivirus infection via Fc receptors on cells.

[b]Can cause microcephaly in fetus.

sets up a persistent infection and replicates to high titers in these cells. The salivary glands can then release virus into the saliva. Not all arthropod species can generate virus in their saliva. For example, the normal vector for WEEV is the *Culex tarsalis* mosquito, but certain strains of virus are limited to the midgut of this mosquito, cannot infect its salivary glands, and therefore cannot be transmitted to humans.

On biting a host, the female mosquito regurgitates virus-containing saliva into the skin and the victim's bloodstream. The primary target cells of the flaviviruses are of the monocyte-macrophage lineage, including dendritic cells. Although these cells are found throughout the body and may have different characteristics, they express Fc receptors for antibody and release cytokines on challenge. Flavivirus infection is enhanced 200- to 1000-fold by nonneutralizing antiviral antibody that promotes binding of the virus to the Fc receptors and its uptake into the cell. The virus also infects the endothelial cells of capillaries.

These viruses are associated with **mild systemic disease, encephalitis, arthrogenic disease,** or **hemorrhagic disease** (Box 52.2). The ultimate nature of alphavirus and flavivirus disease is determined by (1) the specific tissue tropisms of the individual virus type, (2) the concentration of infecting virus, and (3) individual responses to the infection.

The initial viremia produces systemic symptoms such as fever, chills, headaches, backaches, and other flulike symptoms within 7 days of infection. Most of these symptoms can be attributed to the effects of the interferon and other cytokines produced in response to the viremia and infection of host cells. Most viral infections do not progress beyond the mild systemic disease associated with viremia. A secondary viremia can produce sufficient virus to infect target organs (e.g., brain, liver, skin, vasculature), depending on the tissue tropism of the virus (Fig. 52.4). The virus gains access to the brain by infecting the endothelial cells lining the small vessels of the brain or the choroid plexus. Hemorrhagic disease and shock, as for dengue virus, results from viral and immune-induced cytolysis of infected vascular endothelial cells exacerbated by extensive cytokine production (cytokine storm), which induces vascular leakage.

IMMUNE RESPONSE

Replication of the alphaviruses and flaviviruses produces a double-stranded RNA replicative intermediate that is a good inducer of interferon (IFN)-α and IFN-β. The interferon limits replication of the virus and is also released into the bloodstream to stimulate innate and immune responses. Interferon and other cytokines are produced after infection of plasmacytoid dendritic and other cells in blood, causing rapid onset of the flulike symptoms characteristic of mild systemic disease.

Circulating immunoglobulin (Ig)M is produced within 6 days of infection, followed by production of IgG. Antibody to the viral attachment protein blocks viremic spread of the virus and subsequent infection of other tissues. Through recognition of the type-common antigens expressed on all viruses in the family, immunity to one flavivirus may provide some protection against infection with other flaviviruses. Cell-mediated immunity is also important in controlling the primary infection.

Immunity to these viruses is a double-edged sword. The interferon and cytokine responses cause the prodrome and systemic symptoms, including the arthritides. Inflammation and cytolysis resulting from complement and cell-mediated immune responses can destroy tissues and significantly contributes to the pathogenesis of encephalitis. Hypersensitivity reactions to cell-associated antibody or initiated by formation of immune complexes with virions and viral antigens can activate complement and disrupt vascular cells to cause the hemorrhagic symptoms. An antibody to another flavivirus that does not neutralize the virus can enhance the uptake of flaviviruses into macrophages and other cells that express Fc receptors. Immune responses to a related strain of dengue virus that do not prevent infection can exacerbate immunopathogenesis, leading to dengue hemorrhagic fever (DHF) or dengue shock syndrome (DSS).

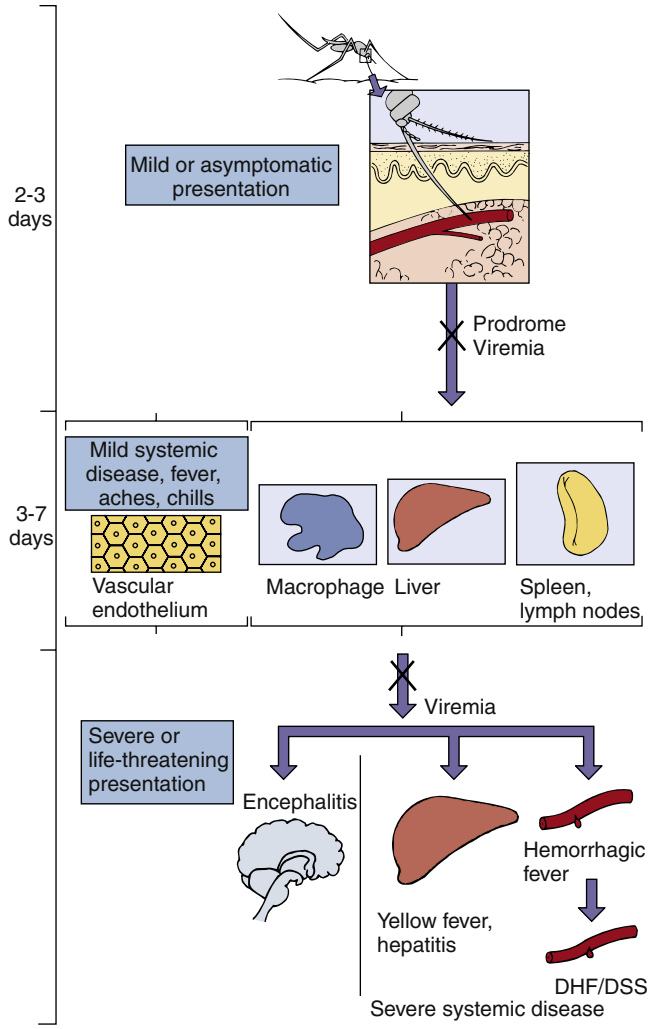

Fig. 52.4 Disease syndromes of the alphaviruses and flaviviruses. Primary viremia may be associated with mild systemic disease. Most infections are limited to this. If sufficient virus is produced during the secondary viremia to reach critical target tissues, then severe systemic disease or encephalitis may result. If antibody is present *(X),* viremia is blocked. For dengue virus, rechallenge with another strain can result in severe dengue hemorrhagic fever *(DHF),* which can cause dengue shock syndrome *(DSS)* because of the loss of fluids from the vasculature.

BOX 52.3 Epidemiology of Alphavirus and Flavivirus Infection

Disease/Viral Factors

Enveloped virus must stay wet and can be inactivated by drying, soap, and detergents.
Virus can infect mammals, birds, reptiles, and insects.
Asymptomatic or nonspecific (flulike fever or chills), encephalitis, hemorrhagic fever, or arthralgia.

Transmission

Specific arthropods characteristic of each virus (zoonosis: arbovirus).

Who Is at Risk?

People who enter ecologic niche of arthropods infected by arboviruses.

Geography/Season

Endemic regions for each arbovirus are determined by habitat of mosquito or other vector.
Aedes mosquito, which carries dengue and yellow fever, is found in urban areas and in pools of water.
Culex mosquito, which carries St. Louis encephalitis and West Nile encephalitis viruses, is found in forest and urban areas.
Disease is more common in summer.

Modes of Control

Mosquito breeding sites and mosquitoes should be eliminated.
Live attenuated yellow fever virus and inactivated Japanese encephalitis virus vaccines.

EPIDEMIOLOGY

Alphaviruses and most flaviviruses are prototypical arboviruses (Box 52.3). To be an arbovirus, the virus must be able to (1) infect both vertebrates and invertebrates, (2) initiate a sufficient viremia in a vertebrate host for a sufficient time to allow acquisition of the virus by the invertebrate vector, and (3) initiate a persistent productive infection of the salivary gland of the invertebrate to provide virus for the infection of other host animals. **Humans are usually "dead-end" hosts** in that they cannot spread the virus back to the vector because they do not maintain a persistent viremia. *If the virus is not in the blood, the mosquito cannot acquire it*. A full cycle of infection occurs when the virus is transmitted by the arthropod vector and amplified in a susceptible, immunologically naive host **(reservoir),** allowing reinfection of other arthropods (Fig. 52.5). The vectors, natural hosts, and geographic distribution of representative alphaviruses and flaviviruses are listed in Table 52.2.

These viruses are usually restricted to a specific arthropod vector, its vertebrate host, and their ecologic niche. The most common vector is the mosquito, but ticks and sandflies spread some arboviruses. Even in a tropical region overrun with mosquitoes, spread of these viruses is still restricted to a specific genus of mosquitoes. Not all arthropods can act as good vectors for each virus. For example, *C. quinquefasciatus* is resistant to infection by WEEV (alphavirus) but is an excellent vector for St. Louis encephalitis virus (flavivirus).

Birds and small mammals are the usual reservoir hosts for the alphaviruses and flaviviruses, but reptiles and amphibians also can act as hosts. A large population of viremic animals can develop in these species to continue the infection cycle of the virus. For example, West Nile encephalitis virus (WNV) was first noted in 1999 as an outbreak in New York by the unusual deaths of captive birds at the Bronx Zoo. RT-PCR analysis identified the virus as WNV. The virus is transmitted by *C. pipiens* mosquitoes, and crows, blue jays, and other wild birds are the reservoir. The virus spread throughout the United States, and by 2006, the virus and human disease had been noted in almost every state. WNV establishes a sufficient viremia in humans to be a risk factor for transmission through blood transfusions. Documentation of two such cases has led to screening blood donors for WNV and rejecting donors who have fever and headache during the week of blood donation.

Arbovirus diseases occur during the summer months and rainy seasons, when the arthropods breed, and the

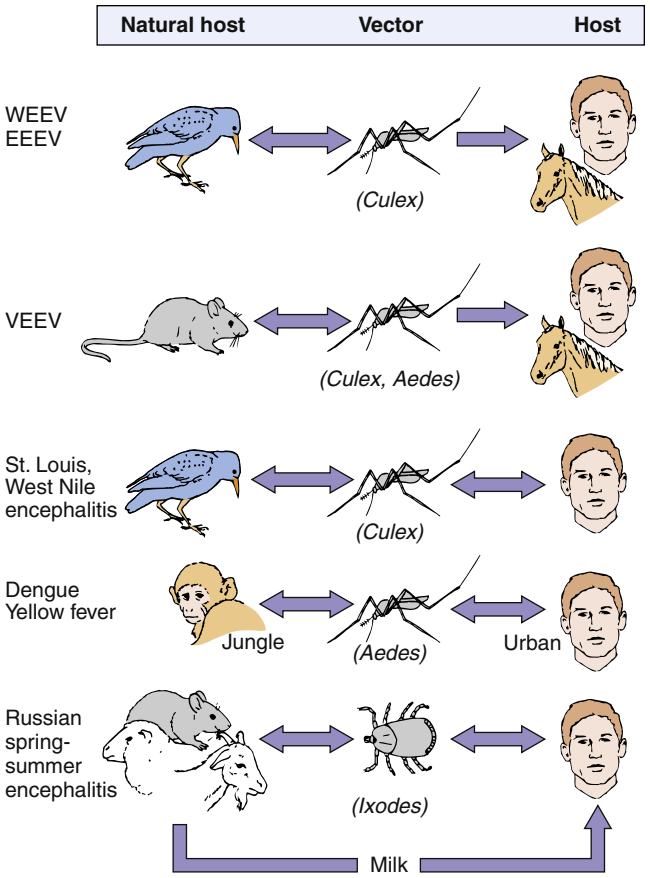

Fig. 52.5 Patterns of alphavirus and flavivirus transmission. Birds and small mammals are the hosts that maintain and amplify an arbovirus, which is spread by the insect vector during a blood meal. A *double arrow* indicates a cycle of replication in both host (including man) and vector. "Dead-end" infections with no transmission of the virus back to the vector are indicated by the single arrow. *EEEV,* Eastern equine encephalitis virus; *VEEV,* Venezuelan equine encephalitis virus; *WEEV,* western equine encephalitis virus.

arboviruses are cycled among a host reservoir (birds), an arthropod (e.g., mosquitoes), and human hosts. This cycle maintains and increases the amount of virus in the environment. In the winter, the vector is not present to maintain the virus. The virus may either (1) persist in arthropod larvae or eggs or in reptiles or amphibians that remain in the locale or (2) migrate with the birds and then return during the summer.

When humans travel into the ecologic niche of the mosquito vector, they risk being infected by the virus. Pools of standing water, drainage ditches, and trash dumps in cities can also provide breeding grounds for mosquitoes such as *Aedes aegypti,* which is the vector for yellow fever, dengue, and chikungunya viruses. An increase in the population of these mosquitoes, as has occurred in the United States, increases the risk for human infection. Health departments in many areas monitor birds and mosquitoes caught in traps for arboviruses and initiate control measures such as insecticide spraying when necessary.

Urban outbreaks of arbovirus infections occur when the reservoirs for the virus are humans or urban animals (see Fig. 52.5). Yellow fever, dengue, Zika and chikungunya viruses are transmitted by *Aedes* mosquitoes in a **sylvatic** or **jungle cycle,** in which monkeys are the natural host, and also in an **urban cycle,** in which humans are the host. *A. aegypti,* a vector for each of these viruses, is a household mosquito. It breeds in pools of water, open sewers, and other accumulations of water in cities. The incidence of chikungunya has greatly increased since 2000 and is prevalent from western Africa across southern Asia to the Philippines and in South America, the Caribbean Islands, and tropical United States. St. Louis encephalitis and WNV are maintained in an urban environment because their vectors, *Culex* mosquitoes, breed in stagnant water, including puddles and sewage, and the reservoir group includes common city birds (e.g., crows).

In addition to transmission by mosquitos, Zika virus also can be spread in blood, during unprotected sex, and in utero to the fetus. According to the Centers for Disease Control and Prevention, risk for transmission by these routes remains for at least 3 months after a potential exposure (travel to an endemic region).

CLINICAL SYNDROMES

More humans are infected with alphaviruses and flaviviruses than show significant characteristic symptoms. The incidence of arbovirus disease is sporadic. Alphavirus infections are usually asymptomatic or cause low-grade disease such as **flulike symptoms** (chills, fever, rash, aches) that correlate with systemic infection during the initial viremia. EEEV, WEEV, and Venezuelan equine encephalitis virus (VEEV) infections can progress to **encephalitis** in humans. The equine encephalitis viruses are usually more of a problem to livestock than to humans. An affected human may experience fever, headache, and decreased consciousness 3 to 10 days after infection. Unlike herpes simplex virus encephalitis, the disease will often resolve without significant sequelae, but there is the possibility of paralysis, mental disability, seizures, and death.

The name **chikungunya** (Swahili for "that which bends up") refers to the crippling arthritis associated with serious disease caused by infection with these viruses. A typical symptomatic infection presents as a week of fever and joint pain.

Most flavivirus infections are relatively benign, but serious **aseptic meningitis** and **encephalitic** or **hemorrhagic disease** can occur. The encephalitis viruses include **St. Louis, West Nile,** Japanese, Murray Valley, and Russian spring-summer viruses. Symptoms and outcomes are similar to those of the togavirus encephalitides. Approximately 20% of individuals infected with WNV will develop West Nile fever, characterized by fever, headache, tiredness, and body aches, occasionally with a rash on the trunk of the body and swollen lymph glands usually lasting only a few days (Clinical Case 52.1). Encephalitis, meningitis, or meningoencephalitis occurs in approximately 1% of WNV-infected individuals. Individuals older than 50 years and the immunocompromised are at higher risk for serious disease.

The hemorrhagic viruses are dengue and yellow fever viruses. **Dengue virus** is a major worldwide problem, with at least 100 million cases of dengue fever and 300,000 cases of **DHF** occurring per year. The virus and its vector are present in central and northern South America, and cases have occurred in Puerto Rico, Texas, and Florida. The incidence of the more serious DHF has quadrupled since

Clinical Case 52.1 **West Nile Encephalitis Virus**

Hirsch and Warner (*N Engl J Med* 348:2239–2247, 2003) described the case of a 38-year-old Massachusetts woman who presented with a progressively worsening headache with photophobia and fever. Because it was August, she was on summer vacation and 10 days earlier (−10) had traveled to St. Louis and stayed for 8 days. While there, she walked in the woods and visited the zoo. A day before the onset of these symptoms (−1), she vacationed along the Atlantic shore and noted that she had been bitten by mosquitos and removed ticks from her dog. Four days later (+4), she was admitted with fever (40° C), chills, rapid heartbeat, confusion, lightheadedness, and lethargy. Although appearing alert, oriented, and only slightly ill, her neck was rigid and Kernig sign was present. The signs of meningitis prompted testing of cerebrospinal fluid, which contained IgM to WNV and low titers to SLE virus. Patient antibody neutralized WNV but not SLE virus infection of tissue culture cells, suggesting that the activity to SLE was caused by cross-reactivity between flaviviruses. Tests for other organisms were negative. She was treated empirically for meningitis and for HSV (acyclovir). Antibacterial and anti-HSV treatment for meningitis and encephalitis was necessary until the laboratory results were available. On day 5 post onset, she became more lethargic and had difficulty answering questions. MRI indicated subtle changes in the brain. On day 6, she could not distinguish her right from her left hand, but her headache lessened, and she could respond to commands. On day 7, she had a tremor in her right arm, but her mental status was improving, and by day 8, she was alert and lucid. On day 9, a cranial MRI was normal; on day 10, she was recovered; and on day 11, she was released from the hospital. The season of the year, exposure to insects, and travel by this woman were suggestive of several different arboviral encephalitis diseases in addition to WNV. Viruses in the differential diagnosis included eastern equine encephalitis, SLE, Powassan virus (tick-borne flavivirus), HSV, and WNV. Unlike HSV encephalitis, flavivirus meningoencephalitis usually resolves with limited sequelae.

HSV, Herpes simplex virus; *Ig,* immunoglobulin; *MRI,* magnetic resonance imaging; *SLE,* St. Louis encephalitis; *WNV,* West Nile virus.

1985. Dengue fever is also known as **breakbone fever;** the symptoms and signs consist of high fever, headache, rash, hemorrhagic presentations, and back and bone pain that last 6 to 7 days. Petechiae (10 or more per square inch) under the cuff while testing blood pressure *(tourniquet test)* is indicative of dengue. On rechallenge with another of the four related strains, dengue can also cause **DHF** and **DSS.** Nonneutralizing antibody promotes uptake of the virus into macrophages, which causes memory T cells to become activated, release cytokines, and initiate inflammatory reactions. These reactions and the virus result in weakening and rupture of the vasculature, internal bleeding, and loss of plasma, leading to shock symptoms and internal bleeding. Dengue is endemic in at least 100 countries in Asia, the Pacific, the Americas, Africa, and the Caribbean, accounting for 40% of the world's population. The World Health Organization (WHO) estimates that 50 to 100 million infections occur yearly, including 500,000 DHF cases and 22,000 deaths, mostly among children.

Yellow fever infections are characterized by severe systemic disease, with degeneration of the liver, kidney, and heart, as well as hemorrhage. Liver involvement causes the jaundice from which the disease gets its name, but massive gastrointestinal hemorrhages ("black vomit") may also occur. The mortality rate associated with yellow fever during epidemics is as high as 50%.

Zika virus infection is usually asymptomatic. Disease resembles mild cases of dengue and chikungunya with fever, rash, headache, muscle and joint pain and conjunctivitis. Infection correlates with higher incidence of Guillain-Barré syndrome. Despite a lack of symptoms, the virus can be transmitted sexually and vertically to the fetus for at least 3 months after infection. Infection of the fetus can cause microcephaly and other congenital abnormalities.

LABORATORY DIAGNOSIS

Detection and characterization of the alphaviruses and flaviviruses is now performed by RT-PCR testing of viral mRNA in blood or other samples. Monoclonal antibodies to the individual viruses have become a useful tool for distinguishing the individual species and strains of viruses. The alphaviruses and flaviviruses can be grown in both vertebrate and mosquito cell lines, but most are difficult to isolate. A variety of serologic methods can be used to diagnose infections, but the serologic cross-reactivity among viruses limits distinction of the actual viral species in many cases.

TREATMENT, PREVENTION, AND CONTROL

No treatments exist for arbovirus diseases, other than supportive care. *The easiest means of preventing the spread of any arbovirus is elimination of its vector and breeding grounds.* After 1900, when Walter Reed and his colleagues discovered that yellow fever was spread by *A. aegypti,* the number of cases was reduced from 1400 to none within 2 years, purely through control of the mosquito population. Many public health departments monitor bird and mosquito populations in a region for arboviruses and periodically spray to reduce the mosquito population. Avoidance of the breeding grounds of a mosquito vector is also a good preventive measure.

A live vaccine against yellow fever virus and killed vaccines against EEEV, WEEV, Japanese encephalitis virus, and Russian spring-summer encephalitis virus are available. A live Japanese encephalitis virus vaccine is used in China. These vaccines are meant for people working with the virus or at risk for contact. A live vaccine against VEEV is available but only for use in domestic animals. Vaccines consisting of all four strains of dengue virus are being developed to ensure that immune enhancement of the disease on subsequent challenge does not occur. An interesting approach to the dengue virus vaccine consists of chimeric viruses in which the glycoprotein and other genes for each of the other dengue virus strains is inserted into either an attenuated dengue 2 virus or the 17D yellow fever virus.

The yellow fever vaccine is prepared from the 17D strain isolated from a patient in 1927 and grown for long periods

in monkeys, mosquitoes, embryonic tissue culture, and embryonated eggs. The vaccine is administered intradermally and elicits lifelong immunity to yellow fever and possibly other cross-reacting flaviviruses.

Rubella Virus

Rubella virus has the same structural properties and mode of replication as the other togaviruses. However, unlike the other togaviruses, rubella is a **respiratory virus** and **does not cause readily detectable cytopathologic effects.**

Rubella is one of the five **classic childhood exanthems,** along with measles, roseola, fifth disease, and chickenpox. Rubella, meaning "little red" in Latin, was first distinguished from measles and other exanthems by German physicians; thus the common name for the disease, **German measles.** In 1941, an astute Australian ophthalmologist, Norman McAlister Gregg, recognized that maternal rubella infection was the cause of congenital cataracts. Maternal rubella infection has since been correlated with several other **severe congenital defects.** This finding prompted the development of a unique program to vaccinate children to prevent infection of pregnant women and neonates.

PATHOGENESIS AND IMMUNITY

Rubella virus is not cytolytic but does interfere with cellular machinery. The replication of rubella prevents (in a process known as **heterologous interference**) the replication of superinfecting picornaviruses. This property allowed the first isolations of rubella virus in 1962.

Rubella infects the upper respiratory tract and then spreads to local lymph nodes, which coincides with a period of lymphadenopathy (Fig. 52.6). This stage is followed by establishment of viremia, which spreads the virus throughout the body. Infection of other tissues and the characteristic mild rash occur. The prodromal period lasts approximately 2 weeks (Fig. 52.7). The infected person can shed virus in respiratory droplets during the prodromal period and for as long as 2 weeks after the onset of the rash.

IMMUNE RESPONSE

Antibody is generated after the viremia, and its appearance correlates with the appearance of the rash. The antibody limits viremic spread, but cell-mediated immunity plays an important role in resolving the infection. Only one serotype of rubella exists, and natural infection produces lifelong protective immunity. Most important, serum antibody in a pregnant woman prevents spread of the virus to the fetus. *Immune complexes most likely cause the rash and arthralgia associated with rubella infection.*

CONGENITAL INFECTION

Rubella infection in a pregnant woman can result in serious congenital abnormalities in the child. If the mother does not have antibody, the virus can replicate in the placenta and spread to the fetal blood supply and throughout the fetus. Rubella can replicate in most tissues of the fetus. The virus may not be cytolytic, but the normal growth, mitosis, and chromosomal structure of the cells of the fetus can be altered by the infection. The alterations can lead to improper development of the fetus, small size of the infected baby, and the **teratogenic effects** associated with congenital rubella infection. The nature of the disorder is determined by the (1) tissue affected and (2) stage of development disrupted. Since the vaccine era, cytomegalovirus has replaced rubella as the most common cause of congenital defects.

The virus may persist in tissues such as the lens of the eye for 3 to 4 years and may be shed up to a year after birth.

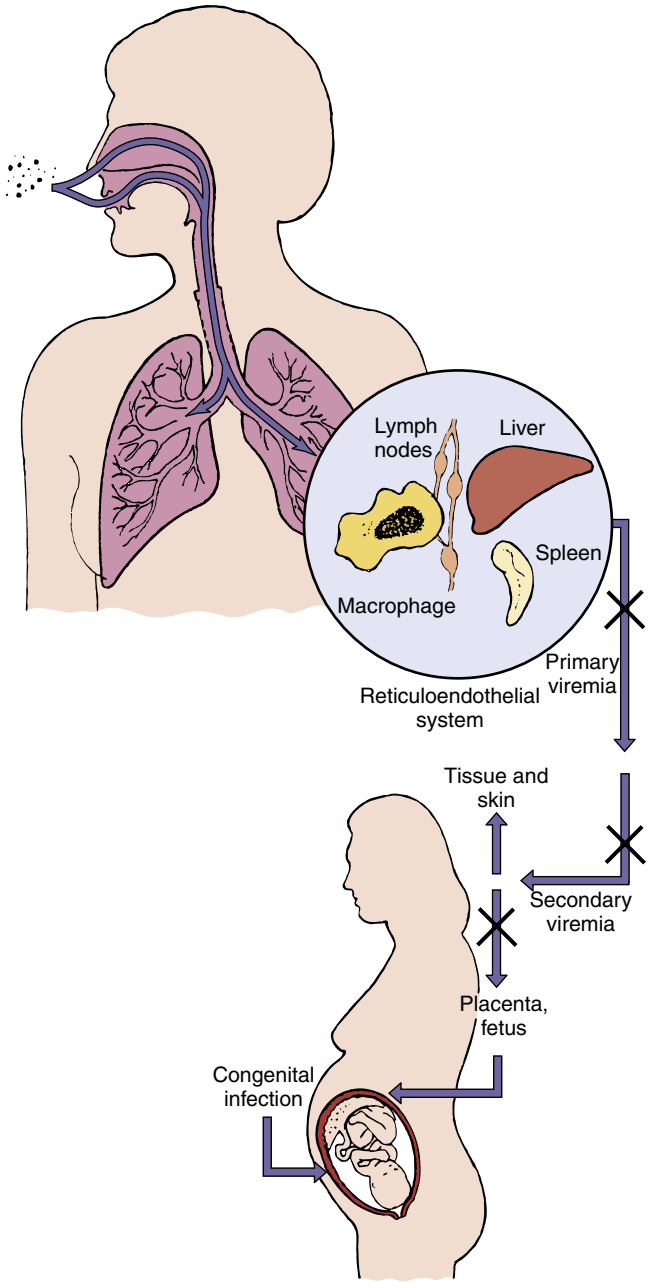

Fig. 52.6 Spread of rubella virus within the host. Rubella enters and infects the nasopharynx and lung and then spreads to the lymph nodes and monocyte-macrophage system. The resulting viremia spreads the virus to other tissues and the skin. Circulating antibody can block the transfer of virus at the indicated points *(X)*. In an immunologically deficient pregnant woman, the virus can infect the placenta and spread to the fetus.

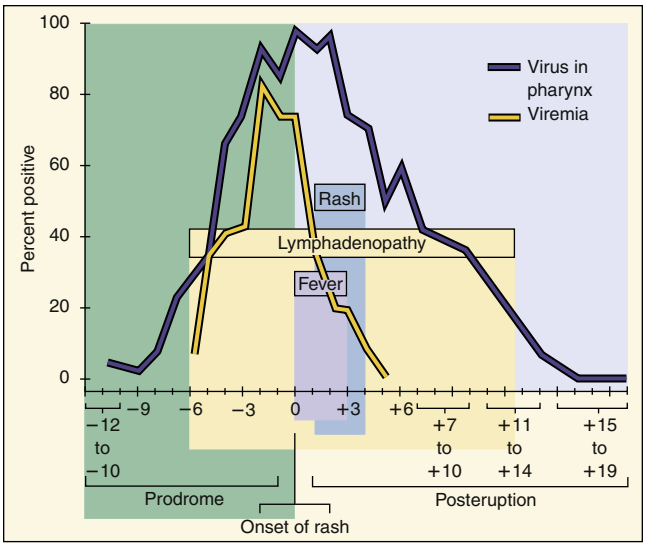

Fig. 52.7 Time course of rubella disease. Rubella production in the pharynx precedes the appearance of symptoms and continues throughout the course of the disease. The onset of lymphadenopathy coincides with the viremia. Fever and rash occur later. The person is infectious as long as the virus is produced in the pharynx. (Modified from Plotkin, S.A., Orenstein, W.A., Offit, P.A., 2008. Vaccines, fifth ed. Saunders, Philadelphia, PA.)

Presence of the virus during the development of the baby's immune response may even have a tolerogenic effect on the system, preventing effective clearance of the virus after birth.

EPIDEMIOLOGY

Humans are the only host for rubella (Box 52.4). The virus is spread in respiratory secretions and is generally acquired during childhood. Spread of virus, before or in the absence of symptoms, and crowded conditions (e.g., day-care centers) promote contagion.

Approximately 20% of women of childbearing age escape infection during childhood and are susceptible to infection unless vaccinated. Programs in many U.S. states test expectant mothers for antibodies to rubella.

Before the development and use of the rubella vaccine, cases of rubella in schoolchildren would be reported every spring, and major epidemics of rubella occurred at regular 6- to 9-year intervals. The severity of the 1964–1965 epidemic in the United States is shown in Table 52.3. Congenital rubella occurred in as many as 1% of all the children born in cities such as Philadelphia during this epidemic. The immunization program has succeeded in eliminating endemic rubella virus infection in the United States.

CLINICAL SYNDROMES

Rubella disease is normally benign in children. After a 14- to 21-day incubation period, the symptoms in children consist of a 3-day **maculopapular** or **macular rash** and swollen glands (Fig. 52.8). Infection in adults, however, can be more severe and include problems such as bone and joint pain (arthralgia and arthritis) and (rarely) thrombocytopenia or postinfectious encephalopathy. Immunopathologic effects resulting from cell-mediated immunity and hypersensitivity reactions are a major cause of the more severe forms of rubella in adults.

Congenital disease is the most serious outcome of rubella infection. The fetus is at major risk until the 20th week of pregnancy. Maternal immunity to the virus resulting from prior exposure or vaccination prevents spread of the virus to the fetus. The most common manifestations of congenital rubella infection are cataracts, mental retardation, cardiac abnormalities, and deafness (Boxes 52.5 and 52.6; see Table 52.3). The mortality in utero and within the first year after birth is high for affected babies.

LABORATORY DIAGNOSIS

Isolation of the rubella virus is difficult and rarely attempted. When isolation of the virus is necessary, the virus is usually

BOX 52.4 Epidemiology of Rubella Virus

Disease/Viral Factors

Rubella infects only humans.
Virus can cause asymptomatic disease.
There is one serotype.

Transmission

Respiratory route

Who Is at Risk?

Children: mild exanthematous disease.
Adults: more severe disease with arthritis or arthralgia.
Fetus <20 weeks: congenital defects.

Modes of Control

Live attenuated vaccine administered as part of the measles-mumps-rubella vaccine.

TABLE 52.3 Estimated Morbidity Associated with the 1964–1965 U.S. Rubella Epidemic

Clinical Events	Number Affected
Rubella cases	12,500,000
Arthritis-arthralgia	159,375
Encephalitis	2,084
DEATHS	
Excess neonatal deaths	2,100
Other deaths	60
Total deaths	2,160
Excess fetal wastage	6,250
CONGENITAL RUBELLA SYNDROME	
Deaf children	8,055
Deaf/blind children	3,580
Mentally retarded children	1,790
Other congenital rubella syndrome symptoms	6,575
Total congenital rubella syndrome	20,000
Therapeutic abortions	5,000

From National Communicable Disease Center, 1969. Rubella surveillance, Report No. 1. U.S. Department of Health, Education, and Welfare, Washington, DC.

BOX 52.5 Prominent Clinical Findings in Congenital Rubella Syndrome

Cataracts and other ocular defects
Heart defects
Deafness
Intrauterine growth retardation
Failure to thrive
Mortality within the first year
Microcephaly
Mental retardation

BOX 52.6 Clinical Summaries

West Nile encephalitis: During August, a 70-year-old man from a swampy area of Louisiana developed fever, headache, muscle weakness, nausea, and vomiting. He had difficulty answering questions. He progressed into a coma. Magnetic resonance imaging results show no specific localization of lesions (unlike in herpes simplex virus encephalitis). His disease progressed to respiratory failure and death. His 25-year-old niece, living next door, complained of sudden onset of fever (39° C [102.2° F]), headache, and myalgias, with nausea and vomiting lasting 4 days. (See website https://doi.org/10.3810/pgm.2003.07.1456).

Yellow fever: A 42-year-old man had fever (103° F), headache, vomiting, and backache that started 3 days after returning from a trip to Central America. He appeared normal for a short time, but then his gums started to bleed; he had bloody urine and vomited blood; and he developed petechiae, jaundice, and a slower and weakened pulse. He started to improve 10 days after the onset of disease.

Rubella: A 6-year-old girl from Romania developed a faint rash on her face, accompanied by mild fever and lymphadenopathy. Over the next 3 days, the rash progressed to other parts of the body. She had no history of rubella immunization.

obtained from urine. The virus can be detected by RT-PCR of viral RNA. The diagnosis can be confirmed by the presence of antirubella-specific IgM. Antibodies to rubella are assayed early in pregnancy to determine the immune status of the woman; this test is required in many states.

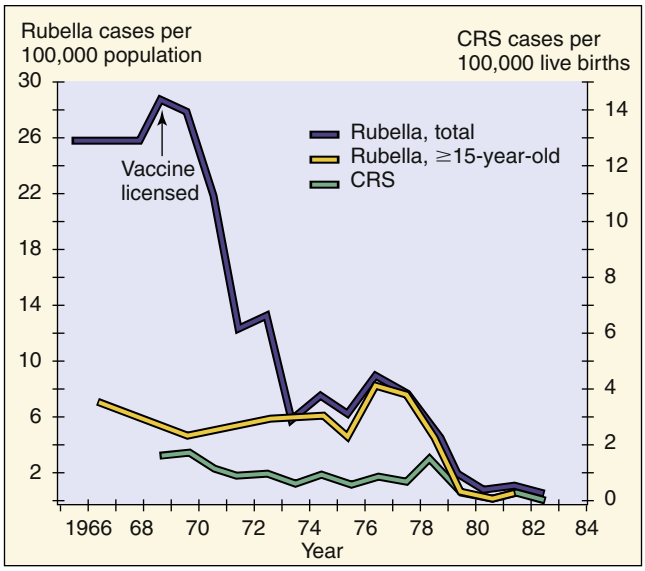

Fig. 52.9 Effect of rubella virus vaccination on the incidence of rubella and congenital rubella syndrome *(CRS).* (Modified from Williams, M.N., Preblud, S.R., 1984. Current trends: rubella and congenital rubella—United States. Morbidity and Mortality Weekly Report 33, 237–247.)

TREATMENT, PREVENTION, AND CONTROL

No treatment is available for rubella. The best means of preventing rubella is vaccination with the live cold-adapted RA27/3 vaccine strain of virus (Fig. 52.9). The live rubella vaccine is usually administered with the measles and mumps vaccines **(MMR vaccine)** after 12 months of age. The triple vaccine is included routinely in well-baby care. Vaccination promotes both humoral and cellular immunity.

The primary reason for the rubella vaccination program is to prevent congenital infection by decreasing the number of susceptible people in the population, especially children. As a result, there are fewer seronegative mothers and a smaller chance they will be exposed to the virus from contact with infectious children. Because only one serotype for rubella exists and humans are the only reservoir, vaccination of a large proportion of the population can significantly reduce the likelihood of exposure to the virus.

For a case study and questions see StudentConsult.com.

Case Studies and Questions

A 27-year-old businessman experienced a high fever, serious retroorbital headache, and severe joint and back pain 5 days after he and his family returned from a trip to Malaysia. The symptoms lasted for 4 days, and then a rash appeared on his palms and soles, which lasted for 2 days. At the same time, the man's 5-year-old son experienced mild flulike symptoms and then collapsed after 2 to 5 days. The boy's hands were cold and clammy, his face was flushed, and his body was warm. There were petechiae on his forehead and ecchymoses elsewhere. He bruised very easily. He was breathing rapidly and had a weak, rapid pulse. He then rapidly recovered after 24 hours.

1. What features of these cases pointed to the diagnosis of dengue virus infection?

2. Of what significance was the trip to Malaysia?

3. What was the source of infection in the father and son?

4. What were the significance of and the pathogenic basis for the petechiae and ecchymoses in the child?

Two weeks after returning from a trip to Pakistan, a 25-year-old man had arthralgia (joint aches) and a mild rash that started on his face and spread to his body. He recalled that he had felt as if he had the flu a few days before the onset of the rash. The rash disappeared in 4 days.

5. What features of this case pointed to the diagnosis of rubella infection?

6. Why is it significant that the symptoms started after a trip outside the United States?

7. What precaution could the man have taken to prevent this infection?

8. How was this infection transmitted?

9. Who was at risk for a serious outcome of this infection?

10. If this disease is normally mild in children, why is their immunization so important?

53 Bunyaviridae and Arenaviridae

A 50-year-old man was visiting family in Liberia and stayed in a house infested with rodents. He developed severe flulike symptoms, a sore throat, and red eyes and was treated with amoxicillin and chloroquine. His condition worsened, with increased fever, severe headache, and swollen lymph nodes, tonsils, and spleen. He began to cough up blood and then went into shock and died.

1. How was this individual infected with Lassa fever virus?
2. What are the unique characteristics of arenaviruses?
3. How are they similar to bunyaviruses? How are they different?

Answers to these questions are available on Student Consult.com.

Summaries Clinically Significant Organisms

BUNYAVIRUSES

Trigger Words

Arboviruses: mosquito, encephalitis
Hantaviruses: rodent, hemorrhagic disease

Biology, Virulence, and Disease

- Medium size, enveloped, (–) segmented RNA genome
- Encodes RNA-dependent RNA polymerase, replicates in cytoplasm
- Antibody can block disease
- Virus spreads in blood to tissues, neurons, and brain
- Prodrome of flulike symptoms caused by interferon and cytokine response
- Encephalitis: La Crosse, California encephalitis
- Hantaviruses: pulmonary syndrome

Epidemiology

- Encephalitis viruses: zoonosis, reservoir in birds, vector is the mosquito
- Hantavirus: inhalation of aerosols from rodent urine or feces

Diagnosis

- RT-PCR, ELISA

Treatment, Prevention, and Control

- Arboviruses: mosquito control
- Hantaviruses: rodent control

ARENAVIRUSES

Trigger Words

- Ribosomes in virion, rodent, Lassa fever virus, hemorrhagic disease, LCM virus, meningitis

Biology, Virulence, and Disease

- Medium size, enveloped, (–) segmented RNA genome
- Nonfunctional ribosomes in virion
- Encodes RNA-dependent RNA polymerase, replicates in cytoplasm
- Antibody can block disease
- Virus spreads in blood to tissues, neurons, and brain
- Prodrome of flulike symptoms caused by interferon and cytokine response
- LCM virus: meningitis
- Lassa fever: hemorrhagic fever

Epidemiology

- Inhalation of aerosols from rodent urine or feces
- LCM virus: worldwide
- Lassa fever: Africa

Diagnosis

- RT-PCR, ELISA

Treatment, Prevention, and Control

- Rodent control

ELISA, Enzyme-linked immunosorbent assay; *LCM,* lymphocytic choriomeningitis, *RT-PCR,* reverse transcriptase-polymerase chain reaction.

The Bunyaviridae and Arenaviridae share several similarities. The viruses of these families are negative-strand ribonucleic acid (RNA)-enveloped viruses with similar modes of replication. Both are zoonoses; most of the Bunyaviridae are arboviruses. The hantaviruses and Arenaviridae are spread by rodents and not insects. Many of the viruses from these families cause encephalitis or hemorrhagic disease.

Bunyaviridae

The Bunyaviridae constitute a "supergroup" of at least **200 enveloped, segmented, negative-strand RNA viruses** (Box 53.1). The supergroup of mammalian viruses is further broken down into genera on the basis of structural and biochemical features: *Bunyavirus, Phlebovirus, Nairovirus,* and *Hantavirus* (Table 53.1). Most of the Bunyaviridae are **arboviruses** (*ar*thropod-*bo*rne) that are spread by mosquitoes, ticks, or flies and are endemic to the environment of the vector. The **hantaviruses** are the exception; they are carried by **rodents.** New human viruses are still being discovered, including the tick-borne Heartland phlebovirus in the United States in 2012. In 2011, the tick-borne severe fever with thrombocytopenia syndrome virus (SFTSV) was discovered in China.

STRUCTURE

The bunyaviruses are roughly spherical particles 90 to 120 nm in diameter. The envelope of the virus contains two glycoproteins (G1 and G2) and encloses three unique negative-strand RNAs, the large **(L),** medium **(M),** and small **(S)** RNAs that are associated with protein to form nucleocapsids (Table 53.2). The genome segments for the La Crosse and related California encephalitis viruses form circles. The nucleocapsids include the RNA-dependent RNA polymerase

BOX 53.1 Unique Features of Bunyaviruses

There are at least 200 related viruses in five genera that share a common morphology and basic components.
Virion is enveloped with three (L, M, S) negative-sense ribonucleic acid nucleocapsids but no matrix proteins.
Virus replicates in the cytoplasm.
Virus can infect humans, animals, and arthropods.
Virus in an arthropod can be transmitted to its eggs.

(L protein) and two nonstructural proteins (NS_s, NS_m) (Fig. 53.1). Unlike other negative-strand RNA viruses, the Bunyaviridae **do not have a matrix protein.** The genera of Bunyaviridae are distinguished by differences in (1) the number and sizes of the virion proteins; (2) the lengths of the L, M, and S strands of the genome; and (3) how they are transcribed.

REPLICATION

The Bunyaviridae replicate in the same way as other enveloped negative-strand RNA viruses. For most Bunyaviridae, the G1 glycoprotein interacts with β-integrins on the cell surface, and the virus is internalized by endocytosis. After fusion of the envelope with endosomal membranes on acidification of the vesicle, the nucleocapsid is released into the cytoplasm, and messenger RNA (mRNA) and protein synthesis begin. Like influenza, the bunyaviruses steal the 5′-capped portion of mRNAs to prime the synthesis of viral mRNAs; but unlike influenza, this occurs in the cytoplasm. Separate positive-strand templates are used to replicate the genome.

The M strand encodes the NS_m nonstructural protein and the G1 (viral attachment) and G2 proteins, and the L strand encodes the L protein (polymerase) (see Table 53.2). The S strand of RNA encodes two nonstructural proteins, N and NS_s. For the *Phlebovirus* group, the S strand is ambisense, such that one mRNA is transcribed from the genome and the other from the (+) RNA template for replication.

The glycoproteins are synthesized and glycosylated in the endoplasmic reticulum, after which they are transferred to the Golgi apparatus but not translocated to the plasma membrane. Virions are assembled by budding into the Golgi apparatus and are released by cell lysis or exocytosis.

PATHOGENESIS

Most of the Bunyaviridae are arboviruses and possess many of the same pathogenic mechanisms as the togaviruses and flaviviruses (Box 53.2). For example, the viruses are spread by an arthropod vector and are injected into the blood to initiate a viremia. Progression past this stage to secondary viremia and further dissemination of the virus can deliver the virus to target sites such as the central nervous system, liver, kidney, and vascular endothelium to cause disease. Many Bunyaviridae cause encephalitis; others cause hepatic necrosis or hemorrhagic disease (e.g., Crimean-Congo hemorrhagic fever and Hantaan hemorrhagic disease) in ways similar to the toga and flaviviruses. In the latter infection, hemorrhagic necrosis of the kidney occurs often. Like togaviruses, flaviviruses, and arenaviruses, the bunyaviruses are good inducers of type 1 interferons. Bunyavirus disease is caused by a combination of immune and viral pathogenesis.

Unlike the other bunyaviruses, rodents are the reservoir and vector for hantaviruses, and humans acquire the virus by breathing aerosols contaminated with infected urine. Hantaviruses target the kidneys and cause chronic asymptomatic infection in rodents, which leads to long-term viral shedding in urine. Human inhalation brings the virus to the lungs, and then it can spread to the vasculature and kidneys, in which it replicates but is not cytolytic. It disrupts endothelial cell function, causing vascular permeability, which can lead to shock and induces cytolytic immune responses to cause hemorrhagic tissue destruction and lethal pulmonary disease.

EPIDEMIOLOGY

Most bunyaviruses are transmitted by infected mosquitoes, ticks, or *Phlebotomus* flies to rodents, birds, and larger animals (Box 53.3). The animals then become the **reservoirs** for the virus, continuing the cycle of infection. Humans are infected when they enter the environment of the insect vector (Fig. 53.2) but are usually dead-end hosts. Transmission occurs during the summer, but unlike many other arboviruses, many of the Bunyaviridae can survive a winter in the mosquito eggs and remain in a locale.

Many of the members of this virus family are found in South America, southeastern Europe, Southeast Asia, and Africa and bear the exotic names of their ecologic niches. Viruses of the **California encephalitis virus group** (e.g., La Crosse virus) are spread by mosquitoes found in the forests of North America (Fig. 53.3). Up to 100 cases of encephalitis are reported during the summer each year in the United States, but most infections are asymptomatic. These viruses are spread mainly by aggressive day-biting *Aedes triseriatus,* which breeds in the water in tree holes and in discarded tires.

The hantaviruses do not have an arthropod vector but are maintained in a rodent species specific for each virus. Humans are infected by close contact with rodents or through inhalation of aerosolized rodent urine. In May 1993, a deadly outbreak of **hantavirus pulmonary syndrome** (HPS) occurred in the Four Corners area of New Mexico. The outbreak is attributed to increased contact with the deer mouse vector during a season of unusually high rainfall, greater availability of food, and a rise in the rodent population. Viruses of the Sin Nombre subfamily were isolated from the victims and rodents. Since this incident, viruses from this subfamily have been detected and associated with outbreaks of respiratory tract disease in the eastern and western United States and in Central and South America.

CLINICAL SYNDROMES

Bunyaviridae, even those that can cause serious disease, usually cause relatively mild nonspecific febrile, flulike, viremia-related illness (Clinical Case 53.1; see Table 53.1) that is indistinguishable from illnesses caused by other viruses. The incubation period for these illnesses is approximately 48 hours, and the fevers typically last 3 days.

Encephalitis illnesses (e.g., La Crosse virus) are sudden in onset after an incubation period of approximately 1 week, and symptoms at this time consist of fever, headache,

TABLE 53.1 Notable Bunyaviridae Genera[a]

Genus	Members	Insect Vector	Pathologic Conditions	Vertebrate Hosts
Bunyavirus	Bunyamwera virus, California encephalitis virus, La Crosse virus, Oropouche virus; 150 members	Mosquito	Febrile illness, encephalitis, rash	Rodents, small mammals, primates, marsupials, birds
Phlebovirus	Rift Valley fever virus, sandfly fever virus, Heartland virus; 38 members	Fly, tick	Sandfly fever, hemorrhagic fever, encephalitis, conjunctivitis, myositis	Sheep, cattle, domestic animals
Nairovirus	Crimean-Congo hemorrhagic fever virus; 6 members	Tick	Hemorrhagic fever	Hares, cattle, goats, seabirds
Uukuvirus	Uukuniemi virus; 7 members	Tick	—	Birds
Hantavirus	Old World; Hantaan virus and others New World; Sin Nombre and others	None None	Hemorrhagic fever with renal syndrome, adult respiratory distress syndrome Hantavirus pulmonary syndrome, shock, pulmonary edema	Rodents Rodents

[a]Additional viruses possess several common properties with Bunyaviridae but are as yet unclassified.

TABLE 53.2 Genome and Proteins of California Encephalitis Virus

Genome[a]	Proteins
L	RNA polymerase, 170 kDa
M	G1 glycoprotein, 75 kDa G2 glycoprotein, 65 kDa NS_m (nonstructural) protein, 15–17 kDa
S	N (nonstructural) protein, 25 kDa NS_s (nonstructural) protein, 10 kDa

[a]Negative-strand RNA.

lethargy, and vomiting. Seizures occur in 50% of patients with encephalitis, usually early in the illness. Signs of meningitis may also be present. The illness lasts 10 to 14 days. Death occurs in less than 1% of patients, but seizure disorders may occur as sequelae in as many as 20%.

Hemorrhagic fevers such as Rift Valley fever are characterized by petechial hemorrhages, ecchymosis, epistaxis, hematemesis, melena, and bleeding of the gums. Death occurs in as many as half of patients with hemorrhagic disease. **HPS** occurs in the Americas and is a terrible disease, manifesting initially as a prodrome of fever, flulike symptoms, and muscle aches but followed rapidly by interstitial pulmonary edema, respiratory failure, shock, and death within days. Hemorrhagic fever with renal syndrome (HFRS) occurs in Europe and Asia and adds petechial rash, systemic hemorrhagic disease, and kidney failure to HPS.

LABORATORY DIAGNOSIS

Detection of viral RNA by reverse transcriptase-polymerase chain reaction (RT-PCR) has become the accepted method for detecting and identifying bunyaviruses. The Sin Nombre and Convict Creek hantaviruses were initially identified with the RT-PCR test, using primers with characteristic hantavirus sequences.

Enzyme-linked immunosorbent assay (ELISA) may detect antigen in clinical specimens from patients with an intense viremia (e.g., Rift Valley fever, HFRS, Crimean-Congo hemorrhagic fever) or from mosquitoes.

TREATMENT, PREVENTION, AND CONTROL

No specific therapy for infections of the Bunyaviridae is available. Human disease is prevented by interruption of the contact between humans and the vector, whether arthropod or mammal. Arthropod vectors are controlled by (1) eliminating the growth conditions for the vector, (2) spraying with insecticide, (3) installing netting or screening at windows and doors, (4) wearing protective clothing, and (5) controlling the tick infestation of animals. Rodent control minimizes the transmission of hantaviruses.

Arenaviruses

The arenaviruses include **lymphocytic choriomeningitis (LCM)** and **hemorrhagic fever viruses,** such as the **Lassa, Junin,** and **Machupo** viruses (Box 53.4). These viruses cause persistent infections in specific rodents and can be transmitted to humans as **zoonoses.**

STRUCTURE AND REPLICATION

Arenaviruses are seen in electron micrographs as **pleomorphic enveloped viruses** (diameter, 120 nm) that have a **sandy appearance** (the name comes from the Greek word ***arenosa,*** meaning "sandy") because of the **ribosomes in the virion**. Although functional, the ribosomes do not seem to serve a purpose. Virions contain a nucleocapsid with **two single-stranded RNA circles** (S, 3400 nucleotides; L, 7200 nucleotides) and a transcriptase. The L strand is a negative-sense RNA and encodes the polymerase. The S strand encodes the nucleoprotein (N protein) and the glycoproteins but is **ambisense.** Whereas the mRNA for the N protein is transcribed directly from the ambisense S strand, the mRNA for the glycoprotein is transcribed from a full-length template of the S strand. Like togaviruses, the glycoproteins are produced as late proteins after genome

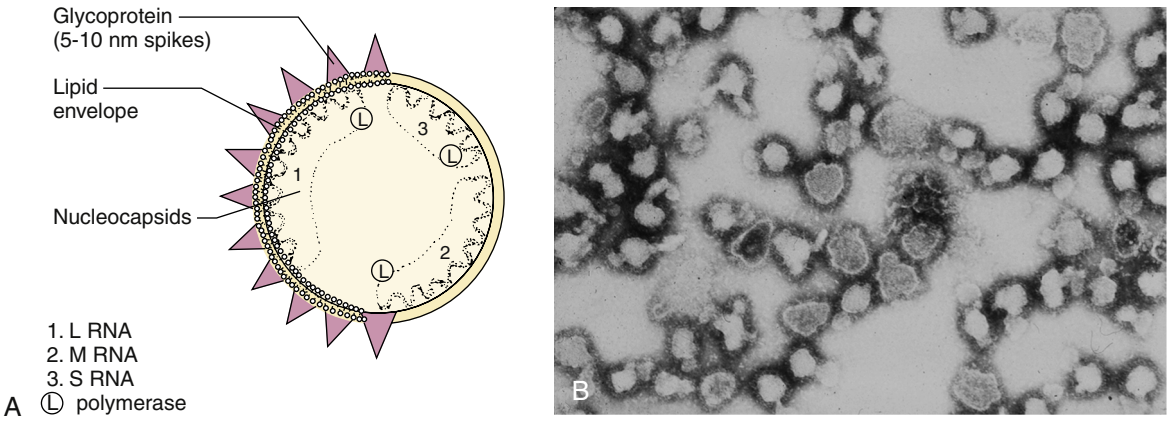

Fig. 53.1 (A) Model of the bunyavirus particle. (B) Electron micrograph of La Crosse variant of bunyavirus. Note the spike proteins at the surface of the virion envelope. *RNA,* Ribonucleic acid. BOX 53.2 Disease Mechanisms for Bunyaviruses

Virus is acquired from an arthropod bite (e.g., mosquito).
For hantaviruses, the virus is acquired from rodent urine or feces.
Initial viremia causes flulike symptoms.
Establishment of secondary viremia may allow virus access to specific target tissues that define the disease, including the central nervous system, organs, and vascular endothelium.
Viral and immunopathogenesis causes tissue disruption.
Antibody is important in controlling viremia; interferon and cell-mediated immunity may prevent the outgrowth of infection and contribute to disease.

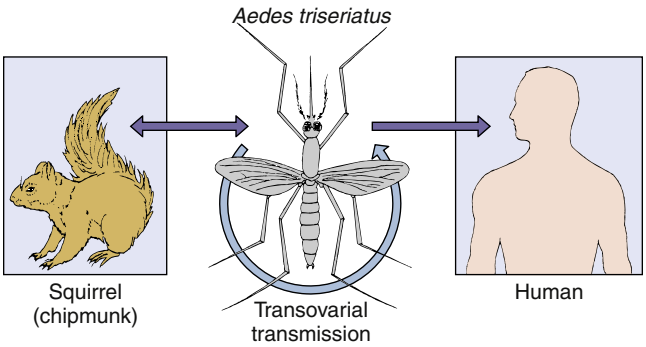

Fig. 53.2 Transmission of La Crosse (California) encephalitis virus.

BOX 53.3 Epidemiology of Bunyavirus Infections

Disease/Viral Factors

Arboviruses able to replicate in mammalian and arthropod cells.
Arboviruses able to pass into ovary and infect arthropod eggs, allowing virus to survive during winter.

Transmission

Arboviruses, via arthropod's blood meal; California encephalitis group, *Aedes* mosquito;
Aedes mosquitoes are aggressive daytime feeders and live in forests.
Aedes mosquitoes lay eggs in small pools of water trapped in places such as trees and tires.
Hantavirus: transmitted in aerosols from rodent urine and feces and by close contact with infected rodents.

Who Is at Risk?

People in habitat of arthropod or rodent vector.
California encephalitis group: campers, forest rangers, woodsmen.

Geography/Season

Disease incidence correlates with distribution of vector.
Disease more common in summer.

Modes of Control

Elimination of vector or vector's habitat.
Avoidance of vector's habitat.

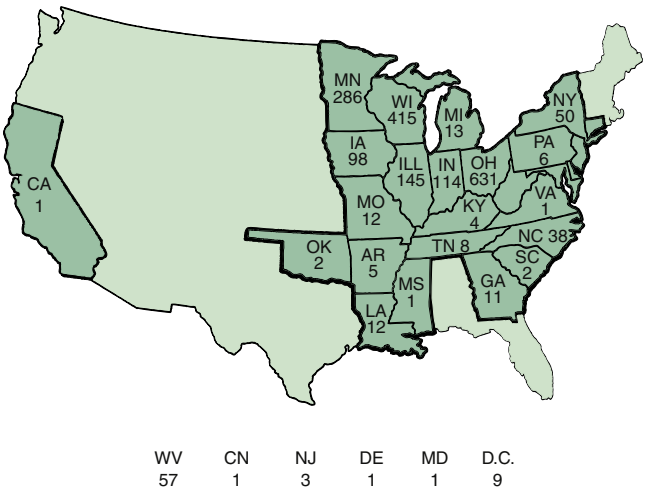

Fig. 53.3 Distribution of California encephalitis, 1964 to 2010. (Courtesy Centers for Disease Control and Prevention, Atlanta, Georgia.)

replication. Arenaviruses replicate in the cytoplasm and acquire their envelope by budding from the host cell plasma membrane.

Arenaviruses readily cause persistent infections. This may result from inefficient transcription of the glycoprotein genes and thus poor virion assembly.

Clinical Case 53.1 **Hantavirus in Virginia**

The Centers for Disease Control and Prevention (*Morb Mortal Wkly Rep* 53:1086–1089, 2004) reported a case of hantavirus in a 32-year-old wildlife sciences graduate student. The patient visited the ED in Blacksburg, Virginia, after experiencing fever, cough, and a "sore chest." The student had been trapping, handling, and studying mice during the previous month. Neither he nor his colleagues wore gloves while handling the mice or their excreta; they did not wash before eating and had numerous mouse bites on their hands. He had a fever of 39.3° C and normal lung function, but a chest radiograph indicated a faint right-sided pneumonia. The man started vomiting in the ED and was admitted. The pneumonia progressed, and he became more hypoxic, eventually requiring intubation and mechanical ventilation. On the next day, he was given activated protein C to prevent disseminated intravascular coagulation. The patient continued to fail and died on the third day after hospitalization. Serum specimens contained IgM and IgG antibody and genomic ribonucleic acid (determined by reverse transcriptase-polymerase chain reaction) to hantavirus, and viral antigens were present in the spleen. Although the hantavirus received its greatest notoriety with the Sin Nombre virus outbreak in the southwestern United States in 1993, it can occur wherever people come in contact with the urine and feces of rodents carrying these viruses. Cases have been reported in 31 of the United States.

ED, Emergency Department; *Ig,* immunoglobulin.

BOX 53.4 Characteristics of Arenaviruses

Virus has **enveloped** virion with two **circular, negative-RNA** genome segments (L, S). Virion appears **sandy because of ribosomes.**
S genome segment is ambisense.
Arenaviruses are zoonoses, establishing persistent infections in rodents.
Pathogenesis of arenavirus infections is largely attributed to immunopathogenesis.

PATHOGENESIS

Arenaviruses are able to infect macrophages, induce cytokine and interferon release, and promote cell and vascular damage. T-cell–induced immunopathologic effects significantly exacerbate tissue destruction. The incubation period for arenavirus infections averages 10 to 14 days.

EPIDEMIOLOGY

Most arenaviruses, except for the virus that causes LCM, are found in the tropics of Africa and South America. The arenaviruses, like the hantaviruses, infect specific rodents and are endemic to the rodents' habitats. Chronic asymptomatic infection is common in these animals and leads to long-term viral shedding in saliva, urine, and feces. Humans may become infected through inhalation of aerosols, consumption of contaminated food, or contact with fomites. Animal bites are not a usual mechanism of spread.

The virus that causes LCM infects hamsters and house mice *(Mus musculus)*. It was found in 20% of mice in Washington, DC. Lassa fever virus infects *Mastomys natalensis*, which is an African rodent. The Lassa fever virus is spread from human to human through contact with infected secretions or body fluids, but the viruses that cause LCM and other hemorrhagic fevers are rarely, if ever, spread in this way.

From 1999 to 2000, three cases of fatal hemorrhagic disease in California were found to be caused by the Whitewater Arroyo arenavirus. This virus is normally found in the white-throated wood rat, so its occurrence in humans constitutes a newly emergent disease. The disease association was made by a special RT-PCR assay.

BOX 53.5 Clinical Summary

Lassa fever: Approximately 10 days after returning from a trip to visit family in Nigeria, a 47-year-old man developed flulike symptoms with a higher than expected fever and malaise. The disease got progressively worse, and after 3 days, the patient developed abdominal pain, nausea, vomiting, diarrhea, pharyngitis, bleeding gums, and began vomiting blood. He developed shock and then died.

CLINICAL SYNDROMES

Lymphocytic Choriomeningitis

The name of this virus, **lymphocytic choriomeningitis virus,** suggests that meningitis is a typical clinical event, but actually, LCM usually causes a febrile illness with flulike myalgia (Box 53.5). Only about 10% of infected persons progress to a central nervous system infection. The meningeal illness, if it occurs, will start 10 days after the initial phase of illness, with full recovery. Perivascular mononuclear infiltrates may be seen in neurons of all sections of the brain and in the meninges of an affected patient.

Lassa and Other Hemorrhagic Fevers

Lassa fever, which is endemic to West Africa, is the best known of the hemorrhagic fevers caused by an arenavirus. Other agents, however, such as the Junin and Machupo viruses, cause similar syndromes in the inhabitants of Argentina and Bolivia, respectively.

Clinical illness is characterized by fever, coagulopathy, petechiae, and occasional visceral hemorrhage, as well as by liver and spleen necrosis, but not vasculitis. Hemorrhage and shock also occur, as does occasional cardiac and liver damage. In contrast to LCM, hemorrhagic fevers cause no lesions in the central nervous system. Pharyngitis, diarrhea, and vomiting may be prevalent, especially in patients with Lassa fever. Death occurs in as many as 50% of those with Lassa fever and in a smaller percentage of those infected with the other arenaviruses that cause hemorrhagic fevers. The diagnosis is suggested by recent travel to endemic areas.

LABORATORY DIAGNOSIS

An arenavirus infection is usually diagnosed on the basis of serologic and genomic (RT-PCR) findings. These viruses are too dangerous for isolation. Throat specimens can yield

arenaviruses; urine is a source for the Lassa fever virus but not for the LCM virus. The risk of infection is substantial for laboratory workers handling body fluids. Therefore if the diagnosis is suspected, laboratory personnel should be so warned and the specimens processed only in facilities that specialize in the isolation of contagious pathogens **(level 3 for LCM and level 4 for Lassa fever and other arenaviruses).**

TREATMENT, PREVENTION, AND CONTROL

The antiviral drug **ribavirin** has limited activity against arenaviruses and can be used to treat Lassa fever. However, supportive therapy is usually all that is available for patients with arenavirus infections.

These rodent-borne infections can be prevented by limiting contact with the vector. For example, improved hygiene to limit contact with mice reduced the incidence of LCM in Washington, DC. In the geographic areas in which hemorrhagic fever occurs, trapping rodents and carefully storing food may decrease exposure to the virus.

The incidence of laboratory-acquired cases can be reduced if samples submitted for arenavirus isolation are processed in at least level 3 or level 4 biosafety facilities and not in the usual clinical virology laboratory.

Case Studies and Questions

A 58-year-old woman complained of flulike symptoms, severe headache, stiff neck, and photophobia. She was lethargic and had a mild fever. The cerebrospinal fluid specimen contained 900 white blood cells per milliliter, mostly lymphocytes, and LCM virus. She recovered after a week. Her home was infested with gray mice *(M. musculus)*.

1. What were the significant symptoms of this disease?

2. How was the virus transmitted?

3. What type of immune response is most important in controlling this infection?

A 15-year-old summer camp counselor in Ohio suddenly complained of headache, nausea, and vomiting; she had a fever and experienced a stiff neck. She was admitted to the hospital, in which a spinal tap and examination of cerebrospinal fluid revealed inflammatory cells. She became lethargic over the next day but became alert again after 4 to 5 days.

4. The physician suspected La Crosse encephalitis virus as the agent. What clues pointed to La Crosse virus?

5. What other agents would also be considered in the differential diagnosis?

6. How was the patient infected?

7. How would transmission of this agent be prevented?

8. How could the local public health department determine the prevalence of La Crosse virus in the environment of the summer camp? What samples would they obtain, and how would they test them?

54 Retroviruses

A 63-year-old woman has tuberculosis and a severe oral *Candida* yeast infection. Her CD4 T-cell level was 50/μL, and 200,000 human immunodeficiency virus (HIV) genomes per milliliter of blood were detected. Although monogamous, she finds out that her husband was not.

1. What cell types does HIV infect, and why does this have such an effect on the patient's immune response?
2. How does the virus replicate?
3. To what other opportunistic infections is this woman susceptible?
4. What are risk factors for infection?
5. How was the HIV infection detected and how was compliance to treatment followed?
6. How can the HIV infection be treated?

Answers to these questions are available on Student Consult.com.

Summaries Clinically Significant Organisms

RETROVIRUSES

Trigger Words

Reverse transcriptase, integration, syncytia
HIV: AIDS, CD4, chemokine co-receptor, opportunistic diseases
HTLV: leukemia, flower cell, CD4 T cell

Biology, Virulence, and Disease

- Virion: medium size, envelope, nucleocapsid, two copies of (+) RNA genome
- Simple retroviruses have three genes: *gag, pol, env*
- Complex retroviruses (HIV, HTLV) have *gag, pol, env,* and other important genes
- Encodes RNA-dependent DNA polymerase (RT), replicates in nucleus
- Virion carries RT, integrase, and protease enzymes
- Replicates through DNA intermediate, integrates viral DNA into host chromosome
- Causes syncytia
- Incapacitates and escapes immune control
- Oncornaviruses may encode oncogene and have a short latency period before cancer
- HTLV-1, no oncogene, long latency period before leukemia
- **HTLV:** acute T-cell lymphocytic leukemia, tropical spastic paraparesis
- **HIV:** initially infects CD4/CCR5 macrophages, dendritic cells, and T cells; initial disease phase resembles mononucleosis followed by latent period; AIDS results when CD4 T cells drop below 200/μL
- **Endogenous retroviruses:** integrated and approximately 8% of human genome

Epidemiology

- Worldwide
- Transmitted in blood and semen
- High-risk groups: promiscuous individuals, IV drug users, infants of infected mothers

Diagnosis

- RT-PCR, ELISA

Treatment, Prevention, and Control

- HIV treatment with nucleoside analogs, protease inhibitors, and other antiviral drugs
- Prevention by screening of blood supply, safe sex, antiviral drug prophylaxis, education

ELISA, Enzyme-linked immunosorbent assay; *HTLV,* human T-cell lymphotropic virus; *IV,* intravenous; *RT-PCR,* reverse transcriptase-polymerase chain reaction.

The retroviruses are probably the most studied group of viruses in molecular biology. These viruses are **enveloped positive-strand ribonucleic acid (RNA)** viruses with a unique morphology and means of replication. In 1970, Baltimore and Temin showed that the retroviruses encode an **RNA-dependent deoxyribonucleic acid (DNA) polymerase (reverse transcriptase [RT])** and replicate through a DNA intermediate. The DNA copy of the viral genome is then integrated into the host chromosome to become a cellular gene. This discovery, which earned Baltimore, Temin, and Dulbecco the 1975 Nobel Prize, contradicted what had been the central dogma of molecular biology—that genetic information passed from DNA to RNA and then to protein.

The first retrovirus to be isolated was the Rous sarcoma virus, shown by Peyton Rous to produce solid tumors (sarcomas) in chickens. Like most retroviruses, the Rous sarcoma virus proved to have a very limited host and species range. Cancer-causing retroviruses have since been isolated from other animal species and are classified as RNA tumor viruses or **oncornaviruses.** Many of these viruses alter cellular growth by expressing analogs of cellular growth-controlling genes **(oncogenes).** Not until 1981, however, when Robert Gallo and his associates isolated human T-cell lymphotropic virus 1 (HTLV-1) from a person with adult human T-cell leukemia, was a human retrovirus associated with human disease.

In the late 1970s and early 1980s, an unusual number of young homosexual men, Haitians, heroin addicts, and hemophiliacs in the United States (the initial "4H club" of risk groups) were noted to be dying of normally benign opportunistic infections. Their symptoms defined a new disease, called **acquired immunodeficiency syndrome (AIDS).** However, as is now known, AIDS is not limited to these groups but can occur in anyone exposed to the virus. Now approximately 37 million men, women, and children around the world are living with the virus that causes AIDS. Montagnier and associates

in Paris, and Gallo and colleagues in the United States, reported the isolation of the human immunodeficiency virus (HIV-1) from patients with lymphadenopathy and AIDS. A closely related virus, designated **HIV-2,** was isolated later and is prevalent in West Africa. HIV appears to have been acquired by humans from chimpanzees and then rapidly spread through Africa and the world by an increasingly mobile population. Although a devastating disease that cannot be completely cured, the development of antiviral drug cocktails (highly active antiretroviral therapy [HAART]) has allowed many HIV patients to resume a normal life.

Endogenous retroviruses, the ultimate parasites, are integrated, are transmitted vertically, and may take up as much as 8% of the human chromosome. Although they may not produce virions, they may still contribute to or influence functions of the body.

Our understanding of the retroviruses has paralleled progress in molecular biology and immunology. In turn, the retroviruses have provided a major tool for molecular biology, the RT enzyme, and through the study of viral oncogenes also have provided a means of advancing our understanding of cell growth, differentiation, and oncogenesis.

The three subfamilies of human retroviruses are the **Oncovirinae** (HTLV-1, HTLV-2, HTLV-5), the **Lentivirinae** (HIV-1, HIV-2), and the **Spumavirinae** (Table 54.1). Although a spumavirus was the first human retrovirus to be isolated, no such virus has been associated with human disease.

Classification

The retroviruses are classified by the diseases they cause, tissue tropism and host range, virion morphology, and genetic complexity (see Table 54.1). The **oncoviruses** include the only retroviruses that can **immortalize or transform target cells.** These viruses are also categorized by the morphology of their core and capsid as type A, B, C, or D, as seen in electron micrographs (Fig. 54.1; see Table 54.1). The **lentiviruses are slow viruses associated with neurologic and immunosuppressive diseases.** The spumaviruses, represented by a foamy virus, cause a distinct cytopathologic effect but, as already noted, do not seem to cause clinical disease.

Structure

The retroviruses are roughly spherical, enveloped, RNA viruses with a diameter of 80 to 120 nm (Fig. 54.2 and Box 54.1). The envelope contains viral glycoproteins and is acquired by budding from the plasma membrane. The **envelope surrounds a capsid that contains two identical copies of the positive-strand RNA genome** inside an electron-dense core. The virion also contains 10 to 50 copies of the **RT and integrase enzymes** and **two cellular transfer RNA (tRNAs).** These tRNAs are base-paired to each copy of the genome to be used as a primer for the RT. The morphology of the core differs for different viruses and is used as a means of classifying the retroviruses (see Fig. 54.1). The HIV virion core resembles a truncated cone (Fig. 54.3).

The genome of the **simple retroviruses** *consists of three major genes that encode polyproteins* for the following enzymatic and structural proteins of the virus: **Gag** (group-specific antigen, *capsid, matrix,* and *nucleic acid–binding proteins*), **Pol** *(polymerase, protease*, and *integrase)*, and **Env** (envelope, *glycoproteins*) (Fig. 54.4 and Table 54.2). At each end of the genome are **long terminal repeat (LTR)** sequences. The LTR sequences contain promoters, enhancers, and other gene sequences used for binding different cellular transcription factors. Oncogenic viruses may also contain a growth-promoting **oncogene.** The **complex retroviruses,** including HTLV, HIV, and other lentiviruses, express early and late proteins and encode several virulence-enhancing proteins that require more complex transcriptional processing (splicing) than the simple retroviruses. Although the genome resembles a messenger RNA (mRNA), unlike a picornavirus genome, it is not infectious because the RT and integrase carried within the virion are required for replication.

The viral glycoproteins are produced by proteolytic cleavage of the polyprotein encoded by the *env* gene. The size of the glycoproteins differs for each group of viruses. For

TABLE 54.1 Classification of Retroviruses

Subfamily	Characteristics	Examples
Oncovirinae	Are associated with cancer and neurologic disorders	—
B	Have eccentric nucleocapsid core in mature virion	Mouse mammary tumor virus
C	Have centrally located nucleocapsid core in mature virion	Human T-cell lymphotropic virus[a] (HTLV-1, HTLV-2, HTLV-5), Rous sarcoma virus (chickens)
D	Have nucleocapsid core with cylindrical form	Mason-Pfizer monkey virus
Lentivirinae	Have slow onset of disease, cause neurologic disorders and immunosuppression, are viruses with D-type cylindrical nucleocapsid core	Human immunodeficiency virus[a] (HIV-1, HIV-2), visna virus (sheep), caprine arthritis/encephalitis virus (goats)
Spumavirinae	Cause no known clinical disease but cause characteristic vacuolated "foamy" cytopathology	Human foamy virus[a]
HERVs	Retrovirus sequences that are integrated into human genome	Human placental virus

[a]Also classified as complex retroviruses because of the requirement for accessory proteins for replication.
HERVs, Human endogenous retroviruses.

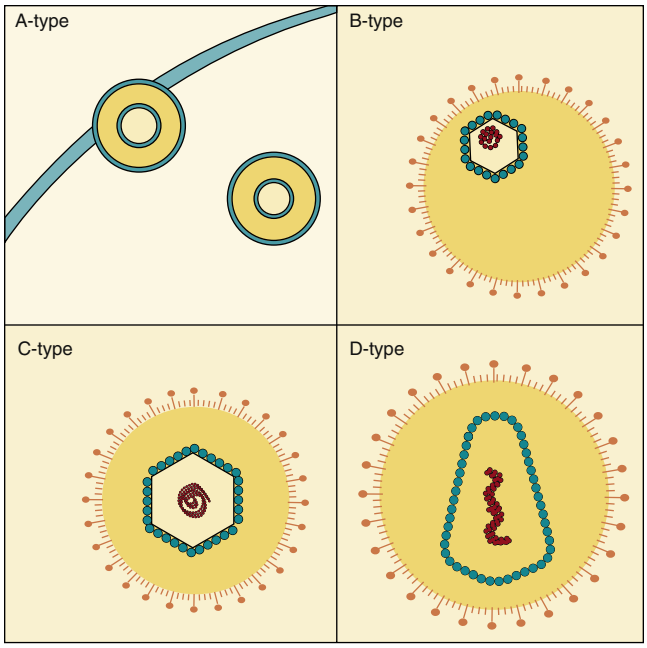

Fig. 54.1 1 Morphologic distinction of retrovirions. The morphology and position of the nucleocapsid core are used to classify the viruses. A-type particles are immature intracytoplasmic forms that bud through the plasma membrane and mature into B-type, C-type, and D-type particles.

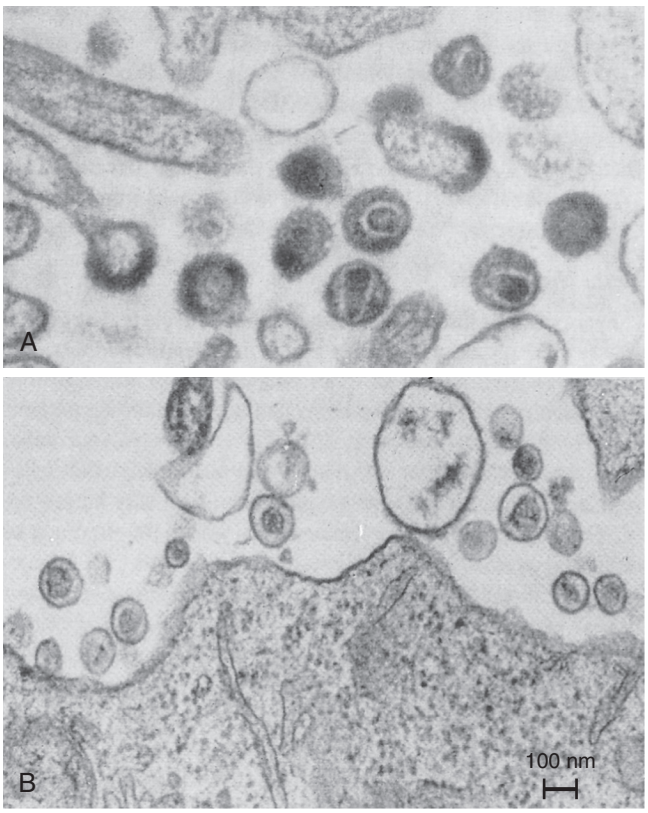

Fig. 54.2 Electron micrographs of two retroviruses. (A) HIV. Note the cone-shaped nucleocapsid in several of the virions. (B) Human T-cell lymphotropic virus. Note the C-type morphology characterized by a central symmetric nucleocapsid. (From Belshe, R.B., 1991. Textbook of Human Virology, second ed. Mosby, St Louis, MO.)

BOX 54.1 Unique Characteristics of Retroviruses

Virus has an **enveloped** spherical virion that is 80 to 120 nm in diameter and encloses a capsid containing **two** copies of the **positive-strand RNA** genome (≈9 kilobases for HIV and human T-cell lymphotropic virus).
RNA-dependent DNA polymerase **(reverse transcriptase),** two copies of tRNA, protease, and integrase enzymes are carried in the virion.
Virus receptor is the initial determinant of tissue tropism.
Replication proceeds through a DNA intermediate termed the *provirus.*
The provirus **integrates** randomly into the host chromosome and becomes a cellular gene.
Transcription of the genome is regulated by the interaction of host transcription factors with promoter and enhancer elements in the long terminal repeat portion of the genome.
Simple retroviruses encode *gag, pol,* and *env* genes. **Complex viruses** also encode accessory genes (e.g., *tat, rev, nef, vif,* and *vpu* for HIV).
Virus assembles and buds from the plasma membrane.
Final morphogenesis of HIV *requires* protease cleavage of Gag and Gag-Pol polypeptides after envelopment.

tRNA, Transfer RNA.

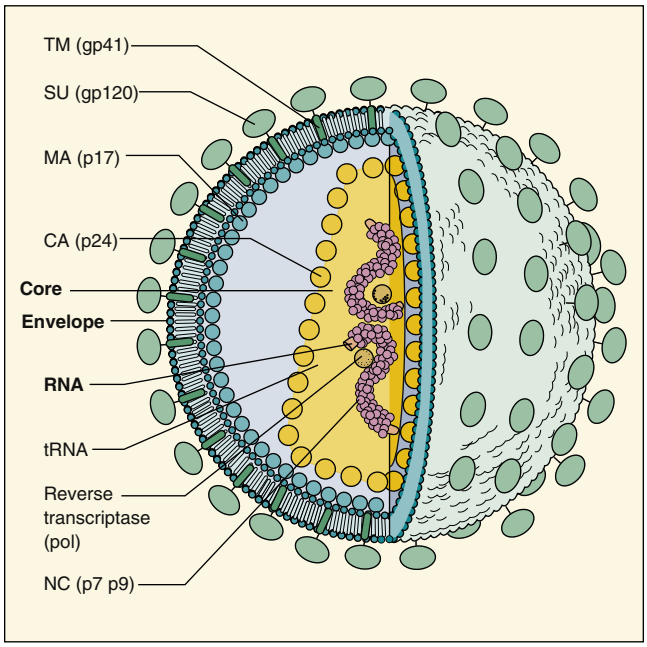

Fig. 54.3 Cross section of HIV. The enveloped virion contains two identical ribonucleic acid *(RNA)* strands, RNA polymerase, integrase, and two transfer RNAs *(tRNA)* base-paired to the genome within the protein core. This is surrounded by proteins and a lipid bilayer. The envelope spikes are the glycoprotein *(gp)*120 attachment protein and gp41 fusion protein. *CA,* Capsid; *MA,* matrix; *NC,* nucleocapsid; *SU,* surface component; *TM,* transmembrane component of envelope glycoprotein. (Modified from Gallo, R.C., Montagnier, L., 1988. AIDS in 1988. Scientific American 259, 41–48. Copyright George Kelvin.)

example, the (glycoprotein) gp62 of HTLV-1 is cleaved into gp46 and p21, and the *gp160 of HIV is cleaved into gp41 and gp120*. These glycoproteins form lollipop-like trimer spikes that are visible on the surface of the virion. The larger of the HIV glycoproteins (gp120), which binds to cell-surface

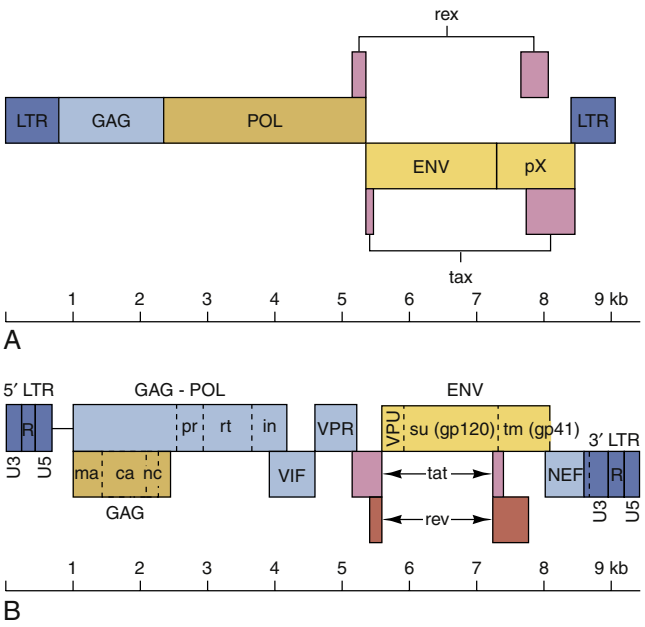

Fig. 54.4 Genomic structure of human retroviruses. (A) Human T-cell lymphotropic virus (HTLV-1). The *pX* gene includes sequences for tax, rex, p12, p13, p30, and HBZ. (B) HIV-1. The genes are defined in Table 54.2 and Fig. 54.3. Unlike the other genes of these viruses, production of the messenger RNA for *tax* and *rex* genes (HTLV-1) and *tat* and *rev* genes (HIV) requires excision of two intron units. HIV-2 has a similar genome map but has a *vpx* but not a *vpu* gene. *ENV,* Envelope glycoprotein gene; *GAG,* group antigen gene; *LTR,* long terminal repeat; *POL,* polymerase gene. Protein nomenclature for HIV: **ca,** Capsid protein; **in,** integrase; **ma,** matrix protein; **nc,** nucleocapsid protein; **pr,** protease; **rt,** reverse transcriptase; **su,** surface glycoprotein component; **tm,** transmembrane glycoprotein component. (Modified from Belshe, R.B., Textbook of Human Virology, second ed. Mosby, St Louis, MO.)

TABLE 54.2 Retrovirus Genes and Their Function

Gene	Virus	Function
gag	All	Group-specific antigen: core and capsid proteins
int	All	Integrase
pol	All	Polymerase: reverse transcriptase, protease, integrase
pro	All	Protease
env	All	Envelope: glycoproteins
pX	HTLV	Sequence containing tax, rex, p12, p13, p30, and HBZ: facilitate persistent viral infection of the host
hbz	HTLV	Regulator of tax, promotes cell proliferation
tax	HTLV	Transactivation of viral and cellular genes
tat	HIV-1	Transactivation of viral and cellular genes
rex	HTLV	Regulation of RNA splicing and promotion of export to cytoplasm
rev	HIV-1	Regulation of RNA splicing and promotion of export to cytoplasm
nef	HIV-1	Decreases cell-surface CD4; facilitates T-cell activation, progression to AIDS (essential)
vif	HIV-1	Virus infectivity, promotion of assembly, blocks a cellular antiviral protein
vpu	HIV-1	Facilitates virion assembly and release, induces degradation of CD4
vpr (vpx[a])	HIV-1	Transport of complementary DNA to nucleus, arresting of cell growth; facilitates replication in macrophages
LTR	All	Promoter, enhancer elements

[a]Only in HIV-2.
HTLV, Human T-cell lymphotropic virus; *LTR,* long terminal repeat (sequence).

receptors, initially determines the tissue tropism of the virus and is recognized by neutralizing antibody. The smaller subunit (gp41 in HIV) forms the lollipop stick and promotes cell-to-cell fusion. The gp120 of HIV is extensively glycosylated, and *its antigenicity can drift and receptor specificity can shift by mutations that occur during the course of a chronic HIV infection*. These factors impede antibody clearance of the virus.

Replication

Replication of HIV will serve as an example for the other retroviruses unless noted. Infection starts with binding of the viral glycoprotein spikes (trimer of gp120 and gp41 molecules) to the primary receptor, **the CD4 protein,** and then a second receptor, a 7-transmembrane G-protein–coupled **chemokine receptor** (Fig. 54.5). *Binding to these receptors is the initial and major determinant of tissue tropism and host range for a retrovirus.* The co-receptor used on initial infection by HIV is **CCR5,** which is expressed on **myeloid and peripheral, activated, central memory, intestinal, and other subsets of CD4 T cells (macrophages, [M]-tropic virus).** Later, during chronic infection of a person, the *env* gene mutates so that the gp120 binds to a different chemokine receptor **(CXCR4),** which is expressed primarily on T cells **(T-tropic virus)** (Fig. 54.6). Binding to the chemokine receptor activates the cell and brings the viral envelope and cell plasma membrane close together, allowing the gp41 to interact with and promote fusion of the two membranes. Binding to CCR5 and gp41-mediated fusion are both targets for antiviral drugs. HIV can also bind to a cellular adhesion molecule, α-4 β-7 integrin (also known as VLA-4 [very late antigen-4] and the gut homing receptor for T cells), and dendritic cell–specific intercellular adhesion molecule-3-grabbing nonintegrin (DC-SIGN) on dendritic and other cells.

Once the genome is released into the cytoplasm, the early phase of replication begins. The RT, encoded by the *pol* gene, uses the tRNA in the virion as a primer and synthesizes a **complementary** negative-strand DNA **(cDNA).** The RT also acts as a ribonuclease H, degrades the RNA genome, and then synthesizes the positive strand of DNA (Fig. 54.7). The RT is the major target for antiviral drugs. During the synthesis of the virion DNA **(provirus),** sequences from each end of the genome (U3 and U5) are duplicated, attaching the LTRs to both ends. This process creates sequences necessary for integration and *creates enhancer and promoter sequences within the LTR for regulation of transcription*. The DNA copy of the genome is larger than the original RNA.

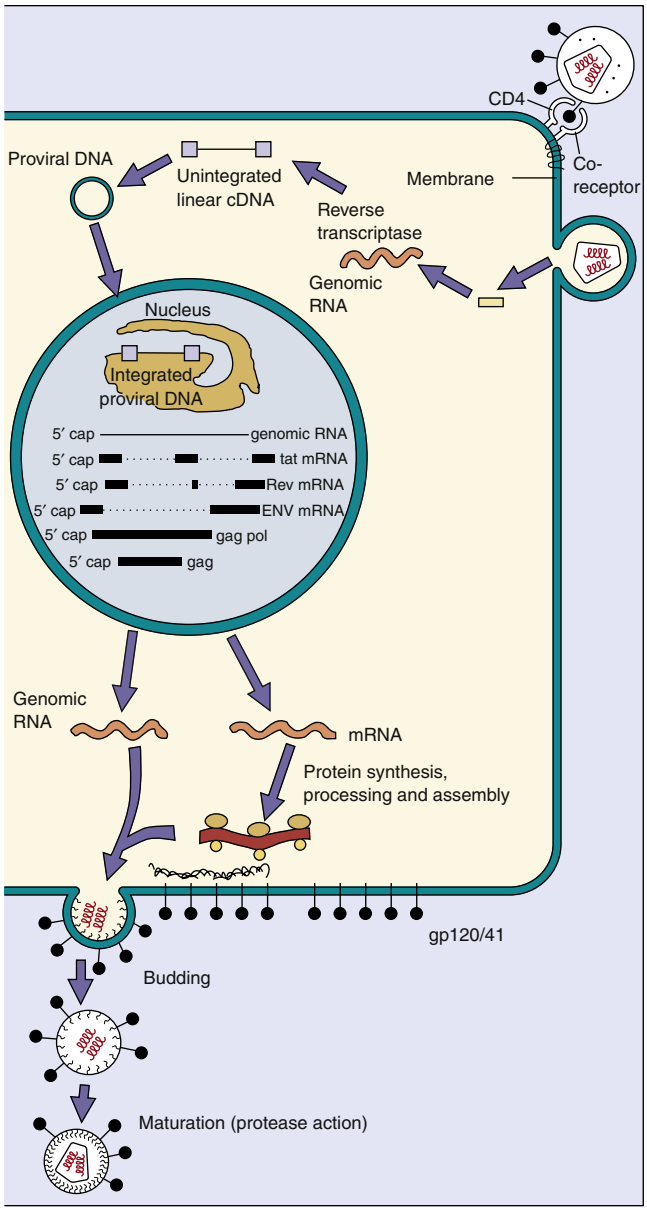

Fig. 54.5 Life cycle of HIV. HIV binds to CD4 and chemokine co-receptors and enters by fusion. The genome is reverse transcribed into deoxyribonucleic acid *(DNA)* in the cytoplasm, enters the nucleus, and is integrated into the nuclear DNA. Transcription and translation of the genome occur as a cellular gene in a fashion similar to that of human T-cell lymphotropic virus (see Fig. 54.7). The virus assembles at the plasma membrane and matures after budding from the cell. *cDNA,* Complementary DNA; *mRNA,* messenger ribonucleic acid. (Modified from Fauci, A.S., 1988. The human immunodeficiency virus: infectivity and mechanisms of pathogenesis. Science 239, 617–622.)

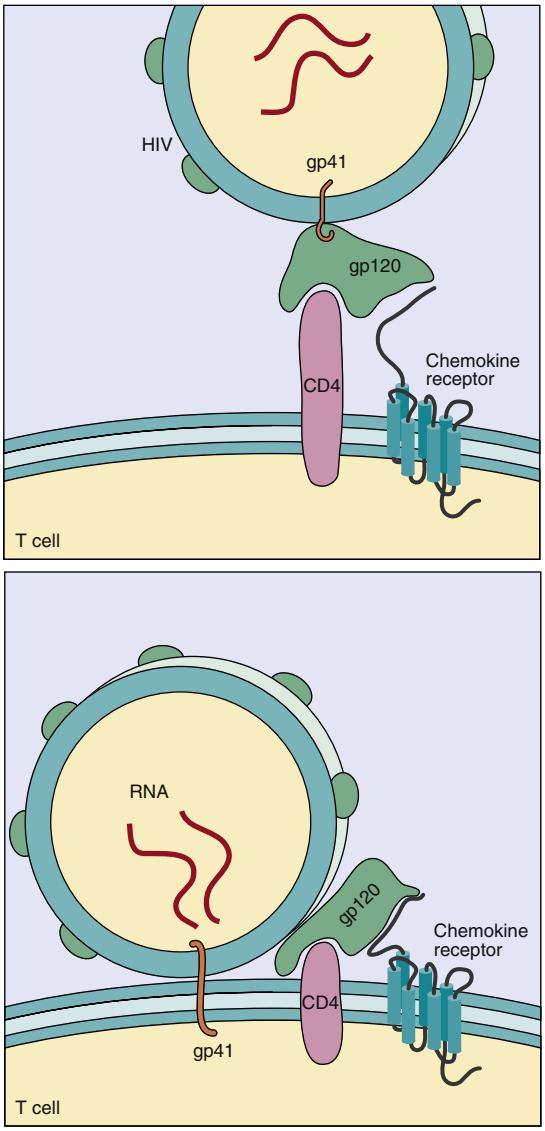

Fig. 54.6 Target cell binding of human immunodeficiency virus *(HIV).* The CCR5 chemokine receptor is a co-receptor with CD4 on initial infection of an individual, and after mutation of the *env* gene, the CXCR4 receptor is also used. *RNA,* Ribonucleic acid. (Modified from Balter, M., 1988. New hope in HIV disease. Science 274, 1988.)

RT is very error prone. For example, the error rate for the RT from HIV is one error per 2000 bases, or approximately five errors per genome (HIV, 9000 base pairs), which is the equivalent of at least one typo on every page of this text but different errors for every book. This genetic instability of HIV is responsible for promoting the generation of new strains of virus during a person's disease, which is a property that may alter the pathogenicity of the virus and promote antiviral resistance or immune escape.

Unlike other retroviruses, the double-stranded cDNA of HIV and other lentiviruses can enter the nucleus through nuclear pores of resting T cells. Dissolution of the nuclear envelope on cell division is required by other retroviruses. The cDNA is then spliced into the host chromosome with the aid of a virus-encoded, virion-carried enzyme, **integrase.** Integration requires cell growth, but the cDNA of HIV and other lentiviruses can remain in the nucleus and cytoplasm in a nonintegrated circular DNA form until the cell is activated. Integrase is a target for an antiviral drug.

Once integrated, the late phase begins and viral DNA **provirus** is transcribed as a cellular gene by the host RNA polymerase II. Transcription of the genome produces a full-length RNA, which for simple retroviruses is processed to produce several mRNAs that contain the *gag, gag-pol,* or *env* gene sequences. The full-length transcripts of the genome can also be assembled into new virions.

Because the provirus acts as a cellular gene, its replication depends on the extent of methylation of the viral DNA and

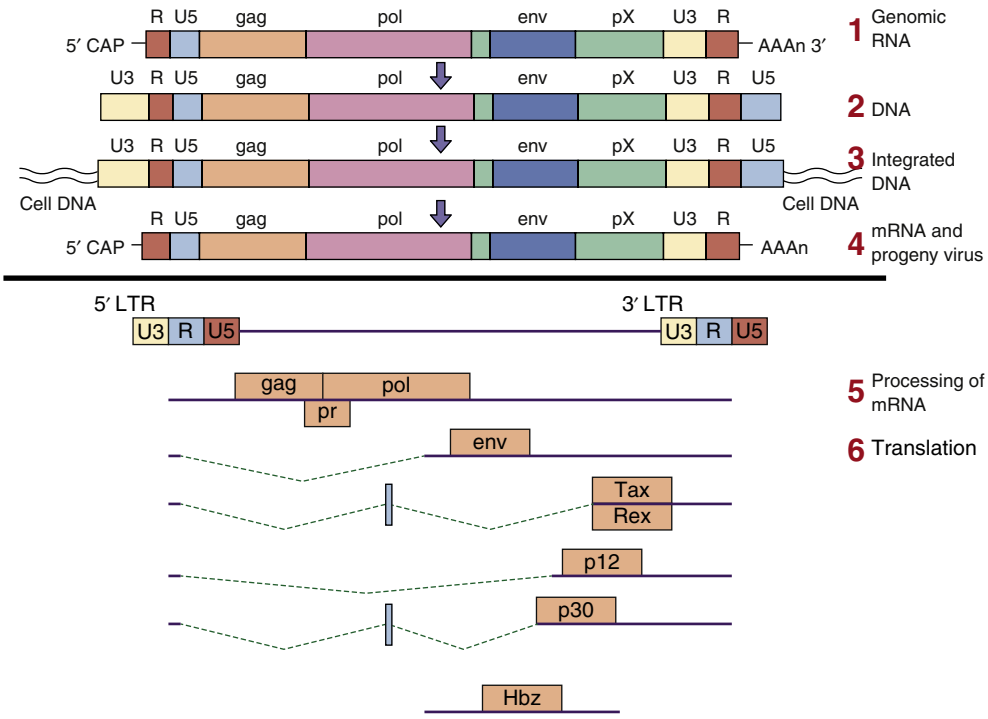

Fig. 54.7 Transcription and translation of human T-cell lymphotropic virus. (A similar but more complex approach is used for HIV.) *(1)* Genomic ribonucleic acid *(RNA)* is reverse transcribed and *(2)* circularized and then *(3)* integrated into the host chromatin. *(4)* A full-length RNA and *(5)* individual messenger RNAs *(mRNAs)* are processed from this RNA. The mRNA for tax, rex, and p30 require excision of two sequences from the *gag-pol* and *env* sequences. The other mRNAs, including the *env* mRNA, require excision of one sequence. *(6)* Translation of these mRNAs produces polyproteins, which are subsequently cleaved. *AAAn,* Polyadenylate. Gene nomenclature: *env,* Envelope glycoprotein; *gag,* group antigen gene; *pr,* protease; *pol,* polymerase; *rex,* regulator of splicing; *tax,* transactivator. Protein nomenclature: **C,** Carboxyl terminus of peptide; **CA,** capsid; **MA,** matrix; **N,** amino terminus; **NC,** nucleocapsid; **PR,** protease; **SU,** surface component; **TM,** transmembrane component of envelope glycoprotein. Prefixes: **gp,** glycoprotein; **gPr,** glycosylated precursor polyprotein; **p,** protein; **PR,** precursor polyprotein. (Adapted from Kannian, P., Green, P.L., 2010. Human T lymphotropic virus type 1 (HTLV-1): molecular biology and oncogenesis. Viruses 2 [9], 2037–2077.)

on the cell's growth rate, but mostly on the ability of the cell to recognize the enhancers and promoter sequences encoded in the LTR region. Stimulation of the cell by cytokines or mitogens produced in response to other infections generates transcription factors that bind to the LTR and for HIV are required to activate transcription of the integrated genome. For other retroviruses that encode viral oncogenes, these proteins promote cell growth and stimulate transcription and hence viral replication. *The ability of a cell to transcribe the retroviral genome is also a major determinant of tissue tropism and host range for a retrovirus.*

HTLV and HIV are **complex retroviruses** and undergo two phases of transcription. During the early phase, HTLV-1 expresses two proteins, **Tax** and **Rex,** which regulate viral replication. Unlike the other viral mRNAs, the mRNA for Tax and Rex requires more than one splicing step. The *rex* gene encodes two proteins that bind to a structure on the viral mRNA, preventing further splicing and promoting mRNA transport to the cytoplasm. The doubly spliced *tax*/*rex* mRNA is expressed early (at a low concentration of Rex), and structural proteins are expressed late (at a high concentration of Rex). Late in the infection, Rex selectively enhances expression of the singly spliced structural genes, which are required in abundance. The tax protein is a **transcriptional activator** and enhances transcription of the viral genome from the promoter gene sequence in the 5′ LTR. Tax also activates other genes, including those for interleukin (IL)-2, IL-3, granulocyte-macrophage colony-stimulating factor, and the receptor for IL-2. Activation of these genes promotes the growth of the infected T cell, which enhances virus replication.

HIV replication is regulated by as many as six **"accessory" gene products** (see Table 54.2). The **Tat** protein, like Tax, is a transactivator of the transcription of viral and cellular genes. The **Rev** protein acts like the Rex protein to regulate and promote transport of viral mRNA into the cytoplasm. The **Nef** protein reduces cell-surface expression of CD4 and major histocompatibility complex I (MHC I) molecules, alters T-cell signaling pathways, regulates the cytotoxicity of the virus, and is required to maintain high viral loads. *The Nef protein appears to be essential for causing the infection to progress to AIDS.* The **Vif** protein promotes assembly and maturation and binds to an antiviral cellular protein (APOBEC-3G) to prevent it from hypermutating and inactivating the cDNA and helps the virus replicate in myeloid and other cells. The **Vpu protein** reduces cell-surface CD4 expression and enhances virion release. The **Vpr protein** (Vpx in HIV-2) is important for transport of the cDNA into the nucleus. Vpr protein also arrests the cell in the G2 phase of the growth cycle, which is likely to be optimal for HIV replication. Vpx facilitates virus replication in dendritic cells and macrophages. Interestingly, this facilitates antigen presentation on MHC-1 antigens, which promotes CD8 cytotoxic T-cell production and can limit HIV-2 disease progression.

The proteins translated from the *gag, gag-pol,* and *env* mRNAs are synthesized as polyproteins and are subsequently cleaved to functional proteins (see Fig. 54.7). The viral glycoproteins are synthesized, glycosylated, and

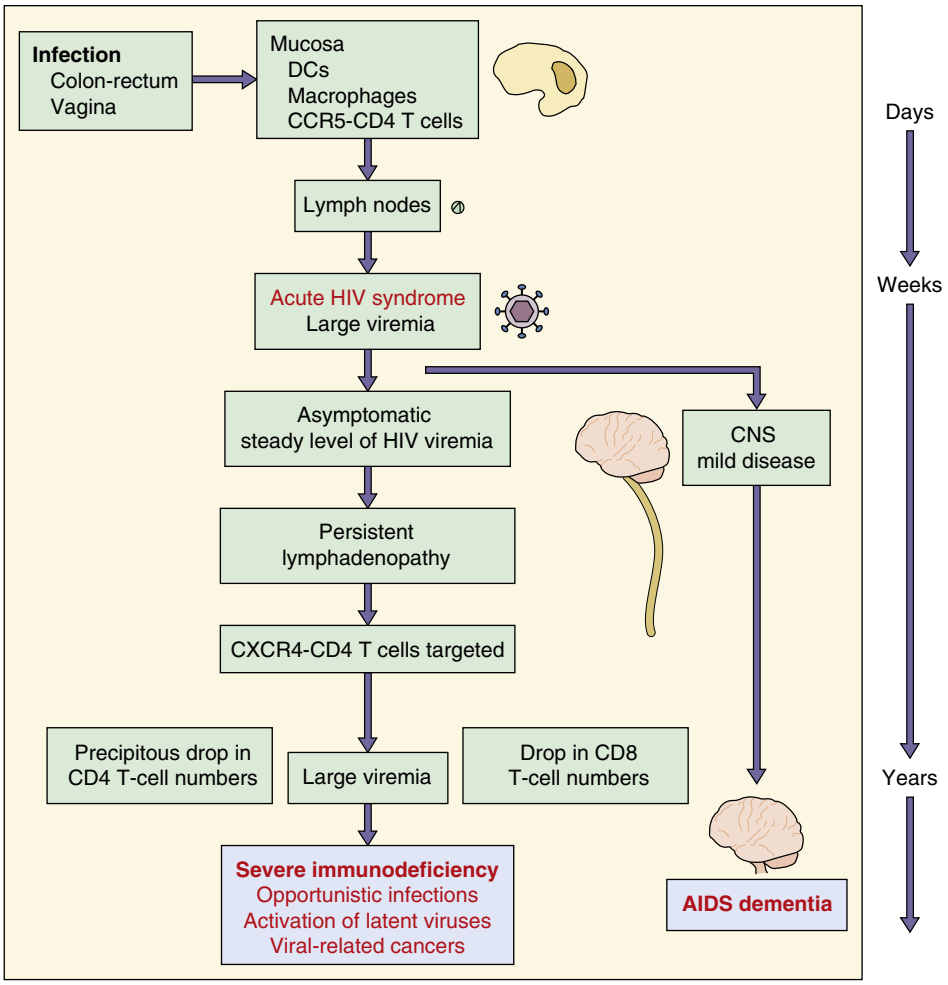

Fig. 54.8 Pathogenesis of human immunodeficiency virus *(HIV)*. HIV causes lytic and latent infection of macrophage, dendritic cells, and CD4 T cells and disrupts neuronal function. The outcomes of these actions are immunodeficiency and acquired immunodeficiency syndrome *(AIDS)* dementia. *CNS,* Central nervous system. (Modified from Fauci, A.S., 1988. The human immunodeficiency virus: infectivity and mechanisms of pathogenesis. Science 239, 617–622.)

processed by the endoplasmic reticulum and Golgi apparatus. These glycoproteins are then cleaved, associate to form trimers, and migrate to the plasma membrane.

The Gag and Gag-Pol polyproteins are acylated and then bind to the plasma membrane containing the envelope glycoprotein. The association of two copies of the genome and cellular tRNA molecules promotes budding of the virion.

Envelopment and release of retroviruses occur at the cell surface. The HIV envelope picks up cellular proteins, including MHC molecules, on budding. After envelopment and release from the cell, the viral protease cleaves the Gag and Gag-Pol polyproteins to release the RT and form the virion core, ensuring inclusion of these components into the virion. The protease step is required for the production of infectious virions and is a target for antiviral drugs.

Replication and budding of the retrovirus do not necessarily kill the cell. HIV can also spread from cell to cell through the production of multinucleated giant cells, or syncytia. Syncytia are fragile, and their formation enhances the cytolytic activity of the virus.

Human Immunodeficiency Virus

There are four genotypes of HIV-1, designated M (main), N, O, and P. Most HIV-1 is of the M subtype, and this is divided into 11 subtypes, or clades, designated A to K (for HIV-2, A to F). The designations are based on differences in the sequence of their *env* (7% to 12% difference) and *gag* genes, and hence the antigenicity and immune recognition of the gp120 and capsid proteins of these viruses.

PATHOGENESIS AND IMMUNITY

The major determinant in the pathogenesis and disease caused by HIV is the **virus tropism for CD4-expressing T cells and myeloid cells** (Fig. 54.8 and Box 54.2). HIV-induced immunosuppression (AIDS) results from a reduction in the number of CD4 T cells, which decimates the ability to activate and control innate and immune responses.

During sexual transmission, HIV infects a mucosal surface, enters, and rapidly infects cells of the mucosa-associated lymphoid tissue (MALT), including the intestine. The

BOX 54.2 Disease Mechanisms of Human Immunodeficiency Virus

HIV primarily infects CD4 T cells and cells of the myeloid lineage (e.g., monocytes, macrophages, alveolar macrophages of the lung, dendritic cells, and microglial cells of the brain).
Virus mutates during chronic infection and switches from myeloid/T-cell tropic to T-cell tropic based on co-receptor preference.
Virus causes lytic infection of activated permissive CD4 T cells and induces apoptosis-like death of nonpermissive CD4 T cells.
Virus causes persistent low-level productive and latent infection of myeloid lineage cells and memory T cells.
Virus causes syncytia formation, with cells expressing large amounts of CD4 antigen (T cells); subsequent lysis of the cells occurs.
Virus alters T-cell, dendritic cell, and macrophage cell function.
Virus reduces CD4 T-cell numbers and helper-cell activation of CD8 T-cell, macrophage, and other cell functions.
CD8 T-cell numbers and macrophage function decrease.
Infected microglial cells disrupt neuronal function.

initial stages of infection are mediated by M-tropic viruses that bind to CD4 and the CCR5 chemokine receptors on dendritic and other monocyte-macrophage lineage cells, as well as memory, TH1, most intestine-associated T cells, and other CD4 T cells. Individuals who are deficient in the CCR5 receptor are also resistant to HIV infection, and CCR5 binding is a target for an antiviral drug. The CCR5-delta 32 mutation that prevents surface expression of this co-receptor is prevalent in northern Europeans (1% are homozygous and 10% to 15% are heterozygous for the mutation).

Targeting of CCR5 or α-4 β-7 integrin–expressing CD4 T cells rapidly depletes the intestinal lymphoid tissue of CD4 T cells. Depletion of the intestinal CD4 T-cell population wreaks havoc on immune regulation of normal gut flora and maintenance of the intestinal mucosal epithelium, leading to leakage and diarrhea.

Macrophages, dendritic cells, memory T cells, and hematopoietic stem cells are persistently infected with HIV and are the major reservoirs and means of distribution of HIV (Trojan horse). HIV can bind to the DC-SIGN lectin molecule and remain on the surface of dendritic cells (including follicular dendritic cells). CD4 T cells can be infected with the cell-bound HIV or by cell-to-cell transmission of virus on binding to the dendritic cell. Late in the disease progression, mutation in the *env* gene for the gp120 occurs for some of the virus, and this shifts its tropism from M-tropic (R5) to T-tropic (X4 virus). The gp120 of the T-tropic virus binds to CD4 and the CXCR4 chemokine receptor. Some viruses may use both receptors (R5X4 viruses). This expands the viral target range to include almost all CD4 T cells.

Killing of CD4 T cells may result from direct HIV-induced cytolysis (including syncytia formation) and cytotoxic T-cell–induced immune cytolysis, but large numbers of nonpermissive resting T cells commit a type of inflammatory cell suicide (pyroptosis) induced by the presence of large amounts of nonintegrated circular DNA copies of the genome. Pyroptosis is an inflammatory form of cell death that may lure more unactivated T cells to the site to be infected and also succumb to pyroptosis.

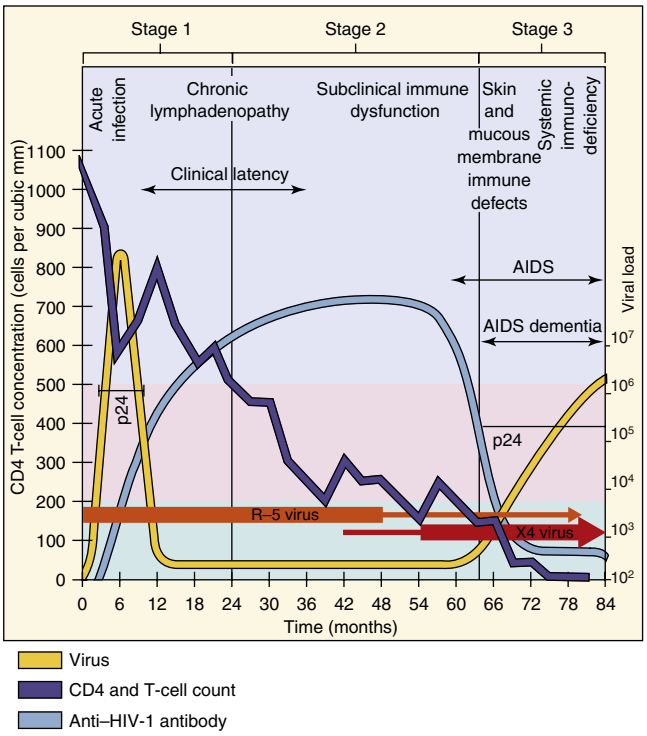

Fig. 54.9 Time course and stages of human immunodeficiency virus *(HIV)*. A long clinical latency period follows the initial mononucleosis-like symptoms. Initial infection is with the R5–M-tropic virus, and following mutation, the X4–T-tropic virus. The progressive decrease in the number of CD4 T cells, even during the latency period, allows opportunistic infections to occur. The stages in HIV disease are defined by the CD4 T-cell levels and occurrence of opportunistic diseases. HIV can be detected by the presence of p24, HIV genome, or antibodies to the virus. (Modified from Redfield, R.R., Burke, D.S., 1996. HIV infection: the clinical picture. Scientific American 259, 90–98; updated 1996.)

The course of HIV disease parallels the reduction in CD4 T-cell numbers and the amount of virus in the blood (Fig. 54.9). HIV infects and depletes the intestinal CCR5-expressing CD4 T cells very soon after infection. During the subsequent acute phase of the infection, there is a large burst of virus production (10^7 particles per milliliter of plasma). T-cell proliferation in response to antigen presentation by infected dendritic cells, macrophages, and even activated CD4 T cells promotes a **mononucleosis-like syndrome.** CD8 T cells kill many infected cells and limit virus production. Virus levels in the blood decrease and the individual is asymptomatic (latent period), but viral replication continues in the lymph nodes, causing disruption of their structure and function, and CD4 T-cell numbers continue to drop. Late in the disease, CD4 levels decrease to the point that they cannot maintain the antiviral action of CD8 T cells, and then virus levels in the blood increase greatly, T-tropic virus rises, CD4 T-cell numbers drop faster, the structures of the lymph nodes are destroyed, and the patient becomes immunodeficient.

The central role of the CD4 helper T cells in the initiation and control of innate and immune responses is indicated by the onset of opportunistic diseases after HIV infection (Fig. 54.10). Activated CD4 T cells initiate immune responses by the release of cytokines required for the activation of epithelial cells, neutrophils, macrophages, other T cells, B cells, and natural killer cells. The CD4 TH17 responses that activate neutrophils and protect the mucoepithelium are

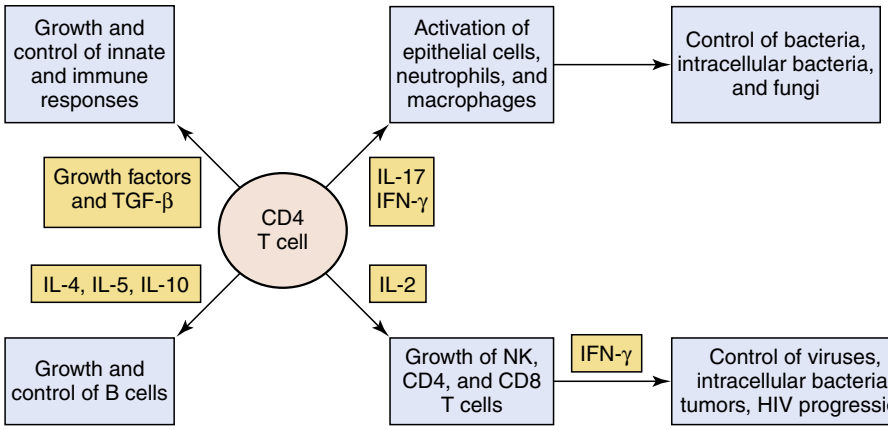

Fig. 54.10 CD4 T cells have a critical role in activating and regulating cell-mediated immune responses, especially toward intracellular pathogens. Human immunodeficiency virus *(HIV)*–induced loss of CD4 T cells results in loss of the functions activated and regulated by the indicated cytokines. *IFN,* Interferon; *IL,* interleukin; *NK,* natural killer; *TGF-β,* transforming growth factor-β.

the first to be depleted (CD4 numbers < 500/μL), increasing susceptibility to fungal and bacterial infections. As the CD4 T cells decrease (CD4 numbers < 200/μL), TH1 responses dissipate and cannot activate sufficient numbers of CD8 T cells and macrophages to control new infections of intracellular bacteria and latent viruses (e.g., herpesviruses and JC polyomavirus progressive multifocal leukoencephalopathy [PML] and Epstein-Barr virus [EBV] and human herpes virus [HHV]-8–associated cancers [Hodgkin and non-Hodgkin lymphomas, Kaposi sarcoma]).

In addition to immunodepression, HIV can also cause neurologic abnormalities. The microglial cell and macrophage are the predominant HIV-infected cell types in the brain. Infected monocytes and microglial cells release neurotoxic substances or chemotactic factors that promote inflammatory responses and neuronal death in the brain. Immunosuppression also puts the individual at risk of opportunistic infections of the brain.

The innate and immune response attempts to restrict viral infection but also contributes to pathogenesis. The infected cells have enzymes that restrict retrovirus replication (including endogenous retroviruses), but HIV can override their actions. The presence of unintegrated HIV cDNA triggers type 1 interferon production and inflammatory cell suicide (pyroptosis). CD8 T cells are critical to limiting HIV disease progression. CD8 T cells can kill infected cells by direct cytotoxic action and can produce suppressive factors that restrict viral replication, including chemokines that also block the binding of virus to its co-receptor. Individuals with certain MHC types (human leukocyte antigen [HLA] B27 or B57) will preferentially bind HIV peptides rather than cellular peptides to make infected cells better targets for CD8 T-cell killing, and these individuals are more resistant to HIV disease. Neutralizing antibodies are generated against gp120. Antibody-coated virus can be infectious, however, and is taken up by macrophages.

HIV has several ways of escaping immune control (Table 54.3). Most significant is the virus' ability to undergo mutation and hence alter its antigenicity and escape antibody clearance. Persistent infection of macrophages and resting CD4 T cells maintains the virus in an immune-privileged cell and cells in immune-privileged tissues (e.g., central nervous system and genital organs). Ultimately, infection of CD4 T cells compromises the entire immune system.

TABLE 54.3 Means of Human Immunodeficiency Virus Escape from the Immune System

Characteristic	Function
Infection of dendritic cells, macrophages, and CD4 T helper cells	Loss of cellular activators and controllers of the immune system
Antigenic drift (via mutation) of gp120	Evasion of antibody detection
Heavy glycosylation of gp120	Evasion of antibody detection
Direct cell-to-cell spread and syncytia formation	Evasion of antibody detection

EPIDEMIOLOGY

AIDS was first noted in homosexual men in the United States but has spread in epidemic proportions throughout the population (Figs. 54.11 and 54.12; Box 54.3). Although the number of HIV-infected people is very large and continues to rise, as of 2016, the rate of increase has begun to decrease because of prevention campaigns.

HIV-1 is genetically most similar to a chimpanzee immunodeficiency virus. HIV-2 is more similar to simian immunodeficiency virus. The initial human infection occurred in Africa before the 1930s but went unnoticed in rural areas. The migration of infected people to the cities and increased nonsterile use of syringes after the 1960s brought the virus into population centers, and cultural acceptance of prostitution promoted its transmission throughout the population.

Geographic Distribution

HIV-1 infections are spreading worldwide, with the largest number of AIDS cases in sub-Saharan Africa, but with a growing number of cases in Asia, the United States, and the rest of the world (see Fig. 54.12). HIV-2 is more prevalent in Africa (especially West Africa) than in the United States and other parts of the world. HIV-2 produces a disease similar to but less severe than AIDS. Heterosexual transmission is the major means of spread of HIV-1 and HIV-2 in Africa, with men and women equally affected by these viruses. The different clades of HIV-1 have different worldwide geographic distributions.

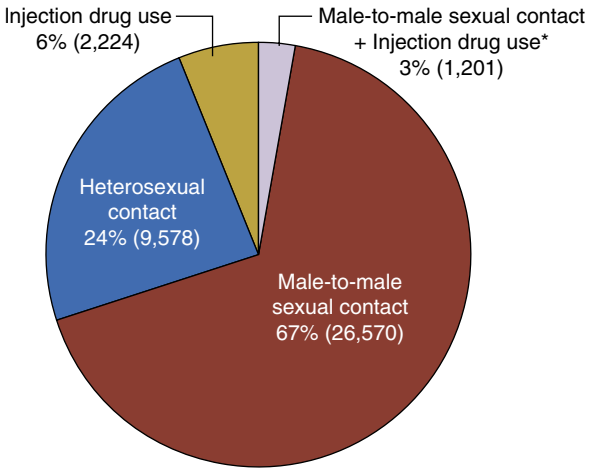

Fig. 54.11 Acquired immunodeficiency syndrome *(AIDS)* statistics for the United States as of 2016. The percentages of AIDS cases are presented by exposure category. In the United States, unlike Africa and many other parts of the world, men having sex with men (MSM) is the largest exposure category. However, intravenous *(IV)* drug abusers and heterosexual partners are becoming more prevalent. (Centers for Disease Control and Prevention, 2016. HIV Surveillance Report. https://www.cdc.gov/hiv/pdf/library/reports/surveillance/cdc-hiv-info-sheet-diagnoses-of-HIV-infection-2016.pdf.) accessed 10.4.2019

Although rare, there are cases of long-term survivors. Some of these result from infection with HIV strains that lack a functional Nef protein. The Nef protein is necessary to promote the progression of HIV infection to AIDS. Resistance to the virus also correlates with a lack of or mutation of the CCR5 chemokine co-receptor for the virus or specific HLA types that promote more vigorous cytotoxic T-cell responses that control the infection.

Transmission

The presence of **HIV in the blood, semen, and vaginal secretions** of infected people and **the long asymptomatic period of infection** are factors that have promoted spread of the disease through sexual contact and exposure to contaminated blood and blood products (Table 54.4). The fetus and newborn are likely to acquire the virus from an infected mother. HIV is *not,* however, transmitted by casual contact, touching, hugging, kissing, coughing, sneezing, insect bites, water, food, utensils, toilets, swimming pools, or public baths.

Populations at Highest Risk

Sexually active people (men who have sex with men [MSM] and heterosexual men and women), IV drug abusers and their sexual partners, and the newborns of HIV-positive

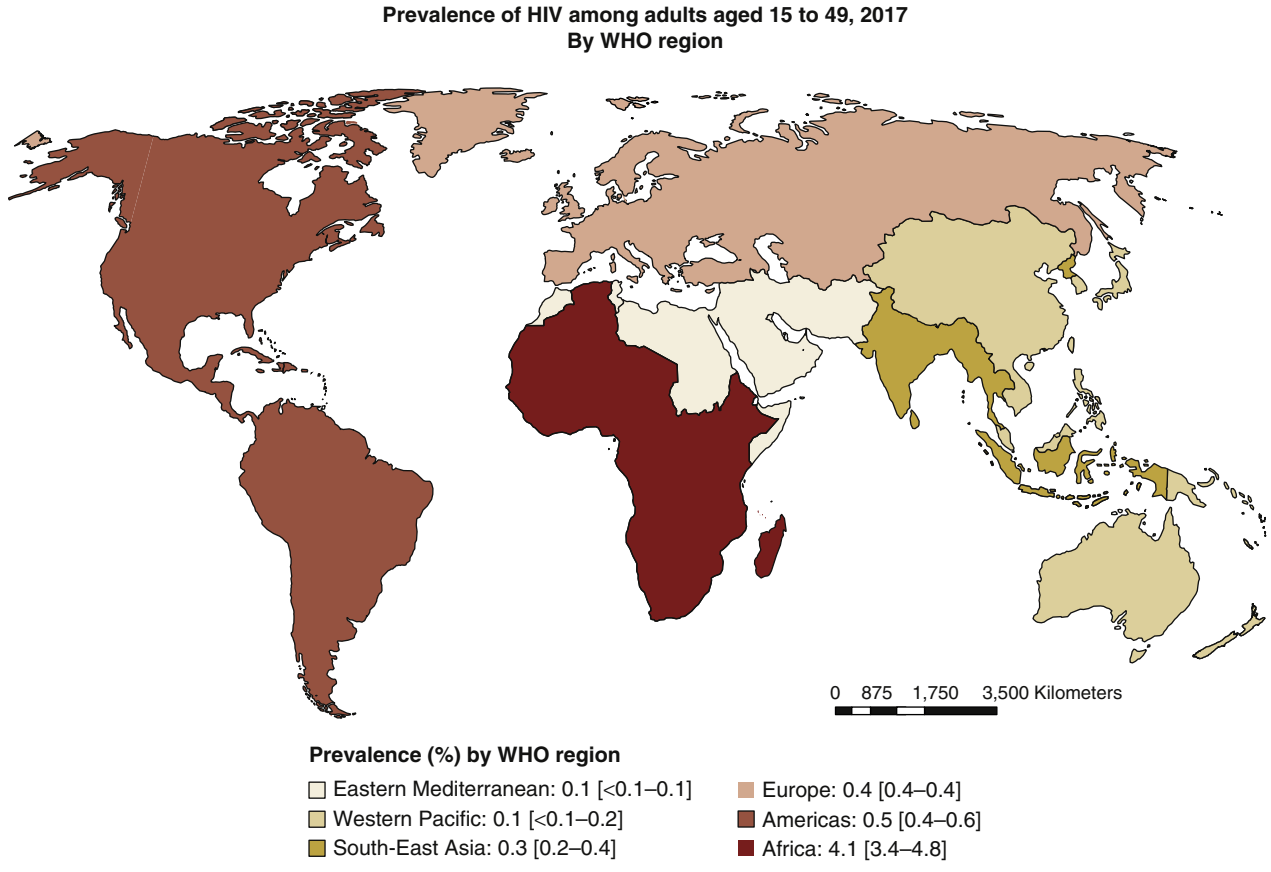

Fig. 54.12 Upper estimates of numbers of people living with HIV infections as of the end of 2017. More than 70 million people have been infected with the HIV virus, about 35 million people have died of HIV, and 36.9 million (31.1 to 43.9 million) people were living with HIV at the end of 2017.The highest rates are in sub-Saharan Africa. (Global Health Observatory Data, 2019. Summary of the global HIV epidemic [2018]. http://www.who.int/gho/hiv/en/ [accessed 13.09.2018.])

BOX 54.3 Epidemiology of Human Immunodeficiency Virus Infections

Disease Viral Factors

Enveloped virus is easily inactivated and must be transmitted in body fluids.
Disease has a long prodromal period.
Virus can be shed before development of identifiable symptoms.

Transmission

Virus is present in blood, semen, and vaginal secretions.
See Table 54.4 for modes of transmission.

Who Is at Risk?

Intravenous drug abusers, sexually active people with many partners (MSM and heterosexual), prostitutes, newborns of HIV-positive mothers, sexual partners of infected individuals.
Blood and organ transplant recipients and hemophiliacs treated before 1985 (before prescreening programs).

Geography/Season

There is an expanding epidemic worldwide.
There is no seasonal incidence.

Modes of Control

Antiviral drugs limit progression of disease.
Antiviral drugs for pre- and post-exposure prophylaxis.
No vaccines available.
Safe, monogamous sex helps limit spread.
Sterile injection needles should be used.
Circumcision.
Large-scale screening programs of blood for transfusions, organs for transplants, and clotting factors used by hemophiliacs.

MSM, Men who have sex with men.

TABLE 54.4 Transmission of Human Immunodeficiency Virus Infection

Routes	Specific Transmission
KNOWN ROUTES OF TRANSMISSION	
Inoculation in blood	Transfusion of blood and blood products Needle sharing among intravenous drug abusers Needlestick, open wound, and mucous membrane exposure in health care workers Tattoo needles
Sexual transmission	Anal and vaginal intercourse
Perinatal transmission	Intrauterine transmission Peripartum transmission Breast milk
ROUTES NOT INVOLVED IN TRANSMISSION	
Close personal contact	Household members Health care workers not exposed to blood

mothers are at highest risk for HIV infections, with black and Hispanic persons disproportionately represented in the HIV-positive population.

As already noted, AIDS was initially described in young, promiscuous, homosexual men and is still prevalent in the gay community. Anal intercourse is an efficient means of viral transmission. However, heterosexual transmission by vaginal intercourse and IV drug abuse have become the major routes by which HIV is being spread in the larger population. The prevalence of HIV in drug abusers stems from sharing contaminated syringe needles, which is a common practice in "shooting galleries." In New York alone, more than 80% of IV drug abusers are positive for the HIV antibody, and these people are now the major source of heterosexual and congenital transmission of the virus. Tattoo needles and contaminated inks are other potential means by which HIV can be transmitted.

Before 1985, people receiving blood transfusions or organ transplants and hemophiliacs receiving clotting factors from pooled blood were at high risk for HIV infection. HIV was spread in many countries by health care workers using shared or improperly sterilized syringe needles or instruments. Proper screening of the blood supply and transplant tissue in the United States and elsewhere has practically eliminated the danger of HIV being transmitted in blood transfusions (see Fig. 54.11). Hemophiliacs who receive pooled clotting factors are protected further by proper handling of the factor (prolonged heating) to kill the virus or by the use of genetically engineered proteins.

Health care workers are at risk for HIV infection from accidental needlesticks or cuts, or through the exposure of broken skin and mucosal membranes to contaminated blood. Fortunately, studies of needlestick victims have shown that seroconversion occurs in less than 1% of those exposed to HIV-positive blood.

CLINICAL SYNDROMES

AIDS is one of the most devastating epidemics ever recorded. Most HIV-infected people will become symptomatic, and the overwhelming majority of them will ultimately succumb to the disease without treatment. HIV disease progresses from an asymptomatic nonspecific or mononucleosis-like disease to profound immunosuppression, referred to as **AIDS** (Clinical Case 54.1; see Fig. 54.9). The diseases related to AIDS mainly consist of opportunistic infections, cancers, and the direct effects of HIV on the central nervous system (Table 54.5).

The initial symptoms after HIV infection (acute phase, 2 to 4 weeks after infection) may resemble those of influenza or heterophile antibody negative mononucleosis, with "aseptic" meningitis or a rash occurring up to 3 months after infection (Box 54.4). As in EBV mononucleosis, the symptoms stem from T-cell responses triggered by a widespread infection of antigen-presenting cells (macrophages). These symptoms subside spontaneously after 2 to 3 weeks and are followed by a period of asymptomatic infection or a persistent generalized lymphadenopathy that may last for several years. During this period, the virus is replicating in the lymph nodes.

Deterioration of the immune response is indicated by increased susceptibility to opportunistic pathogens. The onset of symptoms correlates with a reduction in the number of CD4 T cells to less than 500/μL and increased levels of virus (as determined by genome quantitation techniques) and viral protein p24 in the blood. Full-blown AIDS occurs when **CD4 T-cell counts are less than 200/μL** (oftentimes to 50/μL or undetectable) and **virus load is greater than 75,000 copies/mL** and involves the onset of more

Clinical Case 54.1 **An Early Case of HIV/AIDS**

Elliott and associates (*Ann Int Med* 98:290–293, 1983) reported that in July 1981, a 27-year-old man complained of dysuria, fever, chills, night sweats, weakness, dyspnea, cough with white sputum, anorexia, and a 16-pound weight loss. For the past 7 years, he had been receiving up to 4 monthly infusions of factor VIII concentrate to correct his hemophilia. He did not have any other risk factors for HIV infection. In August, pulmonary infiltrates were visible by chest radiograph, and in September, blood test results were hemoglobin 10.7 g/dL, leukocytes 4200/μL with 50% polymorphonuclear leukocytes, 2% band forms, 36% lymphocytes, and 12% monocytes. Immunoglobulin G antibody was present to cytomegalovirus, Epstein-Barr virus, *Toxoplasma,* hepatitis B surface antigen, and hepatitis B core. An immune deficiency was suggested by a lack of response in tuberculin, mumps, and *Candida* skin tests. The presence of *Pneumocystis jirovecii* in a methenamine silver stain of a transbronchial lung biopsy specimen prompted oral treatment with trimethoprim/sulfamethoxazole. Episodes of thrush caused by *Candida albicans* prompted treatment with ketoconazole. In May of 1982, development of splenomegaly and lymphadenopathy prompted admission to the hospital, with a leukocyte count of 2100/μL and only 11% lymphocytes. At this time, *Mycobacterium avium-intracellulare* was detected in bone marrow, lymph nodes, and granulomas, and total lymphocyte counts were 448/μL, compared with a normal count of 2668/μL; levels were not responsive to mitogen stimulation. In July 1982, total lymphocyte count fell to 220/μL, with 45/μL CD3-positive T cells (normal 1725 and 64, respectively) and a CD4:CD8 ratio of 1:4 (normal 2.2:1). The patient continued to deteriorate and died at the end of September 1982. Cytomegalovirus was isolated from lung and liver and *M. avium-intracellulare* from most tissue samples. In 1981, AIDS was a newly described disease, and HIV had not been discovered. Monoclonal antibodies and immunophenotyping were new technologies. The patient acquired HIV infection from the factor VIII concentrate at a time before routine screening of the blood supply.

TABLE 54.5 Indicator Diseases of Acquired Immunodeficiency Syndrome[a]

Infection	Disease (Selected)
OPPORTUNISTIC INFECTIONS	
Protozoal	Toxoplasmosis of the brain Cryptosporidiosis with diarrhea Isosporiasis with diarrhea
Fungal	Candidiasis of the esophagus, trachea, and lungs *Pneumocystis jirovecii* pneumonia Cryptococcosis (extrapulmonary) Histoplasmosis (disseminated) Coccidioidomycosis (disseminated)
Viral	Cytomegalovirus disease Herpes simplex virus infection (persistent or disseminated) Progressive multifocal leukoencephalopathy (JC virus) Hairy leukoplakia caused by Epstein-Barr virus
Bacterial	*Mycobacterium avium-intracellulare* complex (disseminated) Any "atypical" mycobacterial disease Extrapulmonary tuberculosis *Salmonella* septicemia (recurrent) Pyogenic bacterial infections (multiple or recurrent)
OPPORTUNISTIC NEOPLASIAS	
	Kaposi sarcoma Primary lymphoma of the brain Hodgkin and non-Hodgkin lymphomas HPV-associated cancers
OTHERS	
	HIV wasting syndrome HIV encephalopathy Lymphoid interstitial pneumonia

HPV, Human papillomavirus.

BOX 54.4 Clinical Summary

A 32-year-old former heroin addict had a mononucleosis-like illness for 2 weeks. He recalled experiencing occasional night sweats and fever for 3 years and then presented with thrush, cytomegalovirus retinitis, and *Pneumocystis* pneumonia. His CD4 T-cell count was 50/μL. He was started on highly active antiretroviral therapy.

significant diseases, including HIV wasting syndrome (weight loss and diarrhea for >1 month) and opportunistic infections, malignancies, and dementia (see Table 54.5).

AIDS may be manifested in several different ways, including lymphadenopathy and fever, opportunistic infections, malignancies, and AIDS-related dementia.

Lymphadenopathy and Fever

Lymphadenopathy and fever develop insidiously and may be accompanied by weight loss and malaise. These findings may persist indefinitely or progress. Symptoms may also include opportunistic infections, diarrhea, night sweats, and fatigue. The wasting disease is termed **slim disease** in Africa.

Opportunistic Infections

Normally benign infections caused by agents such as *Candida albicans* and other fungi, DNA viruses capable of recurrent disease, parasites, and intracellularly growing bacteria cause significant disease after HIV depletion of CD4 T cells and subsequent reduction of CD8 T cells (see Table 54.5). ***Pneumocystis jirovecii*–induced *Pneumocystis* pneumonia (PCP)** is a major sign of AIDS. Oral candidiasis (thrush), cerebral toxoplasmosis, and cryptococcal meningitis also often occur, as do prolonged and severe viral infections, including molluscum contagiosum poxvirus, papovaviruses (JC virus, causing PML), and recurrences of the herpesviruses (e.g., herpes simplex virus, varicella-zoster virus, EBV [hairy leukoplakia of the mouth, EBV-associated lymphomas], cytomegalovirus [CMV; especially retinitis, pneumonia, and

bowel disease], HHV-8 [Kaposi sarcoma]). Tuberculosis and other mycobacterial diseases and diarrhea caused by common pathogens (*Salmonella, Shigella,* and *Campylobacter* species) and uncommon agents (cryptosporidia, mycobacteria, and *Amoeba* species) are also common problems.

Malignancies

The most notable malignancy to develop in patients with AIDS is the HHV-8–associated Kaposi sarcoma, which is a rare and otherwise benign skin cancer that disseminates to involve visceral organs in immunodeficient patients. EBV-related lymphomas are also prevalent.

Dementia Related to AIDS

AIDS-related dementia may result from opportunistic infection or HIV infection of the macrophages and microglial cells of the brain. Patients with this condition may undergo a slow deterioration of their intellectual abilities and exhibit other signs of a neurologic disorder, similar to the signs of the early stages of Alzheimer disease. Neurologic deterioration could also result from infection with one of the many opportunistic infections.

LABORATORY DIAGNOSIS

Tests for HIV infection are performed for one of four reasons: (1) to identify those with the infection so that antiviral drug therapy can be initiated, (2) to identify carriers who may transmit infection to others (specifically blood or organ donors, pregnant women, and sex partners), (3) to follow the course of disease and confirm the diagnosis of AIDS, or (4) to evaluate the efficacy of treatment (Table 54.6).

The chronic nature of the disease allows the use of serologic tests to document HIV infection, as supplemented by genome detection and quantitation with PCR-related techniques. HIV is very difficult to grow in tissue culture, and virus isolation is not performed. Recent infection or late-stage disease are indicated by the presence of large quantities of viral RNA in blood samples, the p24 viral antigen, or the RT enzyme (see Fig. 54.9).

Genomics

Newer methods for detection and quantitation of HIV genomes (viral nucleic acid tests **[NATs]**) in blood have become a mainstay for following the course of an HIV infection and the efficacy and patient compliance with antiviral therapy. After converting viral RNA into DNA with an RT (laboratory provided), the cDNA of the genome can be detected by PCR and quantitated by real-time PCR, branched-chain DNA amplification, and other methods (see Chapter 5). Determination of the viral load (amount of genome in blood) is an excellent indicator of the course of disease and efficacy of therapy. These tests are usually more expensive than serologic tests and are not used for screening.

Serology

Screening of blood and organ donors is performed by serology. HIV antibody may develop slowly, taking 4 to 8 weeks in most patients; however, it may take 6 months or more in as many as 5% of those infected (see Fig. 54.9). As such, the new fifth generation screening test is a multiplexed enzyme-linked immunosorbent assay (ELISA) that combines detection of the viral p24 antigen, which is present during the early, acute phase of disease, with detection of patient antibody to HIV-1 and HIV-2. Before the combined assays, Western blot analysis of patient serum was necessary to confirm seropositive results. The Western blot assay (see Fig. 6.6 and Fig. 39.7) demonstrates the presence of antibody to the viral antigens (p24 or p31) and glycoproteins (gp41 and gp120/160). In addition to assays for screening blood, assays of urine, oral mucosal transudate tests, and rapid screening and home screening tests are also available.

TABLE 54.6 Laboratory Analysis for Human Immunodeficiency Virus

Test	Purpose
SEROLOGY	
Combined antigen and antibody enzyme-linked immunosorbent assay	Initial screening
Latex agglutination	Initial screening
Rapid oral antibody test	Initial screening
Urine antibody test	Initial screening
Western blot analysis (for antibody)	Confirmation test[a]
Virion RNA RT-PCR	Detection of virus in blood
Real-time RT-PCR	Quantitation of virus in blood
Branched-chain DNA	Quantitation of virus in blood
p24 antigen	Early marker of infection
Isolation of virus	Test not readily available
CD4 T-cell counts, CD4:CD8 T-cell ratio	Indicators of HIV disease

[a]Western blot confirmation is not necessary with fifth-generation combined p24 antigen and antibody enzyme-linked immunosorbent assay tests.
RT-PCR, Reverse transcriptase-polymerase chain reaction.

Immunologic Studies

The status of an HIV infection can be inferred from an analysis of the T-cell subsets. The absolute number of CD4 lymphocytes and the *ratio of CD4 to CD8 lymphocytes* are *abnormally low* in HIV-infected people. The particular concentration of CD4 lymphocytes identifies the stage of AIDS. The choice to initiate therapy is oftentimes based on CD4 T-cell counts.

TREATMENT, PREVENTION, AND CONTROL

The numbers of approved drugs and combinations of anti-HIV drugs have increased to allow customizing personal therapy to optimize efficacy and limit adverse effects in an individual. The principal (as of 2018) anti-HIV therapies are listed in Box 54.5, but more complete lists are available on line (see Bibliography). The anti-HIV drugs approved by the U.S. Food and Drug Administration are classified by their mechanism of action.

BOX 54.5 Potential Antiviral Therapies for Human Immunodeficiency Virus Infection

Nucleoside Analog Reverse Transcriptase Inhibitors

Azidothymidine (AZT) (Zidovudine) [Retrovir]
3TC (Lamivudine) [Epivir]
Tenofovir disoproxil fumarate (adenosine class) [Viread]
ABC (Abacavir) [Ziagen]
FTC (Emtricitabine) [Emtriva]

Nonnucleoside Reverse Transcriptase Inhibitors

Nevirapine [Viramune]
Doravirine [Pifeltro]
Efavirenz [Sustiva]
Etravirine [Intelence]
Rilpivirine [Edurant]

Protease Inhibitors (PIs)

Tipranavir [Aptivus]
Darunavir [Prezista]
Ritonavir [Norvir]
Fosamprenavir [Lexiva]
Atazanavir [Reyataz]
Saquinavir [Invirase]

Binding and Fusion Inhibitors

CCR5 inhibitor (maraviroc) [Selzentry]
Fusion inhibitor (enfuvirtide) [Fuzeon]

Integrase Inhibitor

Raltegravir [Isentress]
Dolutegravir [Tivicay]

Examples of Highly Active Antiretroviral Therapy

Efavirenz/tenofovir/emtricitabine (EFV/TDF/FTC) [Atripla]
Abacavir/zidovudine/lamivudine [Trizivir]
Dolutegravir/abacavir/lamivudine [Triumeq]
Emtricitabine, rilpivirine, and tenofovir disoproxil fumarate [Complera]
Elvitegravir/cobicistat/tenofovir/emtricitabine [Stribild]
Emtricitabine/tenofovir disoproxil fumarate [Truvada]
Lamivudine/zidovudine [Combivir]
Lopinavir/ritonavir [Kaletra]

Modified from U.S. Department of Health and Human Services, 2018. FDA-approved HIV medicines. https://aidsinfo.nih.gov/understanding-hiv-aids/fact-sheets/21/58/fda-approved-hiv-medicines (accessed 13.09.2018).

Inhibition of binding to the CCR5 co-receptor with a receptor agonist (e.g., maraviroc) or fusion of the viral envelope and cell membrane with a peptide (e.g., enfuvirtide) that blocks the action of the gp41 molecule will prevent the initial infection event. Inhibition of the integrase (e.g., dolutegravir, raltegravir) prevents all subsequent events in the replication of the virus. Inhibition of the RT prevents the initiation of virus replication by blocking cDNA synthesis. Azidothymidine (AZT) and the other nucleotide analogs are phosphorylated by cellular enzymes and incorporated into cDNA by the RT to cause DNA chain termination. Nonnucleoside RT inhibitors (e.g., nevirapine) inhibit the enzyme by other mechanisms. Protease inhibitors (e.g., darunavir) block the morphogenesis of the virion by inhibiting cleavage of the Gag and Gag-Pol polyproteins. The viral proteins and resulting virion are inactive. Most anti-HIV drugs have significant side effects, and the search continues for new anti-HIV drugs. Each of the replicative steps and all of the viral proteins are being targeted for development of new anti-HIV drugs.

AZT was the first successful anti-HIV therapy. Although still given to infants born to HIV-positive mothers for 6 weeks postpartum, the single use of AZT or another nucleotide analog by itself is decreasing. Anti-HIV therapy is currently given as a cocktail of several antiviral drugs termed **highly active antiretroviral treatment (HAART)** (see Box 54.5). Use of a mixture of drugs with different mechanisms of action has less potential to encounter or select for resistance. Multidrug therapy can reduce blood levels of virus to nearly zero and reduce morbidity and mortality in many patients with advanced AIDS. Customization of HAART for each patient can minimize the drug side effects, ease the pill-taking regimen, and allow the patient to return to nearly normal health and lifestyle. Some HAARTs are taken once a day as a single pill, assisting compliance. Therapy should be initiated for individuals showing symptoms of AIDS, AIDS-defining illnesses, or if CD4 T cells drop to less than 350/μL. Therapy may also be considered if viral loads are high (>100,000), even if CD4 numbers are above 350/μL.

Preexposure prophylaxis, or PrEP, has recently been approved for people who have a high risk of HIV infection (e.g., partners of HIV-infected individuals and IV drug users). Currently, the suggested therapy is a single pill of a HAART that combines tenofovir and emtricitabine. This therapy is also appropriate for postexposure prophylaxis (e.g., needlestick).

Effective treatment can reduce HIV to undetectable levels, which almost eliminates the risk of transmission. Even in the absence of a vaccine, combination of proper precautions, continued and effective treatment of HIV-infected individuals, and the administration of PrEP to high-risk individuals will significantly reduce the number of HIV infections in the United States in the near future.

Education

The principal way HIV infection can be prevented and its spread controlled is by educating the population about the methods of transmission and the measures that may curtail viral spread. For instance, monogamous relationships, the practice of safe sex, and use of condoms reduce the possibility of exposure. Because contaminated needles are a major source of HIV infection in IV drug abusers, people must be taught that needles must not be shared. The reuse of contaminated needles in clinics was the source of outbreaks of AIDS in the former Soviet bloc and other countries. In some places, efforts have been launched to provide sterile equipment to IV drug abusers. A successful anti-HIV education campaign in Uganda has been cited as being more effective than antiviral drugs for saving lives.

Blood, Blood Product, and Organ Screening

Potential blood and organ donors are screened before they donate blood, tissue, and blood products. People testing positive for HIV must not donate blood. People who anticipate a future need for blood, such as those awaiting elective

surgery, should consider donating blood beforehand. To limit the worldwide epidemic, blood screening must be initiated in developing nations as well.

Infection Control

The infection-control procedures for HIV infection are the same as those for hepatitis B virus. They include use of universal blood and body fluid precautions, which are based on the assumption that all patients are infectious for HIV and other blood-borne pathogens. Precautions include wearing protective clothing (e.g., gloves, mask, gown) and using other barriers to prevent exposure to blood products. Syringes and surgical instruments should never be reused unless carefully disinfected. Contaminated surfaces should be disinfected with 10% household bleach, 70% ethanol or isopropanol, 2% glutaraldehyde, and 4% formaldehyde, or 6% hydrogen peroxide. Washing laundry in hot water with detergent should be sufficient to inactivate HIV.

Circumcision of males reduces their risk of infection. Circumcision eliminates a site of frequent infections and a unique microbiome that can cause breaks in the skin and inflammation, both of which may increase susceptibility to HIV infection.

Approaches to Vaccine Prophylaxis

There are many difficulties in development of a vaccine against HIV. A successful vaccine must be able to block the initial infection and the movement of infected dendritic cells and T cells to lymph nodes. Otherwise, like herpesviruses, HIV infection rapidly establishes a chronic or latent infection. The vaccine must elicit neutralizing antibody and cell-mediated immunity. A major difficulty is that the primary target of neutralizing antibody, the gp120, is different for the different HIV clades, even within a clade, there are many antigenically distinct mutants and the virus mutates extensively creating different strains during the infection of the individual. Cell-mediated immunity is necessary because the virus can be spread through cell-to-cell bridges and remains latent, hiding from antibody. Finally, testing of the vaccine is difficult and expensive because large numbers of susceptible people must be evaluated, and long-term follow-up is required to monitor the efficacy of each formulation.

Several different approaches have been tried for developing an HIV vaccine. Live attenuated vaccines (e.g., deletion of the *nef* gene) were too dangerous because they still caused disease in infants and may establish chronic infection. Protein subunit vaccines with gp120 or its precursor, gp160, by themselves, elicit only antibody to a single strain of HIV and have not been successful. The stem region of the gp120 does not differ extensively between strains and vaccines that expose this region elicit antibody to multiple strains. Immunization with hybrid HIV vaccines that incorporate the gene for gp160 *(env)* and other HIV genes into a vaccinia, canarypox, or defective adenovirus vector or into a DNA or RNA vaccine can initiate cell-mediated responses. This can be followed by a protein boost with gp120 or gp160 to activate B cells and develop neutralizing antibody. The gp120 and gp160 proteins are genetically engineered and expressed in different eukaryotic cell systems (e.g., yeast, baculovirus).

TABLE 54.7 Mechanisms of Retrovirus Oncogenesis

Disease	Speed	Effect
Acute leukemia or sarcoma	Fast: oncogene	Direct effect Provision of growth-enhancing proteins
Leukemia	Slow: trans-activation	Indirect effect Transactivation protein (Tax) or long terminal repeat promoter sequences that enhance expression of cellular growth genes

TABLE 54.8 Representative Examples of Oncogenes

Function	Oncogene	Virus
Tyrosine kinase	*Src*	Rous sarcoma virus
	Abl	Abelson murine leukemia virus
	Fes	ST feline sarcoma virus

Human T-Cell Lymphotropic Virus and Other Oncogenic Retroviruses

The Oncovirinae were originally called the **RNA tumor viruses** and have been associated with the development of leukemias, sarcomas, and lymphomas in many animals. These viruses are not cytolytic. Members of this family are distinguished by their mechanism of cell transformation (immortalization) and thus the length of the latency period between infection and development of disease (Table 54.7).

The **sarcoma and acute leukemia viruses** have incorporated modified versions of cellular genes (protooncogenes) encoding growth-controlling factors into their genome ***(v-onc).*** These include genes that encode growth hormones, growth hormone receptors, protein kinases, guanosine triphosphate–binding proteins (G-proteins), and nuclear DNA–binding proteins. These viruses can cause transformation of cells relatively rapidly and are highly oncogenic. *No human virus of this type has been identified.*

At least 35 different viral oncogenes have been identified (Table 54.8). Transformation results from the overproduction or altered activity of the growth-stimulating protein encoded by the oncogene. Increased cell growth then promotes transcription, which also promotes viral replication.

Incorporation of the oncogene into many of these viruses causes the coding sequences for the *gag, pol,* or *env* genes to be replaced, such that most of these viruses are defective and require helper viruses for replication. Many of these viruses become endogenous and then are transmitted vertically through the germline of the animal.

The human oncoviruses include HTLV-1, HTLV-2, and HTLV-5, but only HTLV-1 has been definitively associated with disease (i.e., adult T-cell leukemia [ATLL]). HTLV-2 was isolated from atypical forms of hairy cell leukemia, and HTLV-5 was isolated from a malignant cutaneous lymphoma. HTLV-1 and HTLV-2 share as much as 50% homology. The **leukemia viruses,** including HTLV-1, are competent in terms of replication but cannot transform cells in vitro. They cause cancer after a **long latency period** of at least 30 years. The leukemia viruses promote cell growth in more indirect ways than the oncogene-encoding viruses. HTLV-1 also causes HTLV-1–associated myelopathy (HAM) (**tropical spastic paraparesis**), which is a nononcogenic neurologic disease.

PATHOGENESIS AND IMMUNITY

HTLV-1 is cell associated and is spread in cells after blood transfusion, sexual intercourse, or breastfeeding. The virus enters the bloodstream and infects the CD4 helper T cells. In addition to blood and lymphatic organs, these T cells have a tendency to reside in the skin, contributing to the symptoms of ATLL. Neurons also express a receptor for HTLV-1.

The *PX* gene of HTLV-1 encodes additional proteins (tax, rex, p12, p13, p30, and HBZ) that promote cell growth, cause evasion of immune detection, and facilitate leukemogenic transformation. Tax is a transcriptional regulator that can activate promoters in the viral LTR gene region and specific cellular genes (including growth-controlling and cytokine genes, such as those encoding IL-2, IL-2 receptor, and granulocyte-macrophage colony-stimulating factor) to promote the outgrowth of that cell. The virus also encodes HBZ to limit Tax activity and promote cell proliferation and viral persistence. HBZ and tax are important for promoting leukemogenesis. HTLV-1 can also stimulate growth of the cell by integrating near cellular growth-controlling genes to allow the enhancer and promoter gene sequences encoded in the viral LTR region to promote the expression of the cellular growth-stimulating proteins. Other genetic changes required to produce leukemia are more likely to occur because of the stimulated growth of the infected cell.

There is a long latency period (≈30 years) before the onset of leukemia. Although the virus can induce a polyclonal outgrowth of T cells, HTLV-1–induced ATLL is usually monoclonal.

Antibodies are elicited to the gp46 and other proteins of HTLV-1. HTLV-1 infection also causes immunosuppression.

EPIDEMIOLOGY

HTLV-1 is transmitted and acquired by the same routes as HIV. It is endemic in southern Japan, Australia, the Caribbean, Central Africa, and among African Americans in the southeastern United States. In the endemic regions of Japan and Australia, children acquire HTLV-1 at birth and in breast milk from their mothers, whereas adults are infected sexually. The number of seropositive people in some regions of Japan may be as high as 35% (Okinawa), and 40% in some regions of Australia. The mortality rate from leukemia may be twice that of other regions. IV drug abuse and blood transfusion are becoming the most prominent means of transmitting the virus in the United States, in which the high-risk groups for HTLV-1 infection are the same as those for HIV infection.

HTLV-2 is endemic in many native Amerindian groups. IV drug users are at high risk for infection.

CLINICAL SYNDROMES

HTLV infection is usually asymptomatic but can progress to ATLL in approximately 1 in 20 persons over a 30- to 50-year period. ATLL caused by HTLV-1 is a neoplasia of the CD4 helper T cells that can be acute or chronic. The malignant cells have been termed "flower cells" because they are pleomorphic and contain lobulated nuclei. In addition to an elevated white blood cell count, this form of ATLL is characterized by skin lesions similar to those seen in another leukemia, Sézary syndrome. ATLL is usually fatal within a year of diagnosis, regardless of treatment. HTLV-1 can also cause other diseases, including HAM (tropical spastic paraparesis), uveitis, HTLV-associated infectious dermatitis, and other inflammatory disorders. HAM can lead to demyelination of the spinal cord and paralysis. HTLV infection is also immunosuppressive. HTLV-2 infection is unlikely to cause leukemia but may cause neurologic disease, such as HAM.

LABORATORY DIAGNOSIS

HTLV-1 infection is detected using ELISA to find virus-specific antigens in blood, using RT-PCR for viral RNA, or using ELISA to detect specific antiviral antibodies.

TREATMENT, PREVENTION, AND CONTROL

A combination of AZT and interferon (IFN)-α has been effective in some patients with ATLL. However, no particular treatment has been approved for the management of HTLV-1 infection.

The measures used to limit the spread of HTLV-1 are the same as those used to limit the transmission of HIV. Sexual precautions, screening of the blood supply, and increased awareness of the potential risks and diseases are ways to prevent transmission of the virus. Routine screening for HTLV-1, HIV, hepatitis B virus, and hepatitis C virus is performed to protect the blood supply. Maternal infection of children is very difficult to control, however.

Endogenous Retroviruses

Different retroviruses have integrated into and become a part of the chromosomes of humans and animals. In fact, retrovirus sequences may make up at least 8% of the human genome. Complete and partial provirus sequences with gene sequences similar to those of HTLV, mouse mammary tumor virus, and other retroviruses, can be detected in humans.

These human endogenous retroviruses (HERVs) generally lack the ability to replicate because of deletions or the insertion of termination codons, or because they are poorly transcribed. In addition, our cells express proteins, such as apolipoprotein B editing catalytic (APOBEC) proteins, to suppress the replication of endogenous retroviruses. One such retrovirus can be detected in placental tissue and is activated by pregnancy. This virus produces syncytin, which is necessary to facilitate placental function. Other HERVs are associated with prostate and other cancers, multiple sclerosis, and amyotrophic lateral sclerosis (ALS).

Case Study and Questions

A 28-year-old man had several complaints. He had a bad case of thrush (oral candidiasis) and low-grade fever, had serious bouts of diarrhea, had lost 20 pounds in the past year without dieting, and most seriously, he complained of difficulty breathing. His lungs showed a bilateral infiltrate on radiographic examination, characteristic of *P. jirovecii* pneumonia. A stool sample was positive for *Giardia* organisms. He was a heroin addict and admitted to sharing needles at a shooting gallery.

1. What laboratory tests could be done to support and confirm a diagnosis of HIV infection and AIDS?

2. How did this man acquire the HIV infection? What are other high-risk behaviors for HIV infection?

3. What was the immunologic basis for the increased susceptibility of this patient to opportunistic infections?

4. What precautions should be taken in handling samples from this patient?

5. What precautions could the patient have taken to prevent infection?

6. Several forms of HIV vaccines are being developed. What are possible components of an HIV vaccine? Who would be appropriate recipients of an HIV vaccine?

Thought Question: HERVs are the ultimate passengers in our cells. Infections with EBV or CMV can activate one of the HERVs; infections with other retroviruses (HTLV or HIV) or other stimuli may activate other HERVs. Consider their possible influence on the functioning and physiology of our cells, immune system, and other functions. (See review by Ryan [*J R Soc Med* 2004;97:560–565] for some answers.)

55 Hepatitis Viruses

A 43-year-old woman complained of fatigue, nausea, and abdominal discomfort. She had a slight fever, her urine was dark yellow, and her abdomen was distended and tender. Serologic assays demonstrated the presence of immunoglobulin (Ig)M antibody to the hepatitis B core antigen (HBcAg) and the presence of the hepatitis B surface antigen (HBsAg) and the hepatitis Be antigen (HBeAg). She also had IgG to hepatitis A virus.

1. Which aspects are common to hepatitis disease and which are specific to hepatitis B virus (HBV)?
2. How does serology define the course of this disease?
3. How is this infection transmitted?
4. How could this infection and disease be prevented? How could it be treated?

A 41-year-old intravenous drug abuser complained of fatigue, nausea, and abdominal discomfort. He had a slight fever, his urine was dark yellow, and his abdomen was distended and tender. Serologic assays demonstrated the presence of IgG antibody to the HBsAg but no hepatitis antigens or other anti-HBV antibodies. Reverse transcriptase-polymerase chain reaction (RT-PCR) analysis of his serum detected the hepatitis C virus (HCV) genome.

5. Is this person infected with HBV? Has this person ever been infected with HBV?
6. What is the most likely disease outcome for this patient? Other patients with this infection?
7. How can this infection be treated?

 **Answers to these questions are available on Student Consult.com.**

Summaries Clinically Significant Organisms

HEPATITIS VIRUSES

Trigger Words

Hepatitis A: acute/sudden onset, picornavirus, fecal-oral
Hepatitis B: blood-borne, STD, hepadnavirus, reverse transcriptase, chronic, Dane particle, HBsAg
Hepatitis C: chronic, blood-borne, flavivirus
Hepatitis D: defective, hepatitis B helper virus, fulminant disease
Hepatitis E: fecal-oral, acute/sudden onset, pregnant women

Biology, Virulence, and Disease

- Liver disease defines symptoms
- Nonlytic viruses: cell-mediated immunity causes symptoms
- Hepatitis A: nonlytic picornavirus, acute onset, no sequelae
- Hepatitis B: hepadnavirus, enveloped and encodes reverse transcriptase
  - Disease followed by serology
  - Chronic disease 5% of time, especially in children
  - Risk for PHC
- Hepatitis C: flavivirus
  - Causes chronic disease in 70% of patients
  - Risk for PHC and cirrhosis after long period
- Hepatitis D: viroid-like, requires HBV as helper virus
- Hepatitis E: Hepevirus, calici-like virus, acute onset, no sequelae, severe for pregnant women

Epidemiology

- HAV, HEV: fecal-oral transmission
- HBV, HCV, HDV: spread in blood, tissue, and semen; STDs

Diagnosis

- RT-PCR, ELISA

Treatment, Prevention, and Control

- HAV: inactivated vaccine, hygiene
- HEV: hygiene
- HBV: virus-like particle HBsAg vaccine, screening of blood supply, safe sex, antiviral drugs
- HCV: screening of blood supply, safe sex, antiviral drugs
- HDV: immunization for HBV

ELISA, Enzyme-linked immunosorbent assay; *HAV,* hepatitis A virus; *HBsAg,* hepatitis B surface antigen; *HBV,* hepatitis B virus; *HCV,* hepatitis C virus; *HDV,* hepatitis D virus; *HEV,* hepatitis E virus; *PHC,* primary hepatocellular carcinoma; *RT-PCR,* reverse transcriptase-polymer chain reaction; *STD,* sexually transmitted disease.

The hepatitis alphabet of viruses includes at least six viruses, A through E and G (Table 55.1; a summary is provided in Box 55.1). Although the target organ for each of these viruses is the liver and the basic hepatitis symptoms are similar, they differ greatly in their structure, mode of replication, mode of transmission, and in the time course and sequelae of the disease they cause. **Hepatitis A** and **hepatitis B viruses (HAV, HBV)** are the classic hepatitis viruses, and **hepatitis C, D, E, and G viruses (HCV, HDV [the delta agent], HEV, and HGV)** are called **non-A, non-B hepatitis (NANBH) viruses.** Other viruses can also cause hepatitis.

Each of the hepatitis viruses infects and initiates inflammatory responses that damage the liver, causing the classic **icteric symptoms of jaundice and the release of liver enzymes.** The specific virus causing the disease can be distinguished by the course, nature, and serology of the disease. These viruses are readily spread because infected people are contagious before, or even without showing symptoms.

Hepatitis A, which is sometimes known as **infectious hepatitis,** is caused by a picornavirus, which is a ribonucleic acid (RNA) virus. It is spread by the fecal-oral route, has an incubation period of approximately 1 month, after which *icteric symptoms start abruptly,* does not cause chronic liver disease, and rarely causes fatal disease.

Hepatitis B, previously known as **serum hepatitis,** is caused by a hepadnavirus with a deoxyribonucleic acid (DNA) genome; is spread parenterally by blood or needles,

by sexual contact, and perinatally; has a median incubation period of approximately 3 months, after which *icteric symptoms start insidiously;* is followed by chronic hepatitis in 5% to 10% of patients; and is causally associated with primary hepatocellular carcinoma (PHC). More than one-third of the world's population has been infected with HBV, resulting in 1 to 2 million deaths per year. The incidence of HBV is decreasing, however, especially in infants, because of the development and use of the HBV subunit vaccine.

HCV is caused by a flavivirus with an RNA genome, is spread by the same routes as HBV with more than 170 million chronically infected carriers of the disease, is more likely to cause asymptomatic infection and cause chronic disease than HBV, and increases risk for PHC.

HGV is also a flavivirus and causes chronic infections.

HEV is an enteric, encapsidated virus with an RNA genome in its own family, and its disease resembles HAV but can be severe in pregnant women.

Hepatitis D, or **delta hepatitis,** is unique in that it requires actively replicating HBV as a "helper virus" and occurs only in patients who have active HBV infection. HBV provides an envelope for HDV RNA and its antigens. HDV exacerbates the symptoms caused by HBV.

Hepatitis A Virus

HAV causes infectious hepatitis and is spread by the fecal-oral route. HAV infections often result from consumption

BOX 55.1 Everything You Want to Know About Hepatitis Viruses a la Dr. Seuss

Hepatitis A, B, C
Hepatitis D, E, G
Liver is the target
But immune response hurts me
Liver suffers from A to G

Eat the virus, it won't stay
E and A go away
Poop, water, and shellfish dot dot A
That's the acute virus that goes away
Pregnant woman fears the E
It is deadly but not for me

TABLE 55.1 Comparative Features of Hepatitis Viruses

Feature	Hepatitis A	Hepatitis B	Hepatitis C	Hepatitis D	Hepatitis E
Common name	"Infectious"	"Serum"	"Non-A, non-B posttransfusion"	"Delta agent"	"Enteric non-A, non-B"
Virus structure	Picornavirus; capsid, (+) RNA	Hepadnavirus; envelope, DNA	Flavivirus; envelope, (+) RNA	Viroid-like; envelope, circular RNA	Hepevirus capsid, (+) RNA
Transmission	Fecal-oral	Parenteral, sexual	Parenteral, sexual	Parenteral, sexual	Fecal-oral
Onset	Abrupt	Insidious	Insidious	Abrupt	Abrupt
Incubation period (days)	15-50	45-160	14-180+	15-64	15-50
Severity	Mild	Occasionally severe, 3%-10% chronicity in adults; 30%-90% in infants and children	Usually subclinical; 70% chronicity	Co-infection with HBV occasionally severe; superinfection with HBV often severe	Normal patients, mild; pregnant women, severe
Mortality	<0.5%	1%-2%	≈4%	High to very high	Normal patients, 1%-2%; pregnant women, 20%
Chronicity/ carrier state	No	Yes	Yes	Yes	No
Other disease associations	None	Primary hepatocellular carcinoma, cirrhosis	Primary hepatocellular carcinoma, cirrhosis	Cirrhosis, fulminant hepatitis	None
Laboratory diagnosis	Symptoms and anti-HAV IgM	Symptoms, serum levels of HBsAg, HBeAg, and anti-HBc IgM, genome	Symptoms and anti-HCV ELISA, genome testing	Anti-HDV ELISA	—

ELISA, Enzyme-linked immunosorbent assay; *HAV,* hepatitis A virus; *HBc,* hepatitis B core; *HBeAg,* hepatitis Be antigen; *HBsAg,* hepatitis B surface antigen; *HBV,* hepatitis B virus; *HCV,* hepatitis C virus; *HDV,* hepatitis D virus; *IgM,* immunoglobulin M.

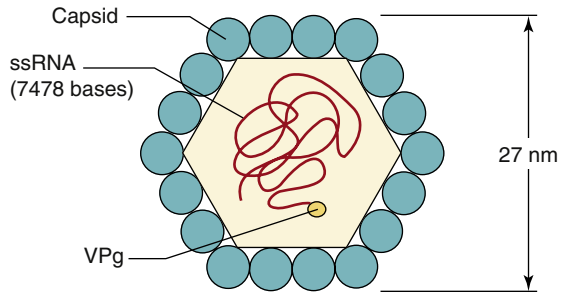

Fig. 55.1 Picornavirus structure of hepatitis A virus. The icosahedral capsid is made up of four viral polypeptides (VP1 to VP4). Inside the capsid is a single-stranded positive-sense ribonucleic acid *(ssRNA)* that has a genomic viral protein *(VPg)* on the 5′ end.

BOX 55.2 Characteristics of Hepatitis A Virus

Stable to:

Acid at pH 1
Solvents (ether, chloroform)
Detergents
Salt water, groundwater (months)
Drying (stable)

Temperature:

4° C for weeks: stable
56° C for 30 minutes: stable
61° C for 20 minutes: partial inactivation

Inactivated by:

Chlorine treatment of drinking water
Formalin (0.35%, 37° C, 72 hours)
Peracetic acid (2%, 4 hours)
β-Propiolactone (0.25%, 1 hour)
Ultraviolet radiation (2 μW/cm^2/min)

of contaminated water, shellfish, or other food. HAV is a **picornavirus** and was formerly called *enterovirus 72*, but it has been placed into its own genus, *Hepatovirus*.

STRUCTURE

HAV has a 27-nm, **naked, icosahedral capsid** surrounding a **positive-sense single-stranded RNA** genome consisting of approximately 7470 nucleotides (Fig. 55.1). As a picornavirus, the HAV genome has a VPg protein attached to the 5′ end and a polyadenylate sequence attached to the 3′ end. The capsid is even more stable than other picornaviruses to acid and other treatments (Box 55.2). There is only one serotype of HAV but there are multiple genotypes.

REPLICATION

HAV replicates like other picornaviruses (see Chapter 46). It interacts specifically with the HAV cell receptor 1 glycoprotein (HAVCR-1, which is also known as T-cell immunoglobulin and mucin domain protein [TIM-1]) expressed on liver cells and T cells. The structure of HAVCR-1 can vary for different individuals, and specific forms correlate with severity of disease. Unlike other picornaviruses, however, HAV is not cytolytic and is released by exocytosis. Laboratory isolates of HAV have been adapted to grow in primary and continuous monkey kidney cell lines, but clinical isolates are difficult to grow in cell culture.

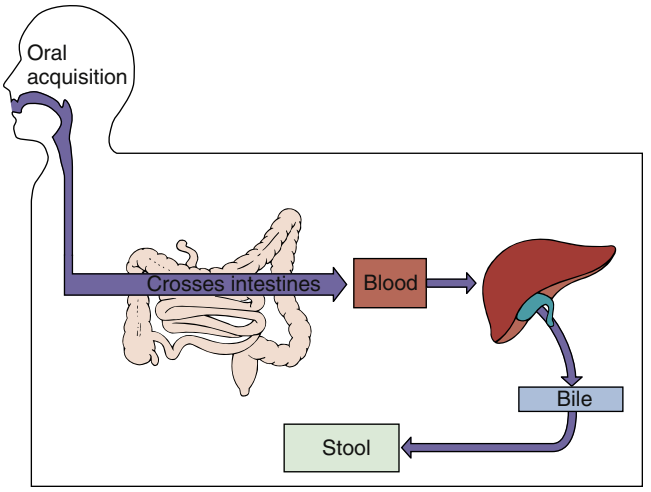

Fig. 55.2 Spread of hepatitis A virus within the body.

PATHOGENESIS

HAV is ingested and probably enters the bloodstream through the epithelial lining of the oropharynx or the intestines to reach its target, which are the parenchymal cells of the liver (Fig. 55.2). The virus replicates in hepatocytes and Kupffer cells. Virus is produced in these cells and is released into the bile and from there into the stool. Virus is shed in large quantities into the stool approximately 10 days before symptoms of jaundice appear or antibody can be detected.

HAV replicates slowly in the liver without producing apparent cytopathic effects. Although interferon limits viral replication, natural killer cells and cytotoxic T cells are required to eliminate infected cells. Antibody, complement, and antibody-dependent cellular cytotoxicity also facilitate clearance of the virus and induction of immunopathology. Icterus, resulting from damage to the liver, occurs because of inflammation of the liver when cell-mediated immune responses and antibody to the virus can be detected. Antibody protection against reinfection is lifelong.

The liver pathology caused by HAV infection is indistinguishable histologically from that caused by HBV. It is most likely caused by immunopathology and not virus-induced cytopathology. However, **unlike HBV, HAV cannot initiate a chronic infection** and is not associated with hepatic cancer.

EPIDEMIOLOGY

Approximately 40% of acute cases of hepatitis are caused by HAV (Box 55.3). The virus spreads readily in a community because most infected people are contagious 10 to 14 days before symptoms occur, and 90% of infected children and 25% to 50% of infected adults have **inapparent but productive** infections.

The virus is released into stool in high concentrations and is spread via the **fecal-oral** route. Virus is spread in contaminated water, in food, and by dirty hands. HAV is resistant to detergents, acid (pH of 1), and temperatures as high as 60° C, and it can survive for many months in fresh water and salt water. Raw or improperly treated sewage can taint the

BOX 55.3 Epidemiology of Hepatitis A Virus and Hepatitis E Virus

Disease/Viral Factors

Capsid viruses are strongly resistant to inactivation.
Contagious period extends from before to after symptoms.
Virus may cause asymptomatic shedding.

Transmission

Virus can be transmitted via fecal-oral route.
Ingestion of contaminated food and water can cause infection.
HAV in shellfish is from sewage-contaminated water.
HEV from pigs and game animals.
Virus can be transmitted by food handlers, day-care workers, and children.

Who Is at Risk?

People in overcrowded, unsanitary areas
Travelers to high-risk regions
Children: mild disease, possibly asymptomatic; day-care centers are a major source of spread of HAV
Adults: abrupt-onset hepatitis
Pregnant women: high mortality associated with HEV

Geography/Season

Virus is found worldwide.
There is no seasonal incidence.

Means of Control

Good hygiene.
HAV: passive antibody protection for contacts
Killed vaccine
Live vaccine in China

HAV, Hepatitis B virus: *HEV,* hepatitis E virus.

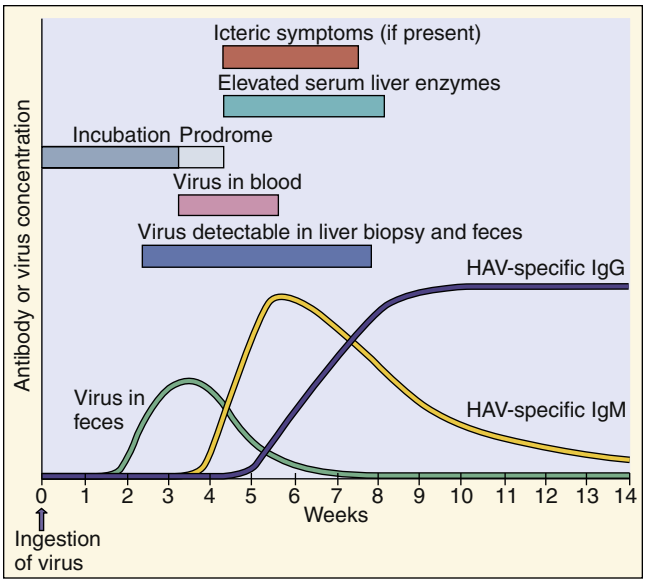

Fig. 55.3 Time course of hepatitis A virus *(HAV)* infection. Note that the person is contagious before onset of symptoms and that symptoms correlate with the onset of immune responses. *Ig,* Immunoglobulin.

water supply and contaminate shellfish. Shellfish, especially clams, oysters, and mussels, are important sources of the virus because they are efficient filter feeders and can therefore concentrate the viral particles, even from dilute solutions. This is exemplified by an epidemic of HAV that occurred in Shanghai, China, in 1988, when 300,000 people were infected with the virus after eating clams obtained from a sewage-polluted river.

HAV outbreaks usually originate from a common source (e.g., water supply, restaurant, day-care center). Asymptomatic shedding and a long (15 to 40 days) incubation period make it difficult to identify the source. Day-care settings are a major source for spread of the virus among classmates and their parents. Because the children and personnel in day-care centers may be transient, the number of contacts at risk for HAV infection from a single day-care center can be great.

HAV infections are relatively common, with greater incidence with poor hygienic conditions and overcrowding. Most people infected with HAV in developing countries are children who have mild illness and then lifelong immune protection against reinfection. In the United States, the incidence has dropped significantly with use of the vaccine.

CLINICAL SYNDROMES

The symptoms caused by HAV are very similar to those caused by HBV and stem from immune-mediated damage to the liver. The **symptoms occur abruptly** 15 to 50 days after exposure, intensify for 4 to 6 days before the icteric (jaundice) phase, and can last for up to 2 months (Fig. 55.3). Initial symptoms include fever, fatigue, nausea, loss of appetite, vomiting, and abdominal pain. The icteric phase is indicated by jaundice, dark urine (bilirubinuria), and pale stool and may be accompanied by abdominal pain. As already noted, disease in children is generally milder than that in adults and is usually asymptomatic. Jaundice is observed in 70% to 80% of adults but in only 10% of children (<6 years of age). Symptoms generally wane during the jaundice period. Viral shedding in the stool precedes the onset of symptoms by approximately 14 days but stops before the cessation of symptoms. Complete recovery occurs 99% of the time within 2 to 4 weeks of onset.

Fulminant hepatitis is less likely for HAV infection but occurs in 1 to 3 persons per 1000 and is associated with an 80% mortality rate. Unlike HBV, immune complex–related symptoms (e.g., arthritis, rash) rarely occur in people with HAV disease.

LABORATORY DIAGNOSIS

The diagnosis of HAV infection is generally made on the basis of the time course of the clinical symptoms, identification of a known infected source, and most reliably, results of specific serologic tests. The best way to demonstrate an acute HAV infection is by finding anti-HAV IgM, as measured by an enzyme-linked immunosorbent assay (ELISA). Virus isolation is not performed, because efficient tissue culture systems for growing the virus are not available. Viral RNA in blood or stool can also be detected by reverse transcriptase polymerase chain reaction (RT-PCR) or real-time PCR analysis to follow the course of the disease.

BOX 55.4 Unique Features of Hepadnaviruses

Virus has enveloped virion containing partially double-stranded, circular DNA genome.
Replication is through an overlapping circular RNA intermediate.
Virus encodes and carries a reverse transcriptase.
Virus encodes several proteins (HBsAg [L, M, S]; HBe/HBc antigens) that share genetic sequences but with different in-frame start codons.
HBV has a strict tissue tropism to the liver.
HBV-infected cells produce and release large amounts of HBsAg particles lacking DNA.
The HBV genome can integrate into the host chromosome.

HBc, Hepatitis B core antigen; *HBe,* hepatitis Be antigen; *HBsAg,* hepatitis B surface antigen; *HBV,* hepatitis B virus.

TREATMENT, PREVENTION, AND CONTROL

The spread of HAV is reduced by interrupting the fecal-oral spread of the virus. This is accomplished by avoiding potentially contaminated water or food, especially uncooked shellfish, and by proper processing of sewage. Proper handwashing, especially in day-care centers, mental hospitals, and other care facilities, is vitally important. Chlorine treatment of drinking water is generally sufficient to kill the virus.

Prophylaxis with immune serum globulin given before or early in the incubation period (i.e., <2 weeks after exposure) is 80% to 90% effective in preventing clinical illness.

Killed HAV vaccines are recommended for all children after 1 year of age and for adults at high risk for infection, including travelers to endemic regions, intravenous drug abusers, and men who have sex with men. The vaccine is administered in two doses, 6 months apart, and can be administered with the HBV vaccine. Live HAV vaccines are in use in China. There is only one serotype of HAV, and HAV infects only humans; these are all factors that help ensure the success of an immunization program.

Hepatitis B Virus

HBV is the major member of the **hepadnaviruses.** Other members of this family (Box 55.4) include woodchuck, ground squirrel, and duck hepatitis viruses. These viruses have limited tissue tropisms and host ranges. HBV infects the liver and, to a lesser extent, the kidneys and pancreas of humans and chimpanzees. Advances in molecular biology have made it possible to study HBV despite the limited host range of the virus and the difficult cell-culture systems in which to grow it.

STRUCTURE

HBV is a small enveloped DNA virus with several unusual properties (Fig. 55.4). Specifically, the **genome is a small, circular, partly double-stranded DNA** of only 3200 bases. Although a DNA virus, it encodes a **reverse transcriptase** and replicates through an **RNA intermediate.**

The virion, also called the **Dane particle,** is 42 nm in diameter. The virions are unusually stable for an enveloped

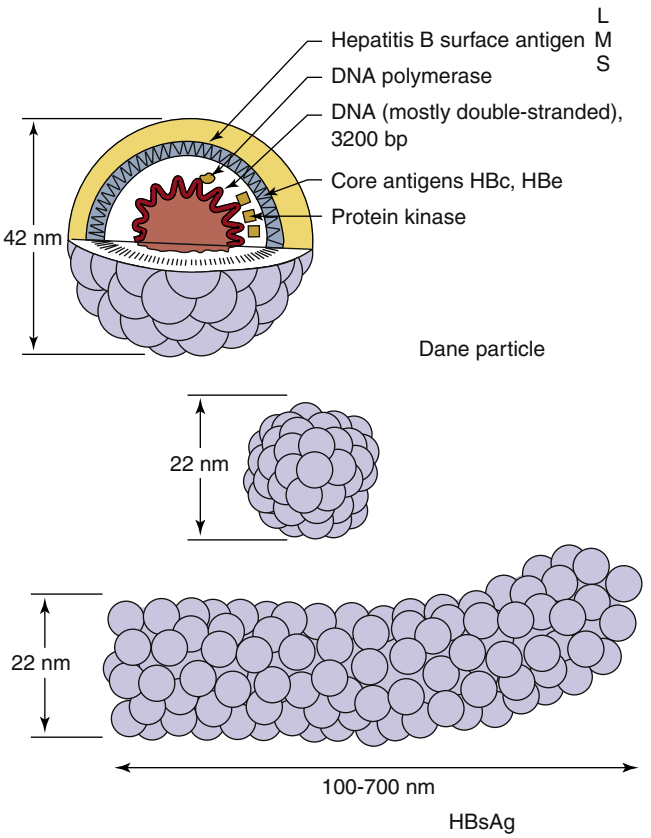

Fig. 55.4 Hepatitis B virus (Dane particle) and hepatitis B surface antigen *(HBsAg)* particles. The spherical HBsAg consists mainly of the S form of HBsAg, with some M. The filamentous HBsAg has S, M, and L forms. *bp,* Base pair; *DNA,* deoxyribonucleic acid; *L,* gp42; *M,* gp36; *S,* gp27.

virus. They resist treatment with ether, low pH, freezing, and moderate heating. These characteristics assist transmission from one person to another and hamper disinfection.

The HBV **virion includes a protein kinase and a polymerase** with reverse transcriptase and ribonuclease H activity, as well as a P protein attached to the genome. All of this is surrounded by an icosahedral capsid formed by the **hepatitis B core antigen (HBcAg)** and an envelope containing three forms of the glycoprotein **hepatitis B surface antigen (HBsAg).** The **hepatitis Be antigen (HBeAg)** protein shares most of its protein sequence with HBcAg but is processed differently by the cell, is primarily secreted into serum, does not self-assemble (like the core capsid antigen), and expresses different antigenic determinants.

HBsAg-containing particles are released into the serum of infected people and outnumber the actual virions. These particles can be spherical (but smaller than the Dane particle) or filamentous (see Fig. 55.4). They are immunogenic and were processed into the first commercial vaccine against HBV.

HBsAg, originally termed the *Australia antigen,* includes three glycoproteins (L, M, and S) encoded by the same gene and read in the same frame but translated into protein from different AUG (adenine, uracil, guanine) start codons. The S (gp27; 24 to 27 kDa) glycoprotein is completely contained in the M (gp36; 33 to 36 kDa) glycoprotein, which is contained in the L (gp42; 39 to 42 kDa) glycoprotein; all share

the same C-terminal amino acid sequences. All three forms of HBsAg are found in the virion. The S glycoprotein is the major component of HBsAg particles; it self-associates into 22-nm spherical particles that are released from the cells. The filamentous particles of HBsAg found in serum contain mostly S, as well as small amounts of the M and L glycoproteins and other proteins and lipids. There are 10 genotypes and serotypes of HBV.

REPLICATION

The replication of HBV is unique for several reasons (see Box 55.4). First, HBV has a distinctly defined tropism for the liver. Its small genome also necessitates economy, as illustrated by the pattern of its transcription and translation. In addition, *HBV replicates through an RNA intermediate and produces and releases antigenic decoy particles (HBsAg)* (Fig. 55.5).

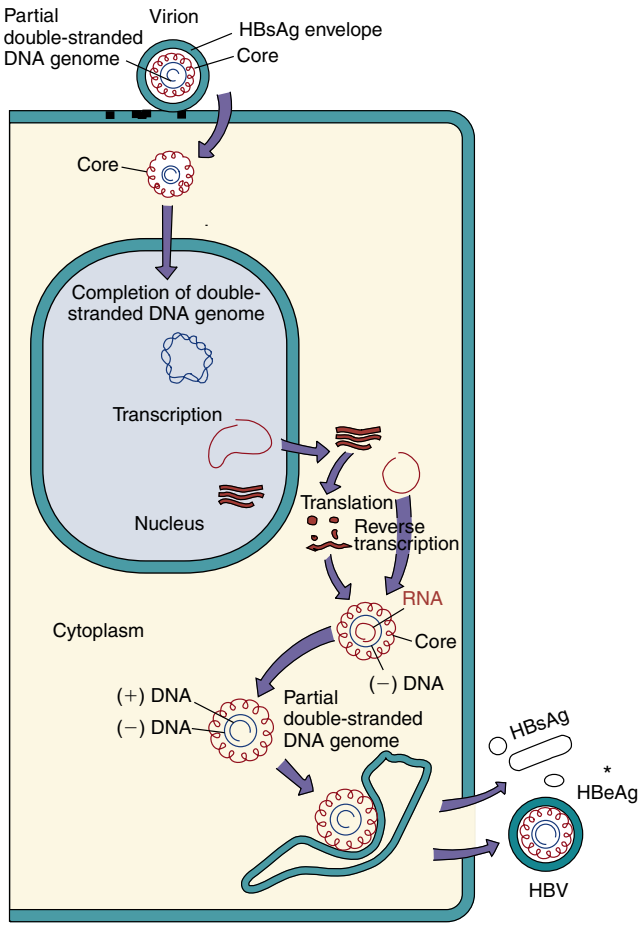

Fig. 55.5 Replication of hepatitis B virus *(HBV)*. After entry into the hepatocyte and uncoating of the nucleocapsid core, the partially double-stranded deoxyribonucleic acid *(DNA)* genome is delivered to the nucleus and completed. Transcription of the genome produces four messenger RNAs (mRNAs), including an mRNA larger than the genome (3500 bases). The mRNA then moves to the cytoplasm and is translated into protein. Core proteins assemble around the 3500-base mRNA, and negative-sense DNA is synthesized by a reverse transcriptase activity in the core. The ribonucleic acid *(RNA)* is then degraded while a positive-sense *(+)* DNA is synthesized. The filled core associates with HBsAg-containing endoplasmic reticulum membranes, is enveloped before completion of the positive-sense DNA, and is then released by exocytosis with HBsAg-containing particles. *HBeAg,* Hepatitis Be antigen; *HBsAg,* hepatitis B surface antigen.

The attachment of HBV to hepatocytes is mediated by the HBsAg glycoproteins. The liver cell receptor is the sodium/bile acid cotransporter (sodium taurocholate cotransporting polypeptide [NTCP]). On penetration into the cell, the nucleocapsid delivers the genome to the nucleus, where the partial DNA strand of the genome is completed to form a complete double-stranded DNA circle, which is a viral minichromosome. Transcription of the genome is controlled by cellular transcription elements found in hepatocytes. The DNA is transcribed from different starting points on the circle but have the same 3′ end. There are three major classes (2100, 2400, and 3500 bases) and two minor classes (900 bases) of overlapping messenger RNAs (mRNAs) (Fig. 55.6). The 3500-base mRNA is larger than the genome. It encodes the HBc and HBe antigens, the polymerase, and a protein primer for DNA replication and acts as the template for

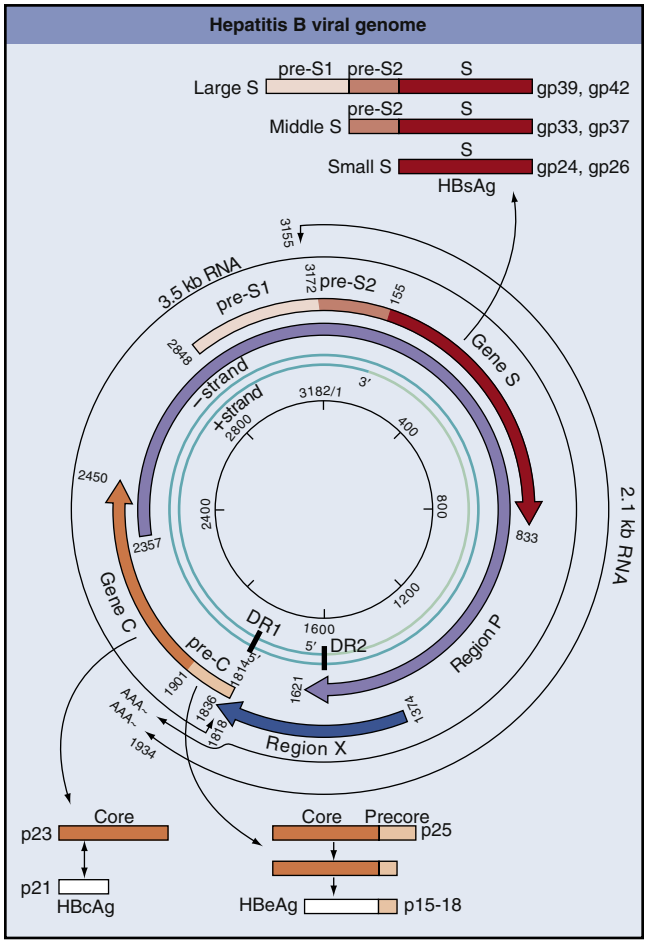

Fig. 55.6 DNA, RNA, messenger RNA (mRNA), and proteins of hepatitis B virus. The *inner green circles* represent the DNA genome, with the nucleotide number at the center. DR1 and DR2 are direct repeat sequences of DNA and are important for replication and integration of the genome. The 3500-base transcript *(outer black thin-line circle)* is larger than the genome and is the template for replication of the genome. Bold arcs represent mRNA for viral proteins. Note that several proteins are translated from the same mRNA but from different AUG codons and that different mRNAs overlap. *AAA,* 3′ PolyA (polyadenylate) at end of mRNA; *AUG,* adenine, uracil, guanine; *C,* C mRNA for hepatitis B core antigen (HBcAg); *HBsAg,* hepatitis B surface antigen; *l,* large glycoprotein; *m,* medium glycoprotein; *P,* polymerase; *s,* small glycoprotein; *S,* mRNA for HBs antigen; *X,* X mRNA. (From Cohen, J., Powderly, W.G., Opal, S.M., 2010. Infectious Diseases, third ed. Mosby, Philadelphia, PA.)

replication of the genome. The HBe and HBc are related proteins that are translated from different in-phase start codons of closely related mRNAs. This causes differences in their processing and structure, with shedding of the HBe from the cell and incorporation of HBc into the virion. Similarly, the 2100-base mRNA encodes the small and medium glycoproteins from different in-phase start codons. The 2400-base mRNA, that encodes the large glycoprotein, overlaps the 2100-base mRNA. The 900-base mRNA encodes the X protein, which promotes viral replication as a transactivator of transcription and as a protein kinase.

Replication of the genome uses the larger than genome 3500-base mRNA. This is packaged into the core nucleocapsid that contains the RNA-dependent DNA polymerase (P protein). This polymerase has **reverse transcriptase** and ribonuclease H activity, but HBV lacks the integrase activity of the retroviruses. The 3500-base RNA acts as a template, and negative-strand DNA is synthesized using a protein primer from the P protein, which remains covalently attached to the 5′ end. After this, the RNA is degraded by the ribonuclease H activity as the positive-strand DNA is synthesized from the negative-sense DNA template. However, this process is interrupted by envelopment of the nucleocapsid at the HBsAg-containing endoplasmic reticulum membrane, capturing genomes containing a complete circular and incomplete DNA strand. The virion and HBsAg-containing particles are then released from the hepatocyte by exocytosis, without killing the cell.

The entire genome can also be integrated into the host cell chromatin. HBsAg, but not other proteins, can often be detected in the cytoplasm of cells containing integrated HBV DNA. Integrated viral DNA is present in hepatocellular carcinomas.

PATHOGENESIS AND IMMUNITY

HBV is a noncytolytic virus that causes disease by initiating inflammation of the liver. HBV can cause acute or chronic, symptomatic or asymptomatic disease. Which of these occurs is determined by the person's immune response to the infection (Fig. 55.7).

The major source of infectious virus is blood, but HBV can be found in semen, saliva, milk, vaginal and menstrual secretions, and amniotic fluid. The most efficient way to acquire HBV is through injection of the virus into the bloodstream (Fig. 55.8). Common but less efficient routes of infection are sexual contact and birth. The virus starts to replicate in hepatocytes of the liver within 3 days of its acquisition, with minimal cytopathic effect. Symptoms may not be observed for 45 days or longer, because they are primarily caused by immunopathology. The infectious dose, the route of infection, and the person's immune response determine the incubation period. Infection proceeds for a relatively long time without causing liver damage (i.e., elevation of liver enzyme levels) or symptoms. Copies of the HBV genome remain in the nucleus for long periods as small circular DNA minichromosomes or can integrate into the hepatocyte chromatin. The minichromosomes can generate virus and HBsAg. Intracellular buildup of filamentous forms of HBsAg can produce the ground-glass hepatocyte cytopathology characteristic of HBV infection. HBsAg particles continue to be released into the blood even after virion release has ended and until the infection is resolved. *An individual is highly infectious when both the HBsAg and the HBeAg components of the virion can be detected in the blood.*

Cell-mediated immunity and inflammation are responsible for causing the symptoms and effecting resolution of the HBV infection by eliminating the infected hepatocyte. An insufficient T-cell response to the infection generally results in the occurrence of mild symptoms, an inability to resolve the infection, and the development of chronic hepatitis ("no pain, no gain") (see Fig. 55.7). Chronic infection also exhausts CD8 T cells, preventing them from killing infected cells. Antibody (as generated by vaccination) can protect against initial infection by preventing delivery of the virus to the liver. Later in the infection, the large amount of HBsAg in serum binds to and blocks the action of neutralizing antibody, which limits the antibody's ability to resolve an infection. Immune complexes formed between HBsAg and anti-HBs contribute to the development of hypersensitivity reactions (type III), leading to problems such as vasculitis, arthralgia, rash, and renal damage.

Antibodies to HBc and HBe are present in serum but cannot neutralize infection and are nonprotective. The HBeAg protein and HBsAg are released from the cell, elicit and are exposed to antibody in the blood, and are bound to their respective antibodies. As such, Anti-HBe and

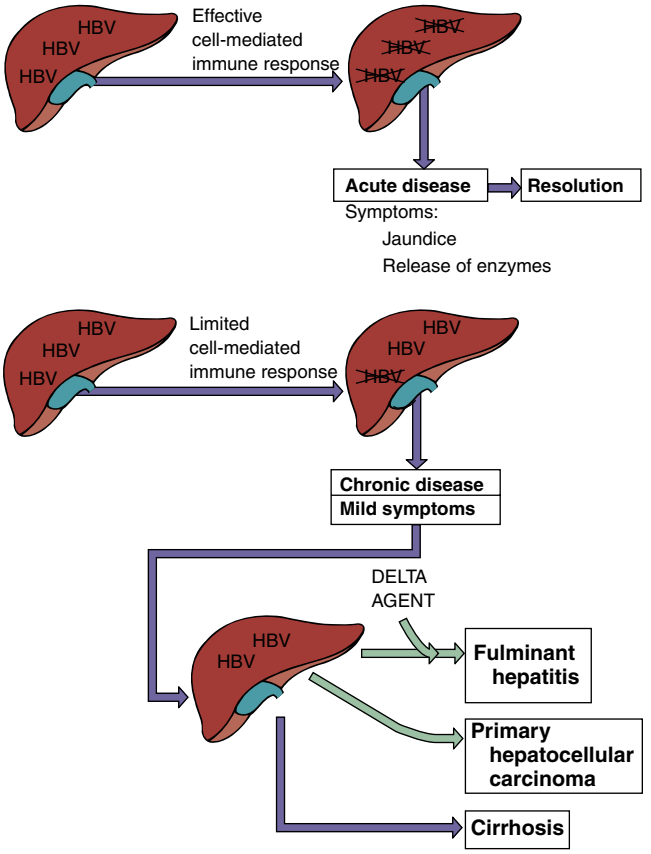

Fig. 55.7 Major determinants of acute and chronic hepatitis B virus *(HBV)* infection. HBV infects the liver but does not cause direct cytopathology. Cell-mediated immune lysis of infected cells produces the symptoms and resolves the infection. Insufficient immunity can lead to chronic disease. Chronic HBV disease predisposes a person to more serious outcomes. *Purple arrows* indicate symptoms; *green arrows* indicate a possible outcome.

Anti-HBs antibodies are not detectable while the antigen is produced. The HBc antigen is present in cells or virions and inaccessible to the antibody in blood. As a result, anti-HBc is free to be detected throughout and after the course of the infection.

Infants and young children have an immature cell-mediated immune response and are less able to resolve the infection, but they suffer less tissue damage and have milder symptoms. As many as 90% of infants infected perinatally become chronic carriers. Viral replication persists in these people for long periods.

During the acute phase of infection, the liver parenchyma shows degenerative changes consisting of cellular swelling and necrosis, especially in hepatocytes surrounding the central vein of a hepatic lobule. The inflammatory cell infiltrate is mainly composed of lymphocytes. Tissue damaging inflammation results from the combined actions of cytolytic cells and the inflammatory cytokines that they produce. Resolution of the infection allows the parenchyma to regenerate. Fulminant infections, activation of chronic infections, or co-infection with the delta agent can lead to permanent liver damage and cirrhosis.

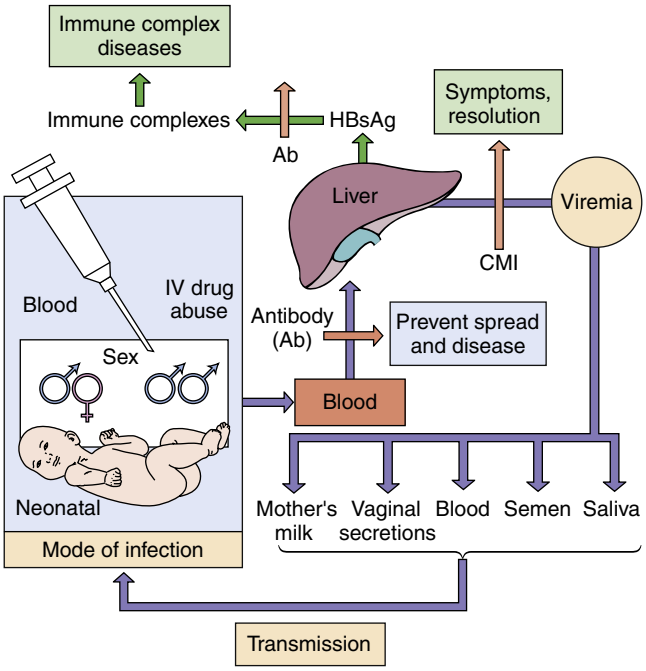

Fig. 55.8 Spread of hepatitis B virus (HBV) in the body. Initial infection with HBV occurs through injection, unprotected sex, and birth. The virus then spreads to the liver, replicates, induces a viremia, and is transmitted in various body secretions in addition to blood to start the cycle again. Symptoms are caused by cell-mediated immunity *(CMI)* and immune complexes between antibody and hepatitis B surface antigen *(HBsAg)*. *IV,* Intravenous.

EPIDEMIOLOGY

In the United States, more than 12 million people have been infected with HBV (1 of 20), with 5000 deaths per year. In the world, one of three people have been infected with HBV, with approximately 1 million deaths per year. More than 350 million people worldwide have chronic HBV infection. In developing nations, as many as 15% of the population may be infected during birth or childhood. High rates of seropositivity are observed in Italy, Greece, Africa, and Southeast Asia (Fig. 55.9). In some areas of the world (southern Africa and southeastern Asia), the seroconversion rate is as high as 50%. PHC, a long-term sequela of the infection, is also endemic in these regions.

The many asymptomatic chronic carriers with virus in blood and other body secretions foster spread of the virus. In the United States, 0.1% to 0.5% of the general population are chronic carriers, but this is very low compared with many areas of the world. Carrier status may be lifelong.

The virus is spread by sexual, parenteral, and perinatal routes. Transmission occurs through contaminated blood and blood components by transfusion, needle sharing, acupuncture, ear piercing, or tattooing and through very close

BOX 55.5 High-Risk Groups for Hepatitis B Virus Infection

People from endemic regions (i.e., China, parts of Africa, Alaska, Pacific Islands)
Babies of mothers with chronic hepatitis B virus
Intravenous drug abusers
People with multiple sex partners
Health care personnel who have contact with blood
Residents and staff members of institutions for the mentally retarded
Hemophiliacs and other patients requiring blood and blood product treatments[a]
Hemodialysis patients and blood and organ recipients[a]

[a]Screening of blood, blood products, and transplantable organs have minimized risk.

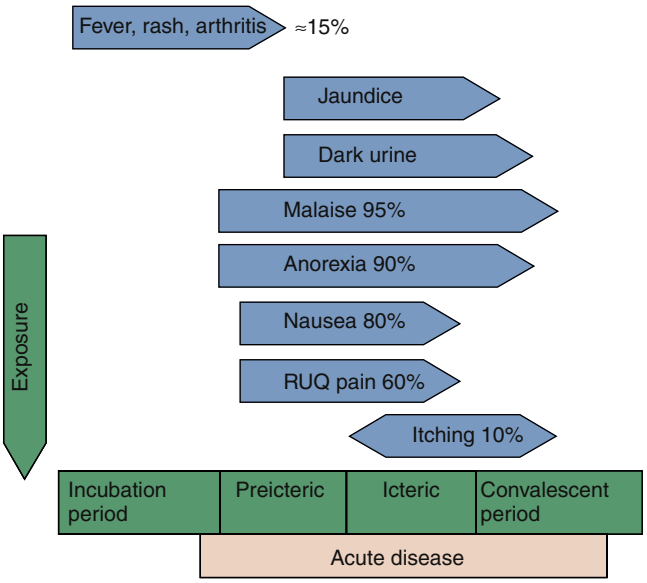

Fig. 55.10 Symptoms of typical acute viral hepatitis B infection are correlated with the four clinical periods of this disease. *RUQ,* Right upper quadrant. (Modified from Hoofnagle, J.H., 1983. Type A and type B hepatitis. Laboratory Medicine 14, 705–716.)

personal contact involving the exchange of semen, saliva, and vaginal secretions (e.g., sex, childbirth) (see Fig. 55.8). Medical personnel are at risk in accidents involving needlesticks or sharp instruments. People at particular risk are listed in Box 55.5. Sexual promiscuity and drug abuse are major risk factors for HBV infection. HBV can be transmitted to babies through contact with the mother's blood at birth and in the mother's milk. Babies born to chronic HBV-positive mothers are at highest risk for infection. Serologic screening of donor units in blood banks has greatly reduced the risk of acquisition of the virus from contaminated blood or blood products. Safer sex habits adopted to prevent human immunodeficiency virus (HIV) transmission and the administration of the HBV vaccine have also been responsible for decreasing the transmission and incidence of HBV.

One of the major concerns related to HBV is its association with PHC. This type of carcinoma probably accounts for 250,000 to 1 million deaths per year worldwide; in the United States, approximately 5000 deaths per year are attributed to PHC.

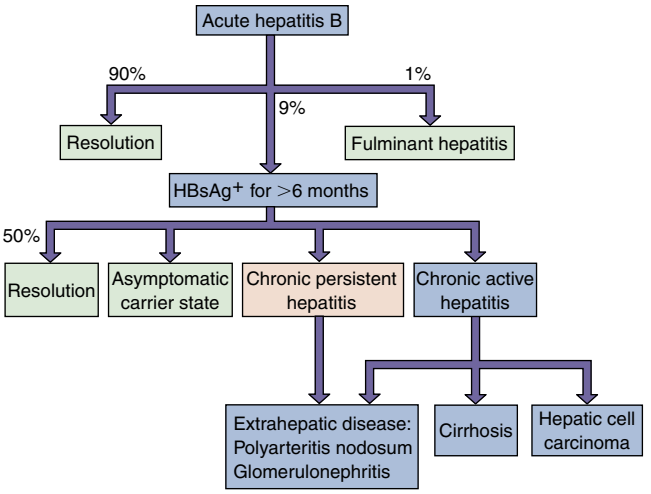

Fig. 55.11 Clinical outcomes of acute hepatitis B infection. *HBsAg,* Hepatitis B surface antigen. (Modified from White, D.O., Fenner, F., 1986. Medical Virology, third ed. Academic, New York.)

CLINICAL SYNDROMES

Acute Infection

As already noted, the clinical presentation of HBV in children is less severe than that in adults, and infection may even be asymptomatic. Clinically apparent illness occurs in as many as 25% of those infected with HBV (Figs. 55.10–55.12).

HBV infection is characterized by a **long incubation period and an insidious onset.** Symptoms during the prodromal period may include fever, malaise, and anorexia, followed by nausea, vomiting, abdominal discomfort, and chills. The classic icteric symptoms of liver damage (e.g., jaundice, dark urine, pale stools) follow soon thereafter. Recovery is indicated by a decline in the fever and renewed appetite.

Fulminant hepatitis occurs in approximately 1% of icteric patients and may be fatal. It is marked by more severe symptoms and indications of severe liver damage, such as ascites and bleeding.

HBV infection can promote hypersensitivity reactions that are caused by immune complexes of HBsAg and antibody. These may produce rash, polyarthritis, fever, acute necrotizing vasculitis, and glomerulonephritis.

Chronic Infection

Chronic hepatitis occurs in 5% to 10% of people with HBV infections, usually after mild or inapparent initial disease. Approximately one-third of these people have chronic active hepatitis, with continued destruction of the liver leading to scarring of the liver, cirrhosis, liver failure, or PHC. The other two-thirds have chronic passive hepatitis and are less likely to have problems. Chronic hepatitis may be detected accidentally by finding elevated liver enzyme levels on a routine blood chemistry profile. Chronically infected people are the major source for spread of the virus and are at risk for fulminant disease if they become co-infected with HDV.

Primary Hepatocellular Carcinoma

The World Health Organization estimates that 80% of all cases of PHC can be attributed to chronic HBV infections.

The HBV genome is integrated into these PHC cells, and the cells express HBV antigens. PHC is usually fatal and is one of the three most common causes of cancer mortality in the world. In Taiwan, at least 15% of the population are carriers of HBV, and nearly half die of PHC or cirrhosis. PHC, like cervical cancer, is a vaccine-preventable human cancer.

HBV may induce PHC by promoting continued liver repair and cell growth in response to inflammation and tissue damage or by integrating into the host chromosome and stimulating cell growth directly. Such integration can stimulate genetic rearrangements, juxtapose viral promoters next to cellular growth-controlling genes, disrupt chromosome structure, and stimulate error prone DNA repair. The HBV X gene also can transactivate (turn on) the transcription of cellular proteins and stimulate cell growth and viability. These actions can promote a subsequent mutation to promote carcinogenesis. The latency period between HBV infection and PHC may be as short as 9 years or as long as 35 years.

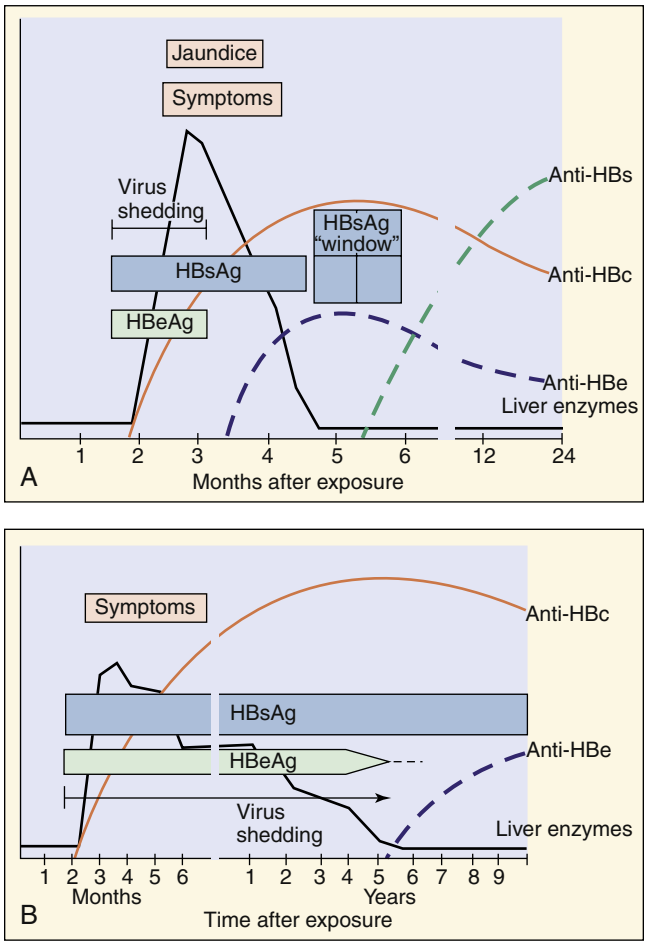

Fig. 55.12 (A) Serologic events associated with the typical course of acute hepatitis B disease. (B) Development of the chronic hepatitis B virus carrier state. Routine serodiagnosis depends on detection of immunoglobulin M anti-HBc during the "hepatitis B surface antigen *(HBsAg)* window," when HBs and anti-HBs are undetectable. *Anti-HBc,* Antibody to hepatitis B core antigen [HBcAg]; *Anti-HBe,* antibody to hepatitis Be antigen [HBeAg]; *Anti-HBs,* antibody to HBsAg. (Modified from Hoofnagle, J.H., 1981. Serologic markers of hepatitis B virus infection. Annual Review of Medicine 32, 1–11.)

LABORATORY DIAGNOSIS

The initial diagnosis of hepatitis can be made on the basis of the clinical symptoms and the presence of liver enzymes in the blood (see Fig. 55.12). However, the serology of HBV infection describes the course and nature of the disease (Table 55.2). Acute and chronic HBV infections can be distinguished by the presence of HBsAg and HBeAg in the serum and the pattern of antibodies to the individual HBV antigens.

HBsAg and HBeAg are secreted into the blood during viral replication. Detection of HBeAg is the best correlate to the presence of infectious virus. A chronic or unresolved infection can be distinguished by the continued finding of HBeAg, HBsAg, or both, and a lack of detectable antibody to these antigens. Antibody to HBsAg indicates resolution of infection or vaccination. Immune complexes of HBeAg and HBsAg and antibody inhibit antibody production and obscure detection of the complexed antigen. Although for different reasons, HBsAg/anti-HBs, HBeAg/anti-HBe, and Clark Kent/Superman can never be seen together at the same time.

Antibody to HBcAg indicates current or prior infection by HBV, and IgM anti-HBc is the best way to diagnose a recent acute infection, especially while the infection is being resolved and when neither HBsAg nor anti-HBs can be detected (the window).

The amount of virus in blood can be determined by quantitative genome assays using PCR and related techniques. Knowing the viral load can help to follow the course of chronic HBV infection and antiviral drug efficacy.

TABLE 55.2 Interpretation of Serologic Markers of Hepatitis B Virus Infection

Serologic Reactivity	DISEASE STATE					HEALTHY STATE	
	Early (Presymptomatic)	Early Acute	Acute	Chronic	Late Acute	Resolved	Vaccinated
Anti-HBc	–	–	+[a]	+	+/–	+	–
Anti-HBe	–	–	–	–	+/–	+/–[b]	–
Anti-HBs	–	–	–	–	–	+	+
HBeAg	–	+	+	+	–	–	–
HBsAg	+	+	+	+	+	–	–
Infectious virus	+	+	+	+	+	–	–

[a]Anti-HBc immunoglobulin M should be present.
[b]Anti-HBe may be negative after chronic disease.
HBc, Hepatitis B core; *HBeAg,* hepatitis Be antigen; *HBsAg,* hepatitis B surface antigen.

TREATMENT, PREVENTION, AND CONTROL

Hepatitis B immunoglobulin may be administered within a week of exposure and to newborn infants of HBsAg-positive mothers to prevent and ameliorate disease. Chronic HBV infection can be treated with drugs targeted at the polymerase (e.g., **lamivudine, entecavir, telbivudine or tenofovir,** which are HIV reverse transcriptase inhibitors) or the nucleoside analogs **adefovir dipivoxil and famciclovir.** These U.S. Food and Drug Administration (FDA)-approved treatments are taken for 1 year. Unfortunately, antiviral drug resistance can develop. **Pegylated interferon (IFN)-α** also can be effective and is taken for at least 4 months.

Transmission of HBV in blood or blood products has been greatly reduced by screening donated blood for the presence of HBsAg and anti-HBc. Additional efforts to prevent transmission of HBV include safe sex and avoiding lifestyles that facilitate spread of the virus. Household contacts and sexual partners of HBV carriers are at increased risk, as are patients undergoing hemodialysis, recipients of pooled plasma products, health care workers exposed to blood, and babies born to HBV-carrier mothers.

Vaccination is recommended for infants, children, and especially for people in high-risk groups (see Box 55.5). Vaccination is useful even after exposure for newborns of HBsAg-positive mothers and people accidentally exposed either percutaneously or permucosally to blood or secretions from an HBsAg-positive person. Immunization of mothers should decrease the incidence of transmission to babies and older children, which also reduces the number of chronic HBV carriers. Prevention of chronic HBV will reduce the incidence of PHC. The single serotype and limited host range (humans) of HBV help facilitate the success of the immunization program.

The HBV vaccines form virus-like particles. The initial HBV vaccine was derived from the 22-nm HBsAg particles in human plasma obtained from chronically infected people. The more recent vaccines are genetically engineered by the insertion of a plasmid containing the S gene for HBsAg into a yeast *(Saccharomyces cerevisiae)*. The protein self-assembles into particles, which enhances its immunogenicity, and is administered with alum. The vaccine must be given in a series of three injections, with the second and third given 1 and 6 months after the first.

A new HBV vaccine, Heplisav-B, is for adults aged 18 and older. It incorporates the yeast-derived HBsAg particles with a cytosine phosphorothioate guanosine (CpG) oligodeoxynucleotide (CpG-ODN) adjuvant. This Toll-like receptor 9 stimulating adjuvant improves the immunogenicity of the vaccine. Only two injections, 1 month apart, are required.

Universal blood and body fluid precautions are used to limit exposure to HBV. It is assumed that all patients are infected. Gloves are required for handling blood and body fluids; wearing protective clothing and eye protection may also be necessary. Special care should be taken with needles and sharp instruments. HBV-contaminated materials can be disinfected with 10% bleach solutions, but unlike most enveloped viruses, HBV is not readily inactivated by detergents.

Hepatitis C and G Viruses

HCV was identified in 1989 after isolation of a viral RNA from a chimpanzee infected with blood from a person with NANBH. The viral RNA obtained from blood was converted to DNA with reverse transcriptase, its proteins were expressed, and antibodies from people with NANBH were then used to detect the viral proteins. These studies led to the development of ELISA, genomic, and other tests for detection of the virus.

HCV is the predominant cause of NANBH viral infections and was the major cause of posttransfusion hepatitis before routine screening of the blood supply for HCV. There are more than 180 million carriers of HCV in the world, which is 3% of the population, and more than 4 million in the United States. HCV is transmitted by means similar to HBV but has an even greater potential for establishing persistent chronic hepatitis. Many HCV-infected individuals also are infected with HBV or HIV. The chronic hepatitis often leads to cirrhosis and potentially to hepatocellular carcinoma.

STRUCTURE AND REPLICATION

HCV is the only member of the *Hepacivirus* genus of the **Flaviviridae** family. There are seven major genotypes of HCV (clades), up to a hundred subtypes, and extensive genetic and antigenic diversity within each subtype. HCV is 30 to 60 nm in diameter, has a **positive-sense RNA genome,** and is **enveloped.** The genome of HCV (9100 nucleotides) encodes 10 proteins, including two glycoproteins (E1, E2) (Fig. 55.13). The **viral RNA-dependent RNA polymerase is error prone** and generates mutations in the glycoprotein and other genes. This generates antigenic variability and antiviral drug resistance. Such variability makes development of a vaccine very difficult.

HCV infects only humans and chimpanzees. HCV binds to multiple cell-surface receptors expressed on hepatocytes and B lymphocytes that also facilitate its entry into the cell. The receptors include CD81 (tetraspanin) surface receptors, scavenger receptor class B type I (SRB1), and use tight junction proteins claudin-1 and occludin as co-receptors. HCV can also coat itself with low-density lipoprotein or very low density lipoprotein and then use the lipoprotein receptor to facilitate uptake into hepatocytes. After entry, the virus replicates like other flaviviruses. The virion assembles at and buds into the endoplasmic reticulum and remains cell associated. HCV proteins inhibit apoptosis and IFN-α action by binding to the tumor necrosis factor receptor and to protein kinase R and proteolytically degrading other proteins in the interferon pathways. In addition to acting with the polymerase, the NS5A protein acts on interferon and other host pathways. These actions prevent the death of the host cell and promote escape from host protections to promote persistent infection.

PATHOGENESIS

The ability of HCV to remain cell associated and prevent host cell death promotes persistent infection but results in liver disease later in life. Up to 10^{12} particles per day can be produced in chronically infected, potentially asymptomatic individuals. The virus' ability to evade interferon action and mutate to change its antigenicity helps the virus escape

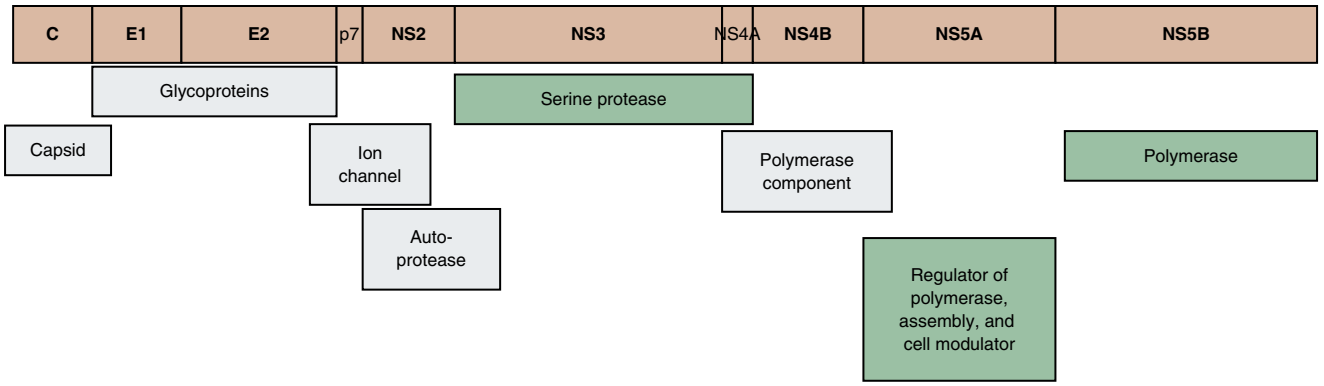

Fig. 55.13 Outcomes of hepatitis C virus infection. Enzymes in green are targets for antiviral drugs.

immune control and establish chronic disease. Cell-mediated immune responses are necessary to resolve the infection, but they also cause tissue damage. Antibody to HCV is not protective. As for HBV, once established, the chronic infection can exhaust CD8 cytotoxic T cells so they cannot resolve the infection. The extent of lymphocytic infiltration, inflammation, portal and periportal fibrosis, and lobular necrosis in liver biopsies can be used to grade the severity of disease. It has been suggested that the cytokines of inflammation and continual liver repair and induction of cell growth occurring during chronic HCV infection are predisposing factors in the development of PHC.

EPIDEMIOLOGY

HCV is **transmitted primarily and efficiently in infected blood** and less efficiently sexually. Intravenous drug abusers and tattoo recipients are at the highest risk of acquiring HCV infection. Screening procedures have led to a reduction in the levels of transmission by blood transfusion and organ donation (Box 55.6). Almost all (>90%) HIV-infected people who are or were intravenous drug users are infected with HCV. Babies born of HCV-positive mothers are also at increased risk for infection. HCV is especially prevalent in southern Italy, Spain, central Europe, Japan, and parts of the Middle East (e.g., almost 20% of Egyptian blood donors are HCV positive). The prevalence of HCV in individuals born between 1945 and 1965 ("baby boomers") is approximately six times higher than the rest of the population. The **high incidence of chronic asymptomatic infections** promotes the spread of the virus in the population.

BOX 55.6 Epidemiology of Hepatitis B, C, and D Viruses

Disease/Viral Factors

Enveloped virus is labile to drying. HBV is less sensitive to detergents than other enveloped viruses.
Virus is shed during asymptomatic periods.
HBV (10%) and HCV (70%) cause chronic infection with potential virus shedding.

Transmission

In blood, semen, and vaginal secretions (HBV: saliva and mother's milk)
Via transfusion, needlestick injury, shared drug paraphernalia, sexual intercourse, and breast-feeding.

Who Is at Risk?

Children: mild asymptomatic disease with establishment of chronic infection.
Adults: insidious onset of hepatitis.
HBV-infected people co-infected or superinfected with HDV: abrupt, more severe symptoms with possible fulminant disease.
Adults with chronic HBV or HCV: at high risk for cirrhosis and primary hepatocellular carcinoma.

Geography/Season

Viruses are found worldwide.
There is no seasonal incidence.

Modes of Control

Avoidance of high-risk behavior.
HBV: virus-like particle (HBsAg) vaccines.
HBV and HCV screening of blood supply.

HBV, Hepatitis B virus; *HCV,* hepatitis C virus; *HDV,* hepatitis D virus.

CLINICAL SYNDROMES

HCV causes three types of disease (Fig. 55.14): (1) acute hepatitis with resolution of the infection and recovery in 15% of cases, (2) chronic persistent infection with possible progression to disease much later in life for 70% of infected persons, and (3) severe rapid progression to cirrhosis in 15% of patients (Clinical Case 55.1). A viremia can be detected within 1 to 3 weeks of a transfusion of HCV-contaminated blood. The viremia lasts 4 to 6 months in people with an acute infection and longer than 10 years in those with a persistent infection. In its acute form, HCV infection is similar to acute HAV and HBV infection, but the inflammatory response is less intense and the symptoms are usually milder. More commonly (>70% of cases), the initial disease is asymptomatic but establishes chronic persistent disease. The predominant symptom is chronic fatigue. Chronic persistent disease often progresses to chronic active hepatitis within 10 to 15 years and to cirrhosis (20% of chronic cases) and liver failure (20% of cirrhotic cases) after 20 years. HCV-induced liver damage may be exacerbated by alcohol, certain medications, and other hepatitis viruses to promote cirrhosis. HCV promotes the development of hepatocellular carcinoma after 30 years in up to 5% of chronically infected patients.

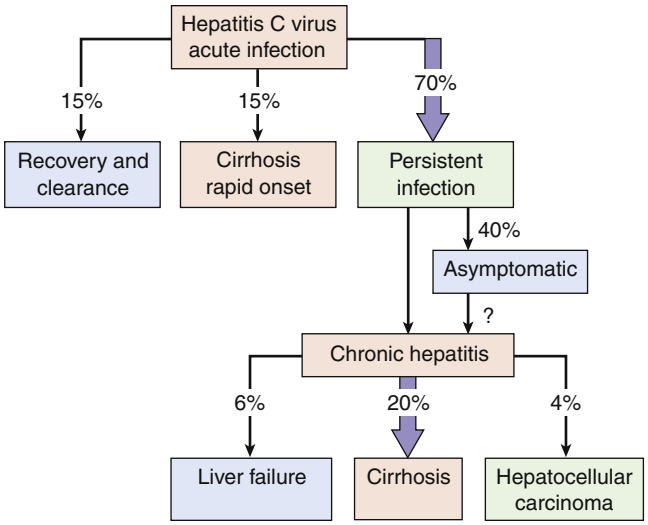

Fig. 55.14 Hepatitis C proteins and their function. Highlighted proteins are targets for antiviral drugs. (Adapted from Scheel, T.K.H., Rice, C.M., 2013. Understanding the hepatitis C virus life cycle paves the way for highly effective therapies. Nature Medicine 19 [7], 837–849.)

Clinical Case 55.1 **Hepatitis C Virus**

In a case reported by Morsica and associates (*Scand J Infect Dis* 33:116–120, 2001), a 35-year-old woman was admitted with malaise and jaundice. Elevated blood levels of bilirubin (71.8 μmol/L; normal value < 17 μmol/L) and ALT (410 IU/l; normal value < 30 IU/L) indicated liver damage. Serology was negative for antibodies to hepatitis A, hepatitis B, hepatitis C, Epstein-Barr virus, cytomegalovirus, and HIV-1. However, HCV genomic RNA sequences were detected by reverse transcriptase polymerase chain reaction analysis. ALT levels peaked on the third week after admission and returned to normal by the eighth week. HCV genomes in blood were undetectable by the eighth week. Anti-HCV antibody was also detected by the eighth week. It was suspected that she was infected by her sexual partner, and this was confirmed by genotyping virus obtained from both individuals. Confirmation was provided by partial sequence analysis of the *E2* gene from the two viral isolates. The 5% genetic divergence detected between the isolates was less than the ≈20% divergence expected for unrelated strains. Before the analysis, the sexual partner was unaware of his chronic HCV infection. Even more than HBV, which is also transmitted by sexual and parenteral means, HCV causes inapparent and chronic infections. Inapparent transmission of the virus, as in this case, enhances spread of the virus. The molecular analysis demonstrates the genetic instability of the HCV genome, which is a possible mechanism for facilitating its chronic infection by changing its antigenic appearance to promote escape from the immune response.

ALT, Aspartate amino transferase; *HBV*, hepatitis B virus; *HCV*, hepatitis C virus.

LABORATORY DIAGNOSIS

The diagnosis and detection of HCV infection are based on ELISA recognition of anti-HCV antibody or detection of the RNA genome. Seroconversion occurs within 7 to 31 weeks of infection. ELISA is used for screening the blood supply from normal donors. Antibody is not always detectable in viremic people, immunocompromised patients, or those receiving hemodialysis. Genome detection and quantitation by RT-PCR, branched-chain DNA, and related techniques is the gold standard for confirming a diagnosis of HCV and for following the success of antiviral drug therapy. Genetic assays are less strain specific and can detect HCV RNA in seronegative people.

TREATMENT, PREVENTION, AND CONTROL

New HCV antiviral regimens using direct acting antivirals (DAAs) has made it possible to cure 90% of individuals infected with HCV (Table 55.3) and have replaced previous therapies. These drugs target the protease (NS3/4A), the NS5A protein, and the polymerase (NS5B). The polymerase inhibitors include nucleotide analogs and nonnucleotide analogs. These antiviral drugs are usually administered as mixtures. Recombinant IFN-α or pegylated interferon (treated with polyethylene glycol to enhance its biological lifetime), alone or with ribavirin, were the only available treatments for HCV until 2011, when the first two virus-specific protease inhibitors were approved for use. This combination was less effective with more side effects.

Precautions for preventing the transmission of HCV are similar to those for HBV and other blood-borne pathogens. The blood supply and organ donors are screened for HCV. Persons with HCV should not share any personal care items or syringe needles that may get contaminated with blood and should practice safe sex. Alcohol drinking should be limited because it exacerbates the liver damage caused by HCV.

Hepatitis G Virus

HGV (also known as GB virus-C [GBV-C]) resembles HCV in many ways. HGV is a flavivirus, is transmitted in blood, and has a predilection for chronic hepatitis infection. It is identified by detection of the genome by RT-PCR or other RNA detection methods.

Hepatitis D Virus

Approximately 15 million people in the world are infected with HDV (delta agent), and the virus is responsible for causing 40% of **fulminant hepatitis** infections. HDV is unique in that it uses HBV and target cell proteins to replicate and produce its one protein. It is a viral parasite, proving that "even fleas have fleas." **HBsAg is essential for packaging the virus.** The delta agent resembles plant virus satellite agents and viroids in its size, genomic structure, and requirement for a helper virus for replication (Fig. 55.15).

STRUCTURE AND REPLICATION

The **HDV RNA genome is very small** (≈1700 nucleotides), and unlike other viruses, the single-stranded RNA is circular and forms a rod shape as a result of its extensive base pairing. The virion is approximately the same size as the HBV virion (35 to 37 nm in diameter). The genome is surrounded by the delta antigen core, which, in turn, is surrounded by an HBsAg-containing envelope. The **delta antigen** exists as a small (24-kDa) or large (27-kDa) form; the small form is predominant.

TABLE 55.3 Hepatitis C Antiviral Drugs and Combinations

Antiviral Drug	Target	Name
Daclatasvir	NS5A	Daklinza
Simeprevir	NS3/4A protease	Olysio
Sofosbuvir	NS5B polymerase	Sovaldi
Elbasvir-grazoprevir	NS5A + NS3/4A protease	Zepatier
Glecaprevir-pibrentasvir	NS3/4A protease + NS5A	Mavyret
Ledipasvir-Sofosbuvir	NS5A + NS5B polymerase	Harvoni
Sofosbuvir-velpatasvir-voxilaprevir	NS5B polymerase + NS5A + NS3/4A protease	Vosevi
Ombitasvir-paritaprevir-ritonavir	NS5A + NS3/4A protease + inhibitor of CYP3A4	Technivie
Ombitasvir-paritaprevir-ritonavir-dasabuvir	NS5A + NS3/4A protease + inhibitor of CYP3A4 + NS5B polymerase	Viekira Pak
Sofosbuvir-velpatasvir	NS5B polymerase + NS5A	Epclusa
Ribavarin	Broad -spectrum antiviral	Copegus, Rebetol, Ribosphere
Peginterferon alfa-2a, peginterferon alfa-2b	Pegylated natural antiviral	Pegasys PegIntron

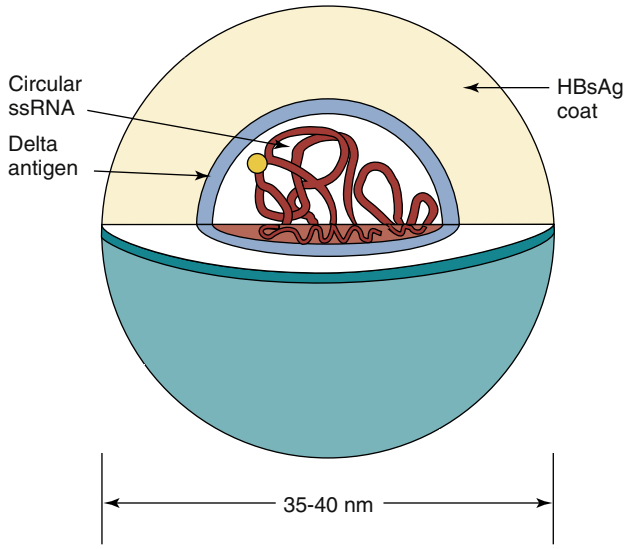

Fig. 55.15 Delta hepatitis virion. *HBsAg,* Hepatitis B surface antigen; *ssRNA,* single-stranded RNA.

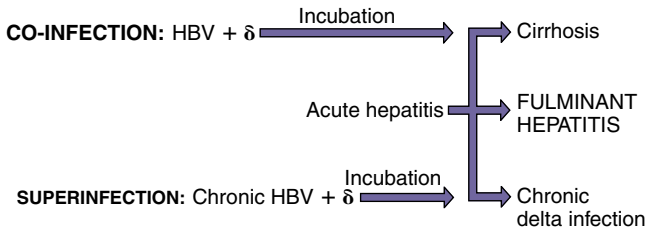

Fig. 55.16 Consequences of delta virus infection. Delta virus *(δ)* requires the presence of hepatitis B virus *(HBV)* infection. Superinfection of a person already infected with HBV (carrier) causes more rapid, severe progression than co-infection *(shorter arrow)*.

The delta agent binds to and is internalized by hepatocytes in the same manner as HBV because it has HBsAg in its envelope. The transcription and replication processes of the HDV genome are unusual. The host cell's RNA polymerase II makes an RNA copy to replicate the genome. The genome then forms an RNA structure called a **ribozyme,** which cleaves the RNA circle to produce an mRNA for the small delta antigen. The gene for the delta antigen is mutated by a cellular enzyme (double-stranded RNA-activated adenosine deaminase) during infection, allowing production of the large delta antigen. Production of this antigen limits replication of the virus but also promotes association of the genome with HBsAg to form a virion, and the virus is then released from the cell.

PATHOGENESIS

The delta agent can replicate and cause disease only in people with active HBV infections. Because the two agents are transmitted by the same routes, a person can be **co-infected** with HBV and the delta agent. A person with chronic HBV can also be **superinfected** with the delta agent. More rapid, severe progression occurs in HBV carriers superinfected with HDV than in people co-infected with HBV and the delta agent because, during co-infection, HBV must first establish its infection before HDV can replicate (Fig. 55.16), whereas superinfection of an HBV-infected person allows the delta agent to replicate immediately and in more cells.

Unlike HBV disease, damage to the liver occurs as a result of the direct cytopathic effect of the delta agent combined with the underlying immunopathology of the HBV disease. The delta agent exacerbates the HBV disease. Persistent delta agent infection is often established in HBV carriers. Antibodies are elicited against the delta agent, but protection is provided by antibodies to HBsAg, generated by vaccination or infection, because it is the external antigen and viral attachment protein for HDV.

EPIDEMIOLOGY

The delta agent infects children and adults with underlying HBV infection (see Box 55.6), and people who are persistently infected with both HBV and HDV are a source for the virus. The agent has a worldwide distribution, infecting approximately 5% of the more than three hundred million HBV carriers, and is endemic in southern Italy, the Amazon Basin, parts of Africa, and the Middle East. Epidemics of HDV infection occur in North America

BOX 55.7 Clinical Summaries

Hepatitis A: A 37-year-old man develops fever, chills, headache, and fatigue 4 weeks after eating at a greasy-spoon diner. Within 2 days, he develops anorexia, vomiting, and right upper quadrant abdominal pain followed by jaundice, dark-colored urine, and pale stools persisting for 12 days. Then symptoms decrease.

Hepatitis B: A 27-year-old IV drug user develops symptoms of hepatitis 60 days after using a dirty needle.

Hepatitis B and D: A different IV drug user develops symptoms of hepatitis, altered mental capacity, and massive hepatic necrosis and then dies.

Hepatitis C: Elevated liver enzymes were detected in an individual during a physical examination. Hepatitis C virus in the blood was detected by enzyme-linked immunosorbent assay. Ten years later, cirrhosis and liver failure developed, requiring a liver transplant.

IV, Intravenous.

and Western Europe, usually in illicit drug users. HDV is spread by the same routes as HBV, and the same groups are at risk for infection, with parenteral drug abusers, hemophiliacs, and others receiving blood products at highest risk. Screening of the blood supply has reduced the risk for recipients of blood products.

CLINICAL SYNDROMES

The delta agent increases the severity of HBV infections (Box 55.7). Fulminant hepatitis is more likely to develop in people infected with the delta agent than in those infected with the other hepatitis viruses. This very severe form of hepatitis causes altered brain function (hepatic encephalopathy), extensive jaundice, and massive hepatic necrosis, which is fatal in 80% of cases. Chronic infection with the delta agent can occur in people with chronic HBV.

LABORATORY DIAGNOSIS

The presence of the agent can be noted by detecting the RNA genome, the delta antigen, or anti-HDV antibodies. ELISA and radioimmunoassay procedures are available for detection. The delta antigen can be detected in the blood during the acute phase of disease in a detergent-treated serum sample. RT-PCR techniques can be used to detect the virion genome in blood.

TREATMENT, PREVENTION, AND CONTROL

There is no known specific treatment for HDV hepatitis. Because the delta agent depends on HBV for replication and is spread by the same routes, prevention of HBV infection prevents HDV infection. Immunization with HBV vaccine protects against delta virus infection. If a person has already acquired HBV, delta agent infection may be prevented by reducing risk of exposure by illicit intravenous drug use.

Hepatitis E Virus

HEV (E-NANBH) (the *E* stands for *enteric* or *epidemic*) is predominantly spread by the fecal-oral route, especially in contaminated water (see Box 55.3). HEV is a member of the Hepeviridae family with a positive-strand RNA genome and naked capsid structure. Although HEV is found throughout the world, it is most problematic in developing countries. In developed countries, HEV is a zoonosis and is acquired from pigs and undercooked pork or game meat. Epidemics have been reported in India, Pakistan, Nepal, Burma, North Africa, and Mexico.

The symptoms and course of HEV disease are similar to those of HAV disease; it causes only acute disease. However, the symptoms for HEV may occur later than those of HAV disease. The mortality rate associated with HEV disease is 1% to 2%, approximately 10 times that associated with HAV disease. HEV infection is especially serious in pregnant women (mortality rate of ≈20%).

Case Studies and Questions

A 55-year-old man **(patient A)** was admitted to the hospital with fatigue, nausea, and abdominal discomfort. He had a slight fever, his urine was dark yellow, and his abdomen was distended and tender. He had returned from a trip to Thailand within the previous month.

A 28-year-old woman **(patient B)** was admitted to the hospital complaining of vomiting, abdominal discomfort, nausea, anorexia, dark urine, and jaundice. She admitted that she was a former heroin addict and that she had shared needles. In addition, she was 3 months pregnant.

A 65-year-old man **(patient C)** was admitted with jaundice, nausea, and vomiting. He had major surgery requiring blood transfusions when he was a child.

1. What clinical or epidemiologic clues would have assisted in the diagnosis of hepatitis A, B, and C?
2. What laboratory tests would have been helpful in distinguishing the different hepatitis infections?
3. What was the most likely means of viral acquisition in each case?
4. What personal and public health precautions should have been taken to prevent the transmission of virus in each case?
5. Which of the patients was susceptible to chronic disease?
6. What laboratory tests distinguish acute from chronic HBV disease?
7. How can HBV disease be prevented? How could it be treated?

56 Prion Diseases

A 73-year-old man complained of weakness, forgetfulness, difficulty speaking, and involuntary movements of his right arm. After 3 months, myoclonus (muscle twitching) and other neurologic signs were noted and he was hospitalized. Protein 14-3-3 was detected in cerebrospinal fluid (CSF), but there was no evidence of an infection. The patient's condition continued to deteriorate, he slipped into a coma, and he died 4 months after the onset of symptoms. At autopsy, brain sections showed vacuolation and amyloid-containing plaques and fibrils, but there was no evidence of inflammatory cells.

1. Which disease signs indicate a prion disease?
2. Why are prions so resistant to disinfection?
3. Why was there no evidence of an immune response?

Answers to these questions are available on StudentConsult.com.

Summaries Clinically Significant Organisms

PRIONS

Trigger Words

Creutzfeldt-Jakob disease, spongiform encephalopathy, kuru, presenile dementia, myoclonus

Biology, Virulence, and Disease

- Prions are infectious protein aggregates resistant to inactivation
- Prions consist of assembled subunits with an alternate conformation of normal host proteins (PrP)
- Normal PrP protein binds to the PrP^{Sc} or the multimeric PrP^{Sc}, which alters its conformation and binds and extends fibrils
- Collect in brain, where they cause spongiform vacuoles
- No immune response, no inflammation
- Acquired, genetic, and sporadic forms of prion disease
- Creutzfeldt-Jakob disease (presenile dementia), kuru, Gerstmann-Sträussler-Scheinker disease, fatal familial insomnia

Epidemiology

- Transmitted on contaminated surgical devices, by injection, in food, or genetic

Diagnosis

- Symptomatology, MRI, indirect assays

Treatment, Prevention, and Control

- Rigorous disinfection procedures
- No means of prevention or control

MRI, Magnetic resonance imaging.

Spongiform encephalopathies, which are slow neurodegenerative diseases, are caused by proteinaceous infectious particles termed *prions.* Unlike conventional viruses, prions have no virion structure or genome, elicit no immune response, and are extremely resistant to inactivation by heat, disinfectants, and radiation (Table 56.1). **Prion diseases can be sporadic, genetic, or acquired.** After long incubation periods, these agents cause damage to the central nervous system, leading to a subacute spongiform encephalopathy. The long incubation period, which can last 30 years in humans, has made the study of these agents difficult.

Acquired (by infection) human prion diseases include kuru, Creutzfeldt-Jakob disease (CJD), and variant CJD (vCJD). Genetic prion diseases include CJD, Gerstmann-Sträussler-Scheinker (GSS) syndrome, and fatal familial insomnia (FFI). Sporadic occurrences of CJD and FFI occur more commonly (85% to 90% of cases) than genetic (10% to 15%) or acquired (1% to 3%). The animal diseases include scrapie, bovine spongiform encephalopathy (BSE; ["mad cow disease"]), chronic wasting disease (in mule, deer, and elk), and transmissible mink encephalopathy (Box 56.1).

Carlton Gajdusek won the Nobel Prize in 1976 for showing that kuru has an infectious etiology and for developing a method for analyzing the agent. Stanley Prusiner won the Nobel Prize in 1997 for developing a hamster infection model for the scrapie agent. He and his coworkers were able to purify, characterize, and then clone the genes for the scrapie and other prion agents and show that the disease-related prion protein is sufficient to cause disease.

Structure and Physiology

The prion is an infectious protein called scrapie-like prion protein (**PrP^{Sc}**), which is protease resistant, hydrophobic, forms fibrillar aggregates, and lacks nucleic acids. It consists of an alternate conformation of a normal cell surface glycoprotein termed cellular prion protein (**PrP^{C}**) (27,000 to 30,000 Da). PrP^{C} is protease sensitive and is held in the cell membrane by a linkage between its terminal serine and a special lipid called glycophosphatidylinositol (GPI-linked protein). PrP^{C} interacts with and modulates the function of numerous membrane proteins in the brain, including potassium channels, *N*-methyl-D-aspartate (NMDA) receptors, and the neural cell adhesion molecule. Binding to PrP^{Sc} changes the conformation of the PrP^{C} protein, which is rich in α-helical configuration to a β-sheet enriched form to produce the aberrant protein termed **PrP^{Sc}**, which builds a fibril (Table 56.2). PrP^{Sc} is protease resistant, aggregates into amyloid rods (fibrils), and is cell free.

The current theory to explain how an aberrant protein could cause disease is called *template-mediated protein refolding.* A linear aggregate of PrP^{Sc} binds to an anionic

TABLE 56.1 Comparison of Classic Viruses and Prions

Characteristic	Virus	Prion
Filterable infectious agents	Yes	Yes
Presence of nucleic acid	Yes	No
Defined morphology (electron microscopy)	Yes	No
Presence of protein	Yes	Yes
DISINFECTION BY:		
Formaldehyde	Yes	No
Proteases	Some	No
Heat (80° C)	Most	No
Ionizing and ultraviolet radiation	Yes	No
DISEASE		
Cytopathologic effect	Yes	No
Incubation period	Depends on virus	Long
Immune response	Yes	No
Interferon production	Yes	No
Inflammatory response	Yes	No

BOX 56.1 Prion Diseases

Human

Kuru
Creutzfeldt-Jakob disease
Variant CJD
Gerstmann-Sträussler-Scheinker syndrome
Fatal familial insomnia
Sporadic fatal insomnia

Animal

Scrapie (sheep and goats)
Transmissible mink encephalopathy
Bovine spongiform encephalopathy (BSE [mad cow disease])
Chronic wasting disease (mule, deer, and elk)

structure on the cell surface, such as a glycosaminoglycan, and the normal PrP^C on the cell surface. This causes the PrP^C to refold, acquire the structure of PrP^{Sc}, and join the chain. Binding to the PrP^{Sc} forces the α-helical structure of the PrP^C to change to a more β-pleated sheet structure of the PrP^{Sc}. The PrP^{Sc} acts as a template to transmit its conformation onto each new PrP^{Sc}, which can then perpetuate the change, analogous to how a mutation in the genetic template of a virus perpetuates a change in the deoxyribonucleic acid (DNA) or ribonucleic acid (RNA) genome. When the string of PrP^{Sc} breaks, it creates new primers on which more prions can be built. The PrP^C continue to be made by the cell, and as they bind to the PrP^{Sc} primers, the cycle continues. The human version of the PrP^C is encoded on chromosome 20. The fact that these plaques consist of host protein may explain the lack of an immune response to these agents in patients with the spongiform encephalopathies.

Different strains of PrP^{Sc} occur because of mutations in the PrP^C (genetic) or because of self-perpetuating alternative folding patterns of the protein (sporadic or acquired).

TABLE 56.2 Comparison of Scrapie Prion Protein and (Normal) Cellular Prion Protein

Characteristic	PrP^{Sc}	PrP^C
Structure	Multimeric	Monomeric
Protease resistance	Yes	No
Presence in scrapie fibrils	Yes	No
Location in or on cells	Cytoplasmic vesicles and extracellular milieu	Plasma membrane
Turnover	Days	Hours

PrP^C, Cellular prion protein; *PrP^{Sc}*, scrapie prion protein.

Specific mutations at codon 129 determine the severity of CJD. Conformational rather than genetic mutation is another property that distinguishes prions from viruses. The different conformational strains can have different properties and varying disease aspects (e.g., incubation period).

Aggregation of other proteins into prions or prion-like structures may cause or contribute to human diseases such as Alzheimer disease, Huntington disease, and Parkinson disease.

Pathogenesis

Prion infection can occur by ingestion, penetration through cuts in the skin, or by direct infection of the brain or neuronal tissue with prion-containing tissue. After ingestion, the prions accumulate in highly enervated secondary lymphoid tissue in follicular dendritic cells and B cells and then travel up neurons to the central nervous system and the brain.

Spongiform encephalopathy describes the appearance of the vacuolated neurons, as well as their loss of function and lack of an immune response or inflammation (Box 56.2). The formation of amyloid-containing plaques and fibrils, a proliferation and hypertrophy of astrocytes, and vacuolation of neurons and adjacent glial cells are observed (Fig. 56.1). The PrP^{Sc} reaches high concentrations in the brain and is taken up by neurons and phagocytic cells but is difficult to degrade, which is a feature that may contribute to the vacuolation of brain tissue. Prions can also be isolated from tissue other than the brain, but only the brain shows any pathologic changes. No inflammation or immune response to the agent is generated, distinguishing this disease from classic viral encephalitis. Protein markers (tau protein or 14-3-3 brain protein) can be detected in the CSF of symptomatic persons, but this is not specific for prion disease.

The incubation period for CJD and kuru may be as long as 30 years, but once the symptoms become evident, disease progresses rapidly and death usually occurs within a year.

Epidemiology

CJD is transmitted predominantly by (1) injection, (2) transplantation of contaminated tissue (e.g., corneas), (3) contact

BOX 56.2 Pathogenic Characteristics of Prions

No cytopathologic effect in vitro
Long doubling time of at least 5.2 days
Long incubation period
Cause vacuolation of neurons (spongiform), amyloid-like plaques, gliosis
Cause loss of muscle control, shivering, tremors, dementia
Lack of antigenicity
Lack of inflammation
Lack of immune response
Lack of interferon production

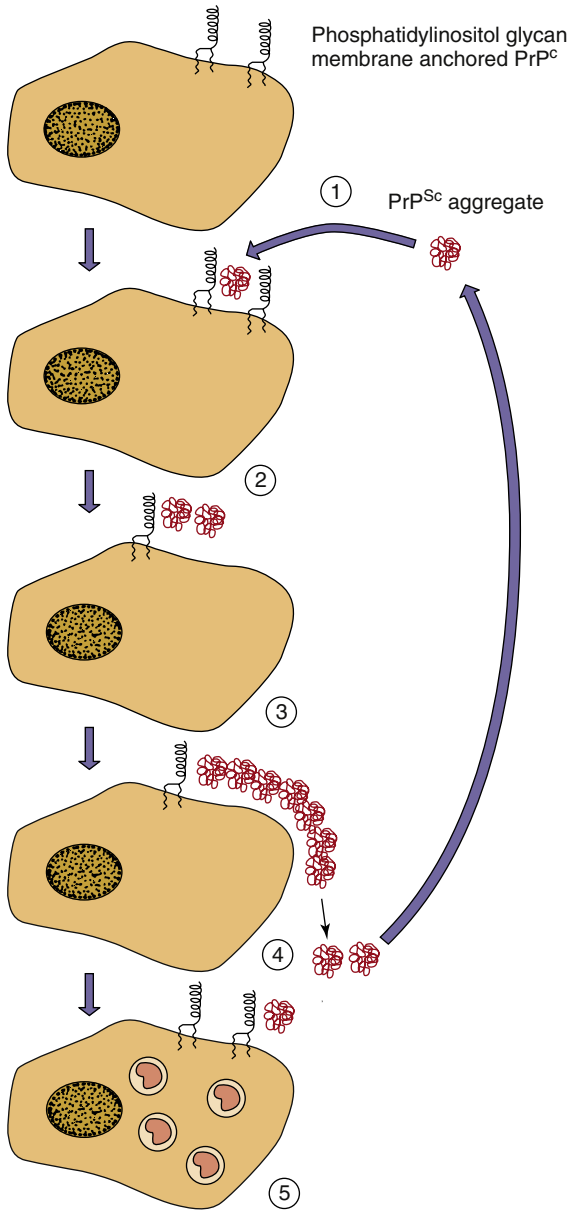

Fig. 56.1 Template-mediated protein refolding model for proliferation of prions. PrP^C is a normal cellular protein that is anchored in the cell membrane by phosphatidylinositol glycan. PrP^{Sc} is a hydrophobic globular protein that aggregates with itself and with PrP^C on the cell surface *(1)*. PrP^C acquires the conformation of PrP^{Sc} *(2)*. The cell synthesizes new PrP^C *(3)*, and a chain is built along cell surface anionic glycosaminoglycans *(4)*. The chain breaks on phagocytosis or from shear forces and releases PrP^{Sc} aggregates that act like seed crystals to start the cycle over. A form of PrP^{Sc} is internalized by neuronal cells and accumulates *(5)*. Other models have been proposed.

BOX 56.3 Epidemiology of Disease Caused by Prions

Disease/Viral Factors

Agents are impervious to standard microbial disinfection procedures.
Diseases have very long incubation periods, as long as 30 years.
Disease acquisition may be infectious, genetic, or sporadic (random occurrence).

Transmission

Transmission is via **infected tissue,** or syndrome may be **inherited.**
Infection can occur by ingestion,through cuts in skin, transplantation of contaminated tissues (e.g., cornea), and use of contaminated medical devices (e.g., brain electrodes).

Who Is at Risk?

Members (especially women and children) of the Fore tribe in New Guinea were at risk for kuru because of ritual cannibalism.
Surgeons, transplant and brain-surgery patients, and others are at risk for CJD and GSS syndrome.

Geography/Season

GSS syndrome and CJD have sporadic occurrence worldwide.
There is no seasonal incidence.

Modes of Control

No treatments are available.
Cessation of ritual cannibalism has led to the disappearance of kuru.
Elimination of animal products from livestock feed to prevent vCJD development and transmission
For GSS syndrome and CJD, neurosurgical tools and electrodes should be disinfected in 5% hypochlorite solution or 1.0 M sodium hydroxide or autoclaved at 15 psi for 1 hour.

CJD, Creutzfeldt-Jakob disease; *GSS,* Gerstmann-Sträussler-Scheinker; *vCJD,* variant Creutzfeldt-Jakob disease.

with contaminated medical devices (e.g., brain electrodes), and (4) food (Box 56.3). CJD usually affects persons older than 50 years. CJD, FFI, and GSS syndrome are also inheritable, and families with genetic histories of these diseases have been identified. The diseases are rare but occur worldwide.

Kuru was limited to a very small area of the New Guinea highlands. The name of the disease means "shivering" or "trembling," and the disease was related to the cannibalistic practices of the Fore tribe of New Guinea. Before Gajdusek intervened, it was the custom of these people to eat the bodies of their deceased kinsmen. When Gajdusek began his study, he noted that women and children, in particular, were the most susceptible to the disease, and he deduced that the reasons were that the women and children prepared the food, and they were given the less desirable viscera and brains to eat. Their risk for infection was higher because they handled the contaminated tissue, making it possible for the agent to be introduced through the conjunctiva or cuts in the skin. In addition, they ingested the neural tissue, which contains the highest concentrations of the kuru agent. Cessation of this cannibalistic custom has stopped the spread of kuru.

An epidemic of BSE (mad cow disease) in 1980 in the United Kingdom and the unusual incidence of a more rapidly progressing CJD in younger people (<45 years) in 1996 prompted concern that contaminated beef was the source

of this new variant of CJD (termed **vCJD**). Infection of cattle was most likely caused by the use of contaminated animal by-products (e.g., sheep entrails, brains) as a protein supplement in cattle feed. Ingestion of contaminated beef is likely to be the cause of 153 cases of vCJD, more than 98% of which have occurred in the United Kingdom.

Clinical Syndromes

The prion agents cause a progressive, degenerative neurologic disease with a long incubation period, but with rapid progression to death after the onset of symptoms (Fig. 56.2; Clinical Case 56.1; Box 56.4). The spongiform encephalopathies are characterized by a loss of muscle control, shivering, myoclonic jerks and tremors, loss of coordination, rapidly progressive dementia, and death.

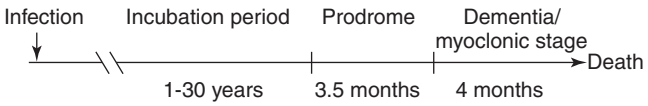

Fig. 56.2 Progression of transmissible Creutzfeldt-Jakob disease.

Clinical Case 56.1 **Transmission of Creutzfeldt-Jakob Disease by Transfusion**

In a case reported by Wroe and associates (*Lancet* 368:2061–2067, 2006), a 30-year-old man consulted his family doctor because of fatigue and inability to concentrate. The symptoms were attributed to a respiratory tract infection. Neurologic exams for the patient at this time were normal. History was significant for the fact that during surgery 7 years earlier, the patient had received packed red cells, including blood from a donor who died 1 year later with vCJD. Within 6 months of his initial presentation, the patient had difficulty maintaining balance, a tendency to stagger, some memory problems, a tremor in his hands, and "searing pain" in his legs. At this time, there was no evidence of changes in vision or mental status. After another 6 weeks, his mental status and memory decreased, balance and walking became difficult and painful, magnetic resonance neuroimaging and electroencephalogram indicated changes, and a new blood test showed the presence of the vCJD prion protein (PrP^{Sc}). The patient's mental status and physical ability continued to decline; he became mute, bedridden, poorly responsive, and he died 8 years and 8 months after the transfusion. Western immunoblot of autopsy samples from the brain and tonsils contained the PrP^{Sc} protein. PrP plaques and spongiform encephalopathy were noted in the brain.

Because of the long incubation period for prion diseases, prevention of transfusion transmission of CJD is difficult. vCJD has a more rapid onset of disease, and this case shows the classic progression through the five stages: (1) incubation (6 years), (2) prodromal fatigue and difficulty concentrating (18 months), (3) progressive neurologic decline (9 months), (4) late neurologic phase (4 months), and (5) terminal phase. Immunoblot analysis of treated prion protein can now distinguish the PrP^{Sc} from the normal protein in samples that can be taken from the patient's tonsils (or at autopsy, from the brain).

CJD, Creutzfeldt-Jakob disease; *vCJD,* variant Creutzfeldt-Jakob disease.

Laboratory Diagnosis

There are no methods for directly detecting prions in tissue, and there is no serologic response. The initial diagnosis must be made on clinical grounds. Initial confirmation of the diagnosis can be made by magnetic resonance imaging, detection of elevated levels of 14-3-3 protein or tau protein in CSF, or a proteinase K–resistant form of PrP in a Western blot using antibody to PrP in a tonsil biopsy. The ability of PrPSc to initiate the polymerization of normal PrP is utilized in the protein-misfolding cyclic assay (PMCA) to amplify the number of PrP^{Sc} units and can be used to detect the presence of prions. A new assay called real-time quaking-induced conversion **(RT-QuIC)** tests CSF or nasal-brushing specimens for the presence of PrP^{Sc}. The aggregation of PrP into prion fibrils enhances the fluorescence of thioflavin T, which can be readily measured. At autopsy, the characteristic amyloid plaques, spongiform vacuoles, and immunohistologically detected PrP can be observed.

Treatment, Prevention, and Control

No treatment exists for kuru or CJD. The causative agents are also impervious to the disinfection procedures used for other viruses, including formaldehyde, detergents, and ionizing radiation. Autoclaving at 15 psi for 1 hour (instead of 20 minutes) or treatment with 5% hypochlorite solution or 1.0 M sodium hydroxide can be used for decontamination. Because these agents can be transmitted on instruments and brain electrodes, such items should be carefully disinfected before being reused.

The outbreak of BSE and vCJD in the United Kingdom promoted legislation to ban animal products in livestock feed and encouraged more careful monitoring of cattle. Prion disease has not been a problem in cattle in the United States. Cattle must be younger than 5 years old to minimize the possibility of accumulation of aberrant PrP and so that muscle tissue would have the lowest amount of PrP.

BOX 56.4 **Clinical Summaries**

Creutzfeldt-Jakob disease: A 63-year-old man complained of poor memory and difficulty with vision and muscle coordination. Over the course of the next year, he developed senile dementia and irregular jerking movements, progressively lost muscle function, and then died.

Variant Creutzfeldt-Jakob disease: A 25-year-old is seen by a psychiatrist for anxiety and depression. After 2 months, he has problems with balance and muscle control and has difficulty remembering. He develops myoclonus and dies within 12 months of onset.

Case Study and Questions

A 70-year-old woman complained of severe headaches, appeared dull and apathetic, and had a constant tremor in the right hand. One month later, she experienced memory loss and moments of confusion. The patient's condition continued to deteriorate, and at 2 months after onset of symptoms, an abnormal electroencephalograph tracing showing periodic biphasic and triphasic slow-wave complexes was obtained. By 3 months, the patient was in a coma-like state. She also had occasional spontaneous clonic twitching of the arms and legs and a startle myoclonic jerking response to a loud noise. The patient died of pneumonia 4 months after the onset of symptoms. No gross abnormalities were noted at autopsy. Astrocytic gliosis of the cerebral cortex, with fibrils and intracellular vacuolation throughout the cerebral cortex, was seen on microscopic examination. There was no swelling and no inflammation.

1. What viral neurologic diseases would have been considered in the differential diagnosis formulated on the basis of the symptoms described? What other diseases?

2. What key features of the postmortem findings were characteristic of the diseases caused by prions?

3. What key features distinguish the prion diseases from conventional neurologic viral diseases?

4. What precautions should the pathologist have taken for protection against infection during the postmortem examination?

SECTION 6

Mycology

SECTION OUTLINE

57 Fungal Classification, Structure, and Replication

This chapter provides an overview of fungal classification, structure, and reproduction. The very basic aspects of fungal cell organization and morphology are discussed, as well as the broad categories of human mycoses. We have purposely simplified the fungal taxonomy and use it to highlight the major phyla of fungi causing disease in humans: the Ascomycota (Ascomycetes), the Basidiomycota (Basidiomycetes), the Glomeromycota (Mucormycetes), and the Microspora (Microsporidia).

The Importance of Fungi

The fungi represent a ubiquitous and diverse group of organisms, the main purpose of which is to degrade organic matter. All fungi lead a heterotrophic existence as saprobes (organisms that live on dead or decaying matter), symbionts (organisms that live together and in which the association is of mutual advantage), commensals (organisms living in a close relationship in which one benefits from the relationship and the other neither benefits nor is harmed), or as parasites (organisms that live on or within a host from which they derive benefits without making any useful contribution in return; in the case of pathogens, the relationship is harmful to the host).

Fungi have emerged in the past two decades as major causes of human disease (Table 57.1), especially among those individuals who are immunocompromised or hospitalized with serious underlying diseases. Among these patient groups, fungi serve as opportunistic pathogens, causing considerable morbidity and mortality. The overall incidence of specific invasive mycoses continues to increase with time, and the list of opportunistic fungal pathogens likewise increases each year. In short, *there are no nonpathogenic fungi!* This increase in fungal infections can be attributed to the ever-growing number of immunocompromised patients, including transplant patients, individuals with acquired immunodeficiency syndrome (AIDS), patients with cancer and undergoing chemotherapy, and those individuals who are hospitalized with other serious underlying conditions and who undergo a variety of invasive procedures.

Fungal Taxonomy, Structure, and Replication

The fungi are classified in their own separate kingdom called Kingdom Fungi. They are eukaryotic organisms that are distinguished from other eukaryotes by a rigid cell wall composed of chitin and glucan and a cell membrane in which ergosterol is substituted for cholesterol as the major sterol component (Fig. 57.1).

Classic fungal taxonomy relies heavily on morphology and mode of spore production. Increasingly, however, ultrastructural features and biochemical and **molecular characteristics** are brought to bear, often resulting in changes in the original taxonomic designation. The advent of rapid deoxyribonucleic acid (DNA) sequencing has resulted in a revolution in fungal taxonomy based on a phylogenetic approach to species recognition that relies on comparative analysis of variable nucleic acid characters to define a fungal species. Thus a species is defined as a group of organisms that share concordance of multiple gene genealogies (DNA sequences at different gene locations), rather than organisms that share a common morphology or that can mate together.

Fungi may be unicellular or multicellular. The simplest grouping, based on morphology, lumps fungi into either **yeasts** or **molds.** A yeast can be defined morphologically as a cell that reproduces by budding or by fission (Fig. 57.2), in which a progenitor or "mother" cell pinches off a portion of itself to produce a progeny or "daughter" cell. The daughter cells may elongate to form sausage-like **pseudohyphae.** Yeasts are usually unicellular and produce round, pasty, or mucoid colonies on agar. Molds, on the other hand, are multicellular organisms consisting of threadlike tubular structures, called **hyphae** (see Fig. 57.2), which elongate at their tips by a process known as **apical extension.** Hyphae are either **coenocytic** (hollow and multinucleate) or **septate** (divided by partitions or cross-walls) (see Fig. 57.2). The hyphae form together to produce a matlike structure called a **mycelium.** The colonies formed by molds are often described as **filamentous, hairy,** or **woolly.** When growing on agar or other solid surfaces, molds produce hyphae, termed **vegetative hyphae,** which grow on or beneath the surface of the culture medium, and hyphae that project above the surface of the medium **(aerial hyphae).** The aerial hyphae may produce specialized structures known as **conidia** (asexual reproductive elements) (Fig. 57.3). The conidia may be produced by either a blastic (budding) process or a thallic process, in which hyphal segments fragment into individual cells or **arthroconidia.** The conidia are easily airborne and serve to disseminate the fungus. The size, shape, and certain developmental features of conidia are used as a means of identifying fungi to genus and species. Many fungi of medical importance are termed **dimorphic** because they may exist in both a yeast form and a mold form.

Most fungi exhibit aerobic respiration, although some are facultatively anaerobic (fermentative), and others are strictly anaerobic. Metabolically fungi are heterotrophic and biochemically versatile, producing both primary (e.g.,

Table 57.1 Incidence and Mortality Rates of Selected Invasive Fungal Infections

	Number of Cases per Year	Mortality Rates (% in Infected Populations)
Pathogen	**Incidence**	
Candida species	>700,000	46-75
Cryptococcus neoformans	>1,000,000	20-70
Aspergillus species	>300,000	30-95
Pneumocystosis	>400,000	20-80
Agents of mucormycosis	>11,000	30-90
Endemic mycoses	>100,000	<1-70
Blastomycosis	~3,000	<2-68
Coccidioidomycosis	~20,000	<1-70
Histoplasmosis	~25,000	28-50
Paracoccidioidomycosis	~4,000	5-27
Talaromycosis (Penicilliosis)	>8,000	2-75

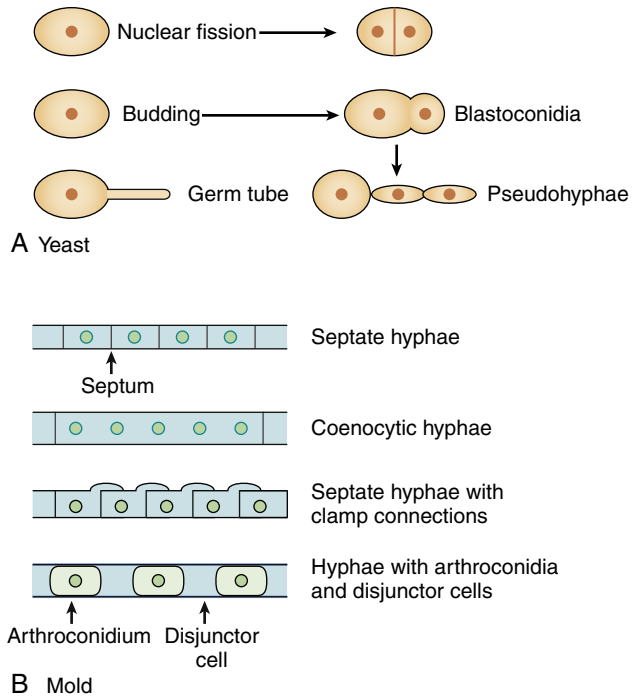

Fig. 57.2 Fungal cell morphology. (A) Yeast cells reproducing by nuclear fission and by blastoconidia formation. The elongation of budding yeast cells to form pseudohyphae is shown, as is the formation of a germ tube. (B) Types of hyphae seen with various molds.

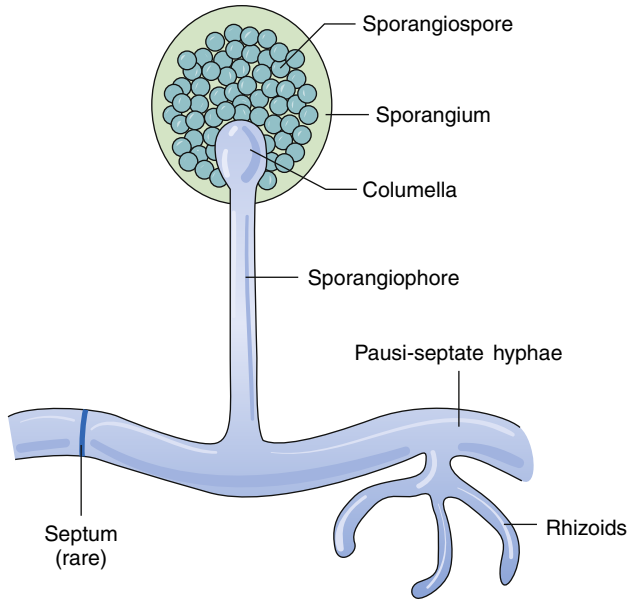
citric acid, ethanol, glycerol) and secondary (e.g., antibiotics [penicillin], ergot alkaloids, aflatoxins) metabolites. Relative to the bacteria, fungi are slow growing, with cell-doubling times in terms of hours rather than minutes.

A simplified taxonomic scheme listing the four major taxa of fungi of medical importance is shown in Table 57.2. Of the estimated several hundred thousand different fungi, fewer than 500 are known to cause human disease, although this number appears to be increasing.

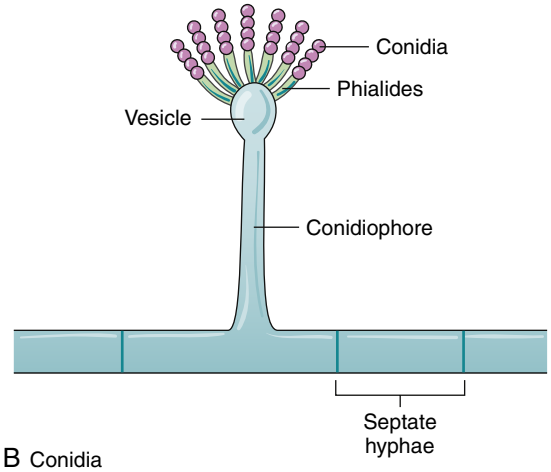
Fungi reproduce by the formation of spores that may be sexual (involving meiosis, preceded by fusion of the protoplasm and nuclei of two compatible mating types) or asexual (involving mitosis only). The fungi in the Ascomycota, Basidiomycota, the Glomeromycota and the Microspora produce both sexual and asexual spores (Table 57.3). The form of the fungus producing sexual spores is termed the **teleomorph,** and the form producing asexual spores is termed the **anamorph.** The fact that the teleomorph and anamorph of the same fungus have different names (e.g., *Ajellomyces capsulatum* [teleomorph] and *Histoplasma capsulatum* [anamorph]) is a source of confusion for nonmycologists.

In light of this confusion and to recognize the effect of molecular taxonomy, the code of mycologic nomenclature was modified to apply a policy in which a given fungus will have only one name; it will no longer be necessary to provide different names for different morphologies of the same fungus. All legitimate names proposed for a species can serve as the correct name for that species. At this time it is permissible to refer to a fungus by its asexual designation if that is the form usually obtained in culture. For example, *H. capsulatum* is the anamorph of the ascomycete *A. capsulatum*. The anamorph is the stage that is most often encountered in culture, and only under special conditions is the sexual stage formed. Thus the clinical isolate is known as *H. capsulatum*.

Asexual spores consist of two general types: **sporangiospores** and **conidia.** Sporangiospores are asexual spores produced in a containing structure or **sporangia** (see Fig. 57.3) and are characteristic of genera belonging to the Mucorales, such as *Rhizopus* and *Mucor* spp. Conidia are asexual spores that are borne naked on specialized structures as seen in *Aspergillus* spp. (see Fig. 57.3), *Penicillium* spp., and the dermatophytes.



A Sporangiospores Mucormycete (*Rhizopus* spp.)



B Conidia (*Aspergillus* spp.)

Fig. 57.3 Examples of asexual spore formation and associated structures seen with a (A) Mucorales and an (B) *Aspergillus* spp.

Ascomycota (Ascomycetes)

The phylum Ascomycota contains almost 50% of all named fungal species and accounts for ~80% of fungi of medical importance. Sexual reproduction leads to the development of ascospores, which are produced in a specialized saclike structure known as an ascus. Asexual reproduction consists of the production of conidia, from a generative or conidiogenous cell.

The Ascomycota consists of four classes of medical importance: Pneumocystidomycetes, Saccharomycetes, Eurotiomycetes, and Sordariomycetes. The class Pneumocystidomycetes contains the genus *Pneumocystis*, which was formerly classified as a protozoan but now reassigned to the Kingdom Fungi on the basis of gene sequence comparisons. The Saccharomycetes contains the ascomycetous yeasts, whereas the Eurotiomycetes and the Sordariomycetes contain the filamentous ascomycetes.

Pneumocystidomycetes: Pneumocystidomycetes is a new class that was recently described to include an organism, *Pneumocystis carinii*, which was formerly considered to be a protozoan. The reclassification of *Pneumocystis* was based on molecular evidence that it was most closely related to the ascomycete *Schizosaccharomyces pombe.* Further molecular studies resulted in the naming of human-derived strains as *P. jirovecii.* The organism exists in a vegetative trophic form that reproduces asexually by binary fission. Fusion of compatible mating types results in a spheric cyst or spore case, which on maturity contains eight spores.

Saccharomycetes: The class Saccharomycetes contains the ascomycetous yeasts (order Saccharomycetales), which are characterized by vegetative yeast cells that proliferate by budding or fission (see Fig. 57.2A). Many members of the order Saccharomycetales have an anamorphic stage belonging to the genus *Candida* (see Table 57.2). This genus, which consists of approximately 200 anamorphic species, has teleomorphs in more than 10 different genera, including *Clavispora, Debaryomyces, Issatchenkia, Kluyveromyces*, and *Pichia.* Under the "one fungus one name" concept, many of these will be renamed.

Eurotiomycetes: In the class Eurotiomycetes, sexual reproduction leads to the formation of a thin-walled sac, or ascus, which contains the haploid ascospores. This class has seven orders that include species pathogenic to humans. Among the more important are the order Onygenales, which contains the dermatophytes and a number of dimorphic systemic pathogens (including *H. capsulatum* and *Blastomyces dermatitidis*) and the order Eurotiales, which contains the teleomorphs of the anamorphic genera *Aspergillus* and *Penicillium.*

Sordariomycetes: In the class Sordariomycetes, the order Hypocreales contains the teleomorphs of the anamorphic genus *Fusarium,* and the order Microascales contains the teleomorphs (*Pseudallescheria*) of the anamorphic genus *Scedosporium* (see Table 57.2). In addition, the teleomorphs of numerous melanized (dematiaceous) fungi of medical importance belong to orders in this class.

Basidiomycota (Basidiomycetes)

Most members of the Basidiomycetes have a separate filamentous form, but some are typical yeasts. Sexual reproduction leads to the formation of haploid basidiospores on the outside of a generative cell termed a **basidium.** The most prominent human pathogens in the phylum Basidiomycetes are the basidiomycetous yeasts with anamorphic stages belonging to the genera *Cryptococcus, Malassezia*, and *Trichosporon.* The genus *Cryptococcus*, which contains more than 30 different species, has teleomorphs (sexual stages) that have been assigned to the genera *Filobasidium* and *Filobasidiella.*

The filamentous basidiomycetes are increasingly recognized as causes of opportunistic fungal infections. In culture these

Table 57.2 Medically Important Fungi (Kingdom Fungi)

Taxonomic Designation	Representative Genera	Human Disease
PHYLUM GLOMEROMYCOTA (MUCORMYCETES)		
Order: Mucorales	*Rhizopus, Mucor, Lichtheimia, Saksenaea*	Mucormycosis: opportunistic in patients with diabetes, leukemia, severe burns, or malnutrition; rhinocerebral infections
Order: Entomophthorales	*Basidiobolus, Conidiobolus*	Entomophthoromycosis: subcutaneous and gastrointestinal infections
PHYLUM: BASIDIOMYCOTA (BASIDIOMYCETES)	Teleomorphs of *Cryptococcus, Malassezia,* and *Trichosporon* species	Cryptococcosis and numerous mycoses
PHYLUM: ASCOMYCOTA (ASCOMYCETES)		
Class: Pneumocystidomycetes	*Pneumocystis jirovecii*	*Pneumocystis* pneumonia
Class: Saccharomycetes	Teleomorphs of *Candida* species; *Saccharomyces*	Numerous mycoses
Class: Eurotiomycetes Order: Onygenales	*Arthroderma* (teleomorphs of *Trichophyton* and *Microsporum*); *Ajellomyces* (teleomorphs of *Blastomyces* and *Histoplasma* species)	Dermatophytoses; systemic mycoses
Order: Eurotiales	Teleomorphs of *Aspergillus* species	Aspergillosis
Class: Sordariomycetes Order: Hypocreales	Teleomorphs of *Fusarium* species	Keratitis and other invasive mycoses
Order: Microascales	*Pseudallescheria* (teleomorph of *Scedosporium* species)	Pneumonia, mycetoma, and invasive mycoses
PHYLUM: MICROSPORA (MICROSPORIDIA)	Encephalitozoon, Enterocytozoon, Nosema, Trachipleistophora	Keratoconjunctivitis, sinusitis, pneumonitis, diarrhea, encephalitis, disseminated infection

Modified from Brandt, M.E., Warnock, D.W., 2015. Taxonomy and classification of fungi. In: Jorgensen, J.H., et al. (Eds.), 2015. Manual of Clinical Microbiology, eleventh ed. American Society for Microbiology Press, Washington, DC.

Table 57.3 Biologic, Morphologic, and Reproductive Characteristics of Pathogenic Fungi

Organism Group	Representative Genera	Morphology	Reproduction
Mucormycetes	*Rhizopus, Mucor, Lichtheimia, Basidiobolus*	Broad, thin-walled, coenocytic hyphae, 6-25 μm with nonparallel sides; spores contained within sporangium; rootlike structures called *rhizoids* characteristic of some genera	Asexual: production of sporangiospores within sporangium Sexual: production of zygospores formed by fusion of compatible mating types
Basidiomycetes	Anamorphic basidiomycetous yeasts (*Cryptococcus, Malassezia, Trichosporon*)	Budding yeasts, hyphae, and arthroconidia Hyphae that produce basidiospores (not seen in nature or in patients) Hyphae with clamp connections	Asexual: production of conidia by budding from a mother cell or within a hyphal fragment Sexual: fusion of compatible nuclei followed by meiosis to form basidiospores or not identified
Pneumocystidomycetes	*Pneumocystis jirovecii*	Trophic forms and cystlike structures	Asexual: binary fission Sexual: fusion of compatible mating types to form zygote; compartmentalization of spores within cyst
Saccharomycetes	*Candida* and *Saccharomyces*	Budding yeasts and hyphae, pseudohyphae	Asexual: production of conidia by budding from a mother cell Sexual: either not seen or by conjugation between two single cells or by "mother-bud" conjugation
Eurotiomycetes	Dermatophytes, *Blastomyces, Histoplasma, Aspergillus, Fusarium, Scedosporium* species	Budding yeasts, septate hyphae, asexual conidia borne on specialized structures	Asexual: production of conidia by budding from a mother cell Sexual: ascospores produced in a specialized structure called an *ascus* or not seen

organisms often produce fast-growing, sterile white colonies with **clamp connections** (see Fig. 57.2B), which are hyphal outgrowths that form a bypass around the septum to facilitate the migration of a nucleus. Whereas most filamentous basidiomycetes are wood-rotting fungi, the most frequently reported cause of human infection is *Schizophylum commune*.

Glomerulomycota (Mucormycetes, formerly Zygomycetes)

The Glomeromycota (Mucormycetes) include molds with broad, sparsely septate, coenocytic hyphae. The subphylum Mucoromycotina has been proposed to accommodate the **Mucorales,** and the subphylum Entomophthoromycotina includes the **Entomophthorales**. These fungi produce **sexual zygospores** after the fusion of two compatible mating types. The asexual spores of the order Mucorales (see Fig. 57.3) are contained within a sporangium (sporangiospores). The sporangia are borne at the tips of stalklike **sporangiophores** that terminate in a bulbous swelling called the **columella** (see Fig. 57.3). The presence of rootlike structures, called **rhizoids,** is helpful in identifying specific genera within the Mucorales. The order Mucorales is the most clinically important and includes the genera *Lichtheimia* (formerly *Absidia*), *Mucor*, *Rhizopus,* and *Rhizomucor*. The other order, the Entomophthorales, is less common and includes the genera *Basidiobolus* and *Conidiobolus*. These organisms cause tropical subcutaneous mucormycosis. The asexual spores are borne singly on short sporophores and are forcibly ejected when mature.

Microspora (Microsporidia)

Microsporidia are obligate intracellular, unicellular, spore-forming eukaryotes. Previously categorized as protists, organisms of the phylum Microspora were recently assigned to the Kingdom Fungi on the basis of genetic studies indicating that these organisms were derived from an endoparasitic chytrid ancestor on the earliest diverging branch of the fungal phylogenetic tree. Furthermore, structural features of the organisms such as the presence of chitin in the spore wall, diplokaryotic nuclei, and electron-dense spindle plaques associated with the nuclear envelope suggest a possible relationship between fungi and microsporidia. Conversely, the life cycle of microsporidia is unique and unlike that of any other fungal species. More than 200 microsporidial genera and 1500 species that are pathogenic in every major animal group have been identified. Presently human infections have been shown to involve nine different genera (*Anncaliia, Encephalitozoon, Endoreticulatus, Enterocytozoon, Nosema, Pleistophora, Vittaforma, Tubulinosema,* and *Trachipleistophora*) and unclassified microsporidia that have been assigned to the collective group *Microsporidium*.

Classification of Human Mycoses

In addition to the formal taxonomic classification of fungi, fungal infections may be classified according to the tissues infected and by specific characteristics of organism groups. These classifications include the superficial, cutaneous, and subcutaneous mycoses; the endemic mycoses; and the opportunistic mycoses (Table 57.4).

SUPERICIAL MYCOSES

The superficial mycoses are those infections that are limited to the very superficial surfaces of the skin and hair. They are nondestructive and of cosmetic importance only. The clinical infection termed **pityriasis versicolor** is characterized by discoloration or depigmentation and scaling of the skin. **Tinea nigra** refers to brown or black pigmented macular patches localized primarily to the palms. The clinical entities of black and white piedra involve the hair and are characterized by nodules composed of hyphae that encompass the hair shaft. The fungi associated with these superficial infections include *Malassezia furfur, Hortaea werneckii, Piedraia hortae,* and *Trichosporon* spp.

CUTANEOUS MYCOSES

Cutaneous mycoses are infections of the keratinized layer of skin, hair, and nails. These infections may elicit a host response and become symptomatic. Signs and symptoms include itching, scaling, broken hairs, ringlike patches of the skin, and thickened, discolored nails. The Dermatophytes are fungi classified in the genera *Trichophyton, Epidermophyton,* and *Microsporum*. Infections of the skin involving these organisms are called **dermatophytoses. Tinea unguium** refers to infections of the toes involving these agents. Onychomycoses includes infections of the nails caused by the dermatophytes, as well as nondermatophytic fungi, such as *Candida* spp. and *Aspergillus* spp.

SUBCUTANEOUS MYCOSES

Subcutaneous mycoses involve the deeper layers of the skin, including the cornea, muscle, and connective tissue and are caused by a broad spectrum of taxonomically diverse fungi. The fungi gain access to the deeper tissues usually by traumatic inoculation and remain localized, causing abscess formation, nonhealing ulcers, and draining sinus tracts. The host immune system recognizes the fungi, resulting in variable tissue destruction and frequently epitheliomatous hyperplasia. Infections may be caused by hyaline molds, such as *Acremonium* spp., *Sarocladium* spp., and *Fusarium* spp., and by pigmented or dematiaceous fungi, such as *Alternaria* spp., *Cladosporium* spp., and *Exophiala* spp. (phaeohyphomycoses, chromoblastomycoses). Subcutaneous mycoses tend to remain localized and rarely disseminate systemically.

ENDEMIC MYCOSES

The endemic mycoses are fungal infections caused by the classic dimorphic fungal pathogens *H. capsulatum, B. dermatitidis, Emergomyces pasteurianus (*formerly *Emmonsia pasteuriana), E. africanus, Coccidioides immitis, C. posadasii, Paracoccidioides brasiliensis,* and *Talaromyces (Penicillium) marneffei.* These fungi exhibit thermal dimorphism (exist as yeasts or spherules at 37° C and molds at 25° C) and are generally confined to geographic regions in which they occupy specific environmental or ecologic niches. The endemic mycoses are often referred to as **systemic mycoses**

Table 57.4 Classification of Human Mycoses and Representative Etiologic Agents

Superficial Mycoses	Cutaneous and Subcutaneous Mycoses	Endemic Mycoses	Opportunistic Mycoses
Black piedra: *Piedraia hortae* Tinea nigra: *Hortae werneckii* Pityriasis versicolor: *Malassezia furfur* White piedra: *Trichosporon* spp.	Dermatophytoses: *Microsporum* spp. *Trichophyton* spp. *Epidermophyton floccosum* Tinea unguium: *Trichophyton* spp. *E. floccosum* Onychomycosis: *Candida* spp. *Aspergillus* spp. *Trichosporon* spp. *Geotrichum* spp. Mycotic keratitis: *Fusarium* spp. *Aspergillus* spp. *Candida* spp. Chromoblastomycosis: *Fonsecaea* spp. *Phialophora* spp.	Blastomycosis: *Blastomyces dermatitidis* Histoplasmosis: *Histoplasma capsulatum* Coccidioidomycosis: *Coccidioides immitis/posadasii* Penicilliosis: *Talaromyces (Penicillium) marneffei* Paracoccidioidomycosis: *Paracoccidioides brasiliensis* Emmonsiasis Emergomycosis: *Emergomyces pasteurianus* *E. africanus*	Aspergillosis: *Aspergillus fumigatus* *A. flavus* *A. niger* *A. terreus* Candidiasis: *Candida albicans* C. *glabrata* C. *parapsilosis* C. *tropicalis* Cryptococcosis: *Cryptococcus neoformans* Trichosporonosis: *Trichosporon* spp. Hyalohyphomycosis: *Acremonium* spp. *Fusarium* spp. *Paecilomyces* spp. *Scedosporium* spp. Mucormycosis: *Rhizopus* spp. *Mucor* spp. *Lichtheimia corymbifera* Phaeohyphomycosis: *Alternaria* spp. *Curvularia* spp. *Bipolaris* spp. *Exophiala* spp. Pneumocystosis: *Pneumocystis jirovecii* Microsporidiosis

because these organisms are true pathogens and can cause infection in healthy individuals. All of these agents produce a primary infection in the lung, with subsequent dissemination to other organs and tissues.

OPPORTUNISTIC MYCOSES

The opportunistic mycoses are infections attributable to fungi that are normally found as human commensals or in the environment. With the exception of *Cryptococcus neoformans* and *C. gattii*, these organisms exhibit inherently low or limited virulence and cause infection in individuals who are debilitated, immunosuppressed, or who carry implanted prosthetic devices or vascular catheters. Virtually any fungus can serve as an opportunistic pathogen, and the list of those identified as such becomes longer each year. The most common opportunistic fungal pathogens are the yeasts *Candida* spp. and *C. neoformans*, the mold *Aspergillus* spp., and *P. jirovecii*. Because of its inherent virulence, *C. neoformans* is often considered a "systemic" pathogen. Although this fungus may cause infection in immunologically normal individuals, it clearly is seen more frequently as an opportunistic pathogen in the immunocompromised population.

Summary

With the ever-increasing number of individuals at risk for fungal infection, it is imperative that physicians "think fungus" when confronting a suspected infection. The list of documented fungal pathogens is extensive, and one can no longer ignore or dismiss fungi as "contaminants" or clinically insignificant when isolated from clinical material. It is also apparent that the prognosis and response to therapy may vary with the type of fungus causing infection and with the immunologic status of the host. Thus physicians must become familiar with the various fungi, their epidemiologic and pathogenic features, and the optimal approaches to diagnosis and therapy. These issues will be discussed in detail in subsequent chapters according to the classification scheme shown in Table 57.4.

Questions

1. How do fungi differ from bacteria (size, nucleus, cytosol, plasma membrane, cell wall, physiology, generation time)?
2. How does the plasma membrane of fungi differ from that of other eukaryotic (e.g., mammalian) cells?
3. What is the difference between a yeast and a mold?
4. What do the terms anamorph and teleomorph mean, and why are they important?

58 Pathogenesis of Fungal Disease

Although a great deal is known regarding the molecular and genetic basis for bacterial and viral pathogenesis, our understanding of the pathogenesis of fungal infections is limited. Relatively few fungi are sufficiently virulent to be considered **primary pathogens** (Table 58.1). Primary pathogens are capable of initiating infection in a normal, apparently immunocompetent host. They are able to colonize the host, find a suitable microenvironmental niche with sufficient nutritional substrates, avoid or subvert the normal host defense mechanisms, and then multiply within the microenvironmental niche. Among the acknowledged primary fungal pathogens are four ascomycetous fungi, the endemic dimorphic pathogens *Blastomyces dermatitidis*, *Coccidioides immitis* (and *Coccidioides posadasii*), *Histoplasma capsulatum*, and *Paracoccidioides brasiliensis*. Each of these organisms possesses putative virulence factors that allow them to actively breach host defenses that ordinarily restrict the invasive growth of other microbes (see Table 58.1). When large numbers of conidia of any of these four fungi are inhaled by humans, even if these individuals are healthy and immunocompetent, infection and colonization, tissue invasion, and systemic spread of the pathogen commonly occur. As with most primary microbial pathogens, these fungi may also serve as **opportunistic pathogens**, given that the more severe forms of each mycosis are seen most often in individuals who are compromised in their innate and/or acquired immune defenses.

In general, healthy immunocompetent individuals have a high innate resistance to fungal infection, despite the fact that they are constantly exposed to the infectious forms of various fungi present as part of the normal commensal flora (endogenous) or in the environment (exogenous). The opportunistic fungal pathogens, such as *Candida* spp., *Cryptococcus neoformans*, and *Aspergillus* spp., generally only cause infection when there are disruptions in the protective barriers of the skin and mucous membranes or when defects in the host immune system allow them to penetrate, colonize, and reproduce in the host (see Table 58.1). However, even with these opportunists, there are factors associated with the organism rather than the host that contribute to the ability of the fungus to cause disease (see Table 58.1).

In addition to their role as opportunistic pathogens, filamentous fungi can produce toxins that have been implicated in a variety of illnesses and clinical syndromes in humans and in animals. These mycotoxins are secondary fungal metabolites that cause diseases, known collectively as **mycotoxicoses**, after ingestion, inhalation, or direct contact with the toxin. Mycotoxicoses may manifest as acute or chronic disease, ranging from rapid death to tumor formation. In this regard, mycotoxicoses are analogous to the pathologies caused by other "poisons" such as pesticides or heavy metal residues. The presenting symptoms and severity of a mycotoxicosis depend on the type of mycotoxin; the amount and duration of exposure; the route of exposure; and the age, sex, and health of the exposed individual. In addition, a variety of other circumstances, such as malnutrition, alcohol abuse, infectious disease status, and other toxin exposures, may act synergistically to compound the effect and severity of mycotoxin poisoning.

Primary Fungal Pathogens

All of the primary systemic fungal pathogens are agents of respiratory infections, and none are obligate parasites. Each has a **saprobic phase** characterized by filamentous septate hyphae, typically found in soil or decaying vegetation, that produce the airborne infectious cells. Likewise, the **parasitic phase** of each fungus is adapted to grow at 37° C and to reproduce asexually in the alternative environmental niche of the host respiratory mucosa (see Chapter 64, Fig. 64.1). This ability to exist in alternate morphogenic forms **(dimorphism)** is one of several special characteristics (virulence factors) that allow these fungi to cope with the hostile environmental conditions of the host (see Table 58.1).

BLASTOMYCES DERMATITIDIS

Like the other endemic dimorphic fungal pathogens, *B. dermatitidis* often causes a self-limited respiratory infection (see Chapter 64). However, blastomycosis is distinguished from the other endemic mycoses by the high incidence of clinical disease, compared with the mild or asymptomatic form among individuals infected in epidemics. The pathogenic potential of *B. dermatitidis* is underscored by the clinical severity of most sporadic cases of blastomycosis.

Important factors for the in vivo survival of *B. dermatitidis*, and any of the endemic dimorphic pathogens for that matter, are the ability of the inhaled pathogen to reach the alveoli, to undergo transformation to an alternate phase (yeast or spherule) capable of replicating at 37° C, and to colonize the respiratory mucosa. After inhalation of conidia or hyphal fragments of *B. dermatitidis*, the elements of the saprobic phase of the fungus presumably contact and adhere to the epithelial layer of the alveolus and then transform into the parasitic yeast phase in a process known as **thermal dimorphism.** This conversion from conidia (2 to 10 μm in diameter) to the larger yeast form (8 to 30 μm in diameter) provides an important survival advantage to the fungus. Whereas the conidia are small enough to be readily ingested and killed by human neutrophils, the yeast cells are able to resist the phagocytic attack of neutrophils and mononuclear cells during the early stages of the inflammatory response. Rather than adapting to the intracellular

TABLE 58.1 Characteristics of Primary and Opportunistic Fungal Pathogens

	Habitat/Infection	Pathogenesis	Putative Virulence Factors	Clinical Forms of Mycosis
PRIMARY PATHOGENS				
Blastomyces dermatitidis Saprobic phase: ▪ Septate mycelium and conidia Parasitic phase: ▪ Large, broad-based, budding yeast	Saprobic habitat: ▪ Soil and organic debris ▪ Endemic area southeastern United States and Ohio-Mississippi River Valley Mode of infection: ▪ Inhalation of conidia	Inhaled conidia convert to yeast; localized yeast invasion of host invokes inflammatory reaction; yeast escapes recognition by macrophages and disseminates via bloodstream	▪ Growth at 37° C ▪ Thermal dimorphism ▪ Modulation of yeast–host immune system interactions ▪ Generation of TH2 response ▪ Shedding of WI-1	▪ Primary pulmonary blastomycosis ▪ Chronic pulmonary blastomycosis ▪ Disseminated blastomycosis ▪ Cutaneous ▪ Bone, genitourinary tract, and brain
Coccidioides immitis (posadasii) Saprobic phase: ▪ Septate hyphae and arthroconidia Parasitic phase: ▪ Spherules with endospores	Saprobic habitat: ▪ Desert soil: southwestern United States, Mexico, regions of Central and South America Mode of infection: ▪ Inhalation of arthroconidia ▪ Percutaneous inoculation (rare)	Inhaled arthroconidia reach alveoli; convert to spherule that gives rise to endospores; endospores phagocytosed but survive; large (60–100 μm) spherules escape phagocytosis; alkaline environment allows survival within phagosome	▪ Growth at 37° C ▪ Thermal dimorphism ▪ Resistance of conidia to phagocytic killing ▪ Stimulation of ineffective TH2 response ▪ Urease production ▪ Extracellular proteinase production ▪ Molecular mimicry	▪ Initial pulmonary infection ▪ Chronic pulmonary coccidioidomycosis ▪ Disseminated coccidioidomycosis ▪ Meningitis ▪ Bone and joints ▪ Genitourinary ▪ Cutaneous ▪ Ophthalmic
Histoplasma capsulatum Saprobic phase: ▪ Septate hyphae, microconidia, and tuberculate macroconidia Parasitic phase: ▪ Small, intracellular, budding yeast	Saprobic habitat: ▪ Soil enriched with bird/bat guano ▪ Eastern half of United States, most of Latin America, parts of Asia, Europe, Middle East; var. *duboisii* occurs in Africa Mode of infection: ▪ Inhalation of conidia	Inhaled conidia convert to yeast; yeast ingested by macrophages; survive and proliferate within phagosome; some yeast forms remain dormant within macrophage, others proliferate and kill macrophages, releasing daughter cells	▪ Growth at 37° C ▪ Thermal dimorphism ▪ Survival in macrophages ▪ Modulate pH of phagosome ▪ Iron and calcium uptake ▪ Alteration of cell wall composition	▪ Clinically asymptomatic pulmonary and "cryptic dissemination" ▪ Acute pulmonary histoplasmosis ▪ Mediastinitis and pericarditis ▪ Chronic pulmonary histoplasmosis ▪ Mucocutaneous ▪ Disseminated
Paracoccidioides brasiliensis Saprobic phase: ▪ Septate hyphae, conidia Parasitic phase: ▪ Yeast with multiple buds	Saprobic habitat: ▪ Soil and vegetation ▪ Central and South America Mode of infection: ▪ Inhalation of conidia	Inhaled conidia convert to large multipolar budding yeast; ingested but not cleared by macrophages; may be dormant for up to 40 years. Disseminate to oral and nasopharyngeal mucosa	▪ Growth at 37° C ▪ Thermal dimorphism ▪ Intracellular survival ▪ Hormonal influences ▪ Alteration of cell wall ▪ Ineffective TH2 response to gp43	▪ Diverse clinical manifestations ▪ Chronic single organ involvement ▪ Chronic multifocal involvement (lungs, mouth, nose) ▪ Juvenile progressive disease: lymph nodes, skin and visceral involvement
OPPORTUNISTIC PATHOGENS				
Candida species Saprobic and parasitic phases are the same: budding yeast, hyphae, pseudohyphae	Saprobic habitat: ▪ Gastrointestinal mucosa, vaginal mucosa, skin, nails Mode of infection: ▪ Gastrointestinal translocation ▪ Intravascular catheters	Mucosal overgrowth with subsequent invasion; usually impaired mucosal barrier; hematogenous dissemination; transfer from hands of health care worker to catheter hub; catheter colonization and hematogenous dissemination	▪ Growth at 37° C ▪ Bud-hyphae transition ▪ Adherence ▪ Cell-surface hydrophobicity ▪ Cell wall mannans ▪ Proteases and phospholipases ▪ Phenotypic switching	▪ Simple mucosal colonization ▪ Mucocutaneous candidiasis ▪ Oral/vaginal thrush ▪ Hematogenous dissemination ▪ Hepatosplenic candidiasis ▪ Endophthalmitis
Cryptococcus neoformans Saprobic and parasitic phases are the same: encapsulated budding yeast	Saprobic habitat: ▪ Soil enriched with bird (pigeon) guano Mode of infection: ▪ Inhalation of aerosolized yeast ▪ Percutaneous inoculation	Inhaled yeast cells ingested by macrophages; survive intracellularly; capsule inhibits phagocytosis; capsule and melanin protect from oxidative injury; hematogenous and lymphatic dissemination to brain	▪ Growth at 37° C ▪ Polysaccharide capsule ▪ Melanin ▪ Alpha-mating type	▪ Primary cryptococcal pneumonia ▪ Meningitis ▪ Hematogenous dissemination ▪ Genitourinary (prostatic) cryptococcosis ▪ Primary cutaneous cryptococcosis

Continued

TABLE 58.1 Characteristics of Primary and Opportunistic Fungal Pathogens—cont'd

	Habitat/Infection	Pathogenesis	Putative Virulence Factors	Clinical Forms of Mycosis
Aspergillus species Saprobic phase: ▪ Septate mycelium, conidial heads, and conidia Parasitic phase: ▪ Septate mycelium; conidia, and conidial heads usually only seen in cavitary lesions	Saprobic habitat: ▪ Soil, plants, water, pepper, air Mode of infection: ▪ Inhalation of conidia ▪ Transfer to wounds via contaminated tape/bandages	Inhaled conidia bind to fibrinogen and laminin in alveolus; conidia germinate, and hyphal forms secrete proteases and invade epithelium; vascular invasion results in thrombosis and infarction of tissue; hematogenous dissemination	▪ Growth at 37° C ▪ Binding to fibrinogen and laminin ▪ Secretion of elastase and proteases ▪ Catalase ▪ Gliotoxin (?) and other mycotoxins	▪ Allergic bronchopulmonary aspergillosis ▪ Sinusitis ▪ Aspergilloma ▪ Invasive aspergillosis ▪ Lung ▪ Brain ▪ Skin ▪ Gastrointestinal ▪ Heart

From Cole, G.T., 2003. Fungal pathogenesis. In: Anaissie, E.J., McGinnis, M.R., Pfaller, M.A., (Eds.), Clinical Mycology. Churchill Livingstone, New York.

microenvironment of phagolysosomes like *H. capsulatum*, *B. dermatitidis* yeast cells shed their immunodominant antigen from the cell surface and subsequently modify their cell wall composition, allowing them to escape recognition by macrophages. Thus they are able to colonize tissue and disseminate through the bloodstream.

Modulation of Yeast and Host Immune System Interactions

The main immunoreactive moiety present on the surface of the yeast cells, but not on the conidia of *B. dermatitidis,* is a 120-kDa cell wall glycoprotein, BAD1 (formerly WI-1). This glycoprotein appears to play a key role in the pathogenesis of *B. dermatitidis*, in that it promotes adhesion of the yeast cell to macrophages and elicits a potent response of both the humoral and cellular immune systems. BAD1 is expressed by all virulent isolates of *B. dermatitidis* examined thus far. BAD1 knockout strains are nonpathogenic in murine models of infection underscoring the prominent role of BAD1 in the pathogenicity of *B. dermatitidis.*

In addition to its role in adhesion, BAD1 has been shown to modulate host immunity early in the course of infection, facilitating the establishment of *B. dermatitidis* in the lung. BAD1 interferes with host immunity by blocking the production of the proinflammatory cytokine, tumor necrosis factor (TNF)-α, by both macrophages and neutrophils, through transforming growth factor (TGF)-β–dependent and (TGF)-β–independent mechanisms. BAD1 displayed on the surface of *B. dermatitidis* yeast cells induces phagocyte TGF-β production, which suppresses TNF-α production. Conversely, soluble BAD1 is released from yeast cells in lung alveoli in vivo and suppresses TNF-α production but in a manner that is independent of TGF-β.

It appears that avirulent mutant strains of *B. dermatitidis* with high levels of expression of BAD1 on their cell surface are recognized by macrophages, phagocytosed, and rapidly eliminated from the host. In contrast, virulent strains of this fungus shed copious amounts of BAD1 during growth and through this process are able to avoid recognition by macrophages. Presentation of BAD1, whether it remains associated with the cell surface or shed into the milieu apart from the cell, is a key aspect of the pathogenicity of this fungus.

It also appears that the carbohydrate composition of the yeast cell wall plays a role in the presentation and shedding of BAD1 and thus in pathogenicity. One of the major components of the yeast cell wall is 1,3-α-glucan. There is an inverse relationship between the amount of 1,3-α-glucan present in the cell wall of *B. dermatitidis* and the amount of detectable BAD1 at the cell surface. Virulent strains of *B. dermatitidis* produce yeast cells that have thickened walls containing large amounts of 1,3-α-glucan and, when mature, have little detectable BAD1 on their cell surface. Conversely, avirulent strains exhibit thin walls that lack 1,3-α-glucan but have abundant BAD1 on their surface. It is speculated that the incorporation of 1,3-α-glucan into the cell wall masks the BAD1 surface glycoprotein and plays a role in releasing a modified antigen (85-kDa component) into the microenvironment of the infection site. By masking the BAD1 antigen, the yeast is able to escape recognition by macrophages and disseminate hematogenously.

Presentation of Surface Antigen Modulates the T-Helper Pathway of Immune Response

Different subsets of CD4 T-helper (TH) cells exist that secrete different patterns of cytokines in response to an antigenic stimulus. After an initial encounter with an antigen, TH cells may become polarized, secreting predominantly interleukin (IL)-2 and interferon (IFN)-γ (TH1 pattern) or predominantly IL-4, IL-5, and IL-10 (TH2 pattern). IFN-γ and IL-2 activate macrophages and cytotoxic T and natural killer (NK) cells, respectively, for clearance of intracellular organisms; whereas TH2 cytokines favor B-cell growth and differentiation, isotype switching to immunoglobulin (Ig) E, and eosinophil differentiation and activation, which are responses that may lead to protection against some pathogens, they also have been implicated in allergy and hypersensitivity reactions.

T-cell–mediated immune response to *B. dermatitidis* is essential for immunoprotection against this pathogen. Mice immunized with BAD1 (WI-1) develop a robust TH2 response to the antigen. Of note, in a mouse infection model of blastomycosis, infected mice that developed features of a TH2 response died with a chronic, progressive infection, whereas those infected animals that developed a TH1 response restricted the spread of the pathogen and were able to respond to antifungal therapy and recover from the disease. Thus a robust TH2 response may not be helpful in clearing *B. dermatitidis* infection and may even retard its clearance. By releasing large amounts of soluble BAD1, the yeast cells of *B. dermatitidis* may be able to outmaneuver both arms of the immune response by evasion of the cellular response and the stimulation of a dominant but ineffective humoral response.

COCCIDIOIDES IMMITIS

C. immitis and *C. posadasii* are primary pathogens capable of causing a wide range of disease states (see Chapter 64). These fungi are endemic to the desert southwest of the United States, and although they both demonstrate different morphologies in their saprobic and parasite phases, they are distinguished from the other endemic dimorphic fungi by the unique features of the parasitic phase (see Chapter 64, Fig. 64.1). Among the various putative virulence factors that may contribute to the pathogenicity of this organism are the resistance of the infective conidia to phagocytic killing, the ability to stimulate an ineffective TH2 immune response (similar to *B. dermatitidis*), the production of urease and extracellular proteinases, and the capacity for molecular mimicry (see Table 58.1).

Resistance of Conidia to Phagocytic Killing

The saprobic phase of *C. immitis* (and *C. posadasii*) consists of septate filamentous hyphae that when mature produce barrel-shaped arthroconidia separated from one another by empty disjunctor cells (see Chapter 57, Fig. 57.2B; Chapter 64, Figs. 64.1D and 64.7). The arthroconidia are very hydrophobic and easily aerosolized. These conidia are small enough (3 to 5 μm × 2 to 4 μm) that, when inhaled, they can be carried deep into the respiratory tract, frequently to the level of the alveoli. The outer wall of the conidia is composed primarily of protein (50%), including small cysteine-rich polypeptides known as **hydrophobins** because of their distinct hydropathic profiles. The remainder of the wall composition includes lipids (25%), carbohydrates (12%), and an unidentified pigment. It is thought that this hydrophobic outer layer has antiphagocytic properties because its removal resulted in increased phagocytosis of *C. immitis* arthroconidia by human polymorphonuclear neutrophils (PMNs), compared with their phagocytosis of intact arthroconidia. Of importance, neither the intact conidia nor the conidia with the outer wall layer removed were effectively killed after ingestion by PMNs. It appears that the infectious arthroconidia of *C. immitis* have both active and passive barriers against attack by the host's innate defenses in the lungs.

Stimulation of an Ineffective TH2 Immune Response by *C. immitis*

It is known that individuals with coccidioidal infections all produce antibody to a predominant glycoprotein (SOWgp) of an outer wall layer of the parasitic cells (spherules). Both arms of the T-helper immune pathway, TH1 and TH2, are stimulated by SOWgp. Activation of the TH1 pathway is known to be associated with spontaneous resolution of coccidioidal infection in mice. Furthermore, it has been shown that mice that are susceptible to infection with *C. immitis* show a TH2 response to infection, whereas resistant strains show more of a TH1 response. Thus similar to that described for *B. dermatitidis*, TH2 responses to SOWgp may not contribute to clearance of *C. immitis* and may even be detrimental in control of the infection. The more severe forms of coccidioidomycosis are accompanied by depressed cell-mediated immunity and high serum levels of *C. immitis*-specific complement fixing antibody, consistent with a predominantly TH2 response. Although not much is known of the cytokine profile of humans during coccidioidal infections, the IL-17, TNF-α, and INF-γ pathways are all important for control of infection. Thus it is reasonable to speculate that immunodominant antigens of *C. immitis* that elicit a profound increase in IL-10 and IL-4 may direct the immune response to a TH2 pathway. Such immunomodulation may contribute to increased severity of the mycotic infection. Patients with defects in their cellular immune response, either because of pharmacologic therapy or because of a gene mutation, appear to be at higher risk for symptomatic and/or severe coccidioidomycosis.

Urease Production

The environmental niche for the saprobic form of *C. immitis* is alkaline desert soil. Both saprobic and parasitic phases of this organism have been shown to release ammonia and ammonium ions when grown in vitro, resulting in an alkalinization of the culture medium. The endospores of *C. immitis* release much more ammonia/ammonium ions than do spherules, when grown in any acidic (pH 5.0) conditions. Newly released endospores have been shown to be surrounded by an alkaline halo produced by the ammonia/ammonium ions.

The endospores of *C. immitis* are readily phagocytosed by alveolar macrophages but once ingested are able to survive intracellularly. It has been shown that viable intracellular endospores are surrounded by an alkaline halo at their cell surface, suggesting that the production of ammonia/ammonium ions may contribute to the survival of the pathogen within the phagosome of the activated macrophage.

The ability of *C. immitis* to generate an alkaline microenvironment and to respond to acidification by increasing the amount of ammonia/ammonium ions released from its parasitic cells are features that may contribute to the pathogenesis of this fungus. Although the details of ammonia generation and how cell-surface alkalinity affects phagocyte function are poorly understood, it has been proposed that the major source of ammonia produced by *C. immitis* is caused by urease activity. Urease is a metalloenzyme that is localized in the cytoplasmic fraction of microbial cells; it catalyzes the hydrolysis of urea to yield ammonia and carbamate. The carbamate subsequently hydrolyzes to yield another molecule of ammonia. The maximum amount of urease protein detected in *C. immitis* is in endosporulating spherules, which correlates with the developmental stage, in which the highest amounts of ammonia/ammonium ion have been recorded. Together this information suggests that urease activity contributes to the pathogenicity of *C. immitis*.

Extracellular Proteinases

Fungal pathogens produce an array of acid, neutral, and alkaline proteinases that are active over a wide pH range and exhibit broad substrate specificity. It has been suggested that certain extracellular enzymes secreted by fungi may play key roles in invasive growth that may ultimately lead to the death of the infected host. Secreted proteinases may permit the ingress of skin and mucosal barriers, partial neutralization of active host defenses, transmigration of endothelial layers, and subsequent hematogenous dissemination, leading to the establishment of infection in various anatomic sites.

C. immitis, as a primary fungal pathogen, is able to breach the respiratory mucosal barrier, enter the bloodstream and/or the lymphatic system, and disseminate to other organs of the body. Both the saprobic (conidial cell) and parasitic forms of the fungus express several proteinases during cell growth. The conidial cell produces a 36-kDa extracellular proteinase capable of breaking down human collagen, elastin, and hemoglobin, as well as IgG and IgA. Cleavage of secretory immunoglobulins by opportunistic fungal pathogens has been correlated with the ability of these organisms to colonize the host mucosa. A 66-kDa alkaline proteinase capable of digesting structural proteins, found in lung tissue, is thought to be secreted during the entire course of disease caused by *C. immitis*. All patients with coccidioidomycosis produce antibodies directed against this enzyme, and it is thought that this alkaline proteinase may play an important role in host tissue colonization and invasion by spherules and endospores of *C. immitis*.

Molecular Mimicry

When molecules produced by a pathogenic microbe are structurally, antigenically, and functionally similar to host molecules, this characteristic is termed **molecular mimicry.** In some instances, infection may result in the generation of antibodies by the host that cross-react with host tissues and produce an autoimmune-type pathology. Fungi have been shown to produce molecules that are functionally, but not necessarily structurally, similar to host molecules ("functional mimicry"). Fungal molecules have been identified that function similar to integrins, complement receptors, and sex hormones.

An estrogen-binding protein has been isolated from cytosolic fractions of *C. immitis*. It is known that physiologic concentrations of progesterone and 17-β-estradiol stimulate the rate of *C. immitis* growth and endospore release. This information coincides with the recognition of pregnancy, especially during the third trimester, as a major risk factor for disseminated coccidioidomycosis.

HISTOPLASMA CAPSULATUM

It is well known that most people infected with *H. capsulatum* recover without complications and without specific antifungal therapy (see Chapter 64). Nevertheless, reactivation of pulmonary and extrapulmonary histoplasmosis in immunocompromised patients who originally experienced cryptic dissemination of the fungus is documented throughout the literature. Inhalation of conidia from the environment, coupled with failure to evacuate the fungus by mucociliary mechanisms, provides the opportunity for the inhaled conidia to transform into yeasts, which are ingested by mononuclear phagocytes. *H. capsulatum* is found almost exclusively within host cells, in which it may actively replicate or remain dormant.

Histoplasma capsulatum Resides in Host Macrophages

Conversion of inhaled conidia of *H. capsulatum* to yeast cells is critical for survival of the pathogen within the host and occurs within hours of infection. Although theoretically a single conidium may be sufficient to establish an infection, it is usually assumed that a very large conidial inoculum is necessary to establish disseminated disease in a healthy, immunocompetent individual. The phagocytes that are mobilized to the site of infection are effective in killing ingested conidia but are less so against the yeast form.

The fact that the macrophages are the primary host cells in which the yeast phase of *H. capsulatum* resides is thought to be an important strategy for survival and dissemination of the pathogen. *H. capsulatum* yeasts gain refuge from extracellular obstacles such as antimicrobial lung surfactant proteins by engaging the β-integrin family of phagocytic receptors to promote entry into macrophages. In addition, *H. capsulatum* yeasts conceal immunostimulatory β-glucans to avoid triggering signaling receptors such as the β-glucan receptor Dectin-1. *H. capsulatum* yeasts counteract phagocyte-produced reactive oxygen species by expression of oxidative stress defense enzymes including an extracellular superoxide dismutase and an extracellular catalase. There are several factors thought to be important in the ability of the fungus to persist within the phagolysosome of the macrophage and add significantly to the pathogenicity of the organism: pH modulation, iron and calcium uptake, and alteration of the yeast cell wall.

Modulation of the pH of the Phagolysosome

The yeast cells of *H. capsulatum* are rapidly ingested by alveolar macrophages. After ingestion, the pH of the phagolysosome containing one or more yeast cells is elevated (6.0 to 6.5) above that which is optimal for many of the lysosomal enzymes. This pH modulation not only interferes with enzyme activity but also influences antigen processing within the cell and contributes to the survival of the pathogen in vivo. Maintenance of this more neutral phagosomal pH has been shown to be essential for *H. capsulatum* infection of macrophages; however, the mechanisms behind this feature of *H. capsulatum* intracellular pathogenesis remain unknown. Although it is tempting to implicate *H. capsulatum* urease in this process, it is not considered to be a major factor because the pH is only elevated in the phagosome containing the yeast cell. If the fungal urease was involved, the ammonia/ammonium ions produced would be expected to diffuse out of the phagosome and raise the pH in the rest of the host cell as well.

Iron and Calcium Uptake

Iron is an important cofactor of several different metalloenzymes and heme-containing proteins. *H. capsulatum* yeasts have multiple strategies to acquire iron within host cells. The ability of the fungus to modulate the intraphagolysosomal pH between 6.0 and 6.5 is critical to the uptake of iron by yeast cells. A pH greater than 6.5 renders iron inaccessible to *H. capsulatum*. An important method by which *H. capsulatum* acquires limited iron intracellularly is by producing siderophores that chelate ferric iron and form soluble iron complexes. *H. capsulatum* yeast cells must use ferrous iron and thus express multiple iron-reducing systems and iron transporters. Mutants of *H. capsulatum* that are unable to make siderophores have reduced proliferation in cultured macrophages and decreased ability to establish a pulmonary infection. Discrepancies in siderophore production between different strains of *H. capsulatum* suggest that there may be alternative iron acquisition strategies that operate in addition to siderophore production.

As with iron, yeast cells within the phagolysosome must have an efficient mechanism for binding and transporting Ca^{2+}. Yeast cells, but not mycelial cells, release large amounts of a calcium-binding protein, CBP1, into the surrounding microenvironment. CBP1 has been suggested to be important in calcium acquisition during intracellular parasitism. The yeast phase–specific expression of CBP1 may provide *H. capsulatum* with another important adaptive mechanism for its survival within the phagolysosome of the macrophage.

Alteration of Yeast Cell Wall Composition

Similar to *B. dermatitidis*, most *H. capsulatum* strains have 1,3-α-glucan in their cell wall. Wild-type yeasts with 1,3-α-glucan can infect and survive within macrophages and can proliferate within the phagolysosome and ultimately kill the phagocyte, releasing yeast cells that go on to infect new macrophages. In contrast to the wild-type parent strain, spontaneous mutants of *H. capsulatum* that have lost the 1,3-α-glucan component have been shown to have significantly attenuated virulence and may infect and persist within macrophages without harm to the host cell. Functionally, α-glucan promotes *Histoplasma* virulence by preventing recognition of yeast by host immune cells. The α-glucan polysaccharide forms the outermost surface of the yeast cell wall, effectively concealing cell wall β-glucans that would normally be detected by Dectin-1 receptors on host macrophages. Dectin-1 is the primary receptor for the detection of fungal β-glucans, inducing an inflammatory response that may include increased production of reactive oxygen species and release of proinflammatory cytokines. Notably, certain North American strains of *H. capsulatum* naturally lack α-glucan; they show variable recognition by Dectin-1 yet remain virulent. The molecular mechanism by which these strains have circumvented the need for α-glucan remains unknown. Thus it appears that distinctive microenvironments found within host cells can influence the selection of variants that have the potential for long-term persistence within the host, as well as those that produce a more rapidly proliferative process.

PARACOCCIDIOIDES BRASILIENSIS

Infection caused by *P. brasiliensis* is initiated by the inhalation of conidia into the lungs, after which the fungus may disseminate hematogenously or lymphatically to virtually all parts of the body (see Chapter 64). A unique feature of paracoccidioidomycosis, compared with the other endemic mycoses, is that primary pulmonary infections that subsequently disseminate most often manifest as mucosal lesions of the mouth, nose, and occasionally the gastrointestinal tract.

The yeast cell wall of *P. brasiliensis* is rich in alkali-soluble glucans such as 1,3-α-glucan. As with several other of the endemic dimorphic fungal pathogens, it is thought that the presence of 1,3-α-glucan in the outermost layer of the yeast cell wall is essential for the survival of the fungus in vivo. It appears that macrophages are key elements of the innate response to infection by *P. brasiliensis*. Macrophages are able to contain *P. brasiliensis* infection but usually do not eliminate the yeast cells. Despite an early clinical resolution of infection, residual lesions containing viable yeast cells may reactivate up to 40 years later, causing relapse and serious sequelae. Characteristics of *P. brasiliensis* that are considered important in the pathogenesis of infection include response to hormonal factors, expression of 1,3-α-glucan, and immune responses to an immunodominant antigen, gp43.

Hormonal Influences on Infection

Although skin test reactivity to paracoccidioidin is comparable among both males and females living in areas endemic for paracoccidioidomycosis, the male/female ratio of symptomatic disease is ~11:1. Subclinical infection appears to occur at the same rate in both genders; however, progression to clinically overt disseminated disease is much more frequent in males. This observation has led to the hypothesis that hormonal factors play a very important role in the pathogenesis of paracoccidioidomycosis.

In contrast to *C. immitis*, in which estrogen stimulates fungal growth and endosporulation, the transition from conidia to the yeast form of *P. brasiliensis* is inhibited by estrogen. This results in rapid clearance of the infection in females, whereas the infection is allowed to progress in males. An alternative explanation is that male sex hormones have an immunoinhibitory effect that facilitates the establishment of infection. This remains an area of active investigation. Regardless, it appears that the early events of host–fungal interaction after natural infection are hormonally modulated and therefore are significantly different in males and females. These differences could account for the markedly higher susceptibility of males to paracoccidioidomycosis.

Role of Cell Wall Glucans in the Pathogenesis of *Paracoccidioides brasiliensis*

The cell wall of *P. brasiliensis* contains four main polysaccharides: galactomannan, 1,3-α-glucan, 1,3-β-glucan, and chitin. The 1,3-α-glucan component is only expressed in the yeast form of the organism, and its expression correlates with virulence. Mutant strains of *P. brasiliensis* that lack this glucan are avirulent and are much more susceptible to digestion by neutrophils.

The 1,3-β-glucan fraction of the cell wall acts as an important immunomodulator and, when exposed on the fungal cell wall, elicits an intense inflammatory response. β-Glucans are unmasked when levels of 1,3-α-glucan are reduced, leading to the hypothesis that the ratio of 1,3-α-glucan to 1,3-β-glucan in the cell wall of *P. brasiliensis* may be more important in pathogenesis than the individual polysaccharide components. It is important to realize that the relationship between the α-/β-glucan ratio in the *P. brasiliensis* cell wall and the type of immune response are similar to those seen in both histoplasmosis and blastomycosis. In each case, a high 1,3-α-glucan content of the yeast cell is related to increased virulence, and absent or decreased levels of this component is related to reduced virulence. Alteration in the cell wall composition of the yeast cells of all three of these dimorphic pathogens is also related to their ability to become sequestered within cells and tissues and to persist as viable elements for years after infection.

Responses to an Immunodominant Antigen, gp43

The yeast phase of *P. brasiliensis* secretes an immunodominant 43-kDa glycoprotein (gp43) that is both an important serodiagnostic antigen and a putative virulence factor. The gp43 antigen is a receptor for laminin-1 and may be

responsible for adhesion of the yeast cell to the host basement membrane. This antigen also binds to macrophages and elicits both a strong humoral response and a delayed-type hypersensitivity (DTH) response in humans.

The immunologic defense against infection with *P. brasiliensis* depends on cellular rather than humoral immunity. An impaired DTH response correlates with increased severity of disease. Mice immunized with gp43 develop both a TH1- and TH2-type immune response, whereas gp43 and a second antigen, gp70, are major contributors to a humoral response in humans. It is possible that patient immune reactivity to gp43 and gp70 is dominated by a TH2 pathway with inadequate T-cell response. If patient cell-mediated immunity to *P. brasiliensis* is actually compromised by such T-cell hyporesponsiveness, this could be a mechanism (as seen in histoplasmosis and coccidioidomycosis) underlying the immunopathogenesis of paracoccidioidomycosis.

Opportunistic Pathogens

The state of the host is of primary importance in determining the pathogenicity of opportunistic fungal pathogens, such as *Candida* spp., *C. neoformans*, and *Aspergillus* spp. In most instances, these organisms may exist as benign colonizers or as environmental saprobes and only cause serious infection when there is a breakdown of host defenses. There are factors associated with these organisms, however, that may be considered "virulence factors," in that they contribute to the disease process and in some instances may explain the differences in pathogenicity of the various organisms.

CANDIDA SPECIES

Candida spp. are the most common of the opportunistic fungal pathogens (see Chapter 65). It is now well established that *Candida* spp. colonize the gastrointestinal mucosa and reach the bloodstream through gastrointestinal translocation or via contaminated vascular catheters, interact with host defenses, and exit the intravascular compartment to invade deep tissues of target organs, such as the liver, spleen, kidneys, heart, and brain. Characteristics of the organism that are thought to contribute to pathogenicity include the ability to adhere to tissues, the ability to exhibit yeast-hyphal dimorphism, cell-surface hydrophobicity, proteinase secretion, and phenotypic switching (see Table 58.1).

The ability of *Candida* spp. to adhere to a variety of tissues and inanimate surfaces is considered important in the early stages of infection. The adherence capability of the various species of *Candida* is directly related to their virulence ranking in various experimental models. Adherence is achieved by a combination of specific (ligand-receptor interaction) and nonspecific (electrostatic, van der Waals forces) mechanisms.

The ability to undergo the yeast-to-hypha transformation has long been considered to have some importance in pathogenicity. Most species of *Candida* are capable of such transformation, which has been shown to be regulated by both pH and temperature. The yeast-hyphal transformation is one way for *Candida* spp. to respond to changes in the microenvironment. The hyphae of *Candida albicans* exhibit **thigmotropism** (a sense of touch), which allows them to grow along grooves and through pores and may aid in infiltration of epithelial surfaces.

The composition of the cell surface of *Candida* spp. may affect both the hydrophobicity of the cell and the immune response to the cell. The type and degree of glycosylation of the mannoproteins on the cell surface may affect the hydrophobicity of the cell and therefore adhesion to epithelial cells. The germ tubes of *C. albicans* are hydrophobic, whereas the buds or blastoconidia are hydrophilic. The various glycoproteins of *C. albicans* also suppress the immune response to the organism by mechanisms that are not well understood.

As discussed with the primary pathogens, the ability of *Candida* spp. to secrete various enzymes may also influence the pathogenicity of the organism. Several species of *Candida* secrete aspartyl proteinases that hydrolyze host proteins involved in defenses against infection, allowing the yeasts to breach connective tissue barriers. Likewise, phospholipases are produced by most species of *Candida* causing infection in humans. These enzymes damage host cells and are considered important in tissue invasion.

The ability of *Candida* spp. to rapidly switch from one morphotype to another has been termed **phenotypic switching.** Although originally applied to changes in gross colony morphology, it is now known that the different switch phenotypes observed on solid culture media represent differences in bud and hypha formation, expression of cell wall glycoproteins, proteolytic enzyme secretion, susceptibility to oxidative damage by neutrophils, and antifungal susceptibility and resistance. Phenotypic switching contributes to the virulence of *Candida* spp. by allowing the organism to rapidly adapt to changes in its microenvironment, facilitating its ability to survive, invade tissues, and escape from host defenses.

CRYPTOCOCCUS NEOFORMANS

C. neoformans is an encapsulated yeast that causes human infection throughout the world. Although this organism can infect apparently normal hosts, it causes disease much more frequently and with greater severity in immunocompromised hosts. In considering the pathogenesis of cryptococcosis, it is useful to consider both host defenses and putative virulence factors.

There are three main lines of defense against infection by *C. neoformans*: alveolar macrophages, inflammatory phagocytic cells, and T-cell and B-cell responses. Development of cryptococcosis largely depends on the competence of the host's cellular defenses and the number and virulence of the inhaled yeast cells.

The first line of defense is the alveolar macrophages. These cells are capable of ingesting the yeast cells but are limited in their ability to kill them. Macrophages that contain ingested yeast cells produce various cytokines for the recruitment of neutrophils, monocytes, NK cells, and cells from the bloodstream into the lung. They also act as antigen-presenting cells and induce the differentiation and proliferation of T and B lymphocytes that are specific for *C. neoformans*. The recruited cells are effective in killing *C. neoformans* by intracellular and extracellular mechanisms (both oxidative and nonoxidative).

The antibody response to this organism is nonprotective but serves to opsonize the yeast cells, enhancing cell-mediated cytotoxicity. Likewise, the complement system enhances the efficacy of the antibody response and provides opsonins and chemotactic factors for phagocytosis and recruitment of inflammatory cells.

An effective host response to *C. neoformans* is a complex interaction of cellular and humoral immune factors. When these factors are impaired, the infection disseminates, usually by migration of macrophages containing viable yeast cells, from the lung to the lymphatics and the bloodstream to the brain.

The main factors that are inherent in *C. neoformans* and that allow the yeast to evade the host defenses and establish infection include the ability to grow at 37° C, to produce a thick polysaccharide capsule, to synthesize melanin, and to be an alpha-mating phenotype (MATalpha) (see Table 58.1).

The capsule of *C. neoformans* protects the cell from phagocytosis and from cytokines induced by the phagocytic process; it also suppresses both cellular and humoral immunity. The capsule can physically block the opsonic effect of complement and anticryptococcal antibodies, and the negative charge that it confers produces an electrostatic repulsion between the yeast cells and the host effector cells. Furthermore, the capsular material interferes with antigen presentation and limits the production of nitric oxide (toxic for cryptococcal cells) by the host cells.

Melanin is produced by the fungus by virtue of a membrane-bound phenoloxidase enzyme and is deposited within the cell wall. It is thought that melanin enhances the integrity of the cell wall and increases the net negative charge of the cell, further protecting it from phagocytosis. Melanization is thought to be responsible for the neurotropism of *C. neoformans* and may protect the cell from oxidative stress, temperature extremes, iron reduction, and microbicidal peptides.

The alpha-mating phenotype is associated with the presence of the gene ***STE12alpha*,** which has been proven to modulate the expression of several other genes whose functions are important for the production of the capsule and melanin.

ASPERGILLUS SPECIES

Aspergillosis is the most common invasive mold infection worldwide. Aspergilli are ubiquitous saprobes in nature and may be found in soil, potted plants, decaying vegetation, pepper, and construction sites. *Aspergillus* spp. can cause disease in humans by airway colonization with subsequent allergic reactions, colonization of preexisting cavities (aspergilloma), or by tissue invasion.

The primary route of infection in aspergillosis is by inhalation of aerosolized conidia (2.5 to 3 μm), which settle in lungs, nasopharynx, or sinuses. In the lungs, alveolar macrophages and neutrophils play a major role in the host defense against *Aspergillus* spp. The macrophages ingest and kill the conidia, whereas the neutrophils adhere to and kill the hyphae that arise on germination of the conidia. Those hyphal forms that are not killed may invade the pulmonary tissue and vasculature, leading to thrombosis and local tissue necrosis and to hematogenous dissemination to other target organs (brain).

Aspergilli secrete various metabolic products, such as gliotoxins, and a variety of enzymes, including elastase, phospholipase, various proteases, and catalase, which may play a role in virulence. Gliotoxin inhibits macrophage phagocytosis, as well as T-cell activation and proliferation; however, it is not known whether clinically significant amounts of gliotoxin are produced in human disease.

Aspergillus fumigatus conidia bind to human fibrinogen and to laminin in the alveolar basement membrane. It is thought that this could be an important first step that allows the fungus to establish residence in host tissues. Binding to fibrinogen and laminin could facilitate adherence of conidia, whereas secretion of elastase and acid proteases could assist with host cell invasion by the hyphae.

Invasive aspergillosis is highly associated with neutropenia and impaired neutrophil function. *Aspergillus* conidia are resistant to killing by neutrophils, but germinating conidia and hyphae are readily killed. In chronic granulomatous disease, neutrophils are unable to generate the respiratory burst to kill catalase-producing microorganisms. Aspergilli produce catalase, which is an enzyme that breaks down hydrogen peroxide. The strong association of aspergillosis with chronic granulomatous disease underscores the importance of neutrophil function in the host defense against aspergillosis and provides indirect evidence for catalase as a virulence factor. The increased risk of aspergillosis in individuals receiving high doses of corticosteroids is generally thought to be caused by impairment of macrophage and perhaps T-cell function. In addition, corticosteroids have been shown to enhance the growth of *Aspergillus* spp. in culture. It is not known whether *Aspergillus* spp. have specific steroid-binding proteins analogous to those that have been found on other fungi.

MYCOTOXINS

There are more than 100 toxigenic fungi and more than 300 compounds now recognized as mycotoxins. The number of people affected by mycotoxicoses, however, is unknown. The majority of mycotoxicoses result from eating contaminated foods. The occurrence of mycotoxins in foods is most commonly caused by preharvest contamination of the material by toxigenic fungi that are plant pathogens. In addition, stored grains may be damaged by insects or moisture, providing a portal of entry for toxigenic fungi present in the storage environment. Mycotoxicoses are more common in resource-poor countries in which methods of food handling and storage are inadequate, malnutrition is prevalent, and there are few regulations designed to protect exposed populations.

Some mycotoxins are dermonecrotic, and cutaneous or mucosal contact with mold-infected substrates may result in disease. Likewise, inhalation of spore-borne toxins also constitutes an important form of exposure. Aside from supportive therapy, there are almost no treatments for mycotoxin exposure. Fortunately, mycotoxicoses are not communicable from person to person.

Among fungal plant pathogens, the elaboration of mycotoxins plays a role in causing or exacerbating the plant disease. Although mycotoxins may be poisonous to humans, and some may have potent immunosuppressive properties, there is very little evidence that mycotoxins enhance the ability of the

TABLE 58.2 Mycotoxin-Related Illnesses Postulated to Affect Humans, Based on Analytic or Epidemiologic Data

Disease	Toxin	Substrate	Fungus	Clinical Presentation
Akakabi-byo (red mold disease)	*Fusarium* metabolites	Wheat, barley, oats, rice	*Fusarium* spp.	Headaches, vomiting, diarrhea
ATA	Trichothecenes (T-2 toxin, DAS)	Cereal grains (toxic bread)	*Fusarium* spp.	Vomiting, diarrhea, angina, skin inflammation
BEN	Ochratoxin	Cereal grains	*Aspergillus* spp. *Penicillium* spp.	Chronic nephritis
Cardiac beriberi	Citreoviridin	Rice	*Penicillium* spp.	Palpitations, vomiting, mania, respiratory failure
Ergotism (gangrenous and convulsive)	Ergot alkaloids	Rye, cereal grains	*Claviceps purpurea* *Claviceps fusiformis*	Gangrenous: vasoconstriction, edema, pruritus, necrosis of extremities Convulsive: numbness, tingling, pruritus, cramps, seizures, hallucinations
Esophageal cancer	Fumonisins	Corn	*Fusarium moniliforme*	Dysphagia, pain, hemorrhage
Hepatitis and hepatic cancer	Aflatoxins	Cereal grains, peanuts	*Aspergillus flavus* *A. parasiticus*	Acute and chronic hepatitis, liver failure
Kodua poisoning	Cyclopiazonic acid	Millet	*Penicillium* spp. *Aspergillus* spp.	Somnolence, tremors, giddiness
Moldy sugarcane poisoning	3-Nitropropionic acid	Sugarcane	*Arthrinium* spp.	Dystonia, seizures, carpopedal spasms, coma
Onyalai disease	*Fusarium* metabolites	Millet	*Fusarium* spp.	Thrombocytopenia, purpura
Stachybotryotoxicosis	Trichothecenes (T-2 toxin, DAS)	Hay, cereal grains, fodder (skin contact, inhaled hay dust)	*Stachybotrys, Fusarium, Myrothecium, Trichoderma, Cephalosporium* spp.	Tremors, loss of vision, dermonecrosis, gastrointestinal bleeding (horses and cattle), nasal inflammation, dermatitis, headache, fatigue, respiratory symptoms (humans), idiopathic pulmonary hemorrhage of infants (?)
Yellow rice disease	Citrinin	Wheat, oats, barley, rice	*Penicillium* spp. *Aspergillus* spp.	Nephropathy

ATA, Alimentary toxic aleukia; *BEN,* Balkan endemic nephropathy; *DAS,* diacetoxyscirpenol.
Data from Kuhn, D.M., Ghannoum, M.A., 2003. Indoor mold, toxigenic fungi, and *Stachybotrys chartarum*: infectious disease perspective. Clinical Microbiology Reviews 16, 144–172; Smith, M., McGinnis, M.R., 2009. Mycotoxins and their effect on humans. In: Anaissie, E.J., McGinnis, M.R., Pfaller, M.A. (Eds.), Clinical Mycology, second ed. Churchill Livingstone, New York; Bennett, J.W., Klich, M., 2003. Mycotoxins. Clinical Microbiology Reviews 16, 497–516.

fungus to grow and cause disease in vertebrate hosts. Those fungi, such as *Aspergillus fumigatus*, which are both important opportunistic pathogens and are capable of producing gliotoxins (inhibitors of T-cell activation and proliferation), generally do not produce the toxin in significant amounts during the course of human disease to have an effect on the disease process. Whereas an opportunistic fungus must be able to grow at human body temperature (37° C) to cause disease, the optimum temperature for biosynthesis of most mycotoxins is much lower (20° C to 30° C). For these and other reasons, the importance of mycotoxin exposure during the course of a mycotic infection with a toxigenic fungus is largely unknown. A listing of mycotoxicoses in which there is considerable evidence for the involvement of a specific mycotoxin is provided in Table 58.2. It should be noted that this list is meant to be representative and not all-inclusive.

Questions

1. What distinguishes a primary pathogen from an opportunistic pathogen?
2. What are the common themes seen in the pathogenesis of the primary fungal pathogens?
3. What is the most important line of defense against the endemic dimorphic fungi?
4. What putative virulence factor is common to both the primary and opportunistic fungal pathogens discussed in this chapter?

59 Role of Fungi in Disease

A summary of fungi (yeasts and molds) most commonly associated with human disease is presented in this chapter. Mycotic diseases in humans develop as pathogenic processes in one or more organ systems. The affected systems may be as superficial as the outer layers of the skin or as deep as the heart, central nervous system, or abdominal viscera. Although a single fungus may be associated with infection involving a single organ system (e.g., *Cryptococcus neoformans* and the central nervous system), more often several different organisms may produce a similar disease syndrome. Because the management of a given infection may differ according to the etiologic agent, to guide subsequent diagnostic and therapeutic efforts it is useful to develop a differential diagnosis that includes the most likely fungal pathogens.

Because the development of a fungal infection depends on factors that often outweigh the virulence potential of the infecting organism, one must take into account numerous factors, such as the immune status of the host, the opportunity for interaction between host and fungus (e.g., Is the fungus **endogenous** to the patient or **exogenous?**), and the potential infectious dose (e.g., in the case of an endemic dimorphic fungus) in determining the possibility of a fungal infection, the significance of the microbiologic data (e.g., culture results), and the necessity to treat and with what agent. Fungal infections often occur in very sick patients, and it is not possible to summarize here the incredibly complex interactions that ultimately lead to the establishment of infection and disease in each organ system. Instead, this chapter provides a very broad listing of the various fungi commonly associated with infections at specific body sites and/or specific clinical manifestations (Table 59.1). This information is meant to be used in conjunction with that in Chapter 60, Table 60.1, as an aid in establishing a differential diagnosis and for the selection of the most likely clinical specimens that will help establish a specific etiologic diagnosis. Other factors that may be important in determining the relative frequency with which specific fungi cause disease (e.g., age, comorbidities, host immunity, epidemiologic exposures and risk factors) are covered in the individual chapters in this text or in the more comprehensive infectious disease texts cited in this and other chapters.

TABLE 59.1 Summary of Fungi Associated with Human Disease

System Affected	Pathogens
UPPER RESPIRATORY INFECTIONS	
Oropharyngeal	*Candida* spp., *Cryptococcus neoformans, Histoplasma capsulatum, Blastomyces dermatitidis, Paracoccidioides brasiliensis, Talaromyces (Penicillium) marneffei, Geotrichum candidum*
Sinusitis	*Aspergillus* spp., Mucormycetes, *Fusarium* spp., dematiaceous molds (e.g., *Alternaria, Bipolaris, Exophiala* spp.)
Laryngeal	*Histoplasma capsulatum, Sporothrix schenckii, Blastomyces dermatitidis*
Esophageal	*Candida* spp.
EAR INFECTIONS	
External otitis	*Aspergillus niger, Candida* spp.
EYE INFECTIONS	
Endophthalmitis	*Candida* spp., *Aspergillus* spp., *Blastomyces dermatitidis, Coccidioides immitis/posadasii, Fusarium* spp., *Histoplasma capsulatum, Cryptococcus neoformans*
Keratitis	*Candida* spp., *Fusarium* spp., dematiaceous molds, *Scedosporium* spp., *Purpureocillium lilacinum*
Sinoorbital	Mucormycetes, *Aspergillus* spp., dematiaceous molds
Dacryocystitis and canaliculitis	*Candida albicans, Aspergillus niger*
PLEUROPULMONARY AND BRONCHIAL INFECTIONS	
Bronchitis	*Aspergillus* spp., *Cryptococcus neoformans*
Pneumonia	*Aspergillus* spp., Mucormycetes, *Fusarium* spp., *Scedosporium apiospermum, Trichosporon* spp., dematiaceous molds, *Cryptococcus neoformans/gattii, Histoplasma capsulatum, Blastomyces dermatitidis, Coccidioides immitis/posadasii, Paracoccidioides brasiliensis, Talaromyces (Penicillium) marneffei, Pneumocystis jirovecii, Candida* spp. (rare)
Fungus ball	*Aspergillus* spp., Mucormycetes, *Scedosporium apiospermum, Fusarium* spp., *Candida* spp.

TABLE 59.1 Summary of Fungi Associated with Human Disease—cont'd

System Affected	Pathogens
Empyema	*Aspergillus* spp., Mucormycetes, *Scedosporium apiospermum, Fusarium* spp., *Candida* spp., *Coccidioides immitis/posadasii*
GENITOURINARY TRACT INFECTIONS	
Vulvovaginal	*Candida* spp., *Saccharomyces cerevisiae*
Cystitis and pyelonephritis	*Candida* spp. (most common), *Cryptococcus neoformans, Aspergillus* spp., *Coccidioides immitis/posadasii, Histoplasma capsulatum, Blastomyces dermatitidis* (rare), *Trichosporon* spp. (rare), *Saprochaete capitata* (formerly *Blastoschizomyces capitatus* [rare]), *Rhodotorula* spp. (rare)
Epididymitis and orchitis	*Candida* spp., *Cryptococcus neoformans, Aspergillus* spp., *Coccidioides immitis/posadasii, Histoplasma capsulatum, Blastomyces dermatitidis* (all rare)
Prostatitis	*Candida* spp. (common), *Cryptococcus neoformans* (common), *Blastomyces dermatitidis* (common), *Histoplasma capsulatum, Aspergillus* spp. (rare), *Coccidioides immitis/posadasii* (rare)
INTRAABDOMINAL INFECTIONS	
Peritonitis	*Candida* spp., *Rhodotorula* spp., *Trichosporon* spp., *Aspergillus* spp. (rare)
Visceral abscesses	*Candida* spp., *Trichosporon* spp., *Saprochaete capitata* (formerly *Blastoschizomyces capitatus*)
CARDIOVASCULAR INFECTIONS	
Endocarditis	*Candida* spp., *Trichosporon* spp., *Rhodotorula* spp., *Aspergillus* spp., other hyaline hyphomycetes (e.g., *Fusarium, Sarocladium* [*Acremonium*]), dematiaceous molds
Pericarditis	*Candida* spp., *Aspergillus* spp., *Histoplasma capsulatum, Coccidioides immitis/posadasii*
CENTRAL NERVOUS SYSTEM	
Meningitis	*Candida* spp., *Cryptococcus neoformans/gattii, Aspergillus* spp., Mucormycetes (rare), *Coccidioides immitis/posadasii, Histoplasma capsulatum, Blastomyces dermatitidis* (rare), *Rhodotorula* spp., *Saprochaete capitata* (formerly *Blastoschizomyces capitatus*), *Talaromyces (Penicillium) marneffei*
Brain abscess	*Candida* spp., *Cryptococcus neoformans/gattii, Aspergillus* spp., Mucormycetes, *Scedosporium apiospermum, Trichosporon* spp., *Trichoderma* spp., dematiaceous molds (especially *Cladophialophora bantiana* and *Curvularia* [*Bipolaris*] *hawaiiensis*), endemic dimorphic fungi (rare)
SKIN AND SOFT-TISSUE INFECTIONS	
Superficial and cutaneous	Dermatophytes, *Candida* spp., *Neoscytalidium* spp., *Scopulariopsis* spp., *Aspergillus* spp., *Malassezia* spp., *Purpureocillium lilacinum*
Subcutaneous	Dematiaceous molds, *Fusarium* spp., *Acremonium* spp., *Scedosporium apiospermum, Sporothrix schenckii, Basidiobolus* sp., *Conidiobolus* sp.
Wounds (surgical or traumatic)	*Candida* spp., Mucormycetes, *Aspergillus* spp., *Fusarium* spp., *Trichosporon* spp., *Rhodotorula* spp., *Lomentospora* (*Scedosporium*) *prolificans*
Cutaneous nodules (hematogenous)	*Candida* spp., *Aspergillus* spp., Mucormycetes, *Cryptococcus neoformans, Trichosporon* spp., *Blastomyces dermatitidis, Coccidioides immitis/posadasii, Talaromyces (Penicillium) marneffei, Fusarium* spp., *Acremonium* spp., dematiaceous molds (rare), *Histoplasma capsulatum* var. *duboisii*
BONE AND JOINT INFECTIONS	
Osteomyelitis	*Blastomyces dermatitidis, Coccidioides immitis/posadasii, Candida* spp., *Cryptococcus neoformans, Aspergillus* spp., Mucormycetes, dematiaceous molds (mycetoma), other hyaline hyphomycetes (e.g., *Trichosporon*), *Histoplasma capsulatum* var. *duboisii*
Arthritis	*Coccidioides immitis/posadasii, Blastomyces dermatitidis, Cryptococcus neoformans, Candida* spp., *Aspergillus* spp., dematiaceous molds (mycetoma; rare), *Histoplasma capsulatum* (rare), *Paracoccidioides brasiliensis* (rare), *Sporothrix schenckii* (rare)
OTHER INFECTIONS	
Prosthetic joint	*Candida* spp., all others very rare
Hematogenous dissemination	*Candida* spp., *Histoplasma capsulatum, Blastomyces dermatitidis, Coccidioides immitis/posadasii, Cryptococcus neoformans/gattii, Paracoccidioides brasiliensis, Sporothrix schenckii, Aspergillus* spp., *Fusarium* spp., *Trichosporon* spp., *Malassezia* spp., *Saprochaete capitata* (formerly *Blastoschizomyces capitatus*), *Talaromyces (Penicillium) marneffei,* others (e.g., *Rhodotorula, Acremonium, Saccharomyces* spp. in neutropenic or transplant patients)

60 Laboratory Diagnosis of Fungal Disease

The spectrum of mycotic disease ranges from superficial cutaneous and mucosal infections that may be locally irritating to highly invasive processes associated with classic systemic and opportunistic pathogens. Serious infections are reported with an ever-increasing array of pathogens, including well-known pathogenic fungi, such as *Candida*, *Cryptococcus neoformans*, *Histoplasma capsulatum*, and *Aspergillus*, as well as lesser known hyaline and dematiaceous molds (see Chapter 57, Tables 57.1 and 57.2). Modern medical mycology has become the study of mycoses caused by a variety of taxonomically diverse fungi.

Opportunistic mycoses pose a significant diagnostic challenge to clinicians and mycologists alike because of the complexity of the patient population at risk and the increasing array of fungi that may infect these individuals. Successful diagnosis and treatment of mycotic infections in the compromised patient is highly dependent on a team approach involving clinicians, medical mycologists, and pathologists.

This chapter provides a general description of the principles of specimen collection and processing necessary for the diagnosis of most fungal infections. An overview of direct microscopy, culture, immunologic, and molecular diagnostic testing also is provided. Specific details of these and other procedures used in the diagnosis of fungal infections may be found in several reference texts listed in the Bibliography.

Clinical Recognition of Fungal Infections

Prompt diagnosis of invasive mycoses requires a high index of suspicion and an appreciation of specific risk factors that may predispose a patient to such infections. Clinical suspicion; thorough history and physical examination, including a search for cutaneous and mucosal lesions; inspection of all implanted devices (catheters, etc.); a careful ophthalmologic examination; diagnostic imaging studies; and, finally, procurement of appropriate specimens for laboratory diagnosis are all essential steps that must be taken to optimize the diagnosis and treatment of fungal infections. Unfortunately, although specific fungi may be associated with "classic" case scenarios, such as onychomycosis and lower extremity skin lesions caused by *Fusarium* in a patient with neutropenia or sinus infection caused by *Rhizopus* in a diabetic patient with ketoacidosis, clinical signs and symptoms are not specific for fungal infections and are often not helpful in distinguishing between bacterial and fungal infections in a patient at risk for both types of infection. Increasingly, it is also important to know not only that the patient is infected with a fungus but what the fungus is to provide the best treatment and clinical support. Thus diagnosis of fungal infections depends on three basic laboratory approaches: (1) microbiologic, (2) immunologic, and (3) histopathologic (Box 60.1). These approaches may be supplemented by molecular and biochemical methods of organism detection and identification. Use of the newer methods for detection of fungal antigens and nucleic acids offers great promise for rapid diagnosis of fungal infections.

Conventional Laboratory Diagnosis

SPECIMEN COLLECTION AND PROCESSING

As with all types of infectious processes, the laboratory diagnosis of fungal infection is directly dependent on the proper

BOX 60.1 Laboratory Methods for Diagnosing Fungal Disease

collection of appropriate clinical material and prompt delivery of the specimens to the clinical laboratory. Selection of specimens for culture and microscopic examination is based not only on information obtained from clinical examination and radiographic studies but also on consideration of the most likely fungal pathogen that may cause a specific type of infection (Table 60.1). Specimens should be collected aseptically or after proper cleaning and decontamination of the site to be sampled. An adequate amount of clinical material must be submitted promptly for culture and microscopy. Unfortunately, many specimens submitted to the laboratory are of poor quality and insufficient amount and are not appropriate to make a diagnosis. Specimens should be submitted whenever possible in a sterile leak-proof container and be accompanied by a relevant clinical history. The laboratory depends on clinical information in making decisions as to the best way to process the specimen to ensure recovery of the etiologic agent. The clinical history also is useful in interpreting

Table 60.1 Body Sites, Specimen Collection, and Diagnostic Procedures for Selected Fungal Infections

Infection Site and Infecting Organism	Specimen Options	Collection Methods	Diagnostic Procedure
BLOOD			
Candida, Cryptococcus neoformans, Histoplasma capsulatum, Fusarium, Aspergillus terreus, Talaromyces marneffei, Trichosporon	Whole blood	Venipuncture (sterile)	Culture, broth, culture, lysis-centrifugation, nucleic acid amplification
	Serum	Venipuncture (sterile)	Antigen (*Aspergillus, Candida, Cryptococcus,* and *Histoplasma*), nucleic acid amplification β-D-glucan
	Urine	Sterile	Antigen (*Histoplasma*)
BONE MARROW			
Histoplasma capsulatum, Talaromyces marneffei	Aspirate	Sterile	Microscopic examination, culture
	Serum	Venipuncture (sterile)	Serology, (*Histoplasma*) antigen, antibody
	Urine	Sterile	Antigen (*Histoplasma*)
CENTRAL NERVOUS SYSTEM			
Candida, Cryptococcus neoformans/gattii, Aspergillus, Scedosporium, dematiaceous molds, Mucormycetes, *Histoplasma, Coccidioides*	Spinal fluid	Sterile	Microscopic examination, culture, antigen (*Cryptococcus*)
	Biopsy	Sterile, nonsterile to histopathology	Microscopic examination, culture (do not grind tissue)
	Serum	Sterile	Antigen (*Aspergillus, Cryptococcus,* and *Histoplasma*)
BONE AND JOINT

	Urine	Sterile	Antigen (*Histoplasma*)
	Biopsy	Sterile, nonsterile to histopathology	Microscopic examination, culture (do not grind tissue)

KOH, Potassium hydroxide.

the results of culture and other laboratory testing, especially when dealing with specimens from nonsterile sites such as sputum and skin. Furthermore, clinical information alerts the laboratory personnel that they may be dealing with a potentially dangerous pathogen, such as *Coccidioides immitis/posadasii* or *H. capsulatum*.

Transportation of specimens to the laboratory should be prompt; however, delayed processing of specimens for fungal culture may not be as detrimental as with specimens for bacteriologic, virologic, or parasitologic examination. In general, if processing is delayed, the specimens for fungal culture may be stored at 4° C for a short time without loss of organism viability.

Similar to specimens for bacteriologic examination, there are some specimens that are better than others for the diagnosis of fungal infections (see Table 60.1). Cultures of blood and other normally sterile body fluids should be done if clinical indications suggest a hematogenous process or involvement of a closed space such as the central nervous system. Skin lesions should be biopsied and material sent for both histopathologic examination and culture. Oral and vaginal mucosal infections are generally best diagnosed by clinical presentation and direct microscopic examination of secretions or mucosal scrapings because cultures often yield growth that represents normal flora or even contaminants. Similarly, diagnosis of gastrointestinal fungal infections is best made by biopsy and histopathologic examination rather than by culture. Twenty-four–hour collections of sputum or urine are not appropriate for mycologic examination because they typically become overgrown with both bacterial and fungal contaminants.

Table 60.2 Selected Methods and Stains Commonly Used for Direct Microscopic Detection of Fungal Elements in Clinical Specimens

Method/Stain	Use	Comments
Calcofluor white stain	Detection of all fungi, including *Pneumocystis jirovecii*	Rapid (1-2 min); detects fungal cell wall chitin by bright fluorescence Used in combination with potassium hydroxide Requires fluorescent microscope with proper filters Background fluorescence may make examination of some specimens difficult
Fluorescent monoclonal antibody treatment	Examination of respiratory specimen for *P. jirovecii*	Sensitive and specific method for detecting the cysts of *P. jirovecii* Does not stain the extracystic (trophic) forms
Giemsa stain	Examination of bone marrow, peripheral blood smears, touch preparations of tissue, and respiratory specimens	Detect intracellular *Histoplasma capsulatum* and both intracystic and trophic forms of *P. jirovecii* Does not stain the cyst wall of *Pneumocystis* Does stain organisms other than *Histoplasma* and *Pneumocystis*
Gram stain	Detection of bacteria and fungi	Commonly performed on clinical specimens Will stain most yeasts and hyphal elements Most fungi stain gram-positive, but some, such as *Cryptococcus neoformans*, exhibit stippling or appear gram-negative
H&E stain	General purpose histologic stain	Best stain to demonstrate host reaction in infected tissue Stains most fungi, but small numbers of organisms may be difficult to differentiate from background Useful in demonstrating natural pigment in dematiaceous fungi
GMS stain	Detection of fungi in histologic sections and *P. jirovecii* cysts in respiratory specimens	Best stain for detecting all fungi Stains hyphae and yeast forms black against a green background Usually performed in histopathology laboratory
Mucicarmine stain	Histopathologic stain for mucin	Useful for demonstrating capsular material of *C. neoformans* May also stain the cell walls of *Blastomyces dermatitidis* and *Rhinosporidium seeberi*
PAS stain	Histologic stain for fungi	Stains both yeasts and hyphae in tissue. PAS-positive artifacts may resemble yeast cells

GMS, Gomori methenamine silver; *H&E,* hematoxylin and eosin; *PAS,* periodic acid–Schiff.
Modified from Pfaller, M.A., McGinnis, M.R., 2009. The laboratory and clinical mycology. In: Anaissie, E.J., McGinnis, M.R., Pfaller, M.A. (Eds.), Clinical Mycology, second ed. Churchill Livingstone, New York.

STAINS AND DIRECT MICROSCOPIC EXAMINATION

Direct microscopic examination of tissue sections and clinical specimens is generally considered to be among the most rapid and cost-effective means of diagnosing fungal infections. Microscopic detection of yeasts or hyphal structures in tissue may be accomplished in less than an hour, whereas culture results may not be available for days or even weeks. In certain instances, the fungus may not only be detected but identified by microscopy because it possesses a distinctive morphology. Specifically, detection of characteristic cysts, yeast cells, or spherules can provide an etiologic diagnosis of infections caused by *Pneumocystis jirovecii, H. capsulatum*, *Blastomyces dermatitidis*, or *C. immitis/posadasii*, respectively. Although the morphologic appearance of *Candida*, a mucoromycete, or *Trichosporon* in tissue may lead to the diagnosis of the type of infection (i.e., candidiasis, mucormycosis, trichosporonosis), the actual species of fungus causing the infection would remain unknown, pending culture. Microscopic detection of fungi in tissue serves to guide the laboratory in selecting the most appropriate means to culture the specimen and is helpful in determining the significance of culture results. The latter is especially true when the organism isolated in culture is a known component of the normal flora or is frequently found in the environment.

Direct microscopy is clearly useful in diagnosing fungal infection; however, both false-negative and false-positive results may occur. Microscopy is less sensitive than culture, and a negative direct examination does not rule out a fungal infection.

A number of different stains and microscopic techniques may be used to detect and characterize fungi directly in clinical material (Table 60.2). The approaches used most often in the clinical mycology laboratory include the fluorescent reagent calcofluor white or staining of smears and touch preparations with either Gram or Giemsa stains. Calcofluor white stains the cell walls of fungi, causing the fungi to fluoresce for easier and faster detection (Fig. 60.1). The Gram stain is useful for detection of yeasts, such as species of *Candida* or *Cryptococcus* (Fig. 60.2), and filamentous fungi, such as *Aspergillus* (Fig. 60.3). Fungi are typically gram-positive but may appear speckled or gram-negative (see Figs. 60.2 and 60.3). The Giemsa stain is especially useful for detecting the intracellular yeast forms of *H. capsulatum* in peripheral blood smears, bone marrow, or touch preparations of tissue (Fig. 60.4).

The respiratory pathogen *P. jirovecii* may be detected in induced sputum or specimens obtained by bronchoscopy.

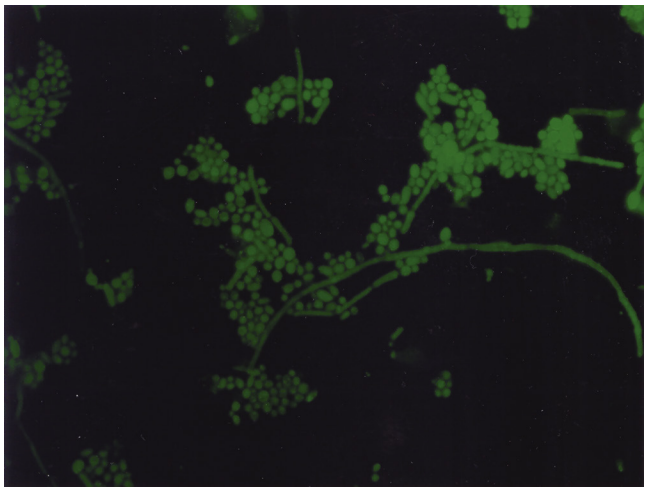

Fig. 60.1 Calcofluor white stain demonstrating budding yeasts and pseudohyphae of *Candida albicans*.

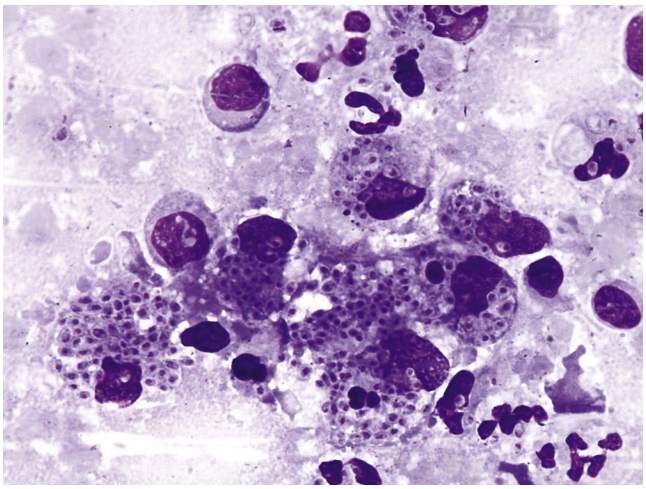

Fig. 60.4 Giemsa stain showing intracellular yeast forms of *Histoplasma capsulatum*.

Fig. 60.2 Gram stain of *Cryptococcus neoformans*. These are variable-sized, encapsulated, budding yeasts showing a stippled pattern resulting from uneven retention of crystal violet stain.

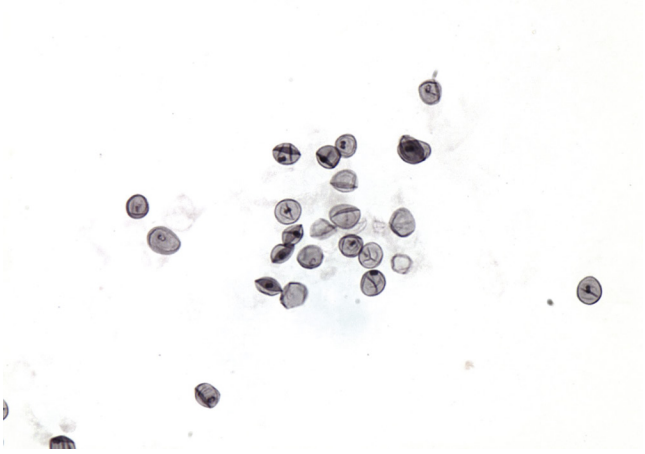

Fig. 60.5 Silver stain of *Pneumocystis jirovecii* cysts.

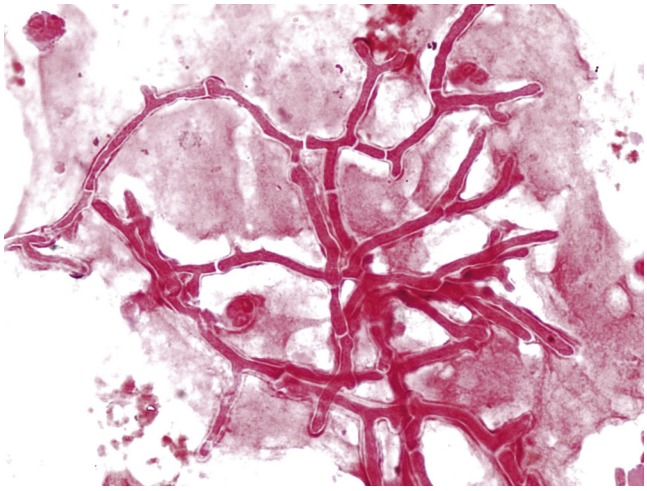

Fig. 60.3 Gram stain of *Aspergillus*. This specimen did not retain the crystal violet stain and appears gram-negative.

The cysts may be stained with Gomori methenamine silver (GMS) stain (Fig. 60.5) or by a fluorescent monoclonal antibody, and the trophic and intracystic forms are stained with the Giemsa stain (Fig. 60.6).

Stains such as hematoxylin and eosin (H&E), GMS, and periodic acid–Schiff (PAS) are performed in the cytology and/or histopathology laboratory and are used for detection of fungi in cytologic preparations, fine-needle aspirates, tissues, body fluids, and exudates (see Tables 60.1 and 60.2). These stains can detect fungi such as *B. dermatitidis*, *H. capsulatum*, *C. immitis*/*posadasii*, *Candida* spp., *C. neoformans,* and the hyphae of Mucormycetes (Fig. 60.7), *Aspergillus,* and other molds. Fungi may be visualized with the H&E stain, but small numbers of organisms may be missed. The more fungus-specific stains are the GMS and PAS stains. These stains are useful in detecting small numbers of organisms and for clearly defining characteristic features of fungal morphology. Histologic examination of fixed tissue provides the opportunity to determine whether the fungus is invading the tissue or merely present superficially; this information is helpful in distinguishing between infection and colonization. The microscopic morphologic features of several of the more common fungal pathogens are presented in Table 60.3.

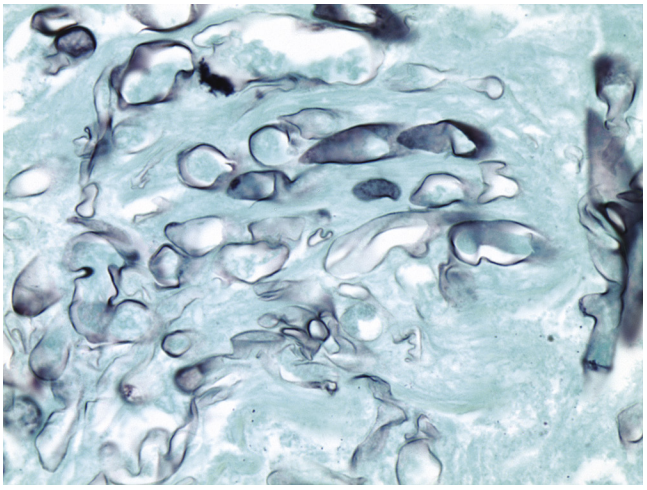

Fig. 60.7 Silver stain of *Rhizopus*.

CULTURE

The most sensitive means of diagnosing a fungal infection is usually considered to be isolation of the fungus in culture. Culture also is necessary, in most instances, to identify the etiologic agents. Optimal recovery of fungi from clinical material depends on procurement of an adequate clinical specimen and then using culture methods that will ensure the recovery of organisms that are usually present in small amounts and are slow growing. No single culture medium is sufficient to isolate all medically important fungi, and it is generally accepted that at least two types of media, selective and nonselective, should be used. The nonselective medium will permit the growth of rapidly growing yeasts and molds, as well as the more slowly growing fastidious fungi. Fungi will grow in most media used for bacteria; however, growth may be slow, and a more enriched medium, such as brain heart infusion (BHI) agar or SABHI (Sabouraud dextrose and BHI) agar, is recommended. Fastidious dimorphic fungi, such as *H. capsulatum* and *B. dermatitidis*, usually require a blood-containing medium, such as BHI with 5% to 10% sheep blood, for optimal recovery from clinical material. Cycloheximide is often added to this medium to inhibit the more rapidly growing yeasts and molds that may contaminate the specimen. Although cycloheximide does not affect the endemic dimorphic pathogens, it will inhibit the growth of many opportunistic pathogens (e.g., *Candida*, *Aspergillus*) that also might be the etiologic agent of infection. For this reason, one should always pair cycloheximide-containing media with complementary media without cycloheximide. Specimens that may be contaminated with bacteria should be inoculated onto selective media, such as SABHI or BHI supplemented with antibiotics (penicillin plus streptomycin is often used). Specific fungi may require specialized media. For example, *Malassezia furfur*, an agent that causes superficial skin infections and infections of vascular catheters, requires a medium containing olive oil or another source of long-chain fatty acids for optimal recovery.

Media have been formulated to provide the presumptive identification of yeast based on colonial morphologic features. The addition of certain substrates or chromogens to the agar medium allows the direct detection of specific enzymatic activities characteristic of selected species of yeast. CHROMagar Candida is one such medium that can be used for simultaneous isolation and presumptive identification of *Candida albicans*, *C. tropicalis*, and *C. krusei*. CHROMagar is selective for fungi, and use of this medium shortens the time to presumptive identification of the organisms and allows easier detection of multiple yeast species present in a specimen based on characteristic colors of colonies produced by different species of *Candida* (see Fig. 65.5). CHROMagar may be coupled with the rapid trehalose test (RAT) for the identification of *C. glabrata* and has been shown to be useful in the rapid identification and determination of fluconazole susceptibility of *Candida* species directly from positive blood cultures. Other chromogenic media and a rapid colorimetric test based on the detection of L-proline aminopeptidase and β-galactose-aminidase have been developed specifically for the rapid identification of *C. albicans*.

The detection of fungemia is an important measure in diagnosing invasive fungal infection. Although contamination of blood cultures with a fungus may take place, for the most part, blood cultures positive for fungi are significant. Unfortunately, blood cultures are often negative, despite the presence of disseminated disease, especially when the infecting organism is a mold. Detection of fungemia has improved with the development of continuous-monitoring blood culture instruments and improved media formulations that take into account the growth requirements of fungi, as well as bacteria. In addition to these broth-based systems, the agar-based lysis-centrifugation method provides a flexible and sensitive method for detection of fungemia caused by yeasts, molds, and dimorphic pathogens (see Table 60.1).

Once inoculated, fungal cultures should be incubated in air at the proper temperature and for a sufficient period of time to ensure the recovery of fungi from clinical specimens. Most fungi grow optimally at 25° C to 30° C, although most species of *Candida* can be recovered from blood cultures incubated at 35° C to 37° C. Culture dishes should be sealed with gas-permeable tape

to prevent dehydration. Specimens submitted for fungal culture are generally incubated for 2 weeks; however, most blood cultures become positive within 5 to 7 days. Determination of the clinical significance of a fungal isolate must be made in consultation with the responsible clinician in the context of the clinical setting of the patient.

IDENTIFYING CHARACTERISTICS OF VARIOUS FUNGI

Determination of the identity of the specific etiologic agent of mycotic disease may have a direct bearing on prognosis and therapeutic considerations. It is becoming clear that a single therapeutic approach, for example, using amphotericin B, is inadequate for many fungal infections (see Chapter 61). The identification of fungal pathogens may have additional diagnostic and epidemiologic implications. Knowing the genus and species of the infecting agent also can provide access to fungal registries and to the literature in which the experiences of others may serve as a guide to the clinical course of infection and response to therapy, especially for the more unusual opportunistic mycoses.

Distinguishing yeastlike fungi from molds is the first step in identifying a fungal isolate. Gross colony morphology usually provides a good clue: yeastlike fungi form pasty, opaque colonies, and molds form large, filamentous colonies that vary in texture, color, and topography. Microscopic examination provides further delineation and often is all that is required for identification of many fungi (see Table 60.3). Identification of genus and species, depending on the fungus, requires more detailed microscopic study to delineate characteristic structures. Yeast identification usually requires additional biochemical and physiologic testing, whereas the identification of both yeasts and molds may be enhanced by specialized immunologic, molecular, and proteomic characterization (see Table 60.3).

Among the newer rapid methods for identification of *Candida* and other yeasts are the techniques of peptide nucleic acid (PNA)–fluorescence in situ hybridization (FISH) and matrix-assisted laser desorption ionization–time of flight (MALDI-TOF) mass spectrometry (MS). The PNA FISH tests (OpGen, Gaithersburg, MD) are based on a fluorescein-labeled PNA probe that specifically detects *C. albicans, C. tropicalis,* or *C. glabrata* as individual species or detects a yeast species group (e.g., *C. albicans* and *C. parapsilosis* fluoresce green and *C. glabrata* and *C. krusei* fluoresce red with the Yeast Traffic Light PNA FISH kit) in blood cultures by targeting species-specific rRNA sequences. The probes are added to smears made directly from the contents of the blood culture bottle and are hybridized for 90 minutes. Recent modifications to the probes and reagents have resulted in a second-generation test (*Quick*FISH) that shortens the assay time to 30 minutes. Smears are subsequently examined by fluorescence microscopy. The test has been shown to have excellent sensitivity (99%), specificity (100%), positive predictive value (100%), and negative predictive value (99.3%). This approach may provide a time savings of 24 to 48 hours, compared with conventional laboratory methods used for identification. It allows physicians to be notified of the yeasts identity along with positive blood culture results. Rapid, accurate identification of *C. albicans, C. tropicalis, C. parapsilosis, C. glabrata,* and *C. krusei* should promote optimal antifungal therapy with the most cost-effective agents, resulting in improved outcomes and significant antifungal savings for hospitals.

MALDI-TOF MS uses species-specific patterns of peptides and protein masses to identify microorganisms. It has been shown to be highly accurate in identifying a broad array of bacteria and recently has been shown to provide a rapid and reliable tool for the identification of yeasts, yeastlike fungi, and molds. The technique involves extraction of proteins from the fungal cells, spotting of the specimen on a grid, and overlaying the spot with a matrix. The spectrum is generated rapidly (≈10 minutes per specimen) and is compared with a reference database. In several studies, the method has been shown to be highly accurate and to provide a combination of the lowest expenditure of consumables, easy interpretation of results, and a fast turnaround time. Limitations include a lack of robust databases for the less common yeasts and relatively poor performance in identifying molds aside from *Aspergillus* species.

The identification of yeastlike fungi to the species level often requires the determination of the biochemical and physiologic profile of the organism in addition to the assessment of the microscopic morphology (see Table 60.3). Although nucleic acid sequencing and proteomic methods are rapidly becoming the standard methods for identification of molds, the classical method for the identification of a mold is based almost entirely on its microscopic morphology. The important features include the shape, method of production, and arrangement of conidia or spores and the size and appearance of the hyphae. The preparation of material for microscopic examination must be done in such a way that it produces minimal disruption of the arrangement of the reproductive structures and their conidia or spores. Determination of the presence of melanin and thermal-regulated dimorphism also are important features. Immunologic and/or nucleic acid probe–based tests are often used to identify the endemic dimorphic pathogens, and nucleic acid sequencing is applied as an aid in the identification of a variety of molds. The characteristic features of several of the commonly isolated filamentous and dimorphic pathogens are listed in Table 60.3.

Amplification-based molecular approaches are being developed to provide more rapid and objective identification of both yeasts and molds compared with traditional phenotypic methods. Ribosomal targets and internal transcribed spacer (ITS) regions have shown particular promise for molecular identification of some fungi. Several recent studies have confirmed the tremendous potential of these approaches as powerful tools in the identification of clinically important yeasts and molds; however, the existing sequence databases are limited with regard to both the quality and accuracy of their entries. Presently, with the availability of improved sequencing techniques, broader and more reliable databases, and more readily available kits and software, this technology has become a competitive alternative to the classic mycologic identification techniques used for clinically important fungi.

Table 60.3 Characteristic Features of Selected Opportunistic and Pathogenic Fungi in Clinical Specimens and in Cultures

Fungus	Microscopic Morphologic Features in Clinical Specimens	CHARACTERISTIC MORPHOLOGIC FEATURES IN CULTURE		Additional Tests for Identification
		Macroscopic	Microscopic	
Candida	Oval budding yeasts 2-6 μm in diameter Hyphae and pseudohyphae may be present	Variable morphology Colonies usually pasty, white to tan and opaque May have smooth or wrinkled morphology	Clusters of blastoconidia, pseudohyphae, and/or terminal chlamydospores in some species	Germ tube production by *Candida albicans, C. dubliniensis,* and *C. stellatoidea* PNA-FISH, MALDI-TOF MS Gene sequencing Carbohydrate assimilation Morphology on corn meal agar, CHROMagar, rapid trehalose test
Cryptococcus neoformans	Spherical budding yeasts of variable size, 2-15 μm Capsule may be present No hyphae or pseudohyphae	Colonies are shiny, mucoid, dome shaped, and cream to tan in color	Budding spherical cells of varying size Capsule present No pseudohyphae Cells may have multiple narrow-based buds	Tests for urease (+), phenoloxidase (+), and nitrate reductase (–) Latex agglutination, LFD or EIA test for polysaccharide antigen Mucicarmine and melanin stains in tissue
Aspergillus	Septate, dichotomously branched hyphae of uniform width (3-6 μm)	Varies with species *A. fumigatus*: blue-green to gray *A. flavus*: yellow-green *A. niger*: black	Varies with species Conidiophores with enlarged vesicles covered with flask-shaped metulae or phialides Hyphae are hyaline and septate	Identification based on microscopic and colonial morphology Gene sequencing MALDI-TOF MS
Mucormycetes	Broad, thin-walled, pauciseptate hyphae, 6-25 μm with nonparallel sides and random branches Hyphae stain poorly with GMS stain and often stain well with H&E stain	Colonies are rapid growing, woolly, and gray-brown to gray-black in color	Broad, ribbon-like hyphae with rare septa Sporangium or sporangiola produced from sporangiophore Rhizoids present in some species	Identification based on microscopic morphologic features Gene sequencing
Dematiaceous molds see chapter 57, Table 57.5	Pigmented (brown, tan, or black) hyphae, 2-6 μm wide May be branched or unbranched Often constricted at point of septation	Colonies are usually rapidly growing, woolly, and gray, olive, black, or brown in color	Varies depending on genus and species Hyphae are pigmented Conidia may be single or in chains, smooth or rough, and dematiaceous	Identification based on microscopic and colonial morphology Gene sequencing
Histoplasma capsulatum	Small (2-4 μm) budding yeasts within macrophages	Colonies are slow growing and white or buff-brown in color (25° C) Yeast phase colonies (37° C) are smooth, white, and pasty	Thin, septate hyphae that produce tuberculate macroconidia and smooth-walled microconidia (25° C) Small, oval, budding yeasts produced at 37° C	Demonstration of temperature-regulated dimorphism by conversion from mold to yeast phase at 37° C; exoantigen and nucleic acid probe tests allow identification without phase conversion
Blastomyces dermatitidis	Large (8-15 μm), thick-walled, broad-based budding yeast	Colonies vary from membranous, yeastlike colonies to cottony, white, moldlike colonies at 25° C When grown at 37° C, yeast phase colonies are wrinkled, folded, and glabrous	Hyaline, septate hyphae with one-celled smooth conidia (25° C) Large, thick-walled, budding yeast at 37° C	Demonstration of temperature-regulated dimorphism; exoantigen and nucleic acid probe tests
Coccidioides immitis/ posadasii	Spherical, thick-walled spherules, 20-200 μm Mature spherules contain small, 2-5 μm endospores	Colonies initially appear moist and glabrous, rapidly becoming downy and gray-white with a tan or brown reverse	Hyaline hyphae with rectangular arthroconidia separated by empty disjunctor cells	Exoantigen and nucleic acid probe tests

Table 60.3 Characteristic Features of Selected Opportunistic and Pathogenic Fungi in Clinical Specimens and in Cultures—cont'd

Fungus	Microscopic Morphologic Features in Clinical Specimens	CHARACTERISTIC MORPHOLOGIC FEATURES IN CULTURE		Additional Tests for Identification
		Macroscopic	Microscopic	
Sporothrix schenckii	Yeastlike cells of varying sizes Some may appear elongated or cigar shaped Tissue reaction forms asteroid bodies	Colonies initially smooth, moist, and yeastlike, becoming velvety as aerial hyphae develop (25° C) Tan to brown pasty colonies at 37° C	Thin, branching, septate hyphae Conidia borne in rosette-shaped clusters at the end of the conidiophore (25° C) Variable-sized budding yeasts produced at 37° C	Demonstration of thermal dimorphism; exoantigen and nucleic acid probe
Talaromyces marneffei	Oval intracellular yeast cells with septum	Colonies produce diffusible red pigment at 25° C	Septate hyphae with metulae, phialides with chains of conidia in a "paint brush" distribution (25° C) Yeast cells divide by fission (37° C)	Demonstration of thermal dimorphism Gene sequencing
Pneumocystis jirovecii	Cysts are round, collapsed, or crescent shaped Trophic forms seen on special stains	(Not applicable)	(Not applicable)	Immunofluorescent stain, GMS, Giemsa, toluidine blue stains (see Table 60.2)

EIA, Enzyme immunoassay; *GMS,* Gomori methenamine silver; *H&E,* hematoxylin and eosin; *LFD,* lateral flow device, *PNA-FISH,* peptide nucleic acid–fluorescent in situ hybridization; *MALDI-TOF MS,* matrix-assisted laser desorption–time of flight mass spectrometry.

Immunologic, Molecular, and Biochemical Markers for Direct Detection of Invasive Fungal Infections

Rapid, sensitive, and specific diagnostic tests for serious fungal infections would allow more timely and focused application of specific therapeutic measures. As such, tests for the detection of antibodies and antigens, metabolites, and fungus-specific nucleic acids have great appeal. Considerable progress has been made in several of these areas in recent years (Table 60.4), although with few exceptions, such testing still remains confined to reference laboratories or the research setting.

Determination of antibody (Ab) and/or antigen (Ag) titers in serum may be useful in diagnosing fungal infections. When performed in a serial fashion, Ab/Ag titers also provide a means of monitoring the progression of disease and the patient's response to therapy. With the exception of antibody tests for histoplasmosis and coccidioidomycosis, however, most tests for antibodies lack both sensitivity and specificity for diagnosis of invasive fungal infections.

Detection of fungal cell wall and cytoplasmic antigens and metabolites in serum or other body fluids represents the most direct means of providing a serologic diagnosis of invasive fungal infection (see Table 60.4). The best examples of this approach are the commercially available tests for the detection of polysaccharide antigens of *C. neoformans* and *H. capsulatum*. These tests have proven to be of great value in the rapid diagnosis of cryptococcal meningitis and disseminated histoplasmosis, respectively. Immunoassays for detection of *Aspergillus* galactomannan and *Candida* mannan and anti-mannan are now commercially available.

Another fungal-specific cell wall component is 1,3-β-glucan. This material may be detected in the serum of patients infected with *Candida*, *Aspergillus*, and *P. jirovecii* through its interaction in the limulus lysate assay. Studies of this test for β-glucan, which indicates the presence of fungi but does not identify the genus causing the infection, have been promising in certain highly selected patient populations.

The detection of fungal metabolites has potential for the rapid diagnosis of both candidiasis and aspergillosis (see Table 60.4). The detection of D-arabinitol in serum appears to be an indication of hematogenously disseminated candidiasis, whereas detection of elevated levels of D-mannitol in bronchoalveolar lavage fluid may be useful in the diagnosis of pulmonary aspergillosis. Because of the lack of a commercially available test and problems with method-dependent variability in sensitivity and specificity, the diagnostic utility of metabolite detection remains uncertain.

The application of the polymerase chain reaction (PCR) to directly detect fungal-specific nucleic acids in clinical material offers great promise for the rapid diagnosis of fungal infections. A variety of target sequences have been investigated and found to be of potential diagnostic value for most of the more common opportunistic and systemic fungal pathogens (see Table 60.4). Recent developments, such as real-time, gene chip technology, and the coupling of nanotechnology with magnetic resonance detection will facilitate the broad use of this technology, although it is not yet available in most mycology laboratories. A recent meta-analysis of PCR in the diagnosis of invasive candidiasis found that the use of whole blood as the test sample, multilocus panfungal targets (e.g., rRNA, P450 gene targets), and an in vitro detection limit no higher than 10 colony-forming units (CFU)/ml, provided optimal sensitivity and specificity.

Table 60.4 Antigenic, Biochemical, and Molecular Markers for Direct Detection of Invasive Fungal Infections

Organism	Cell Wall or Capsule Components	Cytoplasmic Antigens	Metabolites	Genomic DNA Sequences[a]
Candida	Mannans LA RIA EIA 1,3-β-glucans Limulus test Chitin Spectrophotometry	Enolase EIA Immunoblot Antienolase antibody EIA 47-kD breakdown product of HSP-90 Enzyme-linked dot Immunobinding assay	D-Arabinitol Rapid enzymatic/FID Mass spectroscopy/GLC	Actin Chitin synthase P450 ITS Ribosomal RNA genes
Cryptococcus neoformans	Capsular polysaccharide LA EIA LFD	—	D-Mannitol Mass spectroscopy/GLC	Ribosomal RNA genes ITS *URA5* gene
Aspergillus	Galactomannan LA EIA RIA LFD 1,3-β-glucans Limulus test Chitin Spectrophotometry	—	D-Mannitol GLC/FID Mass spectroscopy/GLC	P450 Ribosomal RNA genes ITS Alkaline protease Mitochondrial
Blastomyces dermatitidis	Cell wall RIA for 120-kD cell wall adhesion protein	—	—	Ribosomal RNA genes ITS
Histoplasma capsulatum	Cell wall RIA and EIA for polysaccharide antigen	—	—	Ribosomal RNA genes ITS
Talaromyces marneffei	Cell wall mannoprotein EIA	—	—	ITS
Coccidioides immitis	—	—	—	Ribosomal RNA genes

[a]All sequences detected by polymerase chain reaction.

EIA, Enzyme immunoassay; *FID,* flame ionization detector; *GLC,* gas-liquid chromatography; *HSP-90,* heat shock protein-90; *ITS,* internal transcribed spacer; *LA,* latex agglutination; *LFD,* lateral flow device; *P450,* lanosterol 14-alpha-demethylase gene; *RIA,* radioimmunoassay.

Modified from Mujeeb, I., et al., 2002. Fungi and fungal infections. In: McClatchey, K.D. (Ed.), Clinical Laboratory Medicine, second ed. Lippincott Williams & Wilkins, Philadelphia, PA.

There are now several commercially available PCR assays on the market, including Septifast by Roche (Roche Diagnostics, Indianapolis, IN), which is able to detect several species of *Candida* and *A. fumigatus;* the MycAssay (Myconostica, Cambridge, UK); and AsperGenius (PathoNostics, Maastricht, the Netherlands) for the diagnosis of invasive aspergillosis. Septifast has been evaluated in both neutropenic and nonneutropenic patients, with disappointing results. There were false-positive and false-negative results for both *Candida* and *Aspergillus*; thus the Septifast system has limited sensitivity and specificity and does not look promising for fungal infections. The MycAssay *Aspergillus* also has been evaluated in several studies with a performance similar to that of the galactomannan assay. The MycAssay for *Pneumocystis* also has been reported to have a sensitivity and specificity of 100% in bronchoalveolar lavage (BAL) in a recent comparative study. The PathoNostics AsperGenius assay is validated for use with BAL and can be used to diagnose invasive aspergillosis and detect azole resistance in the same sample. One of the most promising assays for candidiasis is the T2Candida test (T2Biosystems, Lexington, MA), which can detect five *Candida* species directly in whole blood, without the need for culture. It has been compared with various automated blood culture systems and against spiked blood samples and patient samples, and had both good sensitivity and specificity, and reduced time to positivity. The T2Candida test has a limit of detection of 1 CFU/ml.

In addition to detection of fungi in clinical material, immunologic, molecular, and proteomic methods also have proven useful in the identification of fungi in culture. Nucleic acid probes are useful in identifying the endemic dimorphic pathogens, and analysis of ribosomal deoxyribonucleic acid sequences is being applied to both common and uncommon opportunistic yeasts and molds. With the expansion of fungal databases, MALDI-TOF MS is rapidly becoming established as a rapid, accurate, and cost-effective approach to the identification of yeasts and molds from culture. Exoantigen immunodiffusion tests are widely applied to identify *H. capsulatum*, *B. dermatitidis*, and *C. immitis*/*posadasii*, obviating the need to demonstrate thermal dimorphism in the identification of these agents (see Table 60.3).

Questions

1. Why is it important to know which fungus is causing a given infection?
2. The laboratory procedure used to identify yeasts differs from that for molds. How and why?
3. Discuss the different ways the endemic dimorphic pathogens are identified.
4. What are the advantages of direct microscopic examination of clinical material for the diagnosis of fungal infection?

61 Antifungal Agents

Antifungal therapy has undergone a tremendous transformation in recent years. Once the sole domain of the agents amphotericin B and 5-fluorocytosine (flucytosine, 5-FC), which were toxic and difficult to use, the treatment of mycotic disease has now been advanced by the availability of several new, systemically active agents and new formulations of other older agents that provide comparable if not superior efficacy with significantly less toxicity.

In this chapter, we will review the antifungal agents, both systemic and topical (Table 61.1). We will discuss their spectrum, potency, mode of action, and clinical indications for use as therapeutic agents. Furthermore, we will discuss the mechanisms of resistance to the various classes of antifungal agents and the in vitro methods for determining the susceptibility and resistance of fungi to the available agents.

The terminology appropriate for this discussion is summarized in Box 61.1 and Fig. 61.1, respectively.

Systemically Active Antifungal Agents

Amphotericin B and its lipid formulations are polyene macrolide antifungals used in the treatment of serious life-threatening mycoses (see Table 61.1). Another polyene, nystatin, is a topical agent. A lipid formulation of nystatin has been developed for systemic use but remains investigational.

The basic structure of polyenes consists of a large lactone ring, a rigid lipophilic chain containing three to seven double bonds, and a flexible hydrophilic portion bearing several hydroxyl groups (Fig. 61.2). Amphotericin B contains seven conjugated double bonds and may be inactivated by heat, light, and extremes of pH. It is poorly soluble in water and is not absorbed by the oral or intramuscular route of administration. The conventional formulation of amphotericin B for intravenous (IV) administration is amphotericin B deoxycholate. The lipid formulations of amphotericin B were developed in an effort to circumvent the nephrotoxic nature of conventional amphotericin B and in most instances have replaced the deoxycholate form.

Amphotericin B (and its lipid formulations) exerts its antifungal action by at least two different mechanisms. The primary mechanism involves the binding of amphotericin B to ergosterol, the principal membrane sterol of fungi. This binding produces ion channels, which destroy the osmotic integrity of the fungal cell membrane and lead to leakage of intracellular constituents and cell death (Fig. 61.3). Amphotericin B also binds to cholesterol, which is the main membrane sterol of mammalian cells, but it does so less avidly than to ergosterol. The binding of amphotericin B to cholesterol accounts for most of the toxicity observed when amphotericin B is administered to humans. An additional mechanism of action of amphotericin B involves direct membrane damage resulting from the generation of a cascade of oxidative reactions triggered by the oxidation of amphotericin B itself. This process may be a major contributor to the rapid fungicidal activity of amphotericin B via the generation of toxic free radicals.

The spectrum of activity of amphotericin B is broad and includes most strains of *Candida*, *Cryptococcus neoformans*, *Aspergillus* spp., the Mucormycetes, and the endemic dimorphic pathogens (*Blastomyces dermatitidis*, *Coccidioides immitis*, *Histoplasma capsulatum*, *Paracoccidioides brasiliensis*, and *Talaromyces marneffei*) (see Table 61.2). *Aspergillus terreus*, *Fusarium* spp., *Scedosporium* spp., *Lomentospora prolificans*, *Trichosporon* spp., and certain dematiaceous fungi may be resistant to amphotericin B. Likewise, reduced susceptibility to amphotericin B has been noted among some strains of *C. guilliermondii*, *C. glabrata*, *C. krusei*, *C. lusitaniae*, *C. auris,* and *C. rugosa*. Resistance to amphotericin B has been associated with alterations in membrane sterols (usually a reduction in ergosterol).

Amphotericin B is widely distributed in various tissues and organs, including liver, spleen, kidney, bone marrow, and lung. Although negligible concentrations of amphotericin B can be found in the cerebrospinal fluid, it is generally effective in treating fungal infections of the central nervous system. Amphotericin B is considered to be fungicidal against most fungi.

The primary clinical indications for amphotericin B include invasive candidiasis, cryptococcosis, aspergillosis, mucormycosis, blastomycosis, coccidioidomycosis, histoplasmosis, paracoccidioidomycosis, talaromycosis, and sporotrichosis. The lipid formulations of amphotericin B offer an improved efficacy-to-toxicity profile and are primarily recommended for the treatment of documented fungal infections in individuals failing conventional amphotericin B or with impaired renal function.

The main adverse effects of amphotericin B include nephrotoxicity, as well as infusion-related side effects, such as fever, chills, myalgias, hypotension, and bronchospasm. The major advantage of the lipid formulations of amphotericin B are the significantly reduced side effects, especially nephrotoxicity. The lipid formulations are not superior to conventional amphotericin B in terms of efficacy and are much more expensive.

AZOLES

The azole class of antifungals may be divided in terms of structure into the imidazoles (two nitrogens in the azole ring) and the triazoles (three nitrogens in the azole ring) (see Fig. 61.2). Among the imidazoles, only ketoconazole has systemic activity. The triazoles all have systemic activity and include fluconazole, itraconazole, voriconazole, posaconazole, and isavuconazole (see Table 61.1).

Both imidazoles and triazoles act by inhibiting the fungal cytochrome P450-dependent enzyme lanosterol 14-α-demethylase (Fig. 61.4). This enzyme is involved in the conversion of lanosterol to ergosterol, and its inhibition

TABLE 61.1 Systemic and Topical Antifungal Agents in Use and in Development

Antifungal Agents	Route	Mechanism of Action	Comments
ALLYLAMINES			
Naftifine Terbinafine	Topical Oral, topical	Inhibition of squalene epoxidase	Terbinafine has very broad spectrum and acts synergistically with other antifungals
ANTIMETABOLITE			
Flucytosine	Oral	Inhibition of DNA and RNA synthesis	Used in combination with amphotericin B and fluconazole; toxicity and secondary resistance are problems
IMIDAZOLES			
Ketoconazole, bifonazole, clotrimazole, econazole, miconazole, oxiconazole, sulconazole, terconazole, tioconazole	Oral, topical	Inhibits lanosterol 14-α-Demethylase cytochrome P450-dependent enzymes	Ketoconazole has modest broad-spectrum activity and toxicity problems
TRIAZOLES			
Fluconazole	Oral, IV	Same as imidazoles but more specific binding to target	Limited spectrum (yeasts); good central nervous system penetration; good in vivo activity; primary and secondary resistance seen with *Candida krusei, C. auris,* and *C. glabrata*, respectively
Itraconazole	Oral	Same as imidazoles but more specific binding to target enzyme	Broad-spectrum activity; erratic absorption; toxicity and drug interactions are problems
Voriconazole	Oral, IV	Same as imidazoles but more specific binding to target enzyme	Broad spectrum, including yeasts and molds; active versus *Candida krusei*; many drug interactions Agent of first choice for invasive aspergillosis
Posaconazole	Oral, IV	Same as imidazoles but more specific binding to target enzyme	Broad spectrum including activity versus Mucormycetes
Isavuconazole	Oral, IV	Same as imidazoles but more specific binding to target enzyme	Broad spectrum, including yeasts and molds; approved for treatment of invasive aspergillosis and invasive mucormycosis
ECHINOCANDINS			
Caspofungin, anidulafungin, micafungin	IV	Inhibition of fungal cell wall glucan synthesis	Caspofungin is approved for treatment of invasive candidiasis and aspergillosis; anidulafungin is approved for treatment of invasive candidiasis; micafungin is approved for treatment of invasive candidiasis; fungicidal activity against *Candida*
POLYENES			
Amphotericin B	IV, topical	Binds to ergosterol, causing direct oxidative membrane damage	Established agent; broad spectrum; toxic
Lipid formulations (amphotericin B lipid complex or colloidal dispersion, liposomal amphotericin B)	IV	Same as amphotericin B	Broad spectrum; less toxic, expensive
Nystatin	Oral suspension, topical	Same as amphotericin B	Liposomal formulation (IV) under investigation
OTHER			
Nikkomycin Z	IV	Inhibition of fungal cell wall chitin synthesis	Investigational agent: possibly useful in combination with other antifungals
APX001A/APX001	Oral	Inhibition of GPI synthesis	Investigational agent; broad-spectrum activity, including *Candida* spp. and *Aspergillus* spp., as well as other molds that are difficult to treat such as *Mucorales*, *Fusarium solani*, and *Lomentospora prolificans*
VT-1598, VT-1129, and VT-1161	Oral	Inhibitors of fungal-specific 14α-lanosterol demethylase (CYP51A)	Investigational agents: broad-spectrum activity against *Candida* spp., *Coccidioides immitis,* and *C. posadasii*, and *Trichophyton* spp. (VT-1161); in vitro activity against *Candida* spp. including *C. auris*, *Cryptococcus* spp., *Aspergillus* spp., *Rhizopus oryzae*, *Blastomyces dermatitidis*, *Coccidioides* spp., and *Histoplasma capsulatum* (VT-1598); active against many species of *Cryptococcus*, including *C. neoformans* and *C. gattii* (VT-1129)

Continued

TABLE 61.1 Systemic and Topical Antifungal Agents in Use and in Development—cont'd

Antifungal Agents	Route	Mechanism of Action	Comments
CD101	IV and topical	Same as other echinocandins	Investigational agent: active against echinocandin-susceptible and-resistant *Candida* spp. including *C. auris*, as well as *Aspergillus* spp.
SCY-078	Oral	Structurally distinct triterpene class of β-1,3-D-glucan synthase inhibitor	
F901318 (F2G Ltd.)	IV and tral	Inhibitor of dihydroorotate dehydrogenase activity	Investigational agent: in vitro and in vivo activity against the most common *Candida* species and against *C. auris*, *Aspergillus* spp., *Paecilomyces variotii*, and *L. prolificans*
Amorolfine	Topical	Miscellaneous, varied	
Butenafine HC	Topical		
Ciclopirox olamine	Topical		Investigational agent: potent activity against a broad range of filamentous and dimorphic fungi, including *Aspergillus* spp., *H. capsulatum*, *B. dermatitidis*, *C. immitis*, *Fusarium* spp., *T. marneffei*, and *L. prolificans*
Griseofulvin	Oral		
Haloprogin	Topical		
Tolnaftate	Topical		
Undecylenate	Topical		

GPI, Glycosylphosphatidylinositol; *IV,* intravenous.

BOX 61.1 Terminology

Antifungal spectrum: This is the range of activity of an antifungal agent against fungi. A broad-spectrum antifungal agent inhibits a wide variety of fungi, including both yeastlike fungi and molds, whereas a narrow-spectrum agent is active only against a limited number of fungi.

Fungistatic activity: This is the level of antifungal activity that **inhibits** the growth of an organism. This is determined in vitro by testing a standardized concentration of organisms against a series of antifungal dilutions. The lowest concentration of the drug that inhibits the growth of the organism is referred to as the **MIC.**

Fungicidal activity: This is the ability of an antifungal agent to **kill** an organism in vitro or in vivo. The lowest concentration of the drug that kills 99.9% of the test population is called the **MFC.**

Antifungal combinations: These combinations of antifungal agents may be used (1) to enhance efficacy in the treatment of a refractory fungal infection, (2) to broaden the spectrum of empiric antifungal therapy, (3) to prevent the emergence of resistant organisms, and (4) to achieve a synergistic killing effect.

Antifungal synergism: These are combinations of antifungal agents that have enhanced antifungal activity when used together compared with the activity of each agent alone.

Antifungal antagonism: This is a combination of antifungal agents in which the activity of one of the agents interferes with the activity of the other agent.

Efflux pumps: These are families of drug transporters that serve to actively pump antifungal agents out of the fungal cells, decreasing the amount of intracellular drug available to bind to its target.

MFC, Minimum fungicidal concentration; *MIC,* minimum inhibitory concentration.

disrupts membrane synthesis in the fungal cell. Depending on the organism and specific azole, inhibition of ergosterol synthesis results in inhibition of fungal cell growth (fungistatic) or cell death (fungicidal). In general, the azoles exhibit fungistatic activity against yeastlike fungi, such as *Candida* spp. and *C. neoformans*; however, itraconazole, voriconazole, posaconazole, and isavuconazole appear to be fungicidal against *Aspergillus* spp.

Ketoconazole is an orally absorbed, lipophilic member of the imidazole class of antifungal agents. Its spectrum of activity includes the endemic dimorphic pathogens, *Candida* spp., *C. neoformans*, and *Malassezia* spp., although it is generally less active than the triazole antifungal agents (Table 61.2). It is variably active against *Scedosporium* spp. and has little or no useful clinical activity against the Mucormycetes, *Aspergillus* spp., *L. prolificans*, or *Fusarium* spp.

The absorption of ketoconazole by the oral route of administration is erratic and requires an acid gastric pH. Its lipophilicity ensures penetration and concentration into fatty tissues and purulent exudates; however, because it is highly (>99%) protein bound, it penetrates poorly into the central nervous system.

Ketoconazole may cause serious adverse effects, including gastric and hepatic toxicity, nausea, vomiting, and rash. At high doses, significant endocrine side effects have been observed secondary to suppression of testosterone and cortisol levels.

Because of the availability of more potent and less toxic agents, the clinical indications for use of ketoconazole are quite limited. It is at best a second-line agent for the treatment of non–life-threatening, nonmeningeal forms of histoplasmosis, blastomycosis, coccidioidomycosis, and paracoccidioidomycosis in immunocompetent individuals. Similarly, it may be used in the treatment of mucocutaneous candidiasis and lymphocutaneous sporotrichosis.

Fluconazole is a first-generation triazole with excellent oral bioavailability and low toxicity. Fluconazole is used extensively and is active against most species of *Candida*, *C. neoformans*, dermatophytes, *Trichosporon* spp., *H. capsulatum*, *C. immitis*, and *P. brasiliensis* (see Table 61.2). Among *Candida* spp., decreased susceptibility is seen with *C. auris*, *C. krusei*, *C. glabrata, C. guilliermondii,* and *C. rugosa*. Whereas *C. krusei* and *C. auris* must be considered intrinsically resistant to fluconazole, infections with *C. glabrata* may be treated successfully with high doses (e.g., 800 mg/day) of fluconazole. Resistance may develop when fluconazole is used to treat histoplasmosis, and it only has limited activity against *B. dermatitidis*. Fluconazole is not active against the opportunistic molds, including *Aspergillus* spp., *Fusarium* spp., and the Mucormycetes.

Fluconazole is a water-soluble agent and may be administered orally or intravenously. Protein binding is low, and the drug is distributed to all organs and tissues, including the central nervous system. Severe side effects such as exfoliative dermatitis or liver failure are uncommon.

Because of its low toxicity, ease of administration, and fungistatic activity against most yeastlike fungi, fluconazole has an important role in the treatment of candidiasis, cryptococcosis, and coccidioidomycosis. It is used as

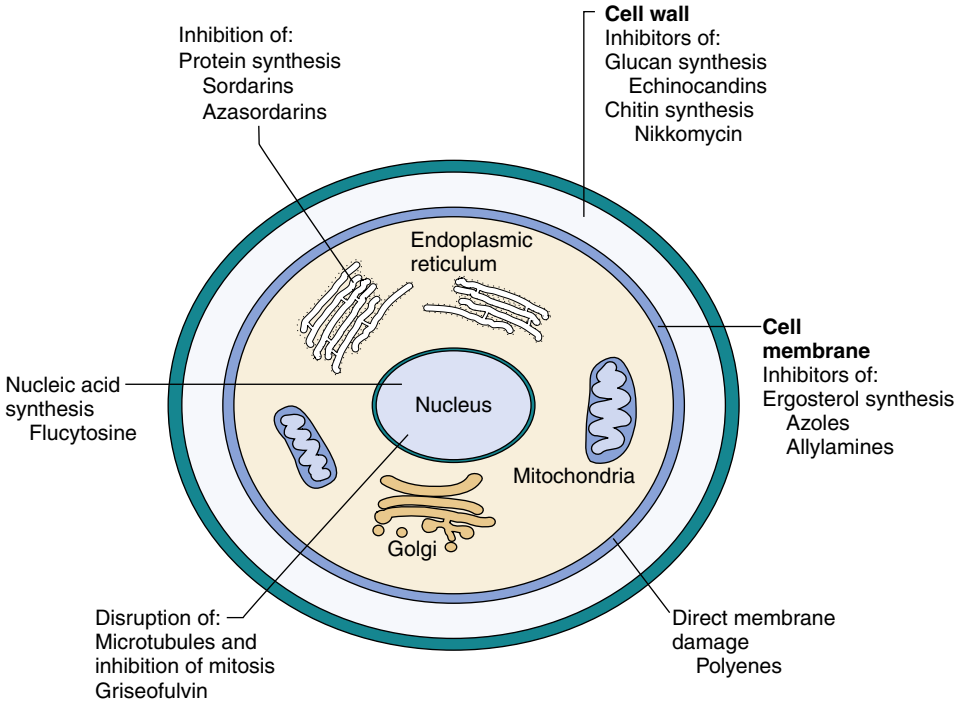

Fig. 61.1 Sites of action of antifungals.

primary therapy for candidemia and mucosal candidiasis and as prophylaxis in selected high-risk populations. It is used in maintenance therapy of cryptococcal meningitis in patients with acquired immunodeficiency syndrome (AIDS) and is the agent of choice in the treatment of meningitis caused by *C. immitis*. Fluconazole is a second-line agent in the treatment of histoplasmosis, blastomycosis, and sporotrichosis.

Itraconazole is a lipophilic triazole that may be administered orally in capsule or in solution. Itraconazole has a broad spectrum of antifungal activity, including against *Candida* spp., *C. neoformans*, *Aspergillus* spp., dermatophytes, dematiaceous molds, *Scedosporium* spp., *Sporothrix schenckii*, and the endemic dimorphic pathogens (see Table 61.2). Itraconazole has activity against some, but not all, fluconazole-resistant strains of *C. glabrata* and *C. krusei*. Itraconazole-resistant strains of *A. fumigatus* have been increasingly reported in some, but not all, regions of the world. The Mucormycetes, *Fusarium*, and *L. prolificans* are resistant to itraconazole.

As with ketoconazole, the oral absorption of itraconazole is erratic and requires an acid gastric pH. Absorption is enhanced with the oral solution when given in the fasting state. Itraconazole is highly protein bound and exhibits fungistatic activity against yeastlike fungi and fungicidal activity against *Aspergillus* spp.

The efficacy of itraconazole in the treatment of hematogenous candidiasis has not been adequately assessed, although it is useful in the treatment of cutaneous and mucosal forms of candidiasis. Itraconazole is often used in the treatment of dermatophytic infections and is the treatment of choice for lymphocutaneous sporotrichosis and non–life-threatening, nonmeningeal forms of histoplasmosis, blastomycosis, and paracoccidioidomycosis. It may be useful in nonmeningeal coccidioidomycosis, for maintenance treatment of cryptococcal meningitis, and for some forms of phaeohyphomycosis (see Table 61.2). Itraconazole is considered a second-line agent for the treatment of invasive aspergillosis; however, it is not useful in the treatment of infections caused by *Fusarium* spp., the Mucormycetes, or *L. prolificans*.

In contrast to fluconazole, drug interactions are common with itraconazole. Severe hepatotoxicity is rare, and other side effects, such as gastrointestinal intolerance, hypokalemia, edema, rash, and elevated transaminases, occur infrequently.

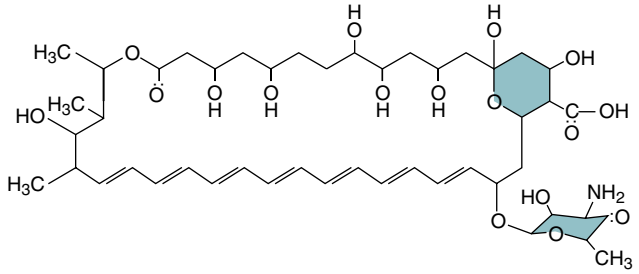
Voriconazole is a broad-spectrum triazole with activity against *Candida* spp., *C. neoformans*, *Trichosporon* spp., *Aspergillus* spp., *Fusarium* spp., dematiaceous fungi, and the endemic dimorphic pathogens (see Table 61.2). Among the *Candida* species, voriconazole is active against *C. krusei* and some but not all strains of *C. albicans* and *C. glabrata* with reduced susceptibility to fluconazole. Although voriconazole has no activity against the Mucormycetes, it is active against fungi that are resistant to amphotericin B, including *A. terreus* and *Scedosporium* spp.

Voriconazole is available in both oral and IV formulations. It has excellent penetration into the central nervous system and other tissues. Voriconazole exhibits fungistatic activity against yeastlike fungi and is fungicidal against *Aspergillus* spp.

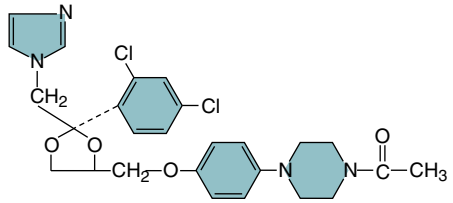
Voriconazole has a primary indication for the treatment of invasive aspergillosis. It is also approved for treatment of infections caused by *Scedosporium* spp. and *Fusarium* spp. in patients intolerant of, or with infections refractory to, other antifungal agents. Voriconazole has proven efficacy in the treatment of various forms of candidiasis and has been used successfully in the treatment of a variety of infections caused by emerging or refractory pathogens, including brain abscesses caused by *Aspergillus* spp. and *Scedosporium* spp.

Voriconazole is generally well tolerated, although approximately one-third of patients experience transient

Amphotericin B (polyene)



Ketoconazole (imidazole)



Fluconazole (triazole)

Caspofungin (echinocandin)

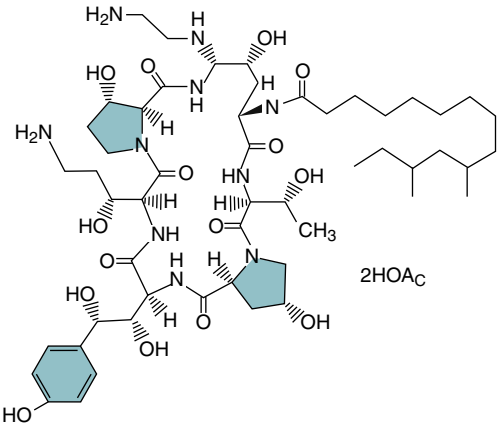

Fig. 61.2 Chemical structures of antifungals representing five different classes.

visual disturbances. Other adverse effects include liver enzyme abnormalities, skin reactions, and hallucinations or confusion. Interactions with other drugs that are metabolized by the hepatic P450 enzyme system are common.

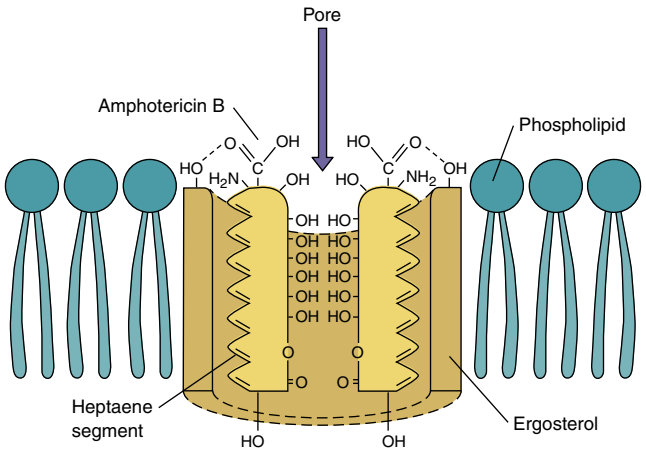

Fig. 61.3 Mechanisms of action of amphotericin B.

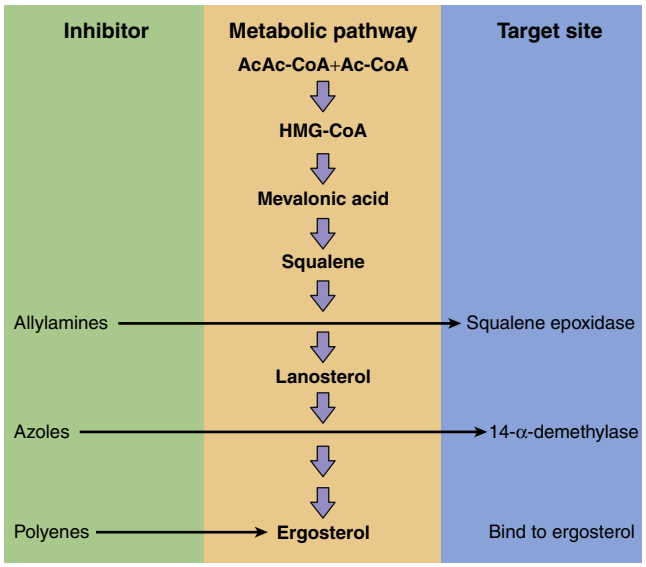

Fig. 61.4 Metabolic pathway for the synthesis of ergosterol, showing sites of inhibition by allylamine, azole, and polyene antifungal agents. *Ac-CoA,* Acetyl-coenzyme A; *HMG-CoA,* hydroxymethyl glutaryl-coenzyme A.

Posaconazole is a triazole derivative with a chemical structure similar to itraconazole. Posaconazole demonstrates potent activity against *Candida*, *Cryptococcus*, dimorphic fungi, and filamentous fungi, including *Aspergillus* and the Mucormycetes.

Posaconazole is available as an oral suspension, IV formulation, and a tablet. In contrast to voriconazole, posaconazole absorption is enhanced with food intake and is greatest with a concomitant fatty meal. There is a relatively wide patient-to-patient variability in peak serum concentrations, suggesting that posaconazole therapeutic drug monitoring may be important in optimizing the use of this agent. Similar to voriconazole, posaconazole exhibits fungistatic activity against yeastlike fungi and is fungicidal against *Aspergillus* spp.

Posaconazole has U.S. Food and Drug Administration (FDA) approval for prophylaxis of invasive fungal infection in hematopoietic stem cell transplant (HSCT) recipients with graft-versus-host disease (GVHD) and patients with hematologic malignancies and prolonged neutropenia. It is also

approved by the FDA for treatment of oropharyngeal candidiasis. In Europe, posaconazole is additionally approved for the following fungal infections refractory to amphotericin B and/or itraconazole: aspergillosis, fusariosis, chromoblastomycosis, mycetoma, and coccidioidomycosis.

Posaconazole is generally well tolerated. The most common adverse events are mild and include gastrointestinal complaints, rash, facial flushing, dry mouth, and headache. As with other azoles, hepatic toxicity has been described, and monitoring of liver function tests is recommended before and during treatment with posaconazole. Interactions with other drugs that are metabolized by the hepatic P450 enzyme system are common.

Isavuconazole is a water-soluble triazole antifungal agent that can be administered orally or intravenously. Isavuconazole has predictable and dose-proportional pharmacokinetics and has completed clinical trials for the treatment of candidemia and invasive candidiasis, treatment of invasive aspergillosis, and treatment of rare mold infections. Isavuconazole has shown good in vitro activity against *Candida* and other yeast species and *Aspergillus* spp. other than *A. niger* and has been cleared by the FDA for the treatment of invasive aspergillosis and invasive mucormycosis.

ECHINOCANDINS

The echinocandins are a novel, highly selective, class of semisynthetic lipopeptides (see Fig. 61.2) that inhibit the synthesis of 1,3-β-glucans, which are important constituents of the fungal cell wall (Fig. 61.5; see Table 61.1 and Fig. 61.1). Because mammalian cells do not contain 1,3-β-glucans, this class of agents is selective in its toxicity for fungi in which the glucans play an important role in maintaining the osmotic integrity of the fungal cell. Glucans are also important in cell division and cell growth. Inhibition of the glucan synthesis enzyme complex results in fungicidal activity against *Candida* spp. and fungistatic activity against *Aspergillus* spp. At the present time, there are three echinocandins (anidulafungin, caspofungin, and micafungin) approved for use in treatment or prevention of various mycoses (see Table 61.1).

The spectrum of activity of the echinocandins is limited to those fungi in which 1,3-β-glucans constitute the dominant cell wall glucan component. As such, they are active against *Candida* and *Aspergillus* spp. and have variable activity against the dematiaceous fungi and the endemic dimorphic pathogens (see Table 61.2). They are inactive against *C. neoformans*, *Trichosporon* spp., *Fusarium* spp. and other hyaline molds, and the Mucormycetes. The echinocandins have excellent activity against fluconazole-resistant strains of *Candida* spp., although strains of *C. glabrata* with coresistance to both azoles and echinocandins have been described in the United States. Primary or acquired resistance to this class of agents appears to be uncommon among clinical isolates of *Candida* spp. and *Aspergillus* spp.

The echinocandins must be administered intravenously and are highly (>95%) protein bound. They are distributed to all major organs, although concentrations in cerebrospinal fluid are low. All of the echinocandins are very well tolerated and have few drug–drug interactions.

TABLE 61.2 Spectrum and Relative Activity of Systemically Active Antifungal Agents

Organism	AMB	FC	ISA	ITZ	FCZ	VCZ	ECH
Candida spp.							
C. albicans	++++	++++	++++	++++	++++	++++	++++
C. glabrata	+++	++++	+++	++	++	+++	++++

0, Inactive or not recommended; +, occasional activity; ++, moderate activity with resistance noted; +++, reliable activity with occasional resistance; ++++, very active, resistance rare or not described; *AMB,* Amphotericin B; *ECH,* echinocandins (anidulafungin, caspofungin, and micafungin); *FC,* flucytosine; *FCZ,* fluconazole; *ISA*, isavuconazole; *ITZ,* itraconazole; *VCZ,* voriconazole.

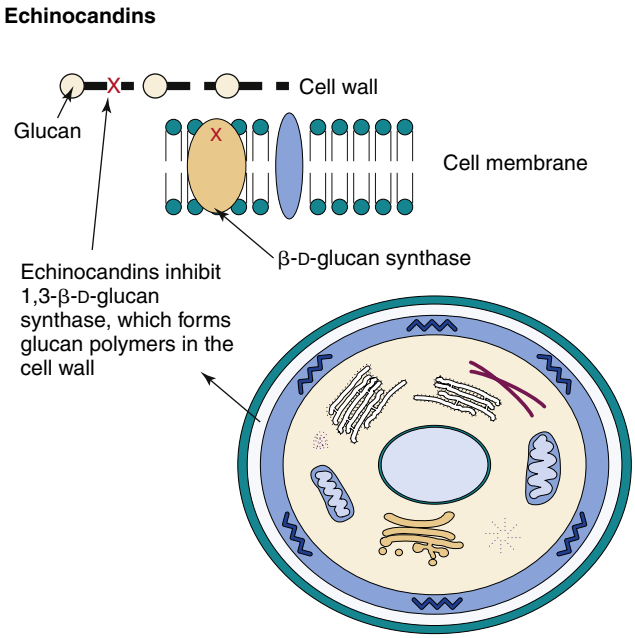

Fig. 61.5 Mechanism of action of the echinocandins.

Among the three echinocandins approved by the FDA, all have similar spectrum and potency against *Candida* and *Aspergillus* species. Caspofungin is approved for the treatment of invasive candidiasis, including candidemia, and for treatment of patients with invasive aspergillosis refractory to or intolerant of other approved antifungal therapies. Anidulafungin is approved for the treatment of esophageal candidiasis and candidemia, and micafungin is approved for treatment of esophageal candidiasis and candidemia, and for prevention of invasive candidiasis.

ANTIMETABOLITES

Flucytosine is the only available antifungal agent that functions as an antimetabolite. It is a fluorinated pyrimidine analog that exerts antifungal activity by interfering with the synthesis of deoxyribonucleic acid (DNA), ribonucleic acid (RNA), and proteins in the fungal cell (see Fig. 61.1). Flucytosine enters the fungal cell via cytosine permease and is deaminated to 5-fluorouracil (5-FU) in the cytoplasm. The 5-FU is converted to 5-fluorouridylic acid, which then competes with uracil in the synthesis of RNA, with resultant RNA miscoding and inhibition of DNA and protein synthesis.

The antifungal spectrum of flucytosine is limited to *Candida* spp., *C. neoformans*, *Rhodotorula* spp., *Saccharomyces cerevisiae*, and selected dematiaceous molds (see Table 61.2). Although primary resistance to flucytosine is rare among isolates of *Candida* spp., resistance may develop among *Candida* and *C. neoformans* during flucytosine monotherapy. Flucytosine is not active against *Aspergillus* spp., the Mucormycetes, or other hyaline molds.

Flucytosine is water soluble and has excellent bioavailability when administered orally. High concentrations of flucytosine may be achieved in serum, cerebrospinal fluid, and other body fluids. Major toxicities are observed when flucytosine serum concentrations exceed 100 μg/ml and include bone marrow suppression, hepatotoxicity, and gastrointestinal intolerance. Monitoring of serum concentrations of flucytosine is important in avoiding toxicity.

Flucytosine is not used as monotherapy because of the propensity for secondary resistance. Combinations of flucytosine with either amphotericin B or fluconazole have been shown to be efficacious in treating both cryptococcosis and candidiasis.

ALLYLAMINES

The allylamine class of antifungal agents includes terbinafine, which has systemic activity, and naftifine, which is a topical agent (see Table 61.1). These agents inhibit the enzyme squalene epoxidase, which results in a decrease in ergosterol and an increase in squalene within the fungal cell membrane (see Figs. 61.1 and 61.4).

Terbinafine is a lipophilic antifungal agent with a broad spectrum of activity that includes dermatophytes, *Candida* spp., *Malassezia furfur*, *C. neoformans*, *Trichosporon* spp., *Aspergillus* spp., *S. schenckii*, and *T. marneffei* (see Table 61.2). It is available in oral and topical formulations and achieves high concentrations in fatty tissues, skin, hair, and nails.

Terbinafine is efficacious in the treatment of virtually all forms of dermatomycoses, including onychomycosis, and exhibits few side effects. It has shown clinical effectiveness in the treatment of sporotrichosis, aspergillosis, and chromoblastomycosis and has shown promise for the treatment of infections caused by fluconazole-resistant *Candida* spp. when used in combination with fluconazole.

GRISEOFULVIN

Griseofulvin is an oral agent used in the treatment of infections caused by dermatophytes. It is thought to inhibit fungal growth by interaction with microtubules within the fungal cell, resulting in inhibition of mitosis (see Table 61.1 and Fig. 61.1).

Griseofulvin is considered a second-line agent in the treatment of dermatophytoses. Newer agents, such as itraconazole and terbinafine, are more rapid acting and provide greater efficacy. Griseofulvin is also associated with a number of mild side effects, including nausea, diarrhea, headache, hepatotoxicity, rash, and neurologic side effects.

Topical Antifungal Agents

A wide variety of topical antifungal preparations is available for the treatment of superficial cutaneous and mucosal fungal infections (see Table 61.1). Topical preparations are available for most classes of antifungal agents, including polyenes (amphotericin B, nystatin, pimaricin), allylamines (naftifine and terbinafine), and numerous imidazoles and miscellaneous agents (see Table 61.1). Creams, lotions, ointments, powders, and sprays are available for use in the treatment of cutaneous infections and onychomycosis, whereas mucosal infections are best treated with suspensions, tablets, troches, or suppositories.

Whether one uses topical or systemic therapy for treatment of cutaneous or mucosal fungal infections usually depends on the status of the host and the type and extent of infection. Whereas most cutaneous dermatophytic

infections and oral or vaginal candidiasis will respond to topical therapy, the refractory nature of infections, such as onychomycosis or tinea capitis ("ringworm" of the scalp), usually calls for long-term systemic therapy.

Investigational Antifungal Agents

At the present time, there are several antifungal agents in various stages of clinical evaluation. These investigational agents include some with established modes of action and some novel classes of antifungal agents, such as a liposomal formulation of nystatin, novel inhibitors of fungal CYP51A (VT-1129, VT-1598, and VT-1161), echinocandins (rezafungin), nonechinocandin glucan synthase inhibitors (SCY-078), an inhibitor of chitin synthesis (nikkomycin Z), an orotomide pyrimidine synthesis inhibitor (F901318), and an inhibitor of fungal glucophosphatidylinositol (GPI) anchor biosynthesis (APX001/APX001A) (see Table 61.1). The mechanisms of action and spectra of activity of liposomal nystatin and the echinocandin rezafungin are essentially the same as that of the currently available members of each class (see Tables 61.1 and 61.2). To a varying degree, the newer agents in each class offer the potential for more favorable pharmacokinetic and pharmacodynamic proprieties, decreased toxicities or drug–drug interactions, or possible improved activity against certain pathogens that are refractory to presently available agents.

VT-1598, VT-1129, and VT-1161 were developed as fungal-specific 14α-lanosterol demethylase (CYP51A) inhibitors that selectively target fungal enzyme over human enzyme and result in fewer drug–drug interactions. VT-1161 shows potent in vitro and in vivo activity against *Candida* spp., *C. immitis,* and *C. posadasii*, and *Trichophyton* spp., but it is not active against *Aspergillus* spp. as monotherapy. VT-1598 displays an even broader antifungal range; it shows in vitro activity against *Candida* spp. including *C. auris*, *Cryptococcus* spp., *Aspergillus* spp., *Rhizopus oryzae*, *B. dermatitidis*, *Coccidioides* spp., and *H. capsulatum.* VT-1129 inhibits the growth of many species of *Cryptococcus*, including *C. neoformans* and *C. gattii.* VT-1129 has been granted Qualified Infectious Disease Product (QIDP) designation and is in phase 1 clinical trials for the treatment of cryptococcal meningitis. VT-1598 is in preclinical development for treatment of coccidioidomycosis, and VT-1161 is in phase 2b clinical trials for the treatment of onychomycosis and recurrent vulvovaginal candidiasis.

CD101, was developed to overcome daily IV administration of an echinocandin while preserving the benefits of low toxicity and fungal-specific activity associated with this drug class. Adjustments to the echinocandin backbone chemical structure lowered the clearance of rezafungin and afforded a longer compound half-life of about threefold longer than that of anidulafungin. Therefore once-weekly IV administration provides appropriate systemic levels of rezafungin for treatment of invasive fungal infections. This compound exhibits activity against echinocandin-resistant *Candida* spp. including *C. auris*, as well as *Aspergillus* spp., and it is currently in phase 2 clinical trials for the treatment of candidemia.

SCY-078 is a structurally distinct triterpene class of β-1,3-D-glucan synthase inhibitor that that has been developed to treat invasive fungal infections in both oral and IV formulations. Unlike current echinocandins, it is orally bioavailable and the activity is not compromised by the most common mutations within the protein target Fks. SCY-078 shows both in vitro and in vivo activity against the most common *Candida* species an against *C. auris, Aspergillus* spp., *Paecilomyces variotii*, and *L. prolificans.* SCY-078 is currently in phase 2 clinical trials in its oral formulation for the treatment of invasive candidiasis. The IV formulation is in phase 1 clinical development.

F901318 is in a new class of orotomide antifungal agents that inhibit an enzyme involved in pyrimidine biosynthesis called dihydroorotate dehydrogenase. It has been developed in both oral and IV formulations for the treatment of systemic mold infections. It shows potent activity against a broad range of filamentous and dimorphic fungi, including *Aspergillus* spp., *H. capsulatum*, *B. dermatitidis*, *C. immitis*, *Fusarium* spp., *T. marneffei*, and *L. prolificans*. Notably, it is active against azole-resistant and amphotericin B–resistant strains of *Aspergillus* spp. F901318 shows little to no activity against *Candida* ssp. or the *Mucorales*. F901318 is currently in phase 1 clinical trials assessing the safety of the IV formulation.

APX001A/APX001 is a small-molecule inhibitor of fungal GPI biosynthesis that exhibits potent broad-spectrum antifungal activity against *Candida* spp. and *Aspergillus* spp., as well as other molds that are difficult to treat such as *Mucorales*, *Fusarium solani*, and *L. prolificans*. The prodrug APX001, may be administered orally and is converted to the active form APX001A in vivo. APX001A is active against fungal isolates that are azole-resistant and/or echinocandin-resistant, including the emerging pathogen *C. auris.* Phase 1 studies have been completed, and phase 2 trials for the treatment of invasive candidiasis and invasive aspergillosis are now underway.

Combinations of Antifungal Agents in the Treatment of Mycoses

The high mortality of opportunistic fungal infections has spurred the development of new antifungal agents, including some with novel mechanisms of action (see Table 61.1). In addition to aggressive use of new antifungal agents, such as voriconazole and caspofungin, as monotherapy, the use of azole-, echinocandin-, and polyene-based combinations for treatment of the more difficult to treat mycoses, such as opportunistic mold infections, is the focus of intense interest and discussion. The rationale behind combination therapy is that by using combinations of antifungal agents, one may achieve a better clinical outcome than with monotherapy. The push toward the use of combination antifungal therapy is especially strong for those infections such as invasive aspergillosis, in which the associated mortality is unacceptably high.

In considering combination therapy, one seeks to achieve **synergy** and avoid **antagonism. Synergy** is achieved when the outcome obtained with the combination of agents is significantly better than that obtained

with either drug alone. Conversely, **antagonism** is when the combination is less active or efficacious than either drug alone. In the case of antifungal therapy, there are several mechanisms that one may consider in developing an effective combination treatment strategy. (1) Different stages of the same biochemical pathway can be inhibited. This is a classic approach for achieving synergy with antiinfective agents. An example of this approach to antifungal therapy would be the combination of terbinafine with an azole, in which both agents attack the sterol pathway at different points (see Fig. 61.4), resulting in inhibition of ergosterol synthesis and disruption of the fungal cell membrane. (2) Increased penetration of one agent into the cell by virtue of the permeabilizing action of another agent on the fungal cell wall or cell membrane can be achieved. The combination of amphotericin B (cell membrane disruption) and flucytosine (inhibition of nucleic acid synthesis intracellularly) is a classic example of this interaction. (3) Inhibition of the transport of one agent out of the cell by another agent can be achieved. Many fungi use energy-dependent efflux pumps to actively pump antifungal agents out of the cell, avoiding the toxic effects of the antifungal. Inhibition of these pumps by agents such as reserpine has been shown to enhance the activity of the azole antifungal agents against *Candida* spp. (4) Simultaneous inhibition of different fungal cell targets can be achieved. Inhibition of fungal cell wall synthesis by an agent such as caspofungin, coupled with disruption of cell membrane function by amphotericin B or azoles, is an example of this type of combination.

Although the potential value of combination antifungal therapy is appealing, there are several possible downsides to this strategy that must be considered. Antagonism among antifungal agents when used in combination also is a distinct possibility and may occur via several different mechanisms. (1) The action of one agent results in a decrease in the target of another agent. The action of azole antifungal agents depletes the cell membrane of ergosterol, which is the primary target for amphotericin B. (2) The action of one antifungal agent results in the modification of the target of another agent. The inhibition of ergosterol synthesis by azole antifungal agents results in the accumulation of methylated sterols, to which amphotericin B binds less well. (3) Blocking of the target site of one agent by another may occur. Lipophilic agents, such as itraconazole, may adsorb to the fungal cell surface and inhibit the binding of amphotericin B to membrane sterols.

Despite these possible positive and negative scenarios, the data supporting the achievement of synergy when various combinations are used clinically are limited. Likewise, antagonism may be demonstrated in the laboratory, but significant antagonism has not been observed clinically with antifungal combinations. By considering all of the laboratory and clinical data for antifungal combination therapy, one arrives at a very limited number of instances in which combination therapy has been shown to be beneficial in the treatment of invasive mycoses (Table 61.3).

The strongest data exist for the treatment of cryptococcosis, in which the combination of amphotericin B and flucytosine has been shown to be beneficial in the treatment of cryptococcal meningitis. These data are less strong for the combination of flucytosine with fluconazole or amphotericin B with triazoles; however, these combinations appear to be beneficial in treating cryptococcosis as well.

Candidiasis is generally treated adequately with a single antifungal agent, such as amphotericin B, an echinocandin, or fluconazole; however, combination therapy may be useful in selected situations. The combination of amphotericin B and fluconazole has proven benefits in treating candidemia; likewise, the combination of terbinafine plus an azole is promising in the treatment of refractory oropharyngeal candidiasis. Flucytosine in combination with either amphotericin B or triazoles has positive effects on survival and tissue burden of infection in animal models of candidiasis. Currently, combination therapy of candidiasis should be reserved for specific individual settings such as meningitis, endocarditis, hepatosplenic infection, and candidiasis that are recurrent or refractory to single-agent therapy.

Although the clinical setting of invasive aspergillosis is where combination therapy is most attractive, the data to support its use are lacking. At the present time, there are no clinical trials published that evaluate the use of combination therapy in the treatment of invasive aspergillosis. Studies in vitro and in animals have produced variable results. Combinations of echinocandins with azoles or amphotericin B have yielded positive results; likewise, amphotericin B plus rifampin appears synergistic. Studies with flucytosine or rifampin plus amphotericin B or azoles have been inconsistent. Despite the desperate need for better treatment options for invasive aspergillosis, there is little evidence that combination therapy will improve clinical outcome. Combination therapy should be used with caution until more clinical data are available.

TABLE 61.3 Summary of Potentially Useful Antifungal Combinations for Treatment of Common Mycoses

Infection	Antifungal Combination	Comments
Candidiasis	AMB + FCZ	Good clinical success in humans with candidemia
	AMB + FC	Clinical success in humans with peritonitis
Cryptococcosis	AMB + FC	Good clinical success in humans with cryptococcal meningitis
	AMB + FCZ	Clinical success in humans with cryptococcal meningitis
	FC + FCZ	Clinical success in humans with cryptococcal meningitis
Aspergillosis	AMB + FC	In vivo benefit (animal model); minimal human data
	AMB + azoles	No benefit in animals
	AMB + echinocandins	In vivo benefit (animal model); minimal human data
	Triazoles + echinocandins	In vivo benefit (animal model); minimal human data

AMB, Amphotericin B; *FC,* flucytosine; *FCZ,* fluconazole.

Mechanisms of Resistance to Antifungal Agents

Given the prominent role of *Candida* spp. as etiologic agents of invasive mycoses, it is not surprising that most of our understanding of the mechanisms of resistance to antifungal agents comes from studies of *C. albicans* and other species of *Candida*. Much less is known of resistance mechanisms in *Aspergillus* spp. and *C. neoformans*, and almost no information on antifungal resistance mechanisms is available for other opportunistic fungal pathogens.

In contrast to mechanisms of resistance to antibacterial agents, there is no evidence that fungi are capable of destroying or modifying antifungal agents as a means of achieving resistance; likewise, antifungal resistance genes are not transmissible from cell to cell in the manner that occurs with many bacterial resistance genes. It is apparent, however, that multidrug efflux pumps, target alterations, and reduced access to drug targets are important mechanisms of resistance to antifungal agents, just as they are for antibacterial resistance (Table 61.4). In contrast to the rapid emergence and spread of high-level multidrug resistance that occurs in bacteria, antifungal resistance usually develops slowly and involves the emergence of intrinsically resistant species or a gradual, stepwise alteration of cellular structures or functions that results in resistance to an agent to which there has been prior exposure.

POLYENES

Resistance to polyenes, and amphotericin B in particular, remains uncommon despite extensive use over more than 60 years. Decreased susceptibility to amphotericin B has been reported in isolates of *C. lusitaniae*, *C. glabrata*, *C. krusei*, *C. guilliermondii*, and *C. auris*. Although primary resistance may be seen, most resistance to amphotericin B among *Candida* spp. is secondary to amphotericin B exposure during therapy. *Aspergillus* spp. are generally susceptible to amphotericin B; however, *A. terreus* is unique in that it appears to be resistant both in vitro and in vivo. Although secondary resistance to amphotericin B has been reported in *C. neoformans*, it is quite rare.

The mechanism of amphotericin B resistance appears to be the result of qualitative and quantitative alterations in the fungal cell. Amphotericin B–resistant mutants of *Candida* spp. and *C. neoformans* have been shown to have a reduced ergosterol content, replacement of polyene-binding sterols (ergosterol) by ones that bind polyenes less well (fecosterol), or masking of ergosterol in the cell membranes so that binding with polyenes is hindered because of steric or thermodynamic factors. The molecular mechanism of amphotericin B resistance has not been determined; however, sterol analysis of resistant strains of *Candida* spp. and *C. neoformans* suggests that they are defective in *ERG2, ERG3,* or *ERG6* genes encoding for the C-8 sterol isomerase, C-5 sterol desaturase enzymes, and C-24 sterol methyltransferase, respectively.

AZOLES

The ubiquitous use of azoles, especially fluconazole, for the treatment and prevention of fungal infections has given rise to reports of emerging resistance to this class of antifungal agents. Fortunately, primary resistance to fluconazole is rare among most species of *Candida* causing bloodstream infection. Among the five most common species of *Candida* isolated from the blood of infected patients (*C. albicans*,

TABLE 61.4 Mechanisms Involved in the Development of Resistance to Antifungal Agents in Pathogenic Fungi

Fungus	Amphotericin B	Flucytosine	Itraconazole	Fluconazole	Echinocandins
Aspergillus fumigatus	—	—	Altered target enzyme, 14-α-demethylase Decreased azole accumulation	—	—
Candida albicans	Decrease in ergosterol Replacement of polyene-binding sterols Masking of ergosterol	Loss of permease activity Loss of cytosine deaminase activity Loss of uracil phosphoribosyl-transferase activity	—	Overexpression or mutation of 14-α-demethylase Overexpression of efflux pumps, *CDR* and *MDR* genes	Mutation in *fks1* gene
C. glabrata	Alteration or decrease in ergosterol content	Loss of permease activity	—	Overexpression of efflux pumps (*CgCDR* genes)	Mutation in *fks1* and/or *fks2* gene
C. krusei	Alteration or decrease in ergosterol content	—	—	Active efflux Reduced affinity for target enzyme, 14-α-demethylase	Mutation in *fks1* gene
C. lusitaniae	Alteration or decrease in ergosterol content Production of modified sterols	—	—	—	—
Cryptococcus neoformans	Defects in sterol synthesis Decreased ergosterol Production of modified sterols	—	—	Alterations in target enzyme Overexpression of *MDR* efflux pump	—

C. glabrata, *C. parapsilosis*, *C. tropicalis*, and *C. krusei*), only *C. krusei* is considered intrinsically resistant to fluconazole. Among the remaining species, approximately 10% of *C. glabrata* exhibit primary resistance to fluconazole, and less than 2% of *C. albicans*, *C. parapsilosis*, and *C. tropicalis* are resistant to this agent. Notably, the newly emergent species, *C. auris*, appears to be intrinsically resistant to fluconazole and exhibits variable resistance to amphotericin B and the echinocandins. The new triazoles (voriconazole, posaconazole, and isavuconazole) are more potent than fluconazole against *Candida* spp., including activity against *C. krusei* and some fluconazole-resistant strains of other *Candida* spp.; however, there is a strong positive correlation between the activity of fluconazole and that of the other triazoles, suggesting some degree of cross-resistance within the class.

Primary resistance to fluconazole is also rare among clinical isolates of *C. neoformans*. Secondary resistance has been described in isolates obtained from individuals with AIDS and relapsing cryptococcal meningitis.

Although resistance to the azoles is considered to be rare among *Aspergillus* spp., increased resistance has been noted in several geographic regions since 1999. Recent evidence from the Netherlands and Denmark suggests the possibility that azole resistance in *A. fumigatus* may be a side effect of environmental fungicide use. Cross-resistance between itraconazole, posaconazole, and voriconazole varies according to the mechanism of resistance.

Azole resistance in *Candida* spp. can be the result of the following mechanisms: a modification in the quantity or quality of the target enzymes, reduced access of the drug to the target, or some combination of these mechanisms. Thus point mutations in the gene *(ERG11)* encoding the target enzyme, lanosterol 14-α-demethylase, leads to an altered target with decreased affinity for azoles. Overexpression of *ERG11* results in overproduction of the target enzyme, creating the need for higher concentrations of the drug within the cell to inactivate all the target enzyme molecules. Upregulation of genes encoding for multidrug efflux pumps results in active efflux of the azole antifungal agents out of the cell. Upregulation of genes encoding the **major facilitator type efflux pump (*MDR*)** leads to fluconazole resistance, and upregulation of genes encoding the **adenosine triphosphate (ATP)–binding cassette transporters (*CDR*)** leads to resistance to multiple azoles. These mechanisms may act individually, sequentially, or simultaneously, resulting in strains of *Candida* that exhibit progressively higher levels of azole resistance.

The mechanisms of azole resistance in *Aspergillus* spp. are now well characterized in *A. fumigatus* but not in other species of *Aspergillus*. It appears that both increased drug efflux and alterations in the 14-α-demethylase target enzyme serve as mechanisms for resistance to itraconazole, posaconazole, and voriconazole among isolates of *A. fumigatus*. Specific mutations in the *CYP51A* gene encoding the target enzyme may result in resistance to one, two, or all three triazoles. Additional and as yet undefined mechanisms of resistance may also contribute to azole resistance in *A. fumigatus* isolates from patients undergoing long-term azole therapy.

Similarly, secondary resistance to fluconazole among isolates of *C. neoformans* has been associated with overexpression of MDR efflux pumps and alteration of the target enzyme. *C. neoformans* has also been shown to have a CDR-type efflux pump.

ECHINOCANDINS

Caspofungin, anidulafungin, and micafungin all demonstrate potent fungicidal activity against *Candida* spp., including azole-resistant strains. Clinical isolates of *Candida* spp. with reduced susceptibility to the echinocandins are uncommon but increasingly recognized among patients undergoing long-term treatment with these agents. Efforts to produce caspofungin-resistant mutants of *C. albicans* in the laboratory have shown that the frequency with which these mutants arise is very low (1 in 10^8 cells), suggesting a low potential for the emergence of resistance in the clinical setting. Echinocandin resistance has likewise been rare among clinical isolates of *Aspergillus*; however, laboratory-derived echinocandin-resistant mutants have been selected.

The mechanism of resistance to the echinocandins that has been characterized in laboratory strains of *C. albicans* and clinical strains of *C. albicans, C. glabrata*, *C. tropicalis, C. krusei,* and *C. lusitaniae* is one of an altered glucan synthesis enzyme complex that shows a decreased sensitivity to inhibition by agents within the class. These strains have point mutations in the *fks1* or *fks2* (*C. glabrata*) gene that encodes for an integral membrane protein (Fks1p, Fks2p), which is the catalytic subunit of the glucan synthesis enzyme complex. The *fks* mutation results in strains that are resistant to all of the echinocandins but retain susceptibility to polyene and azole antifungal agents. Importantly, the activity of the novel glucan synthase inhibitor, SCY-078, is not compromised by the most common mutations in the protein target Fks.

The *fks* gene also is essential in *Aspergillus* spp., and laboratory-derived *fks1* mutants of *A. fumigatus* have been shown to exhibit decreased susceptibility to all the echinocandins in vitro and in vivo. The echinocandin-resistant strain of *A. fumigatus* was shown to have decreased fitness for causing infection relative to a wild-type strain, suggesting that this may account for the paucity of clinical strains expressing echinocandin resistance.

FLUCYTOSINE

Primary resistance to flucytosine is uncommon among clinical isolates of *Candida* spp. and *C. neoformans.* Secondary resistance, however, is well documented to occur among both *Candida* spp. and *C. neoformans* during monotherapy with this agent.

Flucytosine resistance may develop because of decreased uptake of the drug (loss of permease activity) or by loss of enzymatic activity necessary to convert flucytosine to 5-FU (cytosine deaminase) and 5-fluorouridylic acid (FUMP pyrophosphorylase). Uracil phosphoribosyltransferase, another enzyme in the pyrimidine salvage pathway, is also important in the formation of FUMP (5-fluorouracilmonophosphate), and loss of its activity is sufficient to confer resistance to flucytosine.

ALLYLAMINES

Although clinical failures can occur during treatment of fungal infections with terbinafine and naftifine, they have

not been shown to be the result of resistance to these agents. It has been shown that the CDR1 multidrug efflux pump can use terbinafine as a substrate, suggesting that efflux-mediated resistance to allylamines is a possibility.

CLINICAL FACTORS CONTRIBUTING TO RESISTANCE

Antifungal therapy may fail clinically, despite the fact that the drug used is active against the infecting fungus. The complex interaction of the host, the drug, and the fungal pathogen may be influenced by a wide variety of factors, including the immune status of the host, the site and severity of the infection, presence of a foreign body (e.g., catheter, vascular graft), the activity of the drug at the site of infection, the dose and duration of therapy, and patient compliance with the antifungal regimen. It must be recognized that the presence of neutrophils, use of immunomodulating drugs, concomitant infections (e.g., human immunodeficiency virus [HIV]), surgical procedures, age, and nutritional status of the host all may be more important in determining the outcome of the infection than the ability of the antifungal agent to inhibit or kill the infecting organism.

ANTIFUNGAL SUSCEPTIBILITY TESTING

In vitro susceptibility testing of antifungal agents is designed to determine the relative activity of one or more agents against the infecting pathogen in hopes of selecting the best option for treatment of the infection. Thus antifungal susceptibility tests are performed for the same reasons that tests with antibacterial agents are performed. Antifungal susceptibility tests will (1) provide a reliable estimate of the relative activity of two or more antifungal agents against the tested organism, (2) correlate with in vivo antifungal activity and predict the likely outcome of therapy, (3) provide a means with which to monitor the development of resistance among a normally susceptible population of organisms, and (4) predict the therapeutic potential of newly developed investigational agents.

Standardized methods for performing antifungal susceptibility testing are reproducible, accurate, and available for use in clinical laboratories. Antifungal susceptibility testing is now increasingly and appropriately used as a routine adjunct to the treatment of fungal infections. Guidelines for the use of antifungal testing as a complement to other laboratory studies have been developed. Selective application of antifungal susceptibility testing, coupled with broader identification of fungi to the species level, is especially useful in difficult to manage fungal infections. One must keep in mind, however, that the in vitro susceptibility of an infecting organism to the antimicrobial agent is only one of several factors that may influence the likelihood that therapy for an infection will be successful (see the section Clinical Factors Contributing to Resistance).

Questions

1. What is the mechanism of action of the echinocandin antifungal agents? Why is this an advantage for this class of agents?
2. Describe the mechanisms of resistance to the azoles that are known for *Candida albicans.*
3. Why is combination therapy with antifungal agents attractive? Give an example of a mechanism that would likely produce synergy.

62 Superficial and Cutaneous Mycoses

Darrell, a 24-year-old medical student, just loves his new bulldog puppy, Delbert. He recently purchased Delbert from a local "backyard" breeder. Darrell has taken to giving Delbert frequent "smooches" on his muzzle, which Delbert loves, because he knows a treat is soon to follow. After about 3 months of proud puppy ownership and "smooching," Darrell noticed that his mustache began itching, and his upper lip was beginning to swell. Over a 1-week period, his upper lip became swollen and inflamed, and small pustular areas became apparent among the sparse hairs of his moustache. Similar changes also were becoming apparent on Delbert's muzzle. This concerned Darrell, so he promptly took Delbert to the veterinarian. The veterinarian took one look at the pair, wrote a prescription for Delbert, and told Darrell that he should make a visit to the dermatologist.

1. What was the likely cause of Darrell/Delbert's affliction? Be specific.
2. How would you go about making a diagnosis?
3. How would you go about treating this infection?
4. Who gave what to whom?

Summaries Clinically Significant Organisms

DERMATOPHYTES

Trigger Words

Tinea, KOH preparation, ringworm, azoles, terbinafine, circular, scaling lesion with central clearing and hair loss

Biology, Virulence, and Disease

- Include filamentous fungi in the genera *Trichophyton, Epidermophyton,* and *Microsporum*
- Keratinophilic and keratinolytic; able to invade and break down skin, hair, and nails
- In infections of skin, hair, and nails, only outermost keratinized layers invaded
- Various forms of dermatophytosis (tineas or "ringworm") classified according to anatomic site or structure involved
- Clinical signs and symptoms vary

Epidemiology

- Classified into three categories based on natural habitat: geophilic, zoophilic, and anthropophilic
- Geophilic: live in soil, occasional pathogens of both animals and humans
- Zoophilic: parasitize hair and skin of animals but can be transmitted to humans
- Anthropophilic: infect humans, may be transmitted directly or indirectly from person to person
- Occur worldwide, especially in tropical and subtropical regions

Diagnosis

- Demonstration of fungal hyphae by direct microscopy of skin, hair, or nail samples
- Isolation of organisms in culture

Treatment, Prevention, and Control

- Localized infections that do not involve hair or nails may be treated effectively with topical antifungal agents (azoles, terbinafine, haloprogin)
- All others require oral therapy (griseofulvin, itraconazole, fluconazole, terbinafine)

KOH, Potassium hydroxide.

Fungal infections of the skin and skin structures are extremely common. These infections are generally categorized by the structures that the fungi colonize or invade as follows:

1. **Superficial mycoses**: limited to the outmost layers of the skin and hair
2. **Cutaneous mycoses:** infections that involve the deeper layers of the epidermis and its integuments, the hair, and nails
3. **Subcutaneous mycoses**: involving the dermis, subcutaneous tissues, muscle, and fascia.

The subcutaneous mycoses will be discussed separately in Chapter 63. This chapter will deal with the superficial and cutaneous mycoses.

Superficial Mycoses

Agents of superficial mycoses are fungi that colonize the keratinized outer layers of the skin, hair, and nails. Infections caused by these organisms elicit little or no host immune response and are nondestructive and thus asymptomatic. They are usually of cosmetic concern only and are easy to diagnose and treat.

PITYRIASIS (TINEA) VERSICOLOR

Pityriasis versicolor is a common superficial fungal infection that is seen worldwide. In tropical environments, it may affect 30% to 35% of the population. It is caused by the lipophilic yeast species of the *Malassezia furfur* complex: *M. furfur, M. sympodialis, M. globosa, M. restricta, M. slooffiae, M. obtusa, M. dermatis, M. japonica,* and *M. yamatoensis*. In routine clinical reporting referring to these organisms as members of the *M. furfur* complex is usually sufficient.

Morphology

When viewed in skin scrapings, members of the *M. furfur* complex appear as clusters of spherical or oval, thick-walled

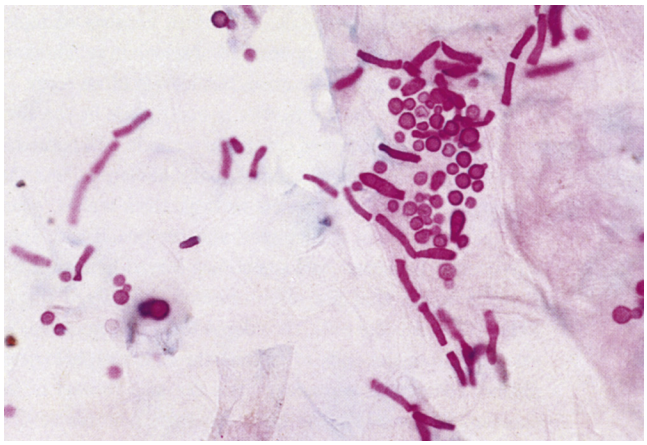

Fig. 62.1 Pityriasis versicolor. Periodic acid–Schiff–stained skin scraping showing yeastlike cells and short, infrequently branched hyphae that are often oriented end to end (×100). (From Connor, D.H., Chandler, F.W., Schwartz, D.A., et al., 1997. Pathology of Infectious Diseases. Appleton & Lange, Stamford, CT.)

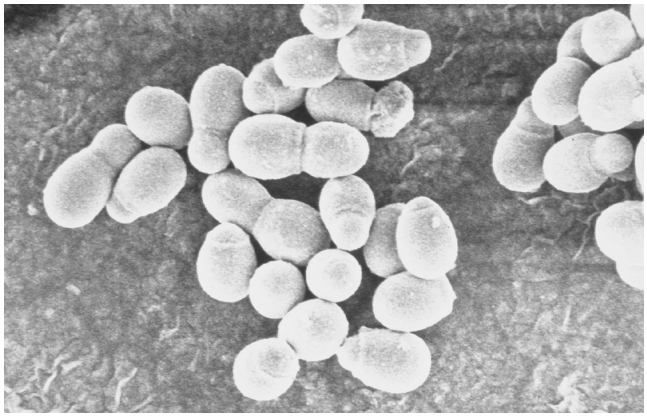

Fig. 62.2 Scanning electron micrograph of *Malassezia furfur* demonstrating the liplike collarette around the point of bud initiation on the parent cell. (Courtesy S.A. Messer.)

yeastlike cells, 3 to 8 μm in diameter (Fig. 62.1). The yeast cells may be mixed with short, infrequently branched hyphae that tend to orient end to end. The yeastlike cells represent phialoconidia and show polar bud formation with a "lip" or collarette around the point of bud initiation on the parent cell (Fig. 62.2). In culture on standard media containing or overlaid with olive oil, species of the *M. furfur* complex grow as cream-colored to tan yeastlike colonies composed of budding yeastlike cells; hyphae are infrequently produced.

Epidemiology

Pityriasis versicolor is a disease of healthy persons that occurs worldwide, but it is most prevalent in tropical and subtropical regions. Young adults are most commonly affected. *M. furfur* and other members of the species complex are not found as saprophytes in nature, and pityriasis versicolor has not been documented in animals. Human infection is thought to result from the direct or indirect transfer of infected keratinous material from one person to another.

Clinical Syndromes

The lesions of pityriasis versicolor are small hypopigmented or hyperpigmented macules. The upper trunk, arms, chest, shoulders, face, and neck are most often involved, but any part of the body may be affected (Fig. 62.3). The lesions are irregular, well-demarcated patches of discoloration that may be raised and covered by a fine scale. Because species of the *M. furfur* complex tend to interfere with melanin production, lesions are hypopigmented in dark-skinned individuals. In light-skinned individuals, the lesions are pink to pale brown and become more obvious when they fail to tan after exposure to sunlight. Little or no host reaction occurs, and the lesions are asymptomatic, with the exception of mild pruritus in severe cases. The *M. furfur* complex has also been associated with folliculitis, obstructive dacryocystitis, systemic infections in patients receiving intravenous lipid infusions, and seborrheic dermatitis, especially in patients with the acquired immunodeficiency syndrome (AIDS).

Fig. 62.3 Pityriasis versicolor. Multiple, pale brown, hyperpigmented patches on chest and shoulders. (From Chandler, F.W., Watts, J.C., 1987. Pathologic Diagnosis of Fungal Infections. American Society for Clinical Pathology Press, Chicago, IL.)

Laboratory Diagnosis

The laboratory diagnosis of pityriasis versicolor is made by the direct visualization of the fungal elements on microscopic examination of epidermal scales in 10% potassium hydroxide (KOH) with or without calcofluor white. The organisms are usually numerous and may be visualized with hematoxylin and eosin (H&E) or periodic acid–Schiff (PAS) stains (see Fig. 62.1). The lesions will also fluoresce with a yellowish color on exposure to a Wood lamp.

Although not usually necessary for establishing the diagnosis, culture may be performed using synthetic mycologic media supplemented with olive oil as a source of lipid. Growth of yeastlike colonies appear after incubation

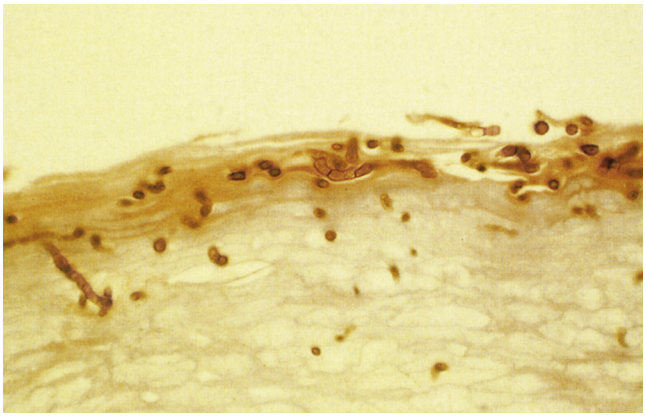

Fig. 62.4 Tinea nigra. Dematiaceous hyphae of *Hortaea werneckii* (hematoxylin and eosin, ×100). (From Connor, D.H., et al., 1997. Pathology of Infectious Diseases. Appleton & Lange, Stamford, CT.)

at 30° C for 5 to 7 days. Microscopically, the colonies are comprised of budding yeastlike cells with occasional hyphae.

Treatment

Although spontaneous cure has been reported, the disease is generally chronic and persistent. Treatment consists of the use of topical azoles or selenium sulfide shampoo. For more widespread infection, oral ketoconazole or itraconazole may be used.

TINEA NIGRA

Tinea nigra is a superficial phaeohyphomycosis caused by the black fungus *Hortaea werneckii* (formerly *Exophiala werneckii*).

Morphology

Microscopically, *H. werneckii* appears as dematiaceous (melanin [brown to black] pigmented), frequently branched, septate hyphae, 1.5 to 3.0 μm wide. Arthroconidia and elongate budding cells are also present (Fig. 62.4). *H. werneckii* also grows in culture on standard mycologic media at 25° C, on which it is a black mold producing annelloconidia (conidia possessing annelids or rings), which often slide down the sides of the conidiophore.

Epidemiology

Tinea nigra is a tropical or subtropical condition. It is likely contracted by traumatic inoculation of the fungus into the superficial layers of the epidermis. It is most prevalent in Africa, Asia, and Central and South America. Children and young adults are most often affected, with a higher incidence in females.

Clinical Syndromes

Tinea nigra appears as a solitary, irregular, pigmented (brown to black) macule, usually on the palms or soles (Fig. 62.5). There is no scaling or invasion of hair follicles, and the infection is not contagious. Because of its superficial location, there is little or no discomfort or host reaction. Because the lesion grossly may resemble a malignant melanoma, biopsy or local excision may be considered. Such invasive procedures may be avoided by a simple microscopic examination of skin scrapings of the affected area.

Fig. 62.5 Tinea nigra. Darkly pigmented macules with irregular edges present on the palm. (From Chandler, F.W., Watts, J.C., 1987. Pathologic Diagnosis of Fungal Infections. American Society for Clinical Pathology Press, Chicago, IL.)

Laboratory Diagnosis

Tinea nigra is easily diagnosed by microscopic examination of skin scrapings placed in 10% to 20% KOH. The pigmented hyphae and yeast forms are confined to the outer layers of the stratum corneum and are easily detected on H&E-stained (see Box 60.1) sections (see Fig. 62.4). Once fungal elements are detected, skin scrapings should be placed on mycologic media with antibiotics. A dematiaceous yeastlike colony should appear within 3 weeks, becoming velvety with age. Microscopic examination reveals two-celled, cylindric, yeastlike cells and, depending on the age of the colony, toruloid hyphae.

Treatment

The infection responds well to topical therapy, including Whitfield ointment, azole creams, and terbinafine.

WHITE PIEDRA

White piedra is a superficial infection of hair caused by yeastlike fungi of the genus *Trichosporon: T. ovoides* (causes scalp hair white piedra), *T. inkin* (causes most cases of pubic white piedra), and *T. asahii*.

Morphology

Microscopic examination reveals hyphal elements, arthroconidia (rectangular cells resulting from the fragmentation of hyphal cells), and blastoconidia (budding yeast cells).

Epidemiology

This condition occurs in tropical and subtropical regions and is related to poor hygiene.

Clinical Syndromes

White piedra affects the hairs of the groin and axillae. The fungus surrounds the hair shaft and forms a white to brown swelling along the hair strand. The swellings are soft and pasty and may be easily removed by running a section of the hair between the thumb and forefinger. The infection does not damage the hair shaft.

Laboratory Diagnosis

When microscopic examination reveals hyphal elements, arthroconidia, and/or budding yeast cells, infected hair should be placed on mycologic media without cycloheximide (cycloheximide will inhibit *Trichosporon* spp.). *Trichosporon* spp. will form cream-colored, dry, wrinkled colonies within 48 to 72 hours on incubation at room temperature. The various species of *Trichosporon* can be identified in the same manner as other yeast isolates. Sugar assimilations, potassium nitrate (KNO_3) assimilation (negative), urease production (positive), and morphology on cornmeal agar (both arthroconidia and blastoconidia are present) should be determined.

Treatment

Treatment may be accomplished by the use of topical azoles; however, improved hygiene and shaving of the infected hair are also effective and usually negate the necessity of medical treatment.

BLACK PIEDRA

Another condition affecting the hair, primarily the scalp, is black piedra. The causative agent of black piedra is *Piedraia hortae*.

Morphology

The organism grows as pigmented (brown to reddish-black) mold. As the culture ages, spindle-shaped ascospores are formed within specialized structures (asci). These structures (asci and ascospores) also are produced within the rock-hard hyphal mass that surrounds the hair shaft.

Epidemiology

Black piedra is uncommon and has been reported from tropical areas in Africa, Asia, and Central and South America. It is thought to be a condition of poor hygiene.

Clinical Syndromes

Black piedra presents as small, dark nodules that surround the hair shafts. It is asymptomatic and generally involves the scalp. The hyphal mass is held together by a cement-like substance and contains asci and ascospores, which is the sexual phase of the fungus.

Laboratory Diagnosis

Examination of the nodule reveals branched, pigmented, hyphae held together by a cement-like substance. *P. hortae* can be cultured on routine mycologic media. Very slow growth may be observed at 25° C and may begin as a yeastlike colony, later becoming velvety as hyphae develop. Asci may be observed microscopically, usually ranging from 4 to 30 μm and containing up to eight ascospores.

Treatment

Treatment of black piedra is easily accomplished by a haircut and proper, regular washings.

Cutaneous Mycoses

The cutaneous mycoses include infections caused by dermatophytic fungi (dermatophytosis) and nondermatophytic fungi (dermatomycosis) (Table 62.1). Because of the overwhelming importance of dermatophytes as etiologic agents of cutaneous mycoses, the majority of this section will deal with those fungi. The nondermatophytic fungi will be discussed regarding their role in onychomycosis. The superficial and cutaneous infections caused by *Candida* spp. will be discussed in Chapter 65.

DERMATOPHYTOSES

The term **dermatophytosis** refers to a complex of diseases caused by any of several species of taxonomically related filamentous fungi in the genera *Trichophyton, Epidermophyton,* and *Microsporum* (Tables 62.1 to 62.3). These fungi are known collectively as **the dermatophytes,** and all possess the ability to cause disease in humans and/or animals. All have in common the ability to invade the skin, hair, or nails. In each case, these fungi are keratinophilic and keratinolytic; thus they are able to break down the keratin surfaces of these structures. In the case of skin infections, the dermatophytes invade only the upper, outermost layer of the epidermis, which is the stratum corneum. Penetration below the granular layer of the epidermis is rare; likewise, with hair and nails, being part of the skin, only the keratinized layers are invaded. The various forms of dermatophytosis are referred to as "tineas" or ringworm. Clinically, the tineas are classified according to the anatomic site or structure affected: (1) tinea capitis of the scalp, eyebrows, and eyelashes; (2) tinea barbae of the beard; (3) tinea corporis of the smooth or glabrous skin; (4) tinea cruris of the groin; and (5) tinea pedis of the foot; (6) tinea unguium of the nails (also known as **onychomycosis**). The clinical signs and symptoms of dermatophytosis vary according to the etiologic agents, the host reaction, and the site of infection.

Morphology

Each genus of dermatophytic mold is characterized by a specific pattern of growth in culture and by the production of macroconidia and microconidia (see Table 62.2). Further identification to species level requires consideration of colony morphology, spore production, and nutritional requirements in vitro.

Microscopically, the genus *Microsporum* is identified by observation of its macroconidia, whereas microconidia are the characteristic structures of the genus *Trichophyton* (see Table 62.2). *Epidermophyton floccosum* does not produce microconidia, but its smooth-walled macroconidia borne in clusters of two or three are quite distinctive (Fig. 62.6). *Microsporum canis* produces characteristic large, multicellular (five to eight cells per conidium), thick- and rough-walled macroconidia (Fig. 62.7). *Trichophyton rubrum* produces microconidia that are teardrop or peg shaped and borne

[f]*T. schoenleinii* is fluorescent.
NA, Not applicable.

along the sides of hyphae (Fig. 62.8), whereas *T. mentagrophytes* complex produces both single, cigar-shaped macroconidia and grapelike clusters of spherical microconidia (Fig. 62.9). *T. tonsurans* produces variably sized and shaped microconidia, with relatively large spherical conidia often located right alongside small, parallel-walled conidia and other microconidia of various sizes and shapes (Fig. 62.10).

In skin biopsies, all of the dermatophytes are morphologically similar and appear as hyaline septate hyphae, chains of arthroconidia, or dissociated chains of arthroconidia that

invade the stratum corneum, hair follicles, and hairs. When the hair is infected, the pattern of fungal invasion can be either **ectothrix, endothrix,** or **favic** depending on the dermatophytic species (Fig. 62.11). Septate hyphae may be seen within the hair shaft in all three patterns. In the **ectothrix** pattern, **arthroconidia** are formed on the outside of the hair (Fig. 62.12; see Fig. 62.11); in the **endothrix** pattern, arthroconidia are formed inside the hair (see Fig. 62.11); and in the **favic** pattern, hyphae, arthroconidia, and empty spaces resembling air bubbles ("honeycomb" pattern) are formed inside the hair (see Fig. 62.11). The dermatophytes can usually be seen on H&E stain; however, they are best visualized with special stains for fungi, such as Gomori methenamine silver (GMS) and PAS (see Fig. 62.12 and Chapter 60).

Ecology and Epidemiology

Dermatophytes can be classified into three different categories based on their natural habitat (see Table 62.3): (1)

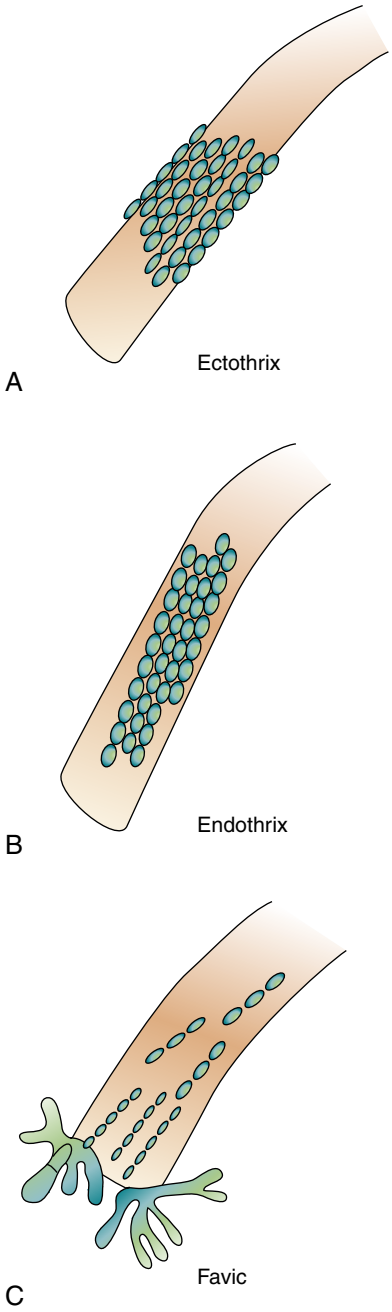

Fig. 62.11 Schematic of (A) ectothrix hair infection, (B) endothrix hair infection, and (C) favic hair infection.

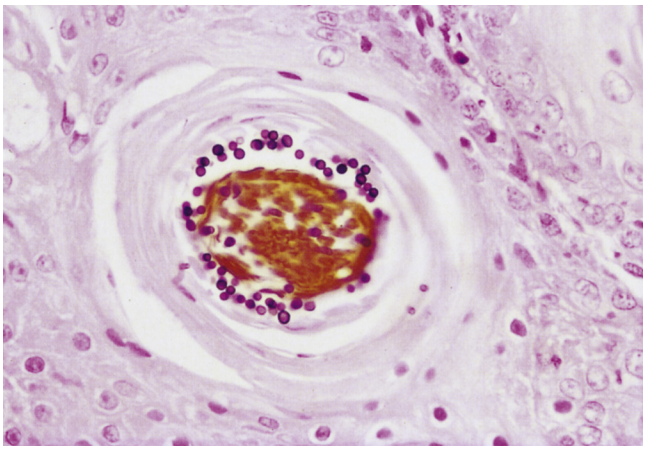

Fig. 62.12 Arthroconidia surrounding a hair shaft. Ectothrix hair infection caused by *Microsporum canis* (Gomori methenamine silver–hematoxylin and eosin, ×160.) (From Connor, D.H., et al., 1997. Pathology of Infectious Diseases. Appleton & Lange, Stamford, CT.)

geophilic, (2) **zoophilic**, and (3) **anthropophilic**. The geophilic dermatophytes live in the soil and are occasional pathogens of both animals and humans. Zoophilic dermatophytes normally parasitize the hair and skin of animals but can be transmitted to humans. Anthropophilic dermatophytes generally infect humans and may be transmitted directly or indirectly from person to person. This classification is quite useful prognostically and emphasizes the importance of identifying the etiologic agent of dermatophytoses. Species of dermatophytes that are considered anthropophilic tend to cause chronic, relatively noninflammatory infections that are difficult to cure. In contrast, the zoophilic and geophilic dermatophytes tend to elicit a profound host reaction, causing lesions that are highly inflammatory and respond well to therapy. In some instances, these infections may heal spontaneously.

The dermatophytes are worldwide in distribution (see Table 62.3), and infection may be acquired from the transfer of arthroconidia or hyphae, or keratinous material containing these elements, from an infected host to a susceptible, uninfected host. Dermatophytes may remain viable in desquamated skin scales or hair for long periods, and infection may be by direct contact or indirect via fomites. Individuals of both sexes and all ages are susceptible to dermatophytosis; however, tinea capitis is more common in prepubescent children, and tinea cruris and tinea pedis are primarily diseases of adult males. Although dermatophytoses occur worldwide, especially in tropical and subtropical regions, individual dermatophyte species may vary in their geographic distribution and in their virulence for humans (see Table 62.3). For example, *T. concentricum*, the cause of tinea imbricata, is confined to the islands of the South Pacific and Asia, whereas *T. tonsurans* has replaced *Microsporum audouinii* as the principal agent of tinea capitis in the United States. Infections caused by dermatophytes are generally endemic but may assume epidemic proportions in selected settings (e.g., tinea capitis in school children). On a worldwide scale, *T. rubrum* and *T. mentagrophytes* complex account for 80% to 90% of all dermatophytoses.

Clinical Syndromes

Dermatophytoses manifest a wide range of clinical presentations, which may be affected by factors such as the species of dermatophytes, the inoculum size, the site of infection, and the immune status of the host (Clinical Cases 62.1 and 62.2). Any given disease manifestation may result from several different species of dermatophytes, as shown in Table 62.1.

The classic pattern of dermatophytosis is the "ringworm" pattern of a ring of inflammatory scaling with diminution of inflammation toward the center of the lesion. Tineas of hair-bearing areas often present as raised, circular or ring-shaped patches of alopecia with erythema and scaling (Fig. 62.13) or as more diffusely scattered papules, pustules,

TABLE 62.3 Classification of Dermatophytes According to Ecologic Niche

Ecologic Niche	Species	Principal Hosts	Geographic Distribution	Prevalence
Anthropophilic	*Epidermophyton floccosum*	—	Worldwide	Common
	Microsporum audouinii	—	Worldwide	Common
	M. ferrugineum	—	Africa, Asia	Endemic
	Trichophyton concentricum	—	Asia, Pacific Islands	Endemic Rare
	T. megninii	—	Europe, Africa	Endemic
	T. mentagrophytes complex	—	Worldwide	Common
	T. rubrum	—	Worldwide	Common
	T. schoenleinii	—	Europe, Africa	Endemic
	T. soudanense	—	Africa	Endemic
	T. tonsurans	—	Worldwide	Common
	T. violaceum	—	Europe, Africa, Asia	Common
Zoophilic	*M. canis*	Cat, dog, horse	Worldwide	Common
	M. (*Lophophyton*) *gallinae*	Fowl	Worldwide	Rare
	M. nanum (*Nannizzia nana*)	Swine	Worldwide	Rare
	M. (*Nannizzia*) *persicolor*	Vole	Europe, United States	Rare
	T. equinum	Horse	Worldwide	Rare
	T. mentagrophytes complex (granular isolates)	Rodent	Worldwide	Common
	T. erinacei	Hedgehog	Europe, New Zealand, Africa	Occasional
	T. simii	Monkey	India	Occasional
	T. verrucosum	Cow	Worldwide	Common
Geophilic	*M. gypseum* complex (*Nannizzia gypsea*)	—	Worldwide	Occasional
	T. vanbreuseghemii (*Arthroderma gertleri*)	—	Worldwide	Rare

Clinical Case 62.1 **Dermatophytosis in an Immunocompromised Host**

Squeo and associates (*J Am Acad Dermatol* 39:379–380, 1998) described a case of a 55-year-old renal transplant recipient with onychomycosis and chronic tinea pedis who presented with tender nodules on his left medial heel. He then developed papules and nodules on his right foot and calf. A skin biopsy demonstrated periodic acid–Schiff–positive, thick-walled, round cells, 2 to 6 μm in diameter in the dermis. Skin biopsy culture grew *Trichophyton rubrum*. *T. rubrum* has been described as an invasive pathogen in immunocompromised hosts. The clinical presentation, histopathology, and early fungal culture growth suggested *Blastomyces dermatitidis* in the differential diagnosis before the final identification of *T. rubrum*.

vesicles, and kerions (severe inflammation involving the hair shaft) (Fig. 62.14). Hairs infected with certain species, such as *M. canis*, *M. audouinii*, and *T. schoenleinii*, often fluoresce yellow-green when exposed to a Wood light (see Table 62.2). Infections of smooth skin commonly present as erythematous and scaling patches that expand in a centripetal pattern with central clearing. Dermatophytoses of the foot and hand may often become complicated

Clinical Case 62.2 **Tinea Capitis in an Adult Woman**

Martin and Elewski (*J Am Acad Dermatol* 49:S177–S179, 2003) described an 87-year-old woman with a 2-year history of a pruritic, painful, scaling scalp eruption and hair loss. Her previous treatment for this condition included numerous courses of systemic antibiotics and prednisone without success. Of interest in her social history was that she had recently acquired several stray cats that she kept inside her home. On physical examination, there were numerous pustules throughout the scalp, with diffuse erythema, crusting, and scale extending to the neck. There was extremely sparse scalp hair and prominent posterior cervical lymphadenopathy. She had no nail pitting. A Wood light examination of the scalp produced negative findings. A skin biopsy specimen and fungal, bacterial, and viral cultures were obtained. Bacterial culture grew rare *Enterococcus* species, whereas viral cultures showed no growth. The scalp biopsy specimen revealed an endothrix dermatophyte infection. Fungal culture grew *Trichophyton tonsurans*. The patient was treated with griseofulvin and Selsun shampoo. When seen at a 2-week follow-up visit, the patient demonstrated new hair growth and a resolution of her pustular eruption. With the brisk clinical response and culture growth of *T. tonsurans*, treatment with griseofulvin was continued for 8 weeks. The scalp hair grew back normally without permanent alopecia. Adults with alopecia require an evaluation for tinea capitis, including fungal cultures.

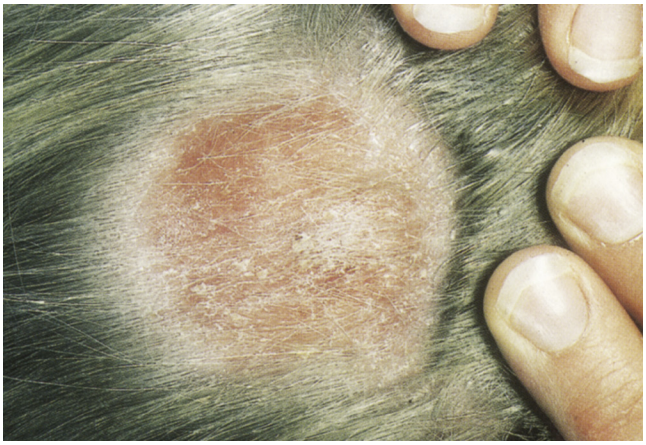

Fig. 62.13 Tinea capitis caused by *Microsporum canis.* (From Hay, R.J., 2003. Cutaneous and subcutaneous mycoses. In: Anaissie, E.J., McGinnis, M.R., Pfaller, M.A. (Eds.), Clinical Mycology. Churchill Livingstone, New York.)

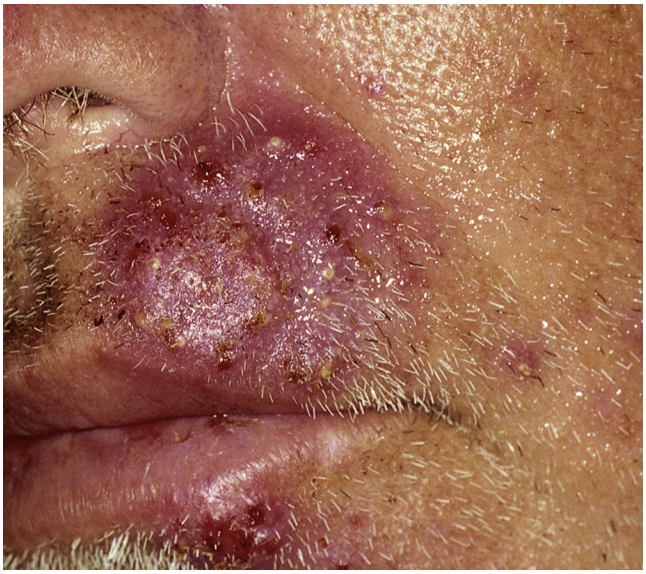

Fig. 62.14 Tinea barbae caused by *Trichophyton verrucosum.* (From Chandler, F.W., Watts, J.C., 1987. Pathologic Diagnosis of Fungal Infections. American Society for Clinical Pathology Press, Chicago, IL.)

by onychomycosis (Fig. 62.15), in which the nail plate is invaded and destroyed by the fungus. Onychomycosis (tinea unguium) is caused by a variety of dermatophytes (see Table 62.1) and is estimated to affect approximately 3% of the population in most temperate countries. It is a disease seen mostly in adults, with toenails affected more commonly than fingernails. The infection is usually chronic, and the nails become thickened, discolored, raised, friable, and deformed (see Fig. 62.15). *T. rubrum* is the most common etiologic agent in most countries. A rapidly progressive form of onychomycosis that originates from the proximal nail fold and involves the upper and underside of the nail is seen in AIDS patients.

Laboratory Diagnosis

The laboratory diagnosis of dermatophytoses relies on the demonstration of fungal hyphae by direct microscopy of skin, hair, or nail samples and the isolation of organisms in culture. Specimens are mounted in a drop of 10% to 20% KOH on a glass slide and examined microscopically. Filamentous, hyaline hyphal elements characteristic of dermatophytes may be seen in skin scrapings, nail scrapings, and hairs. In examining specimens for fungal elements, calcofluor white has been used with excellent results.

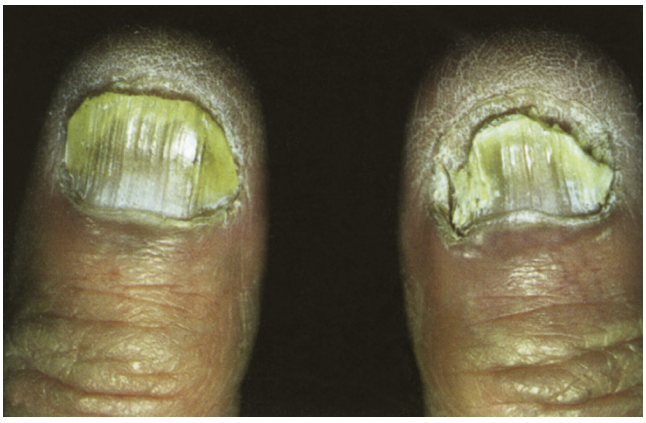

Fig. 62.15 Onychomycosis caused by *Trichophyton rubrum.* (From Hay, R.J., 2003. Cutaneous and subcutaneous mycoses. In: Anaissie, E.J., McGinnis, M.R., Pfaller, M.A. [Eds.], Clinical Mycology. Churchill Livingstone, New York.)

Cultures are always useful and can be obtained by scraping the affected areas and placing the skin, hair, or nail clippings onto standard mycologic media such as Sabouraud agar, with and without antibiotics, or dermatophyte test medium. Colonies develop within 7 to 28 days. Their gross and microscopic appearance and nutritional requirements can be used in identification. More recently molecular and proteomic methods have been used to provide rapid and specific means of identifying those unusual isolates that are difficult to identify using conventional phenotypic approaches.

Treatment

Dermatophytic infections that are localized and that do not affect hair or nails can usually be treated effectively with topical agents; all others require oral therapy. Topical agents include azoles (miconazole, clotrimazole, econazole, tioconazole, and itraconazole), terbinafine, and haloprogin. Whitfield ointment (benzoic and salicylic acids) is an optional agent for dermatophytosis, but responses are usually slower than those seen with agents with specific antifungal activity.

Oral antifungal agents with systemic activity against dermatophytes include griseofulvin, itraconazole, fluconazole, and terbinafine. The azoles and terbinafine are more rapidly and broadly efficacious than griseofulvin, especially for the treatment of onychomycosis.

ONYCHOMYCOSIS CAUSED BY NONDERMATOPHYTIC FUNGI

A number of nondermatophytic molds, as well as *Candida* species, have been associated with nail infections (see Table 62.1). These organisms include *Scopulariopsis brevicaulis*, *Neoscytalidium dimidiatum*, *Scytalidium hyalinum*, and a variety of others, including *Aspergillus*, *Fusarium*, and *Candida* species. Among these organisms, *S. brevicaulis, Neoscytalidium* spp., and *Scytalidium* spp. are proven nail pathogens. The other fungi certainly may be the cause

of nail pathology; however, the interpretation of nail cultures with these organisms should be done with caution because they may simply represent saprophytic colonization of abnormal nail material. Criteria used to determine an etiologic role for these fungi include isolation on multiple occasions and the presence of abnormal hyphal or conidial structures on microscopic examination of nail material.

Infections caused by *S. brevicaulis*, *N. dimidiatum*, and *S. hyalinum* are notoriously difficult to treat because they are not usually susceptible to any antifungals. Partial surgical removal of infected nails, coupled with oral itraconazole or terbinafine or intensive treatment with 5% amorolfine nail lacquer or Whitfield ointment, may be useful in achieving a clinical response.

Case Study and Questions

A 6-month-old infant developed an annular scaling rash with raised borders on the side of her face and neck.

1. Which of the following exposures is likely to be responsible for this infection?
   a. Contact with her favorite blanket
   b. Cuddling with the family cat
   c. Playing in an outside sand box
   d. Contact with "baby-safe" soap

2. Which of the following is the likely etiologic agent of the infection?
   a. *M. canis*
   b. *M. audouinii*
   c. *Candida albicans*
   d. *T. tonsurans*

3. How would you make the diagnosis?
   a. Microscopic examination of a skin scraping treated with KOH
   b. Serology
   c. Skin biopsy stained with GMS
   d. Blood culture

63 Subcutaneous Mycoses

A 40-year-old "ecotourist" was on an extended trip to the jungles of Costa Rica. During this time, she camped, climbed trees, waded in streams, slogged through mud, and endured drenching rains. She lost her shoes about 2 weeks into the "adventure" and continued to hike barefoot for another 2 weeks, during which time she sustained minor cuts and abrasions to both feet. Approximately 6 months after returning home, somewhere in the midwestern United States, she noticed mild swelling of her right foot. There was no pain, inflammation, or drainage from the foot. She comes to you for medical advice.

1. What is the differential diagnosis of this process?
2. What types of fungi might cause this infection?
3. How will you proceed with establishing the diagnosis?
4. What are the therapeutic options and the likelihood that they will be successful?

Answers to these questions are available on www.StudentConsult.com.

Summaries Clinically Significant Organisms

SPOROTRICHOSIS *(Sporothrix schenckii)*

Trigger Words

Thorn prick, rose handler's disease, sphagnum moss, lymphocutaneous nodules

Biology, Virulence, and Disease

- Thermally dimorphic fungus; grows as a mold at room temperature (e.g., 25° C) and as a pleomorphic yeast at 37° C and in tissue
- Infection is chronic; nodular and ulcerative lesions develop along lymphatics that drain primary site of inoculation

Epidemiology

- Sporadic, most common in warmer climates: Japan, North and South America
- Outbreaks related to forest work, mining, gardening
- Classic infection associated with traumatic inoculation of soil, vegetable, or organic matter contaminated with fungus
- Zoonotic transmission reported in armadillo hunters and in association with infected cats

Diagnosis

- Subcutaneous infection with lymphangitic spread
- Definitive diagnosis requires culture of infected pus or tissue
- In tissue, organism appears as a pleomorphic budding yeast

Treatment, Prevention, and Control

- Classic treatment: oral potassium iodide in saturated solution
- Itraconazole: safe, highly effective, treatment of choice
- Alternatives: terbinafine, fluconazole, posaconazole
- Local application of heat shown to be effective

EUMYCOTIC MYCETOMA *(Phaeoacremonium, Curvularia, Fusarium, Madurella, Mediacopsis, Nigrograna, Trematosphaeria, Exophiala, Falciformispora, AND Scedosporium species)*

Trigger Words

Grains, sinus tract, dematiaceous, subcutaneous, mycetoma

Biology, Virulence, and Disease

- Caused by a wide array of true fungi (as opposed to actinomycotic mycetomas, which are caused by bacteria)
- Localized chronic granulomatous infectious process involving cutaneous and subcutaneous tissues
- Painless subcutaneous nodule; increases slowly but progressively in size
- Local spread may breach tissue planes, destroying muscle, fascia, and bone
- Hematogenous or lymphatic spread rare

Epidemiology

- Primarily in tropical areas with low rainfall; most common in Africa and India
- Traumatic implantation into exposed body parts; foot and hand most common; back, shoulders, chest wall may also be involved
- Men more often affected than women
- Etiologic agent varies from country to country
- Mycetomas not contagious

Diagnosis

- Demonstration of grains or granules grossly visible in draining sinus tracts; may also be seen on tissue biopsy
- Microscopic examination of granules
- Culture usually needed for identification of organism

Treatment, Prevention, and Control

- Usually unsuccessful; poor response to most antifungal agents
- Specific antifungal therapy may slow progression: terbinafine, voriconazole, posaconazole
- Local excision usually ineffective; amputation is the only definitive treatment

ENTOMOPHTHOROMYCOSIS *(Conidiobolus coronatus AND Basidiobolus ranarum)*

Trigger Words

Entomophthoromycosis, subcutaneous, Splendore-Hoeppli, mucormycotic

Biology, Virulence, and Disease

- Subcutaneous entomophthoromycosis caused by Mucormycetes of the order Entomophthorales: *Conidiobolus coronatus, Basidiobolus ranarum*
- Chronic subcutaneous form of mucormycosis
- Occurs sporadically as a result of subcutaneous implantation or inhalation of fungus present in plant debris
- *B. ranarum:* infection presents with disk-shaped, rubbery, moveable masses localized to shoulder, pelvis, hips, thighs; may become quite large and ulcerate
- *C. coronatus:* confined to rhinofacial area; facial deformity may be quite dramatic
- Angioinvasion does not occur; dissemination or involvement of deep structures rare

Epidemiology

- Both types seen most commonly in Africa, India
- Both fungi are saprophytes present in leaf and plant debris
- Rare diseases without known predisposing factors
- *B. ranarum*: infection occurs after traumatic implantation of fungus into subcutaneous tissues of thighs, buttocks, trunk; occurs mainly in children; male/female ratio 3:1
- *C. coronatus*: infection occurs after inhalation of fungal spores, with subsequent invasion of tissues of nasal cavity, paranasal sinuses, facial soft tissues; predominantly seen in young adults; male/female ratio 10:1

Diagnosis

- Clinical diagnosis usually evident based on gross physical appearance
- Both types of subcutaneous entomophthoromycosis require biopsy for definitive diagnosis

Treatment, Prevention, and Control

- Both types of infection may be treated with itraconazole; oral potassium iodide in saturated solution may be used
- Facial reconstructive surgery may be necessary in the case of *C. coronatus* infection

Many fungal pathogens can produce subcutaneous lesions as part of their disease process; however, certain fungi are commonly introduced traumatically through the skin and have a propensity to involve the deeper layers of the dermis, subcutaneous tissue, and bone. Although they may ultimately present clinically as lesions on the skin surface, they rarely spread to distant organs. In general, the clinical course is chronic and insidious; once established, the infections are refractory to most antifungal therapy. The main subcutaneous fungal infections include lymphocutaneous sporotrichosis, chromoblastomycosis, eumycotic mycetoma, subcutaneous entomophthoromycosis, and subcutaneous phaeohyphomycosis. Two additional subcutaneous fungal or fungal-like processes, lobomycosis and rhinosporidiosis, are discussed separately in Chapter 66.

The subcutaneous mycoses are clinical syndromes caused by multiple fungal etiologies (Table 63.1). The causative agents of subcutaneous mycoses are generally considered to have low pathogenic potential and are commonly isolated from soil, wood, or decaying vegetation. Exposure is largely occupational or related to hobbies (e.g., gardening, wood gathering). Infected patients generally have no underlying immune defect.

Lymphocutaneous Sporotrichosis

Lymphocutaneous sporotrichosis is caused by *Sporothrix schenckii*, which is a dimorphic fungus that is ubiquitous in soil and decaying vegetation. Recent molecular studies have demonstrated that *S. schenckii sensu lato* is a complex of numerous phylogenetic species. Apart from *S. schenckii sensu stricto*, the species *S. brasiliensis*, *S. globosa*, and *S. luriei* are also involved in human sporotrichosis. *S. brasiliensis* is highly virulent and has caused large epidemics in Brazil; transmission occurs particularly through stray cats. *S. globosa* seems to be less aggressive and is mainly prevalent in Asia, in which children are often infected, but some cases have been reported in the Americas. *S. luriei* is a rare species that only has been reported from South Africa, India, and Italy.

Infection with *Sporothrix* spp. is chronic and is characterized by nodular and ulcerative lesions that develop along lymphatics that drain the primary site of inoculation (Fig. 63.1). Dissemination to the other sites, such as bones, eyes, lungs, and the central nervous system, is extremely rare (<1% of all cases) and will not be discussed further. At room temperature, *Sporothrix* spp. grows as a mold (Fig. 63.2); at 37° C and in tissue, it is a pleomorphic yeast (Fig. 63.3, see Table 63.1).

MORPHOLOGY

Members of the *S. schenckii* complex are thermally dimorphic. Mycelial form cultures grow rapidly and have a wrinkled membranous surface that gradually becomes tan, brown, or black. Microscopically, the mold form consists of narrow, hyaline, septate hyphae that produce abundant oval conidia (2 × 3 μm to 3 × 6 μm) borne on delicate sterigmata or in a rosette or "daisy petal" formation on conidiophores (see Fig. 63.2). The yeast form consists of spheric,

TABLE 63.1 Common Agents of Subcutaneous Mycoses

Disease	Etiologic Agent(s)	Typical Morphology in Tissue	Usual Host Reaction
Sporotrichosis	*Sporothrix schenckii*, *S. brasiliensis*, *S. globosa*, and *S. luriei*	Pleomorphic, spheric to oval or cigar-shaped yeasts, 2- to 10-μm diameter with single or multiple (rare) buds See Fig. 63.3	Mixed suppurative and granulomatous Splendore-Hoeppli material surrounds fungus (asteroid body) See Fig. 63.4
Chromoblastomycosis	*Cladophialophora* (*Cladosporium*) *carrionii* *Fonsecaea pedrosoi* *Phialophora verrucosa* *Rhinocladiella* spp. *Exophiala* spp.	Large, 6- to 12-μm diameter, spheric, thick-walled, brown muriform cells (sclerotic bodies) with septations along one or two planes; pigmented hyphae may be present See Fig. 63.6	Mixed suppurative and granulomatous Pseudoepitheliomatous hyperplasia
Eumycotic mycetoma	*Phaeoacremonium* spp. *Fusarium* spp. *Aspergillus nidulans* *Scedosporium* spp. *Madurella* spp. *Exophiala jeanselmei*, among others	Granules, 0.2 to several millimeter diameter, composed of broad (2- to 6-μm), hyaline (pale granules), or dematiaceous (black granules) septate hyphae that branch and form chlamydoconidia	Suppurative with multiple abscesses, fibrosis, and sinus tracts; Splendore-Hoeppli material
Subcutaneous entomophthoromycosis	*Basidiobolus ranarum* *Conidiobolus coronatus*	Short, poorly stained hyphal fragments, 6- to 25-μm diameter, nonparallel sides, paucisseptate, random branches See Fig. 63.10	Eosinophilic abscesses and granulation tissue, Splendore-Hoeppli material around hyphae
Subcutaneous phaeohyphomycosis	*Exophiala jeanselmei* *E. dermatitidis* *Alternaria* spp. *Chaetomium* spp. *Curvularia* spp. *Phialophora* spp., among others	Pigmented (brown) hyphae, 2- to 6-μm diameter, branched or unbranched, often constricted at prominent septations, yeast forms and chlamydoconidia may be present See Fig. 63.11	Subcutaneous cystic or solid granulomas; overlying epidermis rarely affected

Modified from Chandler, F.W., Watts, J.C., 1987. Pathologic Diagnosis of Fungal Infections. American Society for Clinical Pathology Press, Chicago, IL.

Fig. 63.1 Classic lymphocutaneous form of sporotrichosis, demonstrating a chain of subcutaneous nodules along the lymphatic drainage of the arm. (From Chandler, F.W., Watts, J.C., 1987. Pathologic Diagnosis of Fungal Infections. American Society for Clinical Pathology Press, Chicago, IL.)

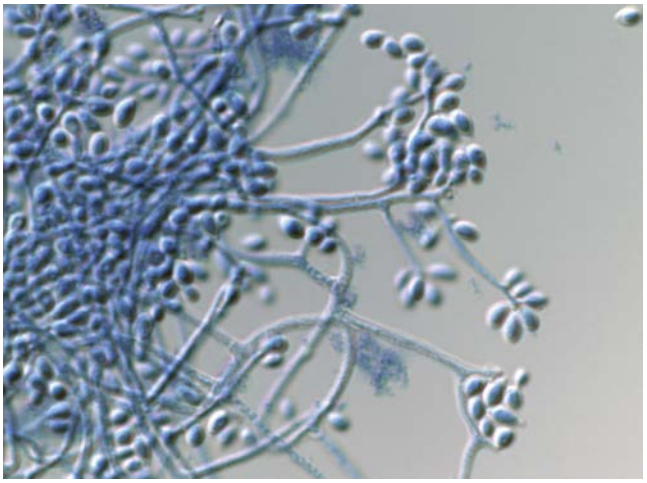

Fig. 63.2 Mold phase of *Sporothrix schenckii*.

oval, or elongated ("cigar-shaped") yeastlike cells, 2 to 10 μm in diameter, with single or (rarely) multiple buds (see Table 63.1 and Fig. 63.3). Although this is the "tissue phase" of *Sporothrix,* yeast forms are rarely seen on histopathologic examination of tissue.

EPIDEMIOLOGY

Sporotrichosis is usually sporadic and is most common in warmer climates. The major known areas of current endemicity are in Japan and in North and South America, especially Mexico, Brazil, Uruguay, Peru, and Colombia. Outbreaks of infection related to forest work, mining, and gardening have occurred. Classic infection is associated with traumatic inoculation of soil or vegetable or organic matter contaminated with the fungus. Zoonotic transmission has been reported in armadillo hunters, and *S. brasiliensis* is transmitted from bites or scratches from stray cats, which are considered a primary host of this fungus. Between 1998 and 2001, a large outbreak (178 patients) of cat-transmitted sporotrichosis caused by *S. brasiliensis* was reported in Rio de Janeiro, Brazil.

CLINICAL SYNDROMES

Lymphangitic sporotrichosis classically appears after local trauma to an extremity (Clinical Case 63.1). The initial site of infection appears as a small nodule, which may ulcerate. Secondary lymphatic nodules appear about 2 weeks after the appearance of the primary lesion and consist of a linear chain of painless, subcutaneous nodules that extend proximally along the course of lymphatic drainage of the primary lesion (see Fig. 63.1). With time, the nodules may ulcerate and discharge pus. Primary cutaneous lesions may remain "fixed" without

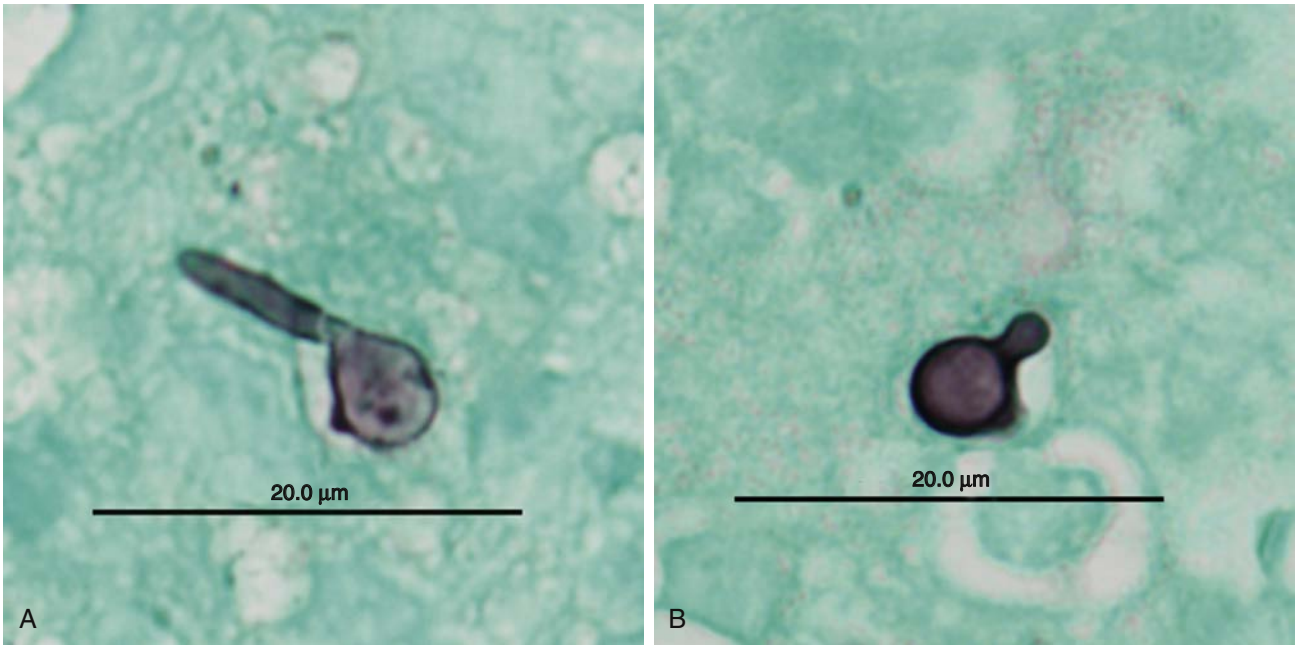

Fig. 63.3 (A and B) Lung biopsy from disseminated sporotrichosis. The yeast in (A) has a long cigar-shaped bud (Gomori methenamine silver). (From Anaissie, E.J., McGinnis, M.R., Pfaller, M.A. (Eds.), 2009. Clinical Mycology. Churchill Livingstone, London, UK.)

Clinical Case 63.1 **Sporotrichosis**

Haddad and colleagues (*Med Mycol* 40:425–427, 2002) described a case of lymphangitic sporotrichosis after injury with a fish spine. The patient was an 18-year-old male fisherman, resident in a rural area of São Paulo state in Brazil, who wounded his third left finger on the dorsal spines of a fish that was netted during his work. Subsequently, the area around the injury developed edema, ulceration, pain, and purulent secretion. The primary care physician interpreted the lesion as a pyogenic bacterial process and prescribed a 7-day course of oral tetracycline. No improvement was noted, and the therapy was changed to cephalexin, with similar results.

At examination 15 days after the accident, the patient presented with an oozing ulcer and nodules on the dorsum of the left hand and arm, forming an ascending nodular lymphangitic pattern. The diagnostic hypotheses considered were localized lymphangitic sporotrichosis, sporotrichoid leishmaniasis, and atypical mycobacteriosis *(Mycobacterium marinum)*. A histopathologic examination of material from the lesion revealed a chronic ulcerated granulomatous pattern of inflammation with intraepidermal microabscesses. No acid-fast bacilli or fungal elements were found. Culture of biopsy material on Sabouraud agar grew a mold characterized by septate, thin hyphae with conidia arranged in a rosette at the end of the conidiophores, consistent with *Sporothrix schenckii*. An intradermal reaction to sporotrichin also was positive. The patient was treated with oral potassium iodide, with clinical resolution at 2 months of therapy.

The clinical presentation in this case was typical of sporotrichosis; however, the source of the infection (fish spine) was unusual. Despite the greater incidence of infection by *M. marinum* among fishermen and aquarists, sporotrichosis must be remembered when these workers show lesions in an ascending lymphangitic pattern after being injured by contact with fish.

lymphangitic spread. Clinically, these lesions appear nodular, verrucous, or ulcerative and in general may resemble a malignant process such as squamous cell carcinoma. Other infectious causes of lymphangitic and ulcerative lesions that must be ruled out include mycobacterial and nocardial infections.

LABORATORY DIAGNOSIS

Definitive diagnosis usually requires culture of infected pus or tissue. *Sporothrix* spp. grow within 2 to 5 days on a variety of mycologic media and appears as a budding yeast at 35° C and as a mold at 25° C (see Figs. 63.2 and 63.3). Laboratory confirmation may be established by converting the mycelial growth to the yeast form by subculture at 37° C or immunologically through the use of the exoantigen test. In tissue, the organism appears as a 2 to 10 μm pleomorphic budding yeast (see Fig. 63.3) but is rarely observed in human lesions. The appearance of eosinophilic **Splendore-Hoeppli** material surrounding yeast cells (asteroid body) may be helpful (Fig. 63.4), but is also seen in other types of infection (see Table 63.1). A serologic test is available commercially but is rarely used in the diagnosis of sporotrichosis.

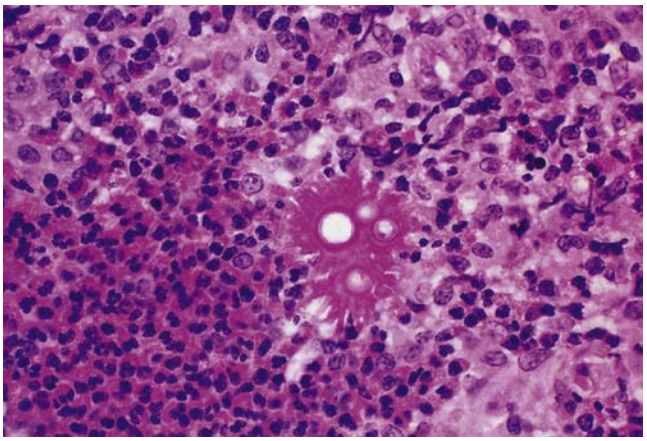

Fig. 63.4 Asteroid body in sporotrichosis. The spheric yeastlike cells are surrounded by Splendore-Hoeppli material (hematoxylin and eosin, ×160). (From Connor, D.H., Chandler, F.W., Schwartz. D.A., et al., 1997. Pathology of Infectious Diseases. Appleton & Lange, Stamford, CT.)

TREATMENT

The classic treatment for lymphocutaneous sporotrichosis is oral potassium iodide in saturated solution. The efficacy and low cost of this medication makes it a favored option, especially in resource-poor countries; however, it must be given daily over 3 to 4 weeks and has frequent adverse effects (nausea, salivary gland enlargement). Itraconazole has been shown to be safe and highly effective at low doses and is the current treatment of choice. Patients who do not respond may be given a higher dose of itraconazole, terbinafine, or potassium iodide. Fluconazole or posaconazole may be used if the patient cannot tolerate these other agents. Spontaneous remission is rare but was seen in 13 of 178 cases in Brazil. The local application of heat has also been shown to be effective.

Chromoblastomycosis

Chromoblastomycosis (chromomycosis) is a chronic fungal infection affecting the skin and subcutaneous tissues. It is characterized by the development of slow-growing verrucous nodules or plaques (Fig. 63.5). Chromoblastomycosis is most commonly seen in the tropics, in which the warm, moist environment, coupled with the lack of protective footwear and clothing, predisposes individuals to direct inoculation with infected soil or organic matter. The organisms most often associated with chromoblastomycosis are pigmented (dematiaceous) fungi of the genera *Fonsecaea*, *Exophiala*, *Cladosporium*, *Cladophialophora*, *Rhinocladiella*, and *Phialophora* (see Table 63.1).

MORPHOLOGY

The fungi that cause chromoblastomycosis are all dematiaceous (naturally pigmented) molds but are morphologically diverse, and most are capable of producing several different forms when grown in culture. For example, *Exophiala* spp. may grow as a mold and produce conidia-bearing cells called **annelids** and as a yeastlike form that may appear in freshly isolated colonies. Although the basic form of these organisms is a pigmented septate mold, the different

Fig. 63.5 Chromoblastomycosis of the foot and leg. (From Connor, D.H., et al., 1997. Pathology of Infectious Diseases. Appleton & Lange, Stamford, CT.)

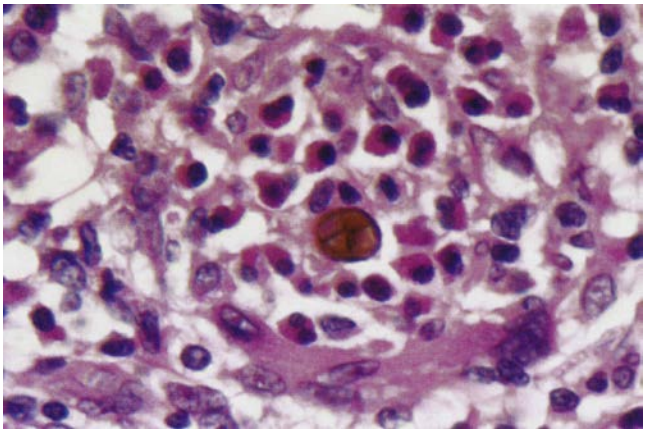

Fig. 63.6 Brown-pigmented muriform cell, or Medlar body, of chromoblastomycosis (hematoxylin and eosin, ×250). (From Connor, D.H., et al., 1997. Pathology of Infectious Diseases. Appleton & Lange, Stamford, CT.)

mechanisms of sporulation produced in culture makes specific identification difficult. Specific identification may require nucleic acid sequence analysis.

In contrast to the diverse morphology seen in culture, in tissue the fungi that cause chromoblastomycosis all characteristically form muriform cells (sclerotic bodies, **Medlar bodies**) that are chestnut brown because of the melanin in their cell walls (Fig. 63.6; see Table 63.1). Muriform cells divide by internal septation and appear as cells with vertical and horizontal lines within the same or different planes (see Fig. 63.6). In addition to muriform cells, pigmented hyphae also may be present. The fungal cells may be free within the tissue, but they are most often contained within macrophages or giant cells.

EPIDEMIOLOGY

Chromoblastomycosis generally affects individuals working in rural areas of the tropics. The etiologic agents grow on woody plants and in the soil. Most infections have been in men and involve legs and arms, which is likely the result of occupational exposure. Other body sites include shoulders, neck, trunk, buttocks, face, and ears. Three fungal species of the order Chaetothyriales account for virtually all cases of chromoblastomycosis: *C. carrionii, F. pedrosoi,* and *P. verrucosa.*

Local climatic factors may influence the distribution of different infections and different etiologic agents. For example, in Madagascar, infections caused by *F. pedrosoi* are seen in areas of high rainfall (200 to 300 cm annually), whereas in the same island, infections caused by *C. carrionii* occur in areas of low rainfall (50 to 60 cm annually). In the Americas, *F. pedrosoi* is the principal cause of chromoblastomycoses, and the lesions most often involve the lower extremities. In contrast, in Australia, the most common cause is *C. carrionii*, and the lesions are most frequently on the upper limbs, especially the hands. Infections by *P. verrucosa* mainly occur in tropical climatic zones, whereas *R. aquaspersa* is a rare agent of chromoblastomycosis in Latin America. There are no reports of person-to-person transmission of the agents of chromoblastomycosis.

CLINICAL SYNDROMES

Chromoblastomycosis tends to be chronic, pruritic, progressive, indolent, and resistant to treatment (Clinical Case 63.2). In most instances, patients do not present until the infection is well established. Early lesions are small, warty papules and usually enlarge slowly. There are different morphologic forms of the disease, ranging from verrucous lesions to flat plaques. Established infections appear as multiple, large, warty, "cauliflower-like" growths that are usually clustered within the same region (see Fig. 63.5). Satellite lesions may occur secondary to autoinoculation. Plaque-like lesions often show central scarring as they enlarge. Ulceration and cyst formation may occur. Large lesions are hyperkeratotic, and the limb is grossly distorted because of fibrosis and secondary lymphedema (see Fig. 63.5).

Clinical Case 63.2 **Chromoblastomycosis**

Marques and associates (*Med Mycol* 42:261–261, 2004) described a 52-year-old farmer from Brazil who presented with complaints of darkly pigmented pruritic skin lesions. The problem had appeared 2 years earlier and had progressed slowly since then. The patient was unaware of previous trauma but recalled an insect bite on his left arm. Initially, the lesion that developed at this site was a small, raised, erythematous papule. Later, a new crop of lesions appeared on the left leg and, more recently, on the forehead and left side of the face. Physical examination revealed extensive lesions in scaly plaques situated at different sites on the face, arm, and leg. Direct KOH examination of biopsies of the lesions showed numerous pigmented, bilaterally dividing, rounded, sclerotic cells (Medlar bodies), confirming the clinical diagnosis of chromoblastomycosis. Cultures of the biopsies grew a darkly pigmented mold that was identified on the basis of characteristic conidiation as *Rhinocladiella aquaspersa*. The lesions improved with ketoconazole therapy, with decreasing pruritic symptoms. Unfortunately, the patient was lost to follow-up. Chromoblastomycosis caused by *R. aquaspersa* is relatively uncommon. Furthermore, this case is unusual in that the lesions were dispersed over three different anatomic regions. Of note, the occurrence of facial lesions is very unusual.

Secondary bacterial infection also may occur and contribute to regional lymphadenitis, lymph stasis, and eventual elephantiasis.

LABORATORY DIAGNOSIS

The clinical presentation (see Fig. 63.5); histopathologic findings of chestnut-brown, muriform cells (see Fig. 63.6); and isolation in culture of one of the causal fungi (see Table 63.1) confirm the diagnosis. Scrapings obtained from the surface of the warty lesions on which small dark dots are observed may result in the demonstration of the characteristic cells when mounted in 20% potassium hydroxide (KOH). Biopsy specimens stained with H&E (see Chapter 60) will also show the organism present in the epidermis or in microabscesses containing macrophages and giant cells. The inflammatory reaction is both suppurative and granulomatous, with dermal fibrosis and **pseudoepitheliomatous hyperplasia.** The organisms are easily cultured from the lesions, although identification may be difficult. There are no serologic tests available for chromoblastomycosis.

TREATMENT

Treatment with specific antifungal therapy is often ineffective because of the advanced stage of infection on presentation. The drugs that appear to be most effective are itraconazole and terbinafine. More recently, posaconazole has been used with modest success. These agents are often combined with flucytosine in refractory cases. In an effort to improve the response to treatment, attempts are often made to shrink larger lesions with local heat or cryotherapy before administering antifungal agents. Because of the risk of recurrences developing within the scar, surgery is not indicated. Squamous cell carcinomas may develop in long-standing lesions, and those with atypical areas or fleshy outgrowths should be biopsied to rule out this complication.

Eumycotic Mycetoma

Eumycotic mycetomas are those caused by true fungi, as opposed to actinomycotic mycetomas, which are caused by aerobic actinomycetes (bacteria). This section will deal only with the eumycotic mycetomas.

As with chromoblastomycosis, most eumycotic mycetomas are seen in the tropics. A mycetoma is defined clinically as a localized, chronic, granulomatous, infectious process involving cutaneous and subcutaneous tissues. It is characterized by the formation of multiple granulomas and abscesses that contain large aggregates of fungal hyphae known as **granules** or **grains.** These grains contain cells that have marked modifications of internal and external structure, ranging from reduplications of the cell wall to the formation of a hard, cement-like extracellular matrix. The abscesses drain externally through the skin, often with extrusion of granules. The process may be quite extensive and deforming, with destruction of muscle, fascia, and bone. The etiologic agents of eumycotic mycetoma encompass a wide range of fungi, including *Phaeoacremonium*, *Curvularia*, *Fusarium*, *Madurella*, *Mediacopsis, Nigrograna, Trematosphaeria, Exophiala*, *Falciformispora,* and *Scedosporium* species (see Table 63.1).

MORPHOLOGY

The granules of eumycotic mycetomas are composed of septate fungal hyphae that are 2 to 6 μm or greater in width and are either dematiaceous (black grain) or hyaline (pale or white grain), depending on the etiologic agent (Fig. 63.7). The hyphae are frequently distorted and bizarre in form and size. Large, spheric, thick-walled chlamydoconidia are often present. The hyphae may be embedded in an amorphous cement-like substance. Splendore-Hoeppli material often interdigitates among the mycelial elements at the periphery of the granule. Eumycotic granules may be differentiated from actinomycotic granules based on morphologic (branched filaments versus septate hyphae and chlamydoconidia) and staining (gram-positive beaded rods versus PAS- and GMS-positive hyphae) characteristics (see Chapter 60). Culture is usually necessary for definitive identification of the fungus (or actinomycete) involved.

EPIDEMIOLOGY

Mycetomas are primarily seen in tropical areas with low rainfall. Eumycotic mycetomas are more frequent in Africa and the Indian subcontinent but also may be seen in Brazil, Venezuela, and the Middle East. Climate has a definite influence on the prevalence and distribution of mycetoma. Rivers that flood each year during the wet season in many countries of Africa and Asia influence the distribution of the causal agents. Rainfall also aids the spread of the etiologic agents on organic matter. All patients are infected from sources in nature via traumatic percutaneous implantation of the etiologic agent into exposed parts of the body. The foot and hand are most common, but back, shoulders, and chest-wall infections are also seen. Men are more often affected than women. Mycetomas are not contagious.

The fungi that cause eumycotic mycetomas differ from country to country, and the agents that are common in one region are rarely reported in others. For example, *M. mycetomatis* is limited to semiarid to arid climates, whereas *Falciformispora* species are found in the rain forest. Locally acquired mycetomata in temperate climates invariably are caused by *S. apiospermum* complex.

CLINICAL SYNDROMES

Similar to chromoblastomycosis, patients with eumycotic mycetoma most commonly present with long-standing infection. The earliest lesion is a small, painless, subcutaneous nodule or plaque that increases slowly but progressively in size. As the mycetoma develops, the affected area gradually enlarges and becomes disfigured as a result of chronic inflammation and fibrosis. With time, sinus tracts appear on the skin surface and drain serosanguineous fluid that often contains grossly visible granules. The infection commonly breaches tissue planes and destroys muscle and bone locally. Hematogenous or lymphatic spread from a primary focus to distant sites or viscera is extremely rare.

LABORATORY DIAGNOSIS

The key to the diagnosis of eumycotic mycetoma is the demonstration of grains or granules. Grains may be grossly visible

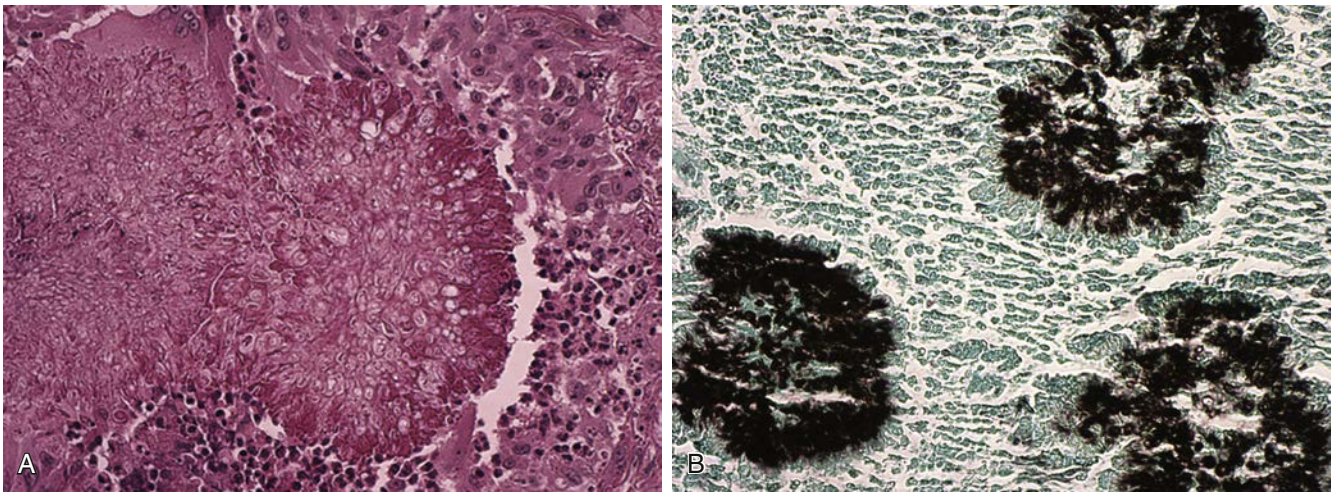

Fig. 63.7 (A) Mycetoma granule of *Curvularia geniculata*. (B) Compact dematiaceous hyphae and chlamydoconidia embedded in cement-like substance.

in draining sinus tracts or may be expressed onto a glass slide. Material may also be obtained by deep surgical biopsy.

Grains can be visualized microscopically by mounting in 20% KOH. The hyphae are usually clearly visible, as is the presence or absence of pigmentation. Grains can be washed and then cultured or fixed and sectioned for histopathology.

Grains are easily visualized in tissue stained with H&E (see Fig. 63.7). Special stains such as PAS and GMS may also be helpful. Although the color, shape, size, and microscopic morphology may be characteristic of a specific causal agent, culture is usually necessary for definitive identification of the organism. Most organisms will grow on standard mycologic medium; however, inclusion of an antibiotic such as penicillin may be useful to inhibit contaminating bacteria, which may overgrow the fungus.

TREATMENT

Treatment of eumycotic mycetoma is usually unsuccessful. Response of the various etiologic agents to amphotericin B, ketoconazole, or itraconazole is variable and often poor, although such therapy may slow the course of infection. Promising treatment responses have recently been reported for terbinafine, voriconazole, and posaconazole. Local excision is usually ineffective or not possible, and amputation is the only definitive treatment. Because these infections are usually slowly progressive and may be slowed further by specific antifungal therapy, the decision to amputate should take into account the rate of progression, the symptomatology, the availability of adequate prosthetics, and the individual circumstances of the patient. For all of these reasons, it is imperative to differentiate eumycotic mycetoma from actinomycotic mycetoma. Medical therapy is usually effective in cases of actinomycotic mycetoma.

Subcutaneous Entomophthoromycosis

Subcutaneous **entomophthoromycosis,** also known as subcutaneous mucormycosis, is caused by Mucormycetes of the orders *Entomophthorales* (*C. coronatus*) and *Basidiobolales* (*B. ranarum*) (see Table 63.1). Both fungi cause a chronic subcutaneous form of mucormycosis that occurs sporadically as a result of traumatic implantation of the fungus present in plant debris in tropical environments. They differ in that they cause infections with different anatomic locations: *B. ranarum* causes subcutaneous infection of the proximal limbs in children, whereas *C. coronatus* infection is localized to the facial area, predominantly in adults (Fig. 63.8 and 63.9).

Fig. 63.8 Subcutaneous entomophthoromycosis caused by *Conidiobolus coronatus.* (From Chandler, F.W., Watts, J.C., 1987. Pathologic Diagnosis of Fungal Infections. American Society for Clinical Pathology Press, Chicago, IL.)

MORPHOLOGY

The appearance of the agents of subcutaneous entomophthoromycosis in tissue differs from that of the mucoraceous

Fig. 63.9 Subcutaneous entomophthoromycosis caused by *Basidiobolus ranarum*. The right thigh is extensively swollen and indurated. (From Chandler, F.W., Watts, J.C., 1987. Pathologic Diagnosis of Fungal Infections. American Society for Clinical Pathology Press, Chicago, IL.)

Mucormycetes. The hyphal elements are sparse and often appear as hyphal fragments surrounded by intensely eosinophilic Splendore-Hoeppli material (Fig. 63.10). The inflammatory response is granulomatous and rich in eosinophils. The hyphal fragments are thin walled and poorly staining. Although septae are infrequent, they are more prominent than those seen with Mucoraceae. The hyphae of the Entomophthoromycota are not angioinvasive.

EPIDEMIOLOGY

Both types of subcutaneous entomophthoromycosis are seen most commonly in Africa and, to a lesser extent, in India. Infection caused by *B. ranarum* has also been reported from the Middle East, Asia, and Europe, whereas that caused by *C. coronatus* has been reported from Latin America, Africa, and India. Both fungi are saprophytes that are present in leaf and plant debris. *B. ranarum* also has been found in the intestinal contents of small reptiles and amphibians. Both are rare diseases without known predisposing factors (e.g., acidosis or immunodeficiency). Infection caused by *B. ranarum* is thought to occur after traumatic implantation of the fungus into the subcutaneous tissues of the thighs, buttocks, and trunk. This form of subcutaneous entomophthoromycosis occurs mainly in children (80% younger than age 20 years) with a male:female ratio of 3:1. *C. coronatus* infections occur after inhalation of the fungal spores, which then invade the tissues of the nasal cavity, the paranasal sinuses, and facial soft tissues. There is a 10:1 male:female ratio, and the disease is seen predominantly among young adults. Infection among children is rare.

CLINICAL SYNDROMES

Patients infected with *B. ranarum* have disk-shaped, rubbery, movable masses that may be quite large and are localized to the shoulder, pelvis, hips, and thighs (see Fig. 63.9). The masses may expand locally and eventually ulcerate. Dissemination or involvement of deeper structures is rare. Sporadic invasive infections with gastrointestinal (GI) involvement in adults and children have been described worldwide. A cluster of GI basidiobolomycosis has also been reported in Arizona; such a presentation may mimic GI malignancy.

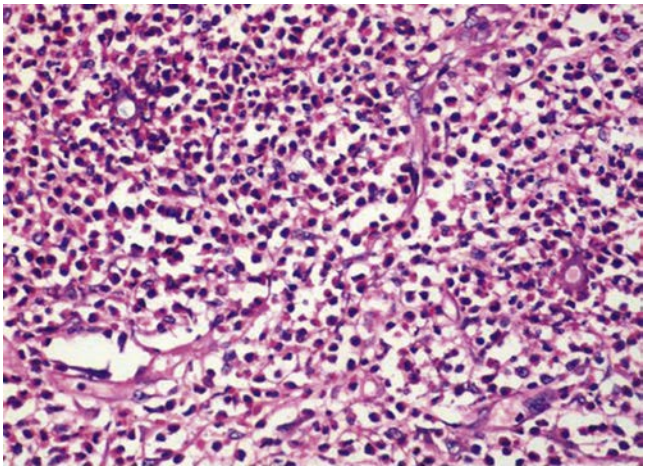

Fig. 63.10 Subcutaneous entomophthoromycosis. Broad hyphal fragments surrounded by eosinophilic Splendore-Hoeppli material (hematoxylin and eosin, ×160). (From Chandler, F.W., Watts, J.C., 1987. Pathologic Diagnosis of Fungal Infections. American Society for Clinical Pathology Press, Chicago, IL.)

C. coronatus infection is confined to the rhinofacial area and often does not come to medical attention until there is a noticeable swelling of the upper lip or face (see Fig. 63.8). The swelling is firm and painless and may progress slowly to involve the nasal bridge and the upper and lower face, including the orbit. The facial deformity can be quite dramatic; however, because of the lack of angioinvasion, intracranial extension does not occur.

LABORATORY DIAGNOSIS

Both types of subcutaneous entomophthoromycosis require biopsy for diagnosis, despite the characteristic clinical features of the infections. The histopathologic picture is the same for both organisms (see Fig. 63.10) and is marked by focal clusters of inflammation, with eosinophils and typical mucormycotic hyphae often surrounded by eosinophilic Splendore-Hoeppli material. The organisms can be cultured from clinical material on standard mycologic medium.

TREATMENT

Surgical excision, potassium iodide, and prolonged azole (usually itraconazole) therapy have been used successfully for infection caused by *Basidiobolus*. For infections caused by *Conidiobolus,* potassium iodide was historically used with variable results. Prolonged oral azole therapy should now be used and is successful. More recently, a combination of itraconazole and potassium iodide has provided encouraging results in a small series of cases, some of which achieved complete resolution of the infection. Facial reconstructive surgery may be necessary in the case of *Conidiobolus* infection because extensive fibrosis remains after eradication of the fungus.

Subcutaneous Phaeohyphomycosis

Phaeohyphomycosis is a term used to describe a heterogeneous array of fungal infections caused by pigmented, or

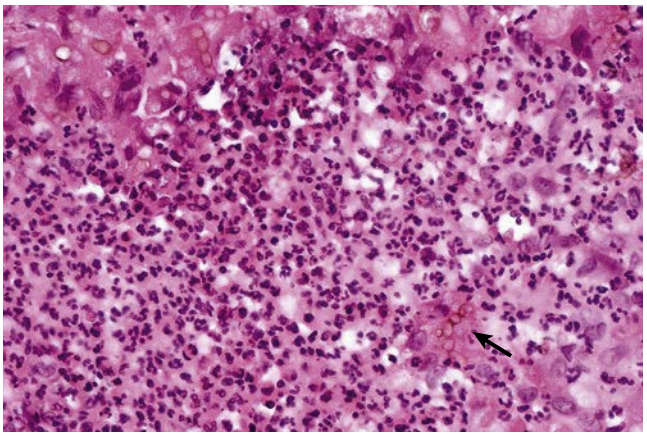

Fig. 63.11 Subcutaneous phaeohyphomycosis. Dematiaceous yeastlike cells and septate hyphae of *Exophiala spinifera* (hematoxylin and eosin, ×250). (From Chandler, F.W., Watts, J.C., 1987. Pathologic Diagnosis of Fungal Infections. American Society for Clinical Pathology Press, Chicago, IL.)

dematiaceous, fungi which are present in tissue as irregular hyphae (Fig. 63.11) rather than the sclerotic muriform cells seen in chromoblastomycosis (see Table 63.1 and Fig. 63.6). These infections may be caused by a wide range of fungi, all of which exist in nature as saprophytes of soil, wood, and decaying vegetation. Phaeohyphomycotic processes may be superficial, subcutaneous, or deeply invasive or disseminated. The superficial (see Chapter 62) and deeply invasive (see Chapter 65) forms are discussed in their respective chapters. The subcutaneous form is discussed in this section.

MORPHOLOGY

The agents of subcutaneous phaeohyphomycosis are numerous and diverse (see Table 63.1), but they all grow as black molds in culture and appear as dark-walled, irregular, hyphal and yeastlike forms in tissue (see Fig. 63.11). The hyphae vary from 2 to 6 μm wide and may be branched or septate and are often constricted at the point of septation. Bizarre, thick-walled, vesicular swellings that may be as large as 25 μm in diameter may be present, as well as budding yeastlike structures. Cell wall pigmentation ranges from light to dark and may require special stains, such as the Fontana-Masson melanin stain, to confirm the dematiaceous nature of the fungus. In culture, the different fungi grow as black or brown molds and are identified by their characteristic mode of sporulation.

EPIDEMIOLOGY

More than 20 different dematiaceous fungi have been cited as causes of subcutaneous phaeohyphomycosis. The most frequent etiologic agents have been *Exophiala, Alternaria*, *Curvularia*, and *Phaeoacremonium* spp. (see Table 63.1). Because these fungi are found in soil and plant debris, the route of infection is thought to be secondary to traumatic implantation of the fungus. Indeed, wood splinters have been found in histopathologic material, suggesting the mode of inoculation and possibly that the formation of the characteristic phaeohyphomycotic cyst is a reaction to implantation. There is no explanation for why some organisms produce phaeohyphomycotic cysts and others develop into mycetomas. Certain etiologic agents, such as *P. verrucosa*, may cause both types of infection.

CLINICAL SYNDROMES

Most commonly, subcutaneous phaeohyphomycosis presents as a solitary inflammatory cyst (Clinical Case 63.3). The lesions generally occur on the feet and legs, although the hands and other body sites may be involved. The lesions grow slowly and expand over a period of months or years. They may be firm or fluctuant and are usually painless. If located near a joint, they may be mistaken for a synovial cyst and may become large enough to interfere with movements. Other manifestations include the formation of pigmented plaquelike lesions that are indurated but nontender.

LABORATORY DIAGNOSIS

The diagnosis is made on surgical excision of the cyst. On histopathologic examination, the appearance is of an

Clinical Case 63.3 **Phaeohyphomycosis in a Renal Transplant Patient**

Marques and associates (*Med Mycol* 44:671–676, 2006) described a case of subcutaneous phaeohyphomycosis in a renal transplant recipient. The patient was a 49-year-old diabetic man who for 5 years had been given immunosuppressive therapy with prednisone and cyclosporine A after kidney transplantation. He presented with a 1-year history of draining foot lesions. The patient denied any history of local trauma but had been working in rural activities at the time of the initial complaint. He had been treated for presumed bacterial infection, without response. Dermatologic examination revealed two confluent erythematous cystic tumors on the dorsum of the left foot, with drainage points emitting a serosanguineous secretion. A local computed tomography scan showed only circumscribed hypodense lesions. A needle aspiration and a large biopsy were obtained to confirm the presumed diagnosis of phaeohyphomycosis. Histopathologic examination revealed intense inflammatory infiltrates and rare hyphal elements. Culture of the biopsy material revealed a slow-growing mold that eventually demonstrated a beige to gray-brown coloration. The organism was eventually identified as *Phaeoacremonium parasiticum* by a combination of morphology and molecular identification methods. The patient was treated with itraconazole coupled with local irrigation and a decrease in the dosing of cyclosporine A and achieved a satisfactory response.

This case illustrates an apparent trend for immunocompromised organ transplant patients with localized *P. parasiticum* infections to have acquired their infections without recognized trauma. It is unclear whether such infections are acquired via minor skin fissures or via inhalation or ingestion of an infectious particle, with subsequent translocation to subcutaneous capillary beds, in which slightly diminished temperature or other local conditions may favor growth.

inflammatory cyst with a fibrous capsule, granulomatous reaction, and central necrosis. Individual and clustered dematiaceous fungal elements are seen within giant cells and extracellularly amid the necrotic debris (see Fig. 63.11). In general, the pigmentation is easily seen on examination of H&E-stained tissue. The organisms can be grown in culture and identified by their pattern of sporulation. Molecular identification of most species is currently performed by the sequencing of ribosomal genes and comparison with dedicated databases.

TREATMENT

The main treatment is surgical excision. Plaquelike lesions may not be amenable to this approach and generally respond to treatment with itraconazole, with or without concomitant flucytosine. Posaconazole, voriconazole, and terbinafine may also be active against these groups of fungi.

Case Study and Questions

A woman developed suppurating, nodular skin lesions on the thenar aspect of her hand, extending up her forearm, after pruning rose bushes in her garden.

1. Which of the following is the likely etiologic agent of this infection?
   a. *B. ranarum*
   b. *S. apiospermum*
   c. *Sporothrix* spp.
   d. *Phaeoacremonium* spp.

2. How would you go about diagnosing the infection?

3. Which of the following antifungal agents may be used to treat this infection?
   a. Fluconazole
   b. Itraconazole
   c. Flucytosine
   d. Griseofulvin

64 Systemic Mycoses Caused by Dimorphic Fungi

Jane and Joan were two avid "outdoors persons" in their mid-30s. In the past 5 years, they had been spelunking in southern Missouri, backpacking in northern Wisconsin, and camping in Arizona. Most recently, they had been renovating an old farmhouse in rural Iowa, and in the process had to tear down an old chicken coop that was attached to the back of the house. About 1 week into the process, they both suffered from a flulike illness, and Jane developed a cough and shortness of breath. They went to the family practice clinic to get "checked out." At the clinic, Joan appeared fine, but Jane was noted to be quite short of breath and appeared ill. The doctor thought it would be a good idea to get a chest radiograph for Jane. Joan got one too, just in case. Jane's chest radiograph showed diffuse bilateral pneumonia. Although Joan's radiograph did not show pneumonia, it was noted that she had a solitary nodule in the right upper lobe.

1. What dimorphic fungal pathogens were Jane and Joan exposed to?
2. What constitutes a dimorphic fungus?
3. Aside from dimorphism, what feature is common to all endemic mycoses?
4. Describe the life cycles of the dimorphic endemic pathogens.
5. What do you think is the cause of Jane's pneumonia? How would you make the diagnosis?
6. How would you treat her pneumonia?
7. What do you think accounts for Joan's lung nodule? How would you make the diagnosis? How would you treat her?

Answers to these questions are available on www.StudentConsult.com.

Summaries Clinically Significant Organisms

BLASTOMYCOSIS (*BLASTOMYCES DERMATITIDIS* AND *B. GILCHRISTII*)

Trigger Words

Mississippi River Valley, broad-based budding yeast, healthy and immunocompromised, granuloma

Biology, Virulence, and Disease

- Thermally dimorphic fungus: large nonencapsulated budding yeast cells in tissue and in culture at 37° C; mold colonies form in culture at 25° C
- Usual route of infection is inhalation of conidia
- Severity of symptoms and course of disease depends on extent of exposure and immune status of exposed individual; most are asymptomatic
- Classic form of blastomycosis: chronic cutaneous involvement

Epidemiology

- Ecologic niche: decaying organic matter
- Area of endemicity: southeastern and southcentral states, especially bordering Ohio and Mississippi river basins; Midwest states and Canadian provinces bordering Great Lakes; and an area in New York and Canada along the St. Lawrence River
- Outbreaks of infection have been associated with occupational or recreational contact with soil

Diagnosis

- Microscopic detection of fungus in tissue or other clinical material, with confirmation by culture
- Antigen detection and PCR

Treatment, Prevention, and Control

- Pulmonary blastomycosis in immunocompromised patients and those with progressive pulmonary disease should be treated
- All patients with evidence of hematogenous dissemination require antifungal therapy
- Lipid formulation of amphotericin B: treatment of choice for meningeal disease and other life-threatening presentations
- Mild or moderate disease: itraconazole; fluconazole, posaconazole, or voriconazole may be substituted for itraconazole

COCCIDIOIDOMYCOSIS (*COCCIDIOIDES IMMITIS* AND *C. POSADASII*)

Trigger Words

Valley fever, coccidioidal granuloma, arthroconidia, spherule, skin test, precipitin test

Biology, Virulence, and Disease

- Coccidioidomycosis caused by two indistinguishable species: *C. immitis* and *C. posadasii*
- *C. immitis* is localized to California; *C. posadasii* causes most infections outside California
- Disease caused by inhalation of infectious arthroconidia
- Asymptomatic or subclinical, self-limited flulike illness, acute and chronic pulmonary disease, single or multisystem dissemination
- Dimorphic fungi; endosporulating spherule in tissue, mold in culture at 25° C and in nature

Epidemiology

- Endemic to U.S. southwestern desert, northern Mexico, scattered areas of Central and South America
- Organism found in soil; growth in environment enhanced by bat and rodent droppings; cycles of drought/rain enhance organism dispersion
- Persons ≥65 years and those with HIV infection disproportionately affected
- Risk of disseminated disease highest in certain ethnic groups (Filipino, African American, Native American, Hispanic), males (9:1), women in third trimester of pregnancy, individuals with cellular immune deficiency, persons at extremes of age

Diagnosis

- Histopathologic examination of tissue or other clinical material, isolation of fungus in culture, serology
- Histopathologic examination that reveals endosporulating spherules in sputum, exudates, or tissue is sufficient to establish the diagnosis
- Culture at 25° C takes days and poses risk to laboratory workers; all work with molds should be performed in suitable biosafety cabinet
- Serology (antigen and antibody) may be useful for initial screening, confirmation, or prognostic evaluation

Continued

Summaries Clinically Significant Organisms—cont'd

Treatment, Prevention, and Control

- Most individuals with primary infection do not require therapy
- For those with concurrent risk factors or a more severe presentation: lipid formulation of amphotericin B followed by an oral azole as maintenance therapy (severe disease)
- Chronic cavitary pulmonary disease: azole for at least 1 year
- Nonmeningeal extrapulmonary disseminated infections: oral azole
- Meningeal coccidioidomycosis: fluconazole; itraconazole, posaconazole or voriconazole are secondary choices

HISTOPLASMOSIS (*HISTOPLASMA CAPSULATUM*)

Trigger Words

Intracellular yeasts, bird and bat droppings, chicken coop, caves, guano, granulomas

Biology, Virulence, and Disease

- Histoplasmosis caused by two varieties of *H. capsulatum*
- *H. capsulatum* var. *capsulatum:* causes pulmonary and disseminated infections
- *H. capsulatum* var. *duboisii:* causes predominantly skin and bone lesions
- Disease caused by inhalation of infectious microconidia
- Severity of symptoms and course of disease depend on extent of exposure and immune status of infected individual; most are asymptomatic, self-limited; flu-like illness also occurs
- Thermally dimorphic fungus: hyaline mold in nature and in culture at 25° C, budding yeast in tissue (intracellular) and in culture at 37° C

Epidemiology

- *H. capsulatum* var. *capsulatum:* localized to Ohio and Mississippi river valleys; occurs throughout Mexico and Central and South America
- *H. capsulatum* var. *duboisii:* confined to tropical Africa (e.g., Gabon, Uganda, Kenya)
- Found in soil with high nitrogen content (e.g., areas contaminated with bird or bat droppings)
- Outbreaks of disease have been associated with exposure to bird roosts, caves, and decaying buildings or urban renewal projects involving excavation and demolition
- Immunocompromised individuals and children most prone to develop symptomatic disease
- Reactivation of disease and dissemination common among immunosuppressed individuals, especially those with AIDS

Diagnosis

- Direct microscopy, culture of clinical material, serology (antigen and antibody), β-D-glucan, and PCR have been useful
- Yeast phase of organism can be detected in sputum, bronchoalveolar lavage fluid, peripheral blood films, bone marrow, and tissue stained with Giemsa, GMS, or PAS stains
- Cultures should be handled in a biosafety cabinet
- Serologic diagnosis includes tests for antibody and antigen

Treatment, Prevention, and Control

- Severe acute infections: lipid formulation of amphotericin B followed by oral itraconazole
- Chronic pulmonary histoplasmosis: lipid formulation of amphotericin B followed by itraconazole
- Disseminated infection: lipid formulation of amphotericin B followed by itraconazole

PARACOCCIDIOIDOMYCOSIS (*PARACOCCIDIOIDES BRASILIENSIS* AND *P. LUTZII*)

Trigger Words

Pilot's wheel, South American blastomycosis, ulcer, multiple buds

Biology, Virulence, and Disease

- Thermally dimorphic fungus: slowly growing mold phase in nature and at 25° C, yeast phase (variable sized with single or multiple buds) in tissue and in culture at 37° C
- Usual route of infection is inhalation or possible traumatic inoculation of conidia or hyphal fragments
- Paracoccidioidomycosis may be subclinical or progressive with acute or chronic pulmonary forms or acute, subacute, or chronic disseminated forms

Epidemiology

- Endemic throughout Latin America, areas of high humidity, rich vegetation, moderate temperatures, acid soil
- Ecologic niche not well established
- Overt disease uncommon among children and adolescents; in adults, disease more common in men aged 30 to 50 years
- Most patients with clinically apparent disease live in rural areas and have close contact with soil
- No reports of epidemics or person-to-person transmission

Diagnosis

- Demonstration of characteristic yeast forms on microscopic examination of clinical material: oval to round with double refractile walls and single or multiple buds; "pilot-wheel" morphology
- May be isolated in culture and should be handled in a biosafety cabinet
- Serology testing may help in suggesting diagnosis, evaluating response to therapy

Treatment, Prevention, and Control

- Itraconazole: treatment of choice for most forms of disease
- More severe or refractory forms: lipid formulation of amphotericin B followed by either itraconazole or sulfonamide therapy

GMS, Gomori methenamine silver; *PAS,* periodic acid-Schiff; *PCR,* polymerase chain reaction.

The dimorphic fungal pathogens are organisms that exist in a mold form in nature or in the laboratory at 25° C to 30° C and in a yeast or spherule form in tissues or when grown on enriched medium in the laboratory at 37° C (Fig. 64.1). The majority of organisms in this group are considered primary systemic pathogens because of their ability to cause infection in both "normal" and immunocompromised hosts and for their propensity to involve the deep viscera after dissemination of the fungus from the lungs after its inhalation from nature. The dimorphic systemic pathogens include *Blastomyces* spp. (*B. dermatitidis, B. gilchristii, B. helicus, B. parvus,* and *B. silverae*), *Coccidioides* spp. (*C. immitis* and *C. posadasii*), *Histoplasma capsulatum* var. *capsulatum* and *H. capsulatum* var *duboisii*, *Paracoccidioides* spp. (*P. brasiliensis* and *P. lutzii*), *Emergomyces* spp. (genus abbreviated *Es.*; *Es. pasteurianus, Es. africanus, Es. orientalis, Es. canadensis,* and *Es. europaeus*), and *Talaromyces* (formerly *Penicillium) marneffei* (Table 64.1). These organisms are also known as endemic pathogens, in that their natural habitat is delimited to specific geographic regions (Fig. 64.2), and infection caused by a particular fungus is acquired by inhalation of spores from that specific environment and geographic location (see Table 64.1). *H. capsulatum, Coccidioides* spp. (*C. immitis* and *C. posadasii*), *Emergomyces* spp. (*Es. pasteurianus* and *Es. africanus*), and *T. marneffei* have emerged as major opportunistic pathogens in individuals with acquired immunodeficiency syndrome (AIDS) and other forms of immunosuppression. Recognition of these endemic mycoses may be complicated by the fact that they may manifest only after the patient has left the area of endemicity. Often, the infection may be quiescent, only to reactivate when the individual becomes immunosuppressed and is living in an area in which the fungus is not endemic. In addition to these dimorphic pathogens, agents formerly classified under the genus *Emmonsia* (now obsolete), namely *Adiaspiromyces crescens* (formerly *Emmonsia crescens*) and *Blastomyces parvus* (formerly *Emmonsia parva*), exist as a filamentous mold in nature at 25° C and as nonreplicating adiaspores in the lungs of animals and humans.

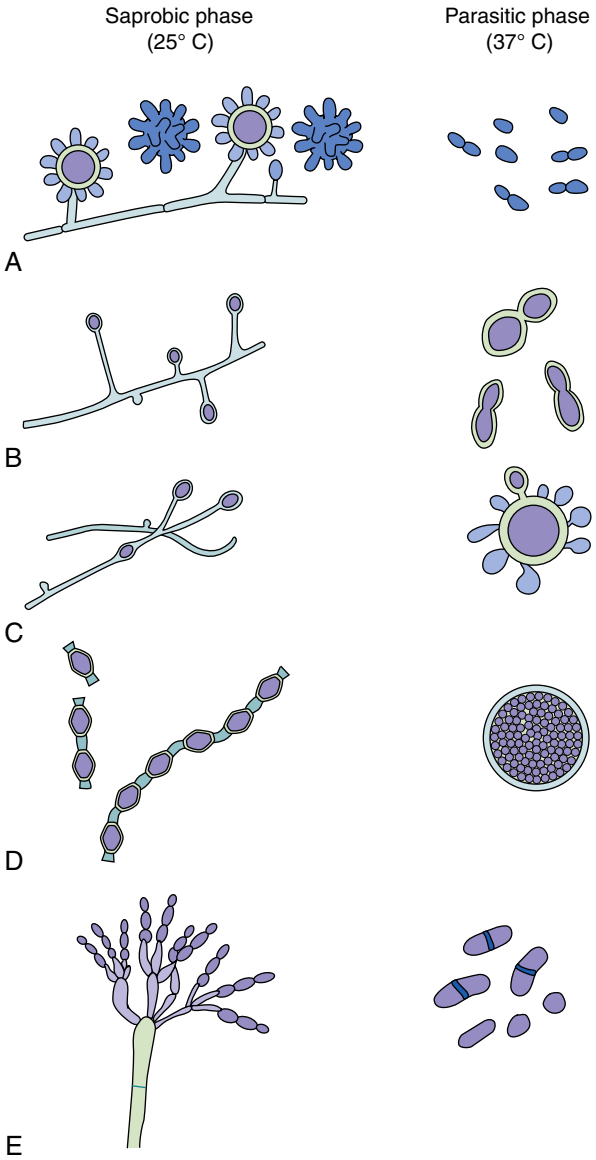

Fig. 64.1 Saprobic and parasitic phases of endemic dimorphic fungi. (A) *Histoplasma capsulatum.* (B) *Blastomyces dermatitidis.* (C) *Paracoccidioides brasiliensis.* (D) *Coccidioides immitis.* (E) *Talaromyces marneffei.*

Blastomycosis

Blastomycosis is a systemic fungal infection caused by dimorphic pathogens *B. dermatitidis* and *B. gilchristii.* Recently additional species of *Blastomyces* have been proposed based on molecular taxonomic findings: *B. percursus*, *B. parvus* (formerly *E. parva*), *B. helicus* (formerly *E. helica*) and *B. silverae*. *B. percursus, B. helicus,* and *B. silverae* are similar to *B. dermatitidis*/*gilchristii* in phenotype and pathogenicity. As such, the more familiar *B. dermatitidis* will be used in this chapter when discussing blastomycosis. *B. parvus* differs from these species in certain phenotypic aspects and exhibits a distinctly different pathogenesis and will be discussed separately.

Like other endemic mycoses, blastomycosis is confined to specific geographic regions, with most infections originating in the Mississippi River basin, around the Great Lakes, and in the southeastern region of the United States (see Fig. 64.2). The disease is also endemic in other parts of the world, including Africa and parts of Central and South America.

MORPHOLOGY

As a thermally dimorphic fungus, *B. dermatitidis* produces nonencapsulated yeastlike cells in tissue and in culture on enriched media at 37° C and white to tan, filamentous, mold colonies on standard mycologic media at 25° C. The mold form produces round to oval or pear-shaped conidia (2 to 10 μm) located on long or short terminal hyphal branches (Fig. 64.3). Older cultures may also produce 7- to 18-μm diameter, thick-walled chlamydospores. This form of *B. dermatitidis* is not diagnostic and may not be distinguishable from the monomorphic *Chrysosporium* spp. or from an early culture of *H. capsulatum*.

The yeast form of *B. dermatitidis* is seen in tissue and in culture at 37° C. This form is quite distinctive (Fig. 64.4). The yeast cells are spherical, hyaline, 8 to 15 μm in diameter, multinucleated, and have thick "double-contoured" walls. The cytoplasm is often retracted from the rigid cell wall as a result of shrinkage during the fixation process. The yeast cells reproduce by the formation of buds or **blastoconidia.** The buds are usually single and attached to the parent cell by broad bases (see Fig. 64.4).

The yeast forms may be visualized in tissue stained with hematoxylin and eosin (H&E); however, the fungal stains, Gomori methenamine silver (GMS) and periodic acid–Schiff (PAS), help locate the organisms and delineate their morphology.

B. parvus differs from the other species in the genus in that it produces thermally dependent and nonreplicating adiaspores at 37° C and in vivo, rather than yeastlike propagules, and exhibits a mold phase in nature and at 25° C. The mold phase produces small single-celled conidia (about 4 μm in size) on the sides of the hyphae or on short side branches. Inside the host, the conidia transform into adiaspores, which resemble the spherules of *Coccidioides* species (Fig. 64.1).

EPIDEMIOLOGY

The ecologic niche of *B. dermatitidis* appears to be in decaying organic matter. Studies in humans and animals indicate that infection is acquired after the inhalation of aerosolized conidia produced by the fungus growing in soil and leaf litter (Fig. 64.5). Outbreaks of infection have been associated with occupational or recreational contact with soil, and infected individuals include all ages and both genders. A large outbreak of blastomycosis in Wisconsin was marked by both geographic and ethnic clustering with a disproportionate number of infections occurring in persons of Hmong ethnicity, suggesting a possible genetic predisposition to infection with this fungus. Blastomycosis is not transmitted from patient to patient; however, laboratory-acquired primary cutaneous and pulmonary blastomycosis has been reported.

In North America, the area of endemicity overlaps that of histoplasmosis (see Fig. 64.2) and includes the southeastern and south central states, especially those bordering the Ohio and Mississippi River basins; the Midwest states and

TABLE 64.1 Characteristics of Endemic Dimorphic Mycoses

Mycosis	Etiology	Ecology	Geographic Distribution	Morphology in Tissue	Clinical Manifestation
Blastomycosis	*Blastomyces dermatitidis* *B. gilchristii*	Decaying organic material	North America (Ohio and Mississippi River valleys) Africa	Broad-based, budding yeasts (8-15 μm in diameter)	Pulmonary disease (<50%) Extrapulmonary: skin, bone, genitourinary, central nervous system Disseminated disease in immunocompromised patients
Coccidioidomycosis	*Coccidioides immitis* *C. posadasii*	Soil, dust	Southwestern United States, Mexico, Central and South America	Spherules (20-60 μm) containing endospores (2-4 μm)	Asymptomatic pulmonary infection (60%) in normal host Progressive pulmonary infection and dissemination (skin, bone, joints, meninges) in immunocompromised patients
Histoplasmosis capsulati	*Histoplasma capsulatum* var. *capsulatum*	Soil with high nitrogen content (bird/bat droppings)	North America (Ohio and Mississippi River valleys), Mexico, Central and South America	Small (2- to 4-μm), oval, narrow-based, budding yeasts (intracellular)	Asymptomatic pulmonary infection (90%) in normal host and low-intensity exposure Disseminated disease in immunocompromised host and in children
Histoplasmosis duboisii	*Histoplasma capsulatum* var. *duboisii*	Soil with high nitrogen content	Tropical areas of Africa	Larger (8- to 15-μm), thick-walled, budding yeast Prominent isthmus and bud scar	Low rate of pulmonary disease Higher frequency of skin and bone involvement
Paracoccidioidomycosis	*Paracoccidioides brasiliensis* *P. lutzii*	Likely soil associated	South and Central America	Thin to moderately thick-walled, multiply budding yeast (15-30 μm; pilot wheel)	Self-limited pulmonary disease Progressive pulmonary infection and dissemination (skin, mucosa, bones, lymph nodes, viscera, and meninges) More common in children and immunocompromised patients
Talaromycosis marneffei	*Talaromyces marneffei*	Soil Bamboo rat	Southeast Asia	Globose to elongated sausage-shaped yeasts (3-5 μm) that are intracellular and divide by fission	Disseminated infection (skin, soft tissues, viscera) more common in AIDS Resembles histoplasmosis, cryptococcosis, or tuberculosis
Emergomycosis	*Emergomyces pasteurianus* *Es. africanus*	Likely soil associated Possible rodent reservoir	Europe, India, China, South Africa	Small (2- to 4-μm in diameter), thin-walled, globose-to-oval yeast cells with single or multiple narrow-based budding Larger cells with broader based buds are sometimes present	Disseminated infection (skin, soft tissues, viscera) more common in AIDS Resembles histoplasmosis, cryptococcosis, or tuberculosis

Modified from Anstead, G.M., Patterson, T.F., 2009. Endemic mycoses. In: Anaissie, E.J., McGinnis, M.R., Pfaller, M.A. (Eds.), Clinical Mycology, second ed. Churchill Livingstone, New York.

Canadian provinces bordering the Great Lakes; and an area in New York and Canada along the St. Lawrence River. Blastomycosis is also endemic in Africa. It is estimated that one to two cases of symptomatic blastomycosis requiring therapy occur per 100,000 population each year in areas with endemic disease. Among animals, dogs are most susceptible; the infection rate is estimated to be 10 times that for humans.

CLINICAL SYNDROMES

The usual route of infection in blastomycosis is inhalation of conidia (see Fig. 64.5 and Clinical Case 64.1). As with most endemic mycoses, the severity of symptoms and course of the disease is dependent on the extent of exposure and the immune status of the exposed individual. Based largely on studies of blastomycosis outbreaks, it appears that symptomatic disease occurs in less than half of infected individuals. Clinical illness caused by *B. dermatitidis* may present as pulmonary disease or an extrapulmonary disseminated disease. Among those patients with extrapulmonary dissemination, two-thirds exhibit involvement of skin and bones. Other sites of hematogenous dissemination include prostate, liver, spleen, kidney, and central nervous system (CNS).

Pulmonary blastomycosis may be asymptomatic or present as a mild flulike illness. More severe infection resembles bacterial pneumonia with acute onset, high fever, lobar infiltrates, and cough. Progression to fulminant adult respiratory distress syndrome with high fever, diffuse infiltrates, and respiratory failure may occur. A more subacute or chronic respiratory form of blastomycosis may resemble tuberculosis or lung cancer, with radiographic presentation of pulmonary mass lesions or fibronodular infiltrates.

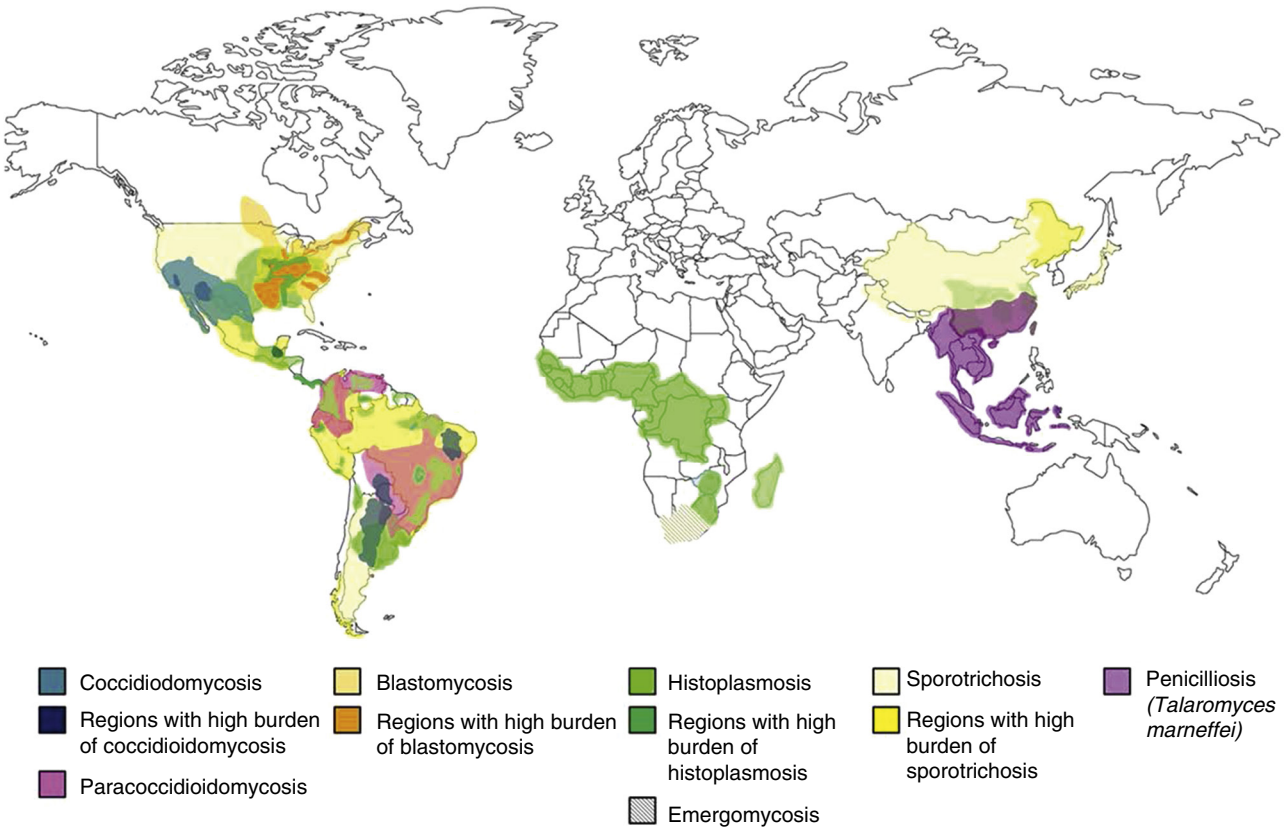

Fig. 64.2 Major geographic regional distribution of the endemic mycoses. (From Lee, P.P., Lau, Y.L., 2017. Cellular and molecular defects underlying invasive fungal infections-revelations from endemic mycoses. Frontiers in Immunology 8, 735.)

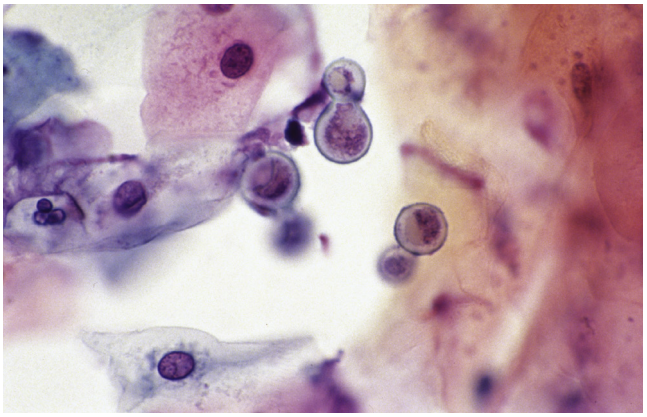

Fig. 64.4 Giemsa stain of *Blastomyces dermatitidis* showing broad-based budding yeast.

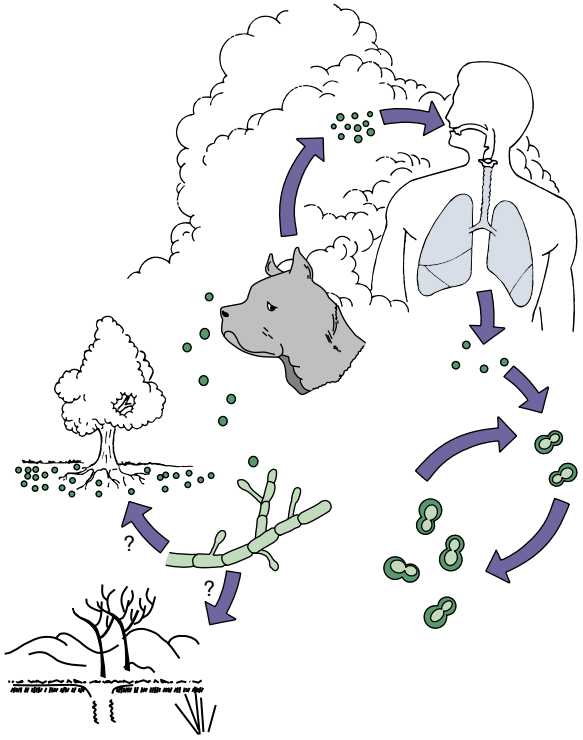

Fig. 64.5 Natural history of the mold (saprobic) and yeast (parasitic) cycle of *Blastomyces dermatitidis*.

Clinical Case 64.1 **Central Nervous System Blastomycosis**

Buhari and colleagues (*Infect Med* 24[Suppl 8]:12–14, 2007) reported a case of CNS blastomycosis. The patient was a 56-year-old homeless man from Detroit who presented with a 2-week history of left hemiparesis, aphasia, and generalized headache. There was no history of rash, respiratory symptoms, or fever. His medical history was significant for a left craniotomy 30 years ago for intracranial hemorrhage caused by trauma. He lived in an abandoned building and was not taking any medications. On examination, he had expressive aphasia, new-onset left hemiparesis, and bilateral carotid bruits. The rest of the physical examination was unremarkable, as there were routine serum chemistries and hematologic parameters. He was negative for antibodies to HIV. A chest radiograph was unremarkable. A contrast-enhanced computed tomography scan of the head demonstrated multiple ring-enhancing lesions in the right cerebrum, with surrounding vasogenic edema and midline shift; significant encephalomalacia and generalized atrophy were present in the left cerebral hemisphere.

Serum and urine tests were negative for *Cryptococcus* (serum) and *Histoplasma* (serum and urine) antigens. Tuberculin skin tests were nonreactive, and imaging studies of the sinuses, chest, and abdomen were unremarkable. A brain biopsy was performed, and histopathologic examination revealed granulomatous inflammation and budding yeasts consistent with *Blastomyces dermatitidis*. Subsequent culture confirmed the diagnosis of CNS blastomycosis. The patient was treated with dexamethasone and amphotericin B but developed hypertension and bradycardia, with subsequent cardiopulmonary arrest and death.

This is an example of an unusual presentation of CNS blastomycosis without any other evidence of disseminated disease. The clinical syndrome of hypertension, bradycardia, and cardiopulmonary arrest suggest that the patient died of increased intracranial pressure, either as a complication of the infection or the diagnostic brain biopsy.

CNS, Central nervous system.

A classic form of blastomycosis is that of chronic cutaneous involvement. The cutaneous form of blastomycosis is almost always the result of hematogenous dissemination from the lung, in most instances without evident pulmonary lesions or systemic symptoms. The lesions may be papular, pustular, or indolent, ulcerative-nodular, and verrucous with crusted surfaces and raised serpiginous borders. They are usually painless and are localized to exposed areas, such as the face, scalp, neck, and hands. They may be mistaken for squamous cell carcinoma. Left untreated, cutaneous blastomycosis takes on a chronic course, with remissions and exacerbations and gradual increase in the size of lesions.

Blastomycosis is relatively uncommon among individuals with AIDS or other immunocompromising conditions. However, when it occurs in these individuals, it tends to be acute, involve the CNS, and have a much poorer prognosis.

The very rare and unusual pulmonary disease caused by *B. parvus* follows the inhalation of aerosolized conidia, released from the mycelial phase of the fungus in soil. In the lungs, the conidia enlarge dramatically, from 2 to 4 μm to 40 to 500 μm in diameter. These swollen cells are termed adiaspores and they neither replicate nor disseminate in vivo. In the host these adiaspores provoke a foreign body reaction, resulting in granulomatous lung disease. In most instances, inhalation of a small number of conidia would have no clinical consequence because the adiaspores do not replicate in vivo; however, disease severity is dependent on inoculum size and host response. The clinical spectrum can range from a subclinical pneumonia to diffuse pulmonary disease with hypoxic respiratory failure and rarely, death.

LABORATORY DIAGNOSIS

The diagnosis of blastomycosis rests with microscopic detection of the fungus in tissue or other clinical material, with confirmation by culture (Table 64.2). The most useful specimens for the diagnosis of pulmonary blastomycosis include sputum, bronchoalveolar lavage, or lung biopsy. Direct examination of material stained with GMS, PAS, Papanicolaou, or Giemsa stains should be performed; likewise, fresh wet preparations of sputum, cerebrospinal fluid (CSF), urine, pus, skin scrapings, and tissue impression smears may be examined directly using calcofluor white and fluorescence microscopy to detect the characteristic yeast forms. When typical broad-based budding yeast forms are present, a definitive diagnosis may be made.

Tissue sections stained with PAS or GMS are most helpful to demonstrate the characteristic adiaspores of *B. parvus*. Adiaspores must be differentiated from the spherules of *C. immitis*. Adiaspores do not contain endospores and are typically much larger than empty spherules of *C. immitis.*

Culture of clinical material on selective and nonselective mycologic media incubated at both 25° C to 30° C and at 37° C should be performed. The mycelial form of the fungus is easily cultured at 25° C to 30° C; however, growth is slow, often requiring 4 weeks or more. The mycelial form (see Fig. 64.3) is not diagnostic, and the identity must be confirmed by conversion to the yeast form at 37° C, by exoantigen testing (immunologic detection of cell-free antigen A), or by nucleic acid probe hybridization. Care should be taken to handle the culture in an appropriate biosafety cabinet because the conidia are infectious.

Although serologic tests to detect antibodies directed at *B. dermatitidis* antigens are available (see Table 64.2), they are neither sensitive nor specific and are of little use in diagnosis. A test to detect antigen in serum and urine is commercially available, but cross-reaction with other endemic mycoses is considerable, and it is unclear what role it will play in diagnosis. Serial urine tests may be useful for monitoring disease. Detection of serum (1-3)-β-D-glucan (BDG) has not been shown to be useful in the diagnosis of blastomycosis, whereas real-time PCR has value when performed on blood, tissue, or respiratory specimens.

TREATMENT

The decision to treat patients with blastomycosis must take into consideration the clinical form and severity of disease, as well as the immune status of the patient and the toxicity of antifungal agents. Clearly, pulmonary blastomycosis in immunocompromised patients and those with progressive pulmonary

TABLE 64.2 Diagnosis of Endemic Dimorphic Mycoses

Mycosis	Culture	MORPHOLOGY IN CULTURE		Histopathology	Serology
		25° C	37° C		
Blastomycosis	Sputum, BAL, lung tissue, skin biopsy, CSF	Mold, round to oval or pear-shaped conidia (2-10 μm diameter)	Thick-walled, broad-based budding yeast (8-15 μm)	Broad-based, budding yeast	Antibody: CF, ID, EIA (poor sensitivity and specificity) Antigen: serum, CSF and urine
Coccidioidomycosis	Sputum, BAL, tissue, CSF	Mold with barrel-shaped arthroconidia (3-6 μm)	NA	Spherules (20-60 μm) containing endospores	Antibody: TP, CF, ID, LPA, EIA (diagnostic and prognostic) Antigen: urine, CSF
Histoplasmosis capsulati	Sputum, BAL, blood, bone marrow, tissue, CSF	Mold with tuberculate macroconidia (8-15 μm) and small, oval microconidia (2-4 μm)	Small (2-4 μm), budding yeast	Intracellular budding yeast	Antibody: CF, ID, EIA Antigen: serum, CSF and urine (92% sensitive in disseminated disease)
Paracoccidioidomycoses	Sputum, BAL, tissue	Mold, round microconidia (2-3 μm) and intercalary chlamydospores	Large (15- to 30-μm), multiple, budding yeast	Large, multiply budding yeasts	Antibody: ID, CF (variable specificity; CF useful for monitoring response)
Talaromycosis marneffei	Blood, bone marrow, tissue, CSF	Mold with diffusible red pigment Conidiophores terminating in conspicuous, penicillus-bearing, ellipsoidal, smooth conidia	Pleomorphic, elongated yeast (1-8 μm) with transverse septa	Intracellular elongated yeast with transverse septa	Under development
Emergomycosis	Blood, bone marrow, respiratory tissue, liver tissue, lymph node, and cutaneous tissue	Mold, septate hyaline hyphae (1-1.5 μm in diameter) with numerous smooth-walled oval conidia	Small yeast cells (2-4 μm in diameter), thin-walled, globose-to-oval with single or multiple narrow-based budding Larger cells with broader based buds are sometimes present	Small (2- to 5-μm), intracellular and extracellular oval to round narrow-budding yeastlike cells similar in size to those of *H. capsulatum*	Under development

disease should be treated; likewise, all patients with evidence of hematogenous dissemination (e.g., skin, bone, all nonpulmonary sites) require antifungal therapy. Amphotericin B, preferably a lipid formulation, is the agent of choice for the treatment of life-threatening or meningeal disease. Mild or moderate disease may be treated with itraconazole. Fluconazole, isavuconazole, posaconazole, or voriconazole may be alternatives for those patients unable to tolerate itraconazole. Depending on the severity of the disease and the status of the host, therapeutic success rates with amphotericin B or azole therapy range from 70% to 95%. Survival for AIDS patients and other immunocompromised patients is about half this figure. The latter patients may require long-term suppressive therapy with itraconazole, or another active azole, in an effort to avoid relapses of the infection.

Coccidioidomycosis

Coccidioidomycosis is an endemic mycosis caused by either of two indistinguishable species, *C. immitis* and *C. posadasii*. The disease is caused by the inhalation of infectious arthroconidia (Fig. 64.6) and may range from asymptomatic infection (in most people) to progressive infection and death. The two species differ in geographic distribution and genotype: *C. immitis* is localized to California, and *C. posadasii* accounts

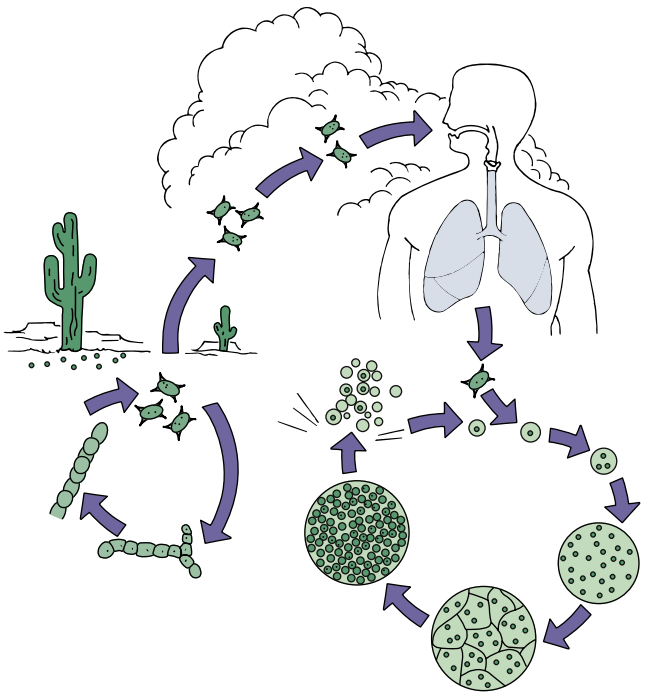

Fig. 64.6 Natural history of the mold (saprobic) and spherule (parasitic) cycle of *Coccidioides immitis*.

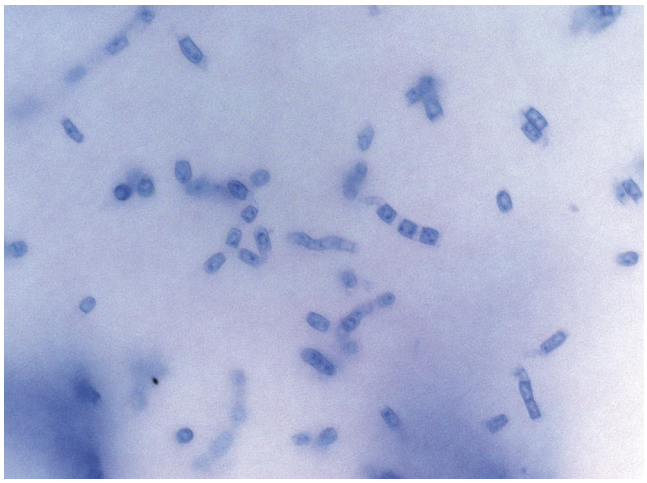

Fig. 64.7 *Coccidioides immitis* mold phase.

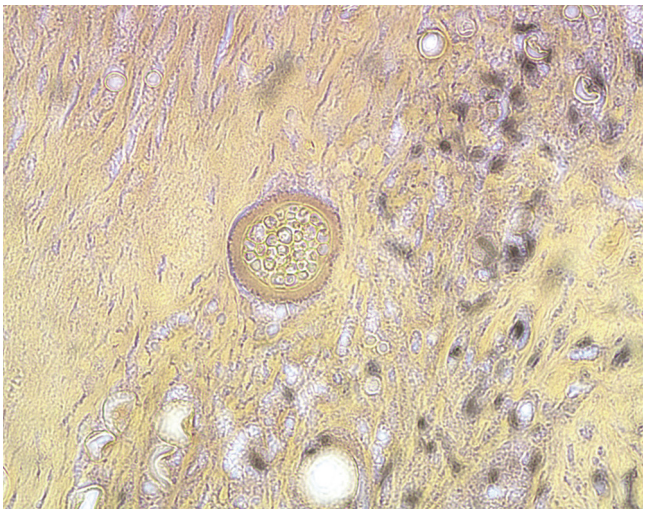

Fig. 64.8 *Coccidioides immitis* spherule filled with endospores.

for the majority of infections outside of California. Aside from these differences, there does not appear to be any additional difference in phenotype or pathogenicity. As such, the more familiar name *C. immitis* will be used in this chapter.

Like syphilis and tuberculosis, coccidioidomycosis causes a wide variety of lesions and has been called "the great imitator." Synonyms for coccidioidomycosis include **coccidioidal granuloma** and **San Joaquin Valley fever,** among others.

MORPHOLOGY

C. immitis (*C. posadasii*) is a dimorphic fungus that exists as a mold in nature and when cultured in the laboratory at 25° C and as an endosporulating spherule in tissue and under very specific conditions in vitro (Figs. 64.7 and 64.8; see Table 64.2 and Fig. 64.1). A variety of mold morphologies may be seen in culture at 25° C. Initial growth is white to gray, moist, and glabrous and occurs within 3 to 4 days. It rapidly develops abundant aerial mycelia, and the colony enlarges into a circular "bloom." Mature colonies usually become tan to brown or lavender.

Microscopically, the vegetative hyphae give rise to fertile hyphae that produce alternating (separated by disjunctor cells) hyaline arthroconidia (see Figs. 64.1 and 64.7). When released, the infectious conidia are typically "barrel-shaped" and have an annular frill at both ends. As the culture ages, the vegetative hyphae also fragment into arthroconidia.

On inhalation, the arthroconidia (2.5 to 4 μm wide) become rounded as they convert to spherules in the lung (see Figs. 64.1 and 64.8). At maturity, the spherules (20 to 60 μm in diameter) produce endospores by a process known as **progressive cleavage.** Rupture of the spherule walls releases the endospores, which in turn form new spherules (see Fig. 64.6). In approximately 10% to 30% of pulmonary cavities associated with coccidioidomycosis, branched, septate hyphae and arthroconidia may be produced.

EPIDEMIOLOGY

In the United States, the region of endemicity for coccidioidomycosis includes central and southern California, southern Arizona, southern New Mexico, parts of Utah and Washington, and western Texas. The region of endemicity extends southwards into the desert regions of northern Mexico and parts of Central and South America (see Fig. 64.2). *C. immitis* is found in soil, and the growth of the fungus in the environment is enhanced by bat and rodent droppings. Exposure to the infectious arthroconidia is greatest in late summer and fall when dusty conditions prevail. Cycles of drought and rain enhance dispersion of the organism because heavy rains facilitate the growth of the organism in the nitrogenous soil wastes, and subsequent drought and windy conditions favor aerosolization of arthroconidia (see Fig. 64.6). Acquisition of coccidioidomycosis occurs principally by inhalation of arthroconidia, and in endemic areas, infection rates may be 16% to 42% by early adulthood. The incidence of coccidioidomycosis is approximately 42.6 cases per 100,000 population annually in the endemic area; however, it is known to disproportionately affect persons 60 years of age and older (≈69 per 100,000) and those residing in the state of Arizona (≈248 per 100,000).

CLINICAL SYNDROMES

C. immitis is probably the most virulent of all human mycotic pathogens (Clinical Case 64.2). The inhalation of only a few arthroconidia produces primary coccidioidomycosis, which may include asymptomatic pulmonary disease (≈60% of patients) or a self-limited flulike illness marked by fever, cough, chest pain, and weight loss. Patients with primary coccidioidomycosis may have a variety of allergic reactions (≈10%) secondary to immune complex formation, including an erythematous macular rash, erythema multiforme, and erythema nodosum.

Primary disease usually resolves without therapy and confers a strong, specific immunity to reinfection, which is detected by the coccidioidin skin test. In endemic regions, primary coccidioidal pneumonia may account for 17% to 29% of all community-acquired pneumonia. In patients symptomatic for 6 weeks or longer, the disease progresses to secondary coccidioidomycosis, which may include nodules, cavitary disease, or progressive pulmonary disease (25% to 30% of cases); single or multisystem dissemination follows in approximately 1% of this population. Extrapulmonary sites of infection include skin, soft tissues, bones, joints, and

Clinical Case 64.2 **Coccidioidomycosis**

Stafford and colleagues (*Infect Med* 24[Suppl 8]:23–25, 2007) described a 31-year-old African American U.S. Army soldier who presented with fever, chills, night sweats, and a nonproductive cough of 4 weeks' duration. In addition, he had recently detected a painless right breast mass. His past medical history was unremarkable. He was stationed at Fort Irwin, California, in which he was working as a telephone repairman. His physical exam was unremarkable, except for a firm, nontender, 3-cm subcutaneous mass overlying the right breast. Multiple small (less than 1 cm), nontender lymph nodes were palpable in the axillae and groin. Laboratory studies revealed a white blood count of 11.9/μL, with 30% eosinophils. Serum chemistries were notable for an elevated alkaline phosphatase level. Results of blood cultures, tests for serum *Cryptococcus* antigen, urinary *Histoplasma* antigen, and HIV antibody were negative, as was a tuberculin skin test. A chest radiograph showed bilateral interstitial micronodules in a miliary pattern, as well as a right-sided paratracheal fullness. A CT scan of the chest confirmed the presence of diffuse, 1- to 2-mm micronodules in all lobes. The CT scan also showed a lobular parenchymal mass lesion in the right middle lobe and a right chest wall mass. A fine-needle aspirate of the right breast mass revealed spherules filled with endospores, consistent with coccidioidomycosis. Culture of the material grew *Coccidioides immitis*. A serology panel for *C. immitis* was positive and revealed immunoglobulin G complement fixation titers at a dilution of greater than 1:256. Cerebrospinal fluid analysis was normal, but a bone scan revealed multiple regions of increased osteoblastic activity involving the left scapula, right anterior fifth rib, and midthoracic vertebral regions. Treatment was initiated with amphotericin B, but increasing neck pain prompted further imaging, which demonstrated a lytic lesion of the C1 vertebral body and a paravertebral mass. Despite antifungal therapy, progressive enlargement of the mass necessitated surgical debridement. The patient was continued on amphotericin B lipid formulation, with plans for long-term, perhaps lifelong, antifungal therapy.

This is an example of the serious problems posed by coccidioidomycosis. Clues to the diagnosis of disseminated coccidioidomycosis in this patient included an infectious prodrome, peripheral eosinophilia, hilar lymphadenopathy, characteristic pattern of organ involvement (lungs, bones, soft tissues), residence in an endemic area, and African American ethnicity (higher risk group for dissemination).

CT, Computed tomography.

meninges. Persons in certain ethnic groups (e.g., Filipino, African American, Native American, and Hispanic) run the highest risk of dissemination, with meningeal involvement a common sequela (Table 64.3). In addition to ethnicity, males (9:1), women in the third trimester of pregnancy, individuals with a cellular immunodeficiency (including AIDS, organ transplantation recipients, and those treated with tumor necrosis factor antagonists), and persons at the extremes of age are at high risk for disseminated disease (see Table 64.3). The mortality in disseminated disease exceeds 90% without treatment, and chronic infection is common.

TABLE 64.3 Risk Factors for Disseminated Coccidioidomycosis

Risk Factor	Highest Risk
Age	Infants and elderly
Sex	Male
Genetics	Filipino > African American > Native American > Hispanic > Asian
Serum CF antibody titer	>1:32
Pregnancy	Late pregnancy and postpartum
Skin test	Negative
Depressed cell-mediated immunity	Malignancy, chemotherapy, steroid treatment, HIV infection

LABORATORY DIAGNOSIS

The diagnosis of coccidioidomycosis includes the use of histopathologic examination of tissue or other clinical material, isolation of the fungus in the culture, and serologic testing (see Table 64.2). Direct microscopic visualization of endosporulating spherules in sputum, exudates, or tissue is sufficient to establish the diagnosis (see Fig. 64.8) and is preferred over culture because of the highly infectious nature of the mold when grown in culture. Clinical exudates should be examined directly in 10% to 20% potassium hydroxide (KOH) with calcofluor white, and tissue from biopsy can be stained with H&E or specific fungal stains such as GMS or PAS (see Fig. 64.8).

Clinical specimens may be cultured on routine mycologic media at 25° C. Colonies of *C. immitis* develop within 3 to 5 days, and typical sporulation may be seen in 5 to 10 days. Because of the highly infectious nature of the fungus, all plates or tubes should be sealed using gas-permeable tape (plates) or screw caps (tubes) and only examined within a suitable biosafety cabinet. The identification of *C. immitis* from culture may be accomplished by using the exoantigen immunodiffusion (ID) test or nucleic acid hybridization. Conversion of the mold into spherules in vitro is not usually attempted outside of a research setting.

Several serologic procedures exist for initial screening, confirmation, or prognostic evaluation (see Table 64.2). For initial diagnosis, the combined use of the ID test and the latex particle agglutination (LPA) test detects approximately 93% of cases. The complement fixation (CF) and tube precipitin (TP) tests also may be used for diagnosis and prognosis. An enzyme immunoassay (EIA) for detection of IgG and IgM antibodies in serum or CSF is available commercially. Prognostic studies frequently use serial CF titers; rising titers are a bad prognostic sign, and falling titers indicate improvement. A coccidioidal urinary antigen test has been developed, but its relatively low sensitivity of 71% limits its clinical utility. Antigen testing may be useful in testing CSF and coupled with CSF antibody testing may achieve a diagnostic yield of 98% in patients with coccidioidal meningitis. Serum (1-3)-β-D-glucan has undergone limited evaluation in the detection of coccidioidomycosis and has a limited role (44% sensitivity) in this

population. A polymerase chain reaction (PCR)-based assay was recently granted approval by the U.S. Food and Drug Administration (FDA) for the detection of *Coccidioides* from clinical samples. Few clinical studies have been published to date, although it appears the sensitivity of PCR is similar to that of culture (~50%).

TREATMENT

Most individuals with primary coccidioidomycosis do not require specific antifungal therapy. For those with concurrent risk factors (see Table 64.3), such as organ transplant, human immunodeficiency virus (HIV) infection, high doses of corticosteroids, or when there is evidence of unusually severe infection, treatment is necessary. Primary coccidioidomycosis in the third trimester of pregnancy or during the immediate postpartum period requires treatment with amphotericin B.

Immunocompromised patients or others with diffuse pneumonia should be treated with amphotericin B followed by an azole (either fluconazole, itraconazole, isavuconazole, posaconazole, or voriconazole) as maintenance therapy. The total length of therapy should be at least 1 year. Immunocompromised patients should be maintained on an oral azole as secondary prophylaxis.

Chronic cavitary pneumonia should be treated with an oral azole for at least 1 year. In cases in which the response is suboptimal, the alternatives are to switch to another azole (e.g., from itraconazole to fluconazole), increase the dose of the azole in the case of fluconazole, or switch to amphotericin B. Surgical treatment is required in the event of rupture of a cavity into the pleural space, hemoptysis, or for localized refractory lesions.

The treatment of nonmeningeal extrapulmonary disseminated infections is based on oral azole therapy with either fluconazole or itraconazole (isavuconazole, posaconazole, and voriconazole also are options). In the case of vertebral involvement or inadequate clinical response, treatment with amphotericin B is recommended, along with appropriate surgical debridement and stabilization.

Meningeal coccidioidomycosis is managed with the administration of fluconazole or itraconazole (secondary choice because of poor CNS penetration) indefinitely. Isavuconazole, posaconazole, and voriconazole also are alternative choices. Intrathecal administration of amphotericin B is recommended only in the event of failure of azole therapy because of its toxicity when administered by this route.

Emergomycosis and Adiaspiromycosis

As a result of molecular taxonomic studies, two new genera have recently been proposed (*Adiaspiromyces* and *Emergomyces*) from within the prior genus *Emmonsia* (now obsolete). *Adiaspiromyces* includes one species that has been associated with human disease. *A. crescens* (formerly *E. crescens*) is the agent of adiaspiromycosis, which is a generally self-limited pulmonary disease described in Chapter 66.

The newly proposed genus, *Emergomyces*, contains *Es. pasteurianus* as the type species (formerly *E. pasteuriana*) and four recently identified species: *Es. africanus*, *Es. orientalis*, *Es. canadensis*, and *Es. europaeus*. *Emergomyces* have been found to cause human disease in immunocompromised patients in Europe, Asia, Africa, and North America. The thermally dimorphic species *Es. pasteurianus* is the most widespread, and *Es. africanus* is the most common endemic mycosis diagnosed in South Africa. The classic clinical picture of emergomycosis is of disseminated disease, often with cutaneous involvement, in immunocompromised individuals. The remaining species of *Emergomyces* are reported from small numbers of infection in Asia (*Es. orientalis*), Europe (*Es. europaeus*), and North America (*Es. canadensis*). The *Emergomyces* spp. are distinguished from the classical *Emmonsia*-like species (*E. parva* [now *Blastomyces parvus*]) and *E. crescens* (now *A. crescens*) by small yeastlike cells rather than adiaspores in the parasitic phase.

MORPHOLOGY

The species of *Emergomyces* are thermally dimorphic fungi that grow as a mold at 25° C and as a yeast at 37° C. At 25° C colonies grow at a slow-to-moderate rate taking on a cerebriform appearance and becoming light brown with powdery segments over time. Light microscopy revealed septate hyaline hyphae (1 to 1.5 μm in diameter) with numerous smooth-walled oval conidia. The conidia are borne on short stalks that formed perpendicular to a swollen vesicle. The vesicles give rise to four-to-eight stalks or pedicles, each forming a terminal conidium, establishing a flower-shaped arrangement of four-to-eight conidia grouped together. When mature, the conidia have distinctly tuberculated cell walls. No adiaspores are seen in any of the cultures incubated at 37° C or 40° C.

On incubation at 37° C for 10 to 14 days, the mycelial cultures convert to the yeast phase. Yeast colonies are smooth and beige to light brown in color. The yeast cells are small (2 to 4 μm in diameter), thin-walled, globose-to-oval with single or multiple narrow-based budding. Larger cells with broader based buds are sometimes present.

EPIDEMIOLOGY

Cases of emergomycosis have been reported from four continents: Europe, Asia, Africa, and North America. As such, there is little in the way of information to document specific areas of endemicity.

The largest described burden of emergomycosis is among HIV-infected persons in South Africa, in which most cases are attributed to *Es. africanus*. The South African cases were all initially diagnosed after the introduction of broad-range PCR for fungal diagnosis and identification in 2008. Thus the apparent clustering of cases and the "emergence" of *Emergomyces* spp. in South Africa may simply represent improved detection of the causative organism rather than introduction of a new opportunistic pathogen. All of the South African cases occurred in adults with late-stage HIV infection and all cases had extensive cutaneous involvement. Although country-level surveillance data are lacking in Africa, a clinical and laboratory surveillance study diagnosed 17 culture-proven cases of emergomycosis over 15 months at public hospitals in Cape Town. Molecular detection of *Es. africanus* was demonstrated in both soil and air samples from South Africa.

Es. pasteuranus is the most widespread species, causing disease on three continents. Emergomycosis caused by *Es. pasteuranus* has been reported from Italy, Spain, France, India, China, and South Africa. The other species are represented by one to four infected patients in discrete geographic locations.

Nearly all cases of emergomycosis have been reported in immunocompromised patients. Most cases have been diagnosed in patients with advanced HIV infection or other defects in cell-mediated immunity, including immunosuppression for organ transplantation.

CLINICAL SYNDROMES

The primary route of infection, conserved among *Emergomyces* spp., is presumed to be inhalation of airborne conidia released from saprophytic mycelia in soil. Once in the human host tissue, conidia of *Emergomyces* spp. convert to yeastlike cells capable of replication and extrapulmonary dissemination. All of the reported cases of disseminated infection caused by *Emergomyces* spp. have occurred in immunocompromised adults, the vast majority of which suffered from late-stage HIV infection. The South African patients all had very low CD4+ T-cell counts (median, 16 cells/mm^3), were profoundly anemic, and had widespread skin lesions. The lesions varied from erythematous papules and plaques to ulcerated, boggy, and crusted plaques. The majority of cases (85%) had chest radiograph findings that mimicked tuberculosis. Although inhalation is presumed to be the route of infection, disease limited to the lungs is uncommon. Extrapulmonary disease involving organs other than skin has been reported, including that of liver, lymph node, and cervix. Disseminated emergomycosis appears to be a progressive disease in many patients, particularly the immunocompromised, in whom case-fatality rates approach 50% and as such antifungal therapy is indicated.

LABORATORY DIAGNOSIS

The yeast cells of *Emergomyces* spp. are readily detected by histopathologic examination of skin biopsies and may be isolated in culture from blood, bone marrow, respiratory tissue, liver tissue, lymph node, and cutaneous tissue. There are no commercially available serologic assays developed specifically for emergomycosis. Cross-reactivity in the *Histoplasma* (galactomannan) antigen EIA test has been reported. Molecular methods have been used for the detection of *Es. africanus* in clinical and environmental samples and for identification of cultured isolates to species level. Identification is usually achieved by amplification and sequencing of the internal transcribed spacer (ITS) region of the ribosomal gene using ITS1 and ITS4 primers, ITS1, and ITS2 primers or 28S rDNA (large subunit or D1/D2) primers. There are no commercially available molecular diagnostic tests for *Emergomyces* spp.

TREATMENT

There are no randomized-controlled trials available to guide the management of disseminated emergomycosis. As such, it seems prudent to follow the Infectious Diseases Society of America guidelines for the management of other endemic mycoses in immunocompromised persons. In general, this includes the use of amphotericin B (preferably a lipid formulation) followed by a triazole antifungal agent for at least 12 months. Longer courses of therapy may be required in patients who do not achieve immune reconstitution.

Histoplasmosis

Histoplasmosis is caused by two varieties of *H. capsulatum*: *H. capsulatum* var. *capsulatum* and *H. capsulatum* var. *duboisii* (see Table 64.1). *H. capsulatum* var. *capsulatum* causes pulmonary and disseminated infections in the eastern half of the United States and most of Latin America, whereas *H. capsulatum* var. *duboisii* causes predominately skin and bone lesions and is restricted to the tropical areas of Africa (see Fig. 64.2).

MORPHOLOGY

Both varieties of *H. capsulatum* are thermally dimorphic fungi existing as a hyaline mold in nature and in culture at 25° C and as an intracellular budding yeast in tissue and in culture at 37° C (Figs. 64.9 to 64.11; see Table 64.2). In culture, the mold forms of *H. capsulatum* var. *capsulatum* and var. *duboisii* are indistinguishable macroscopically and microscopically. The mold colonies grow slowly and develop as white or brown hyphal colonies after several days to a week. The mold form produces two types of

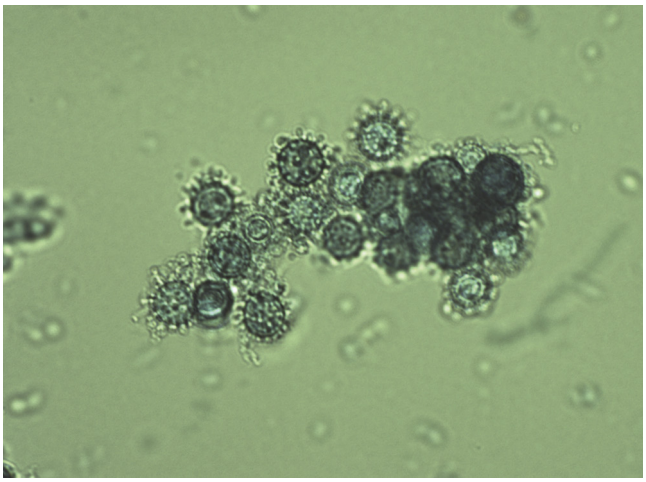

Fig. 64.9 *Histoplasma capsulatum* mold phase showing tuberculate macroconidia.

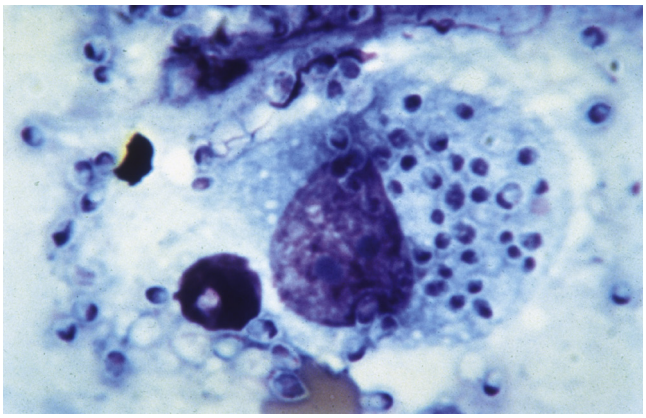

Fig. 64.10 Giemsa-stained preparation showing intracellular yeast forms of *Histoplasma capsulatum* var. *capsulatum*.

conidia: (1) large (8- to 15-μm), thick-walled, spheric macroconidia with spikelike projections (tuberculate macroconidia) that arise from short conidiophores (Fig. 64.12, see Fig. 64.1) and (2) small, oval microconidia (2 to 4 μm) with smooth or slightly rough walls that are sessile or on short stalks (see Figs. 64.1 and 64.12). The yeast cells are thin walled, oval, and measure 2 to 4 μm (var. *capsulatum*) (see Fig. 64.10) or thicker walled and 8 to 15 μm (var. *duboisii*) (see Fig. 64.11). The yeast cells of both varieties of *H. capsulatum* are intracellular in vivo and are uninucleated (see Figs. 64.10 and 64.11).

EPIDEMIOLOGY

Histoplasmosis capsulati is localized to the broad regions of the Ohio and Mississippi River valleys in the United States and occurs throughout Mexico and Central and South America (see Fig. 64.2 and Table 64.1). Outbreaks of histoplasmosis have been reported to occur after outdoor environmental disturbances in nonendemic states including California, Florida, Idaho, Minnesota, Montana, New York, North Dakota, and South Carolina. Cases have also been reported from India, China, and South Africa. Histoplasmosis duboisii, or African histoplasmosis, is confined to the tropical areas of Africa, including Gabon, Uganda, and Kenya (see Fig. 64.2 and Table 64.1).

The natural habitat of the mycelial form of both varieties of *H. capsulatum* is soil with a high nitrogen content, such as that found in areas contaminated with bird or bat droppings. Outbreaks of histoplasmosis have been associated with exposure to bird roosts, caves, and decaying buildings or urban renewal projects involving excavation and demolition. Aerosolization of microconidia and hyphal fragments in the disturbed soil, with subsequent inhalation by exposed individuals, is considered to be the basis for these outbreaks (see Fig. 64.12). Although attack rates may reach 100% in certain exposures, most cases remain asymptomatic and are detected only by skin testing. Immunocompromised individuals and children are more prone to develop symptomatic disease with either variety of *Histoplasma*. Reactivation of the disease and dissemination is common among immunosuppressed individuals, especially those with AIDS.

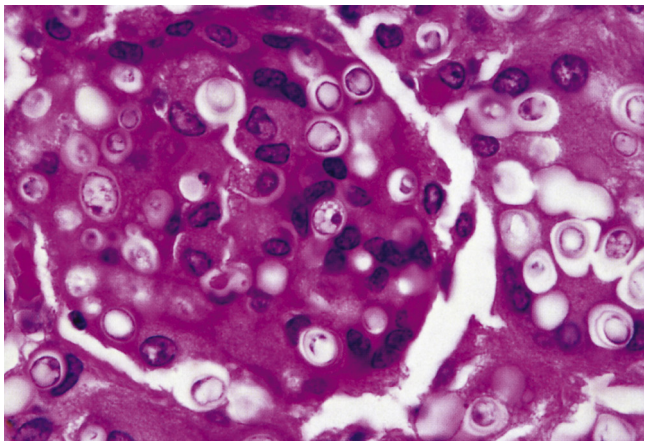

Fig. 64.11 Hematoxylin and eosin–stained tissue section showing intracellular yeast forms of *Histoplasma capsulatum* var. *duboisii.* (From Connor DH., Chandler FW., Schwartz DA.`, et al., 1997. Pathology of Infectious Diseases. Appleton & Lange, Stamford, CT.)

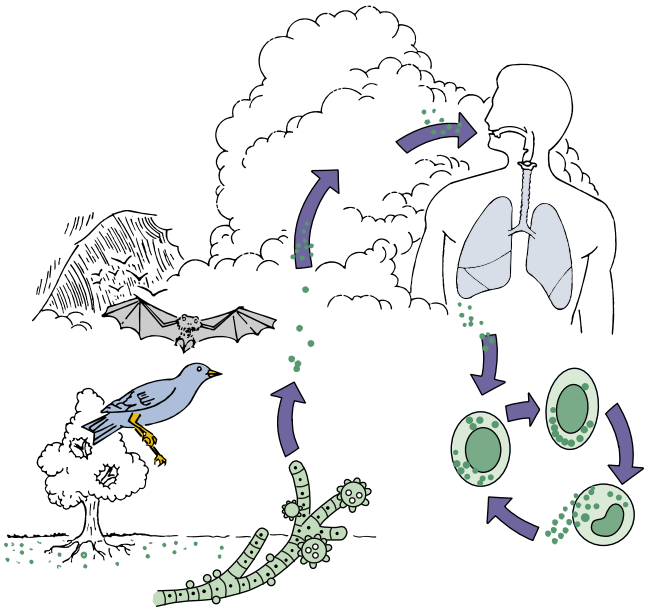

Fig. 64.12 Natural history of the mold (saprobic) and yeast (parasitic) cycle of *Histoplasma capsulatum.*

CLINICAL SYNDROMES

The usual route of infection for both varieties of histoplasmosis is via inhalation of microconidia, which in turn germinate into yeasts within the lung and may remain localized or disseminate hematogenously or by the lymphatic system (Clinical Case 64.3 and see Fig. 64.12). The microconidia are rapidly phagocytosed by pulmonary macrophages and neutrophils, and it is thought that conversion to the parasitic yeast form takes place intracellularly.

Histoplasmosis Capsulati

The clinical presentation of histoplasmosis caused by *H. capsulatum* var. *capsulatum* is dependent on the intensity of exposure and immunologic status of the host. Asymptomatic infection occurs in 90% of individuals after a low-intensity exposure. In the event of an exposure to a heavy inoculum, however, most individuals exhibit some symptoms. The self-limited form of acute pulmonary histoplasmosis is marked by a flulike illness with fever, chills, headache, cough, myalgias, and chest pain. Radiographic evidence of hilar or mediastinal adenopathy and patchy pulmonary infiltrates may be seen. Most acute infections resolve with supportive care and do not require specific antifungal treatment. In rare instances, usually after very heavy exposure, acute respiratory distress syndrome may be seen. In approximately 10% of patients, inflammatory sequelae, such as persistent lymphadenopathy with bronchial obstruction, arthritis, arthralgias, or pericarditis, may be seen. Another rare complication of histoplasmosis is a condition known as mediastinal fibrosis, in which persistent host response to the organism may result in massive fibrosis and constriction of mediastinal structures, including the heart and great vessels.

Progressive pulmonary histoplasmosis may follow acute infection in approximately 1 in 100,000 cases per year. Chronic pulmonary symptoms are associated with apical cavities and fibrosis and are more likely to occur in patients with prior underlying pulmonary disease. These lesions generally do not heal spontaneously, and persistence of the organism leads to progressive destruction and fibrosis secondary to the immune response to the organism.

Disseminated histoplasmosis follows acute infection in 1 in 2000 adults and is much higher in children and immunocompromised adults. Disseminated disease may assume a chronic, subacute, or acute course. Chronic disseminated histoplasmosis is characterized by weight loss and fatigue, with or without fever. Oral ulcers and hepatosplenomegaly are common.

Subacute disseminated histoplasmosis is marked by fever, weight loss, and malaise. Oropharyngeal ulcers and hepatosplenomegaly are prominent. Bone marrow involvement may produce anemia, leukopenia, and thrombocytopenia. Other sites of involvement include the adrenals, cardiac valves, and the CNS. Untreated subacute disseminated histoplasmosis will result in death in 2 to 24 months.

Clinical Case 64.3 **Disseminated Histoplasmosis**

Mariani and Morris (*Infect Med* 24[Suppl 8]:17–19, 2007) described a case of disseminated histoplasmosis in a patient with AIDS. The patient was a 42-year-old El Salvadoran woman who was admitted to the hospital for evaluation of progressive dermatosis involving the right nostril, cheek, and lip, despite antibiotic therapy. She was positive for HIV (CD4 lymphocyte count 21/μL) and had lived in Miami for the past 18 years. The lesion first appeared on the right nostril 3 months before admission. The patient sought medical attention and was treated unsuccessfully with oral antibiotics. Over the following 2 months, the lesion increased in size, involving the right nares and malar region, and was accompanied by fever, malaise, and a 50-lb weight loss. A necrotic area developed on the superior aspect of the right nostril, extending to the upper lip. A presumptive diagnosis of leishmaniasis was entertained, based in part on the patient's country of origin and a possible exposure to a sandfly bite.

Laboratory studies revealed anemia and lymphopenia. A chest radiograph was normal, and a computed tomography scan of the head showed a soft-tissue mass in the right nasal cavity. Histopathologic evaluation of a skin biopsy showed chronic inflammation, with intracytoplasmic budding yeasts. Culture of the biopsy grew *Histoplasma capsulatum*, and results of a urine *Histoplasma* antigen test were positive. The patient was treated with amphotericin B, followed by itraconazole with good results.

This case underscores the ability of *H. capsulatum* to remain clinically latent for many years, only to reactivate on immunosuppression of the host. Cutaneous manifestations of histoplasmosis are usually a consequence of progression from primary (latent) to disseminated disease. Histoplasmosis is not endemic to southern Florida but is endemic to much of Latin America, in which the patient had lived before moving to Miami. A high index of suspicion and confirmation with skin biopsies, cultures, and testing for urinary antigen are crucial for timely and appropriate treatment of disseminated histoplasmosis.

Acute disseminated histoplasmosis is a fulminant process that is most commonly seen in severely immunosuppressed individuals, including those with AIDS, organ transplant recipients, and those receiving steroids or other immunosuppressive chemotherapy. In addition, children younger than 1 year and adults with debilitating medical conditions also are at risk, given sufficient exposure to the fungus. In contrast to the other forms of histoplasmosis, acute disseminated disease may present with a septic shock–like picture, with fever, hypotension, pulmonary infiltrates, and acute respiratory distress. Oral and gastrointestinal ulcerations and bleeding, adrenal insufficiency, meningitis, and endocarditis may also be seen. If untreated, acute disseminated histoplasmosis is fatal within days to weeks.

Histoplasmosis duboisii

In contrast to classic histoplasmosis, pulmonary lesions are uncommon in African histoplasmosis. The localized form of histoplasmosis duboisii is a chronic disease characterized by regional lymphadenopathy, with lesions of the skin and bone. Skin lesions are papular or nodular and eventually progress to abscesses, which then ulcerate. About one-third of patients will exhibit osseous lesions characterized by osteolysis and involvement of contiguous joints. The cranium, sternum, ribs, vertebrae, and long bones are most frequently involved, often with overlying abscesses and draining sinuses.

A more fulminant disseminated form of histoplasmosis duboisii may be seen in profoundly immunodeficient individuals. Hematogenous and lymphatic dissemination to bone marrow, liver, spleen, and other organs occurs and is marked by fever, lymphadenopathy, anemia, weight loss, and organomegaly. This form of the disease is uniformly fatal unless promptly diagnosed and treated.

LABORATORY DIAGNOSIS

The diagnosis of histoplasmosis may be made by direct microscopy, culture of blood, bone marrow, or other clinical material, and by serology, including antigen detection in blood, CSF, and urine (Table 64.4; see Table 64.2). The yeast phase of the organism can be detected in sputum, bronchoalveolar lavage fluid, peripheral blood films, bone marrow, and tissue stained with Giemsa, GMS, or PAS stains (see Fig. 64.10). In tissue sections, cells of *H. capsulatum* var. *capsulatum* are yeastlike,

TABLE 64.4 Laboratory Tests for Histoplasmosis

	SENSITIVITY (% TRUE POSITIVES) IN DISEASE STATES		
Test	**Disseminated**	**Chronic Pulmonary**	**Self-Limited[a]**
Antigen	92	21	39
Culture	85	85	15
Histopathology	43	17	9
Serology	71	100	98

[a]Includes acute pulmonary histoplasmosis, rheumatologic syndrome, and pericarditis.

From Wheat, L.J., 2004. Endemic mycoses. In: Cohen, J., Powderly, W.G. (Eds.), Infectious Diseases, second ed. Mosby, St Louis, MO.

hyaline, spherical to oval, 2 to 4 μm in diameter, and uninucleate and have single buds attached by a narrow base. The cells are usually intracellular and clustered together. The cells of *H. capsulatum* var. *duboisii* are also intracellular, yeastlike, and uninucleate but are much larger (8 to 15 μm) and have thick "double-contoured" walls. They are usually in macrophages and giant cells (see Fig. 64.11).

Because of the high organism burden in patients with disseminated disease, cultures of respiratory specimens, blood, bone marrow, and tissue are of value. They are less useful in self-limited or localized disease (see Table 64.4). Growth of the mycelial form in culture is slow, and once isolated, the identification must be confirmed by conversion to the yeast phase or by use of exoantigen testing or nucleic acid hybridization. As with the other dimorphic pathogens, cultures of *Histoplasma* must be handled with care in a biosafety cabinet.

Serologic diagnosis of histoplasmosis includes tests for both antigen and antibody detection (see Table 64.2). Antibody detection assays include a CF assay and an ID test. These tests are usually used together to maximize sensitivity and specificity, but neither is useful in the acute setting; CF and ID are often negative in immunocompromised patients with disseminated infection. An EIA for detection of IgG and IgM antibodies in serum or CSF is available commercially.

Detection of *Histoplasma* antigen in serum and urine by EIA has become very useful, particularly in diagnosing disseminated disease (see Tables 64.2 and 64.4). The sensitivity of antigen detection is greater in urine specimens than in blood and ranges from 21% in chronic pulmonary disease to 92% in disseminated disease. Serial measurements of antigen may be used to assess response to therapy and for establishing relapse of the disease. Testing CSF for anti-*Histoplasma* IgG and IgM antibody complements antigen detection and improves the sensitivity (98%) for diagnosis of *Histoplasma* meningitis. Both BDG and PCR have been useful in the diagnosis of histoplasmosis. Whereas BDG has only modest sensitivity and specificity (87% and 65%, respectively), PCR has shown excellent sensitivity (100%) and specificity (95%) and has been applied to a wide range of clinical samples.

TREATMENT

Because most patients with histoplasmosis recover without therapy, the first decision must be whether specific antifungal therapy is necessary or not. Some immunocompetent patients with more severe infection may exhibit prolonged symptoms and may benefit from treatment with itraconazole. In cases of severe acute pulmonary histoplasmosis with hypoxemia and acute respiratory distress syndrome, amphotericin B should be administered acutely, followed by oral itraconazole (fluconazole, isavuconazole, posaconazole, and voriconazole also are options) to complete a 12-week course.

Chronic pulmonary histoplasmosis also warrants treatment because it is known to progress if left untreated. Treatment with amphotericin B, followed by itraconazole or another azole for 12 to 24 months, is recommended.

Disseminated histoplasmosis usually responds well to amphotericin B therapy. Once stabilized, the patient may be switched to oral itraconazole (fluconazole, isavuconazole, posaconazole, and voriconazole also are options) to be administered over 6 to 18 months. Patients with AIDS may require lifelong therapy with itraconazole. Alternative azole agents include isavuconazole, posaconazole, voriconazole, or fluconazole; however, secondary resistance to fluconazole has been described in patients on long-term maintenance therapy.

Histoplasmosis of the CNS is universally fatal if not treated. The therapy of choice is amphotericin B followed by fluconazole for 9 to 12 months.

Patients with severe obstructive mediastinal histoplasmosis require amphotericin B therapy. Itraconazole may be used for outpatient therapy.

Paracoccidioidomycosis

Paracoccidioidomycosis is a systemic fungal infection caused by the dimorphic pathogens *P. brasiliensis* and *P. lutzii*. This infection is also known as South American blastomycosis and is the major dimorphic endemic fungal infection in Latin American countries. Primary paracoccidioidomycosis usually occurs in young people as a self-limited pulmonary process. At this stage, it rarely displays a progressive acute or subacute course. Reactivation of a primary quiescent lesion may occur years later, resulting in chronic progressive pulmonary disease with or without involvement of other organs.

MORPHOLOGY

The mold phase of *P. brasiliensis*/*P. lutzii* grows slowly in vitro at 25° C. White colonies become apparent in 3 to 4 weeks, eventually taking on a velvety appearance. Glabrous, wrinkled, brownish colonies also may be seen. The mycelial form is nondescript and nondiagnostic showing hyaline, septate, hyphae with intercalated chlamydoconidia. Specific identification requires conversion to the yeast form or by exoantigen testing.

The characteristic yeast form is seen in tissue and in culture at 37° C. Variable-sized (3 to 30 μm or more in diameter), oval to round, yeastlike cells with double refractile walls and single or multiple buds (blastoconidia) are characteristic of this fungus (Fig. 64.13). The blastoconidia are connected to the parent cell by a narrow isthmus, and six or more of various sizes may be produced from a single cell, such as the so-called "mariner's" or "pilot-wheel" morphology. The variability in size and number of blastoconidia and their connection to the parent cell are identifying features (see Fig. 64.13). These features are best disclosed by the GMS stain but also may be seen in H&E-stained tissues or in KOH mounts of clinical material.

EPIDEMIOLOGY

Paracoccidioidomycosis is endemic throughout Latin America but is more prevalent in South America than in Central America (see Fig. 64.2). The highest incidence is seen in Brazil, followed by Colombia, Venezuela, Ecuador, and Argentina. All patients diagnosed outside of Latin

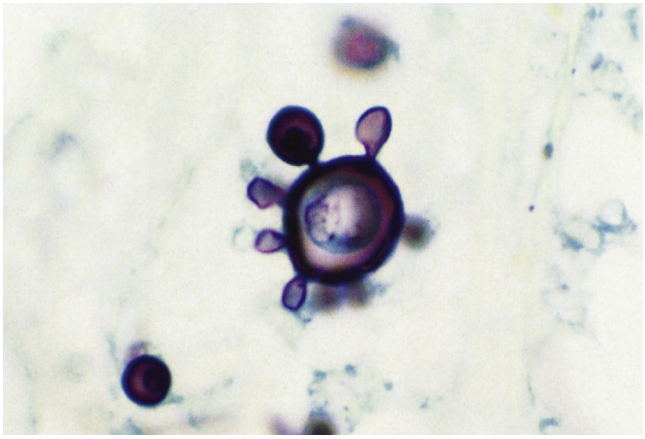

Fig. 64.13 Gomori methenamine silver–stained yeast form of *Paracoccidioides brasiliensis* showing multiple budding "pilot-wheel" morphology. (From Connor, D.H., et al., Pathology of Infectious Diseases. Appleton & Lange, Stamford, CT.)

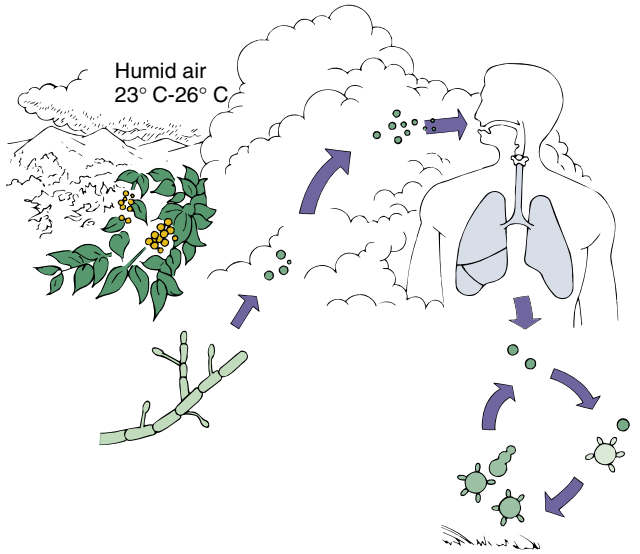

Fig. 64.14 Natural history of the mold (saprobic) and yeast (parasitic) cycle of *Paracoccidioides brasiliensis.*

America had previously lived in Latin America. The ecology of the endemic areas includes high humidity, rich vegetation, moderate temperatures, and acid soil. These conditions are found along rivers from the Amazon jungle to small indigenous forests in Uruguay. *P. brasiliensis* has been recovered from soil in these areas; however, its ecologic niche is not well established. The portal of entry is thought to be either by inhalation or traumatic inoculation (Fig. 64.14), although even this is poorly understood. Natural infection has only been documented in armadillos.

Although infection occurs in children (peak incidence 10 to 19 years), overt disease is uncommon in both children and adolescents. In adults, disease is more common in men aged 30 to 50 years. Estrogen-mediated inhibition of the mold-to-yeast transition may account for the 15:1 male-to-female ratio of clinical disease. Most patients with clinically apparent disease live in rural areas and have close contact with the soil. There are no reports of epidemics or human-to-human transmission. Depression of cell-mediated immunity correlates with the acute progressive form of the disease.

CLINICAL SYNDROMES

Paracoccidioidomycosis may be subclinical or progressive with acute or chronic pulmonary forms or acute, subacute, or chronic disseminated forms of the disease. Most primary infections are self-limited; however, the organism may become dormant for long periods of time and reactivate to cause clinical disease concomitant with impaired host defenses. A subacute disseminated form is seen in younger patients and immunocompromised individuals with marked lymphadenopathy, organomegaly, bone marrow involvement, and osteoarticular manifestations mimicking osteomyelitis. Recurrent fungemia results in dissemination and frequent skin lesions. Pulmonary and mucosal lesions are not seen in this form of the disease.

Adults most often present with a chronic pulmonary form of the disease marked by respiratory problems, often as the sole manifestation. The disease progresses slowly over months to years, with persistent cough, purulent sputum, chest pain, weight loss, dyspnea, and fever. Pulmonary lesions are nodular, infiltrative, fibrotic, and cavitary.

Although 25% of patients exhibit only pulmonary manifestations of the disease, the infection can disseminate to extrapulmonary sites in the absence of diagnosis and treatment. Prominent extrapulmonary locations include skin and mucosa, lymph nodes, adrenal glands, liver, spleen, CNS, and bones. The mucosal lesions are painful and ulcerated and usually are confined to the mouth, lips, gums, and palate. More than 90% of these individuals are male.

LABORATORY DIAGNOSIS

The diagnosis is established by the demonstration of the characteristic yeast forms on microscopic examination of sputum, bronchoalveolar lavage fluid, scrapings, or biopsy of ulcers, pus draining from lymph nodes, CSF, or tissue (see Table 64.2). The organism may be visualized by a variety of staining methods, including calcofluor white fluorescence, H&E, GMS, PAS, or Papanicolaou stains (see Fig. 64.13). The presence of multiple buds distinguishes *P. brasiliensis*/*P. lutzii* from *Cryptococcus neoformans* and *B. dermatitidis*.

Isolation of the organism in culture requires confirmation by demonstration of thermal dimorphism or exoantigen testing (detection of exoantigen 1, 2, and 3). Cultures should be manipulated in a biosafety cabinet.

Serologic testing using either ID or CF to demonstrate antibody may be helpful in suggesting the diagnosis and in evaluating response to therapy (see Table 64.2). Application of both antigen detection and PCR-based diagnostic tests has been limited thus far.

TREATMENT

Itraconazole is the treatment of choice for most forms of the disease and generally must be given for at least 6 months. More severe or refractory infections may require amphotericin B therapy, followed by either itraconazole or sulfonamide therapy. Relapses are common with sulfonamide

therapy, and both dose and duration require adjustment based on clinical and mycologic parameters. Fluconazole has some activity against this organism, although frequent relapses have limited its use for the treatment of this disease.

Talaromycosis (Penicilliosis) *marneffei*

Talaromycosis marneffei is a disseminated mycosis caused by the dimorphic fungus *Talaromyces* (formerly *Penicillium) marneffei*. This infection involves the mononuclear phagocytic system and occurs primarily in HIV-infected individuals in tropical Asia, especially Thailand, northeastern India, China, Hong Kong, Vietnam, and Taiwan (see Fig. 64.2).

MORPHOLOGY

T. marneffei is the only species of *Talaromyces* that is a pathogenic dimorphic fungus. In its mold phase in culture at 25° C, it exhibits sporulating structures that are typical of the genus (see Fig. 64.1). Identification is aided by the formation of a soluble red pigment that diffuses into the agar (see Table 64.3).

At 37° C in culture and in tissue, *T. marneffei* grows as a yeastlike organism that divides by fission and exhibits a transverse septum (Fig. 64.15). The yeast form is intracellular in vivo and, in this way, resembles *H. capsulatum*, although it is somewhat more pleomorphic and elongated and does not bud (see Table 64.2 and Figs. 64.10 and 64.15).

EPIDEMIOLOGY

T. marneffei has emerged as a prominent mycotic pathogen among HIV-infected individuals in Southeast Asia (see Fig. 64.2). Imported cases have been reported in Europe and the United States. Although the disease is found predominantly in HIV/AIDS patients, its epidemiology is changing with better control of HIV infection globally, and non-HIV infected individuals, including those with cell-mediated immunodeficiency, or patients receiving monoclonal antibody therapies (e.g., anti CD-20) and kinase inhibitors, are also vulnerable. Talaromycosis (Penicilliosis) marneffei has become an early indicator of HIV infection in Southeast Asia. Although *T. marneffei* was initially isolated from a bamboo rat, *Rhizomys sinensis*, in Vietnam in 1956, exposure to soil and decaying material, especially under humid and rainy conditions, is likely the critical risk factor; agricultural occupations have been independently associated with increased risk. Attempts to recover the organism from soil have met with only limited success, and proof of an environmental reservoir is still lacking. Notably, isolates from bamboo rats and humans have been shown to share identical genotypes. This suggests that either rodents are vectors for human infections or both humans and rodents are infected from an as yet unidentified environmental source. Laboratory-acquired infection has been reported in an immunocompromised individual exposed to the mycelial form in culture.

CLINICAL SYNDROMES

Talaromycosis marneffei is caused when a susceptible host inhales conidia of *T. marneffei* from the environment, and disseminated infection develops. The infection may mimic tuberculosis, leishmaniasis, and other AIDS-related opportunistic infections, such as histoplasmosis and cryptococcosis. Patients present with fever, cough, pulmonary infiltrates, lymphadenopathy, organomegaly, anemia, leukopenia, and thrombocytopenia. Skin lesions reflect hematogenous dissemination and appear as molluscum contagiosum-like lesions on the face and trunk.

LABORATORY DIAGNOSIS

T. marneffei is readily recovered from clinical specimens, including blood, bone marrow, bronchoalveolar lavage specimens, and tissue. In culture at 25° C to 30° C, isolation of a mold that exhibits typical *Penicillium*-like morphology and a diffusible red pigment is highly suggestive. Conversion to the yeast phase at 37° C is confirmatory. Microscopic detection of elliptic fission yeasts inside phagocytes in buffy coat preparations or smears of bone marrow, ulcerative skin lesions, or lymph nodes is diagnostic (see Fig. 64.15). Serologic tests that detect antigen and antibody have been developed, although no standardized commercial tests are available. PCR and deoxyribonucleic acid (DNA) sequencing methods have been applied for both direct detection from clinical samples, as well as identification of *T. marneffei* from culture.

TREATMENT

Amphotericin B, voriconazole, and itraconazole are often used to treat infection with *T. marneffei.* Administration of amphotericin B for 2 weeks should be followed by itraconazole for another 10 weeks. AIDS patients may require lifelong treatment with itraconazole or voriconazole to prevent relapses of the infection. Fluconazole therapy has been associated with a high rate of failure and is not recommended. The echinocandins, as well as isavuconazole, posaconazole, and terbinafine, may be useful but more data are required.

Case Study and Questions

A 44-year-old man from Ottumwa, Iowa, decides to clean his chimney flue with a bowling ball, which crashes into the fireplace in a cloud of dust, dirt, and feathers. Ten days later, his son and wife, both of whom were in the living room when the bowling ball was dropped, are both admitted to the hospital with fevers, cough, and diffuse pulmonary infiltrates on chest radiography.

1. What is the most likely diagnosis?
   a. Valley fever
   b. Acute pulmonary blastomycosis
   c. Legionnaires' disease
   d. Acute pulmonary histoplasmosis

2. How would you confirm the diagnosis?

3. How would you treat these patients?

65 Opportunistic Mycoses

George is a 45-year-old man who underwent an allogeneic stem cell transplant as part of his treatment for acute leukemia. The transplant went well, and after engraftment, George was discharged from the hospital. During the course of his transplant, George's physicians placed him on antifungal prophylaxis with voriconazole because of concerns regarding aspergillosis, which had been a problem in the hospital during the past few years. After discharge, George did well, and his antifungal prophylaxis was continued; however, on a clinical visit on day 140 posttransplant, he was noted to have a rash and elevated liver function studies. About 1 week later, he began having bloody diarrhea, and his physician became concerned about graft-versus-host disease (GVHD). A rectal biopsy was performed, confirming GVHD, and George's immunosuppressive regimen was increased, as was his daily dose of voriconazole. The signs and symptoms of GVHD continued, and eventually George was readmitted to the hospital, in which he was found to be confused, febrile, and short of breath. A chest radiograph showed a wedge-shaped infiltrate in the right lower lung field, and imaging studies of his sinuses showed bilateral opacification.

1. What is the differential diagnosis of this process?
2. About which fungal pathogens would you be concerned in an immunosuppressed individual receiving voriconazole prophylaxis?
3. How would you go about making a diagnosis?
4. What course of therapy would you undertake?

Answers to these questions are available on www.StudentConsult.com.

Summaries Clinically Significant Organisms

CANDIDIASIS

Trigger Words

Candida, pseudohyphae, endogenous, exogenous, yeast, immunocompromised, vaginal thrush, oropharyngeal

Biology, Virulence, and Disease

- Opportunistic yeasts causing infections ranging from superficial mucosal and cutaneous disease to hematogenously disseminated, often fatal, infections
- Vast majority of infections are caused by five major species: *Candida albicans, C. glabrata, C. parapsilosis, C. tropicalis,* and *C. krusei*
- Morphology ranges from budding yeasts to pseudohyphae and true hyphae
- Reproduction is by formation of blastoconidia (buds)
- Most important group of opportunistic fungal pathogens
- May be community acquired (mucosal infections) or hospital associated (invasive disease)

Epidemiology

- *Candida* spp. are known colonizers of humans and other warm-blooded animals
- Primary site of colonization is the GI tract; commensals in the vagina, urethra, skin, and nails
- Most infections are endogenous, involving normally commensal host flora
- Exogenous transmission in hospitals also occurs
- *C. albicans* predominates in most types of infection
- Consequences of *Candida* BSIs are severe; risk factors include hematologic malignancies and neutropenia, abdominal surgery, prematurity in infants, and age >70 years

Diagnosis

- Clinical appearance, direct microscopic examination, and culture
- Hematogenously disseminated infections and candidemia difficult to diagnose on clinical grounds alone
- Laboratory diagnosis involves procurement of appropriate clinical material, followed by direct microscopic examination; culture; and (increasingly) application of molecular, antigenic, and proteomic analysis

Treatment, Prevention, and Control

- Mucosal and cutaneous infection: topical and systemically active antifungal agents include azoles (itraconazole, fluconazole, miconazole, and many others), polyenes (amphotericin B and nystatin)
- Invasive candidiasis and candidemia: oral or intravenous administration depending on antifungal agent and severity of disease and/or immunosuppression; azoles (fluconazole, voriconazole, posaconazole, isavuconazole), echinocandins (anidulafungin, caspofungin, micafungin), amphotericin B formulations (deoxycholate and lipid formulations), flucytosine

CRYPTOCOCCOSIS

Trigger Words

Capsule, budding yeast, CNS, neurotropic, India ink, antigen, AIDS

Biology, Virulence, and Disease

- Systemic mycosis caused by the fungi *Cryptococcus neoformans* and *C. gattii*
- *C. neoformans* includes capsular serotypes A, D, and AD; var. *grubii* (serotype A) and var. neoformans (serotype D)
- *C. gattii* includes serotypes B and C
- Spherical to oval, encapsulated, yeastlike organisms that replicate by budding
- Both species may cause pulmonary, hematogenously disseminated, and CNS disease

Epidemiology

- Usually acquired by inhaling aerosolized cells of *C. neoformans* and *C. gattii*
- Both species pathogenic for immunocompetent individuals
- *C. neoformans*: most often encountered as opportunistic pathogen; found worldwide in soil contaminated with avian excreta
- *C. gattii*: found in tropical and subtropical climates in association with eucalyptus trees; the focus in the Pacific Northwest has been associated with Douglas fir trees
- Disease is similar, although *C. gattii* infection tends to occur in immunocompetent individuals and has a lower associated mortality
- Incidence has progressively declined since early 1990s because of widespread use of fluconazole and successful treatment of HIV infection with antiviral drugs

Diagnosis

- May present as pneumonic process or (more commonly) as CNS infection
- Diagnosis may be made by culture of blood, CSF, or other clinical material
- Microscopic examination of CSF may reveal characteristic encapsulated budding yeast cells
- Cryptococcal meningitis: diagnosis by detection of polysaccharide antigen in serum or CSF

Continued

Summaries Clinically Significant Organisms—cont'd

Treatment, Prevention, and Control

- Cryptococcal meningitis and other disseminated forms universally fatal if left untreated
- Antifungal therapy: amphotericin B (deoxycholate or lipid formulation) plus flucytosine followed by maintenance/consolidation therapy with fluconazole (preferred) or itraconazole
- Effective management of CNS pressure and IRIS crucial to successful management of cryptococcal meningitis

ASPERGILLOSIS

Trigger Words

Septate branching hyphae, hypersensitivity pneumonitis, angioinvasive, aspergilloma, conidia

Biology, Virulence, and Disease

- Broad spectrum of diseases caused by filamentous fungi (molds) of genus *Aspergillus*
- Exposure to spores in environment may cause allergic reactions in hypersensitized hosts or destructive, invasive, pulmonary, and disseminated disease in highly immunocompromised hosts
- Vast majority of infections caused by *A. fumigatus* (most common), *A. flavus, A. niger*, and *A. terreus*
- Hyaline molds that produce vast amounts of spores (conidia) that serve as infectious propagules on inhalation by host
- Invasive aspergillosis marked by angioinvasion and tissue destruction caused by infarction
- Hematogenous dissemination of infection to extrapulmonary sites (most commonly brain, heart, kidneys, GI tract, liver, spleen) common because of angioinvasive nature of fungus

Epidemiology

- *Aspergillus* spp. common worldwide; conidia ubiquitous in air, soil, decaying matter
- Within hospital environment, *Aspergillus* spp. may be found in air, showerheads, water storage tanks, potted plants
- Conidia (spores) constantly being inhaled; respiratory tract most frequent and important portal of entry
- Host reaction, associated pathologic findings, and outcome of infection depend more on host factors than virulence or pathogenesis of individual species

Diagnosis

- Serologic, culture, histopathologic, molecular, biochemical, and antigenic methods supplemented by imaging studies

Treatment, Prevention, and Control

- Treatment usually involves administration of corticosteroids coupled with pulmonary toilet
- Treatment of chronic pulmonary aspergillosis may involve steroids and long-term antifungal therapy, usually with an azole antifungal agent
- Prophylaxis of high-risk (neutropenic) patients usually accomplished by administration of a mold-active azole (itraconazole, posaconazole, voriconazole)
- Specific antifungal therapy of invasive aspergillosis usually involves administration of voriconazole or a lipid formulation of amphotericin B; isavuconazole has recently been cleared by the U.S. Food and Drug Administration for treatment of invasive aspergillosis
- Efforts to decrease immunosuppression and/or reconstitute host immune defenses important, as is surgical resection of infected tissue if possible
- Resection of aspergillomas only considered in instances of severe hemoptysis

BSI, Bloodstream infections; *CNS,* central nervous system; *CSF,* cerebrospinal fluid; *GI,* gastrointestinal; *IRIS,* immune reconstitution inflammatory syndrome.

The frequency of invasive mycoses caused by opportunistic fungal pathogens has increased significantly over the past two decades. This increase in infections is associated with excessive morbidity and mortality (see Chapter 57, Table 57.1) and is directly related to the increase in patient populations at risk for developing serious fungal infections. High-risk groups include individuals undergoing blood and marrow transplantation (BMT), solid organ transplantation, major surgery (especially gastrointestinal [GI] surgery), those with acquired immunodeficiency syndrome (AIDS), neoplastic disease, immunosuppressive therapy, advanced age, and premature birth (Table 65.1). The most well-known causes of opportunistic mycoses include *Candida albicans, Cryptococcus neoformans,* and *Aspergillus fumigatus* (Box 65.1). The estimated frequency of invasive mycoses caused by these pathogens is >700,000 infections per year for *Candida,* >1,000,000 for *C. neoformans,* and >300,000 for *Aspergillus* (see Chapter 57, Table 57.1). In addition to these agents, of increasing importance is the growing list of "other" opportunistic fungi (see Box 65.1). New and emerging fungal pathogens include species of *Candida* and *Aspergillus* other than *C. albicans* and *A. fumigatus;* microsporidia; opportunistic yeastlike fungi, such as *Trichosporon* spp., *Malassezia* spp., *Rhodotorula* spp., and *Saprochaete capitata* (formerly *Blastoschizomyces capitatus*); the Mucormycetes; hyaline molds, such as *Fusarium, Sarocladium, Scopulariopsis, Purpureocillium (Paecilomyces),* and *Trichoderma* species; and a wide variety of dematiaceous fungi, including *Scedosporium* spp. and *Lomentospora prolificans* (see Box 65.1). Infections caused by these organisms range from catheter-related fungemia and peritonitis to more localized infections involving lung, skin, and paranasal sinuses to widespread hematogenous dissemination. Many of these fungi were previously thought to be nonpathogenic and now are recognized causes of invasive mycoses in compromised patients. Estimates of the annual incidence of the less common mycoses have been virtually nonexistent; however, data from a population-based survey conducted by the Centers for Disease Control and Prevention indicate that mucormycosis occurs at a rate of 1.7 to 3.4 infections per million population per year, hyalohyphomycosis (*Fusarium, Sarocladium,* etc.) at 1.2 infections per million per year, and phaeohyphomycosis (dematiaceous molds) at 1.0 infection per million per year.

Given the complexity of the patients at risk for infection and the diverse array of fungal pathogens, opportunistic mycoses pose a considerable diagnostic and therapeutic challenge. Diagnosis depends on a heightened clinical suspicion (think **fungus**) and obtaining appropriate material for culture and histopathology. Isolation and identification of the infecting organisms is very important in properly managing infections because of the less common opportunistic fungi. Some of these organisms are inherently nonsusceptible to standard azole, echinocandin, or polyene therapy (see Chapter 61) and may require the use of alternative antifungal agents in addition to surgical management and reversal of the underlying impairment of host defenses.

Candidiasis

It is clear that the most important group of opportunistic fungal pathogens is the *Candida* species. *Candida* spp. are

TABLE 65.1 Predisposing Factors for Opportunistic Mycoses

Factor	Possible Role in Infection	Major Opportunistic Pathogens
Antimicrobial agents (number and duration)	Promote fungal colonization Provide intravascular access	*Candida* spp., other yeastlike fungi
Adrenal corticosteroid	Immunosuppression	*Cryptococcus neoformans, Aspergillus* spp., Mucormycetes, other molds, *Pneumocystis*
Chemotherapy	Immunosuppression	*Candida* spp., *Aspergillus* spp., *Pneumocystis*
Hematologic/solid organ malignancy	Immunosuppression	*Candida* spp., *Aspergillus* spp., Mucormycetes, other molds and yeastlike fungi, *Pneumocystis*
Previous colonization	Translocation across mucosa	*Candida* spp.
Indwelling catheter (central venous, pressure transducer, Swan-Ganz)	Direct vascular access Contaminated product	*Candida* spp., other yeastlike fungi
Total parenteral nutrition	Direct vascular access Contamination of infusate	*Candida* spp., *Malassezia* spp., other yeastlike fungi
Neutropenia (WBC < 500/mm^3)	Immunosuppression	*Aspergillus* spp., *Candida* spp., other molds and yeastlike fungi
Extensive surgery or burns	Route of infection Direct vascular access	*Candida* spp., *Fusarium* spp., Mucormycetes
Assisted ventilation	Route of infection	*Candida* spp., *Aspergillus* spp.
Hospitalization or intensive care unit stay	Exposure to pathogens Exposure to additional risk factors	*Candida* spp., other yeastlike fungi, *Aspergillus* spp.
Hemodialysis, peritoneal dialysis	Route of infection Immunosuppression	*Candida* spp., *Rhodotorula* spp., other yeastlike fungi
Malnutrition	Immunosuppression	*Pneumocystis*, *Candida* spp., *C. neoformans*
HIV infection/AIDS	Immunosuppression	*C. neoformans, Pneumocystis, Candida* spp., Microsporidia
Extremes of age	Immunosuppression Numerous comorbidities	*Candida* spp.

AIDS, Acquired immunodeficiency syndrome; *HIV,* human immunodeficiency virus; *WBC,* white blood cells.

the third most common cause of central line–associated bloodstream infections (BSIs), exceeding that of any individual gram-negative pathogen (Table 65.2 and Clinical Case 65.1). Between 1980 and the present, the frequency of *Candida* BSIs has risen steadily in hospitals of all sizes and in all age groups.

Although more than 100 species of *Candida* have been described, only a few have been implicated in clinical infections (see Box 65.1). *C. albicans* is the species most commonly isolated from clinical material and generally accounts for 90% to 100% of mucosal isolates and 40% to 70% of isolates from BSI, depending on the clinical service and the patient's underlying disease (Table 65.3). Approximately 95% of all *Candida* BSIs are accounted for by four species: *C. albicans*, *C. glabrata*, *C. parapsilosis*, and *C. tropicalis* (see Table 65.3). Among these common species, only *C. glabrata* can be said to be truly "emerging" as a cause of BSI, in part because of its intrinsic and acquired resistance to azoles and other commonly used antifungal agents. The remaining 5% of *Candida* BSIs encompasses 12 to 14 different species, including *C. krusei*, *C. lusitaniae*, *C. dubliniensis*, and *C. rugosa*, among others (see Box 65.1). Although these species must be considered "rare" causes of candidiasis, several have been observed to occur in nosocomial clusters and/or to exhibit innate or acquired resistance to one or more established antifungal agents. *C. auris* is an emerging species of great concern worldwide. Originally described in 2009 in association with otitis externa, this multidrug-resistant and highly pathogenic yeast has simultaneously emerged on three continents as an important nosocomial pathogen with evidence of high levels of interhospital and intrahospital transmission and distinct geographically constrained clonal lineages.

TABLE 65.2 Central Line–Associated Bloodstream Infections: Most Frequent Associated Pathogens, National Healthcare Safety Network

4	*Staphylococcus aureus*	13.2
5	*Klebsiella pneumoniae/K. oxytoca*	8.4

[a]Percentage of a total of 96,532 infections.

Data from Wiener, L.M., et al., 2016. Antimicrobial-resistant pathogens associated with healthcare-associated infections: summary of data reported to the National Healthcare Safety Network at the Centers for Disease Control and Prevention, 2011-2014. Infect. Control Hospital Epidemiol. 37, 1288–1301.

MORPHOLOGY

All *Candida* species exist as oval yeastlike forms (3 to 5 μm) that produce buds or blastoconidia. Species of *Candida* other than *C. glabrata* also produce pseudohyphae and true hyphae (Fig. 65.1; see also Chapter 57, Fig. 57.2A and Chapter 60, Fig. 60.1). In addition, *C. albicans* forms germ tubes (Chapter 57, Fig. 57.2) and terminal, thick-walled chlamydoconidia (Fig. 65.2). *C. glabrata*, the second most common species of *Candida* in many settings, is incapable of forming pseudohyphae, germ tubes, or true hyphae under most conditions. In histologic sections, all *Candida* spp. stain poorly with hematoxylin and eosin (H&E) and well with the periodic acid–Schiff (PAS), Gomori methenamine silver (GMS), and Gridley fungus stains.

In culture, most *Candida* spp. form smooth, white, creamy, domed colonies. *C. albicans* and other species may also undergo **phenotypic switching,** in which a single strain of *Candida* may change reversibly among several different morphotypes, ranging from the typical smooth, white colony composed of predominantly budding yeastlike cells to very "fuzzy" or "hairy" colonies composed primarily of pseudohyphal and hyphal forms. The frequency of the switching phenomenon is too high to result from gene mutations and too low to be attributable to mass conversion, in which all cells in the population change their phenotype in response to signals from the environment. It is likely that switching serves as some type of

Clinical Case 65.1 **Candidemia**

Posteraro and associates (*J Clin Microbiol* 44:3046–3047, 2006) described a case of recurrent fungemia in a 35-year-old woman. The patient was seen at 5 weeks' gestation after intrauterine insemination. She presented with fever, tachycardia, and hypotension. The WBC count was 23,500/μL with 78% neutrophils. She experienced a spontaneous abortion. Severe chorioamnionitis was diagnosed, placental and fetal tissues were cultured, and blood cultures and vaginal swabs were obtained. The patient was treated with broad-spectrum antibacterial agents. Five days later, no clinical improvement was seen. The cultured blood and placental samples grew the yeast *Candida glabrata*, which was also isolated from the patient's vaginal cultures. On the basis of fluconazole minimal inhibitory concentrations, indicating that the organism was susceptible, the patient was placed on fluconazole. Four weeks later she experienced complete resolution of her symptoms, with eradication of the fungus from her bloodstream. Antifungal treatment was discontinued, and the patient was sent home, in which she did well. Six months later she was readmitted to the hospital with fever, chills, and fatigue. The WBC count was elevated at 21,500/μL with 73% neutrophils. Consecutive blood cultures were again positive for *C. glabrata*, which was also found in cultures of vaginal fluid. All isolates were found to be resistant to fluconazole. On the basis of these findings, the patient was treated with amphotericin B. Within 1 week, the patient's clinical condition was improved. After 1 month of amphotericin B treatment, blood cultures were sterile, and she was discharged from the hospital. Three years later, she remained free of any evidence of infection.

This is an unusual case, in that the patient was not immunocompromised yet experienced recurrent candidemia with *C. glabrata*. The use of fluconazole as initial therapy, although apparently successful, induced upregulation of drug efflux pumps in the organism and allowed later isolates to become resistant to fluconazole and other azoles.

master system in *C. albicans*, and other species, for rapid response at the level of individual cells to changes in the local microenvironment. It has been postulated that phenotypic switching explains the ability of *C. albicans* to survive in many different environmental microniches within the human host.

EPIDEMIOLOGY

Candida spp. are known colonizers of humans and other warm-blooded animals. As such, they are found in humans and in nature worldwide. The primary site of colonization is the GI tract from mouth to rectum. They also may be found as commensals in the vagina and urethra, on the skin, and under the fingernails and toenails. *C. albicans,* the most common etiologic agent of human disease, has also been found apart from humans and animals in air, water, and soil.

It is estimated that 25% to 50% of healthy persons carry *Candida* as part of the normal flora of the mouth, with *C. albicans* accounting for 70% to 80% of isolates. Oral carriage rates are increased substantially in hospitalized patients; those with human immunodeficiency virus (HIV) infection, dentures, and diabetes; patients receiving antineoplastic chemotherapy; those receiving antibiotics; and children. Virtually all humans may carry one or more *Candida* species throughout their GI tract, and the levels of carriage may increase to that detectable in illness or other circumstances in which the host's microbial suppression mechanisms become compromised.

The predominant source of infection caused by *Candida* spp., from superficial mucosal and cutaneous disease to hematogenous dissemination, is the patient. That is, most types of candidiasis represent **endogenous** infection in which the normally commensal host flora take advantage of the "opportunity" to cause infection. To do so, there must be a lowering of the host's anti-*Candida* barrier. In the cases of *Candida* BSIs, transfer of the organism from the GI mucosa to the bloodstream requires prior overgrowth of the numbers of yeasts in their commensal habitat, coupled with a breach in the integrity of the GI mucosa.

Exogenous transmission of *Candida* also may account for a proportion of certain types of candidiasis. Examples include the use of contaminated irrigation solutions, parenteral nutrition fluids, vascular pressure transducers, cardiac valves, and corneas. Transmission of *Candida* spp. from health care workers to patients and from patient to patient has been well documented, especially in the intensive care unit environment. The hands of health

care workers serve as potential reservoirs for nosocomial transmission of *Candida* spp.

Among the various species of *Candida* capable of causing human infection (see Box 65.1 and Table 65.3), *C. albicans* predominates in most types of infection. Infections of genital, cutaneous, and oral sites almost always involve *C. albicans*. A wider array of *Candida* spp. is seen causing BSIs and other forms of invasive candidiasis, and although *C. albicans* usually predominates (see Table 65.3), the frequency with which this and other species of *Candida* are isolated from blood varies considerably according to the clinical service (see Table 65.3); the age of the patient (Fig. 65.3); and the local, regional, or global setting (Table 65.4). Whereas *C. albicans* and *C. parapsilosis* predominate as causes of BSIs among infants and children, a decrease in *C. albicans* and *C. parapsilosis* infections and a prominent increase in *C. glabrata* infections is seen among older individuals (see Fig. 65.3). Also, although *C. glabrata* is the second most common species causing BSIs in North America, it is seen at a lower frequency in Latin America, in which *C. parapsilosis* and *C. tropicalis* are more common (see Table 65.4).

The differences in the number and types of *Candida* spp. causing infections may be influenced by numerous factors, including patient age, increased immunosuppression, antifungal drug exposure, or differences in infection-control practices. Each one of these factors, alone or in combination, may affect the prevalence of different *Candida* spp. in each institution. For example, the use of azoles (e.g., fluconazole) for antifungal prophylaxis in hematologic malignancy patients and recipients of stem cell transplantation may increase the likelihood of infections caused by *C. glabrata* and *C. krusei*, which are two species with decreased susceptibility to this class of antifungals (see Table 65.3). Also, breaks in infection-control precautions and in the proper care of vascular catheters may lead to more infections with *C. parapsilosis*, which is the predominant species isolated from the hands of health care workers and a frequent cause of catheter-related fungemia. In the last several years, *C. auris* has emerged simultaneously on three continents as an important novel cause of nosocomial infections, with geographically restricted clonal lineages and high interhospital and intrahospital transmission rates. A wide variety of deep-seated infections in addition to candidemia have been reported, and this multidrug-resistant (intrinsically resistant to fluconazole with reported resistances to amphotericin B, the echinocandins, and 5-FC) species has been shown to persist in hospital environments and cause long-term colonization of patients in high-intensity care settings, leading to specific guidelines for the management of patients infected or colonized with this organism.

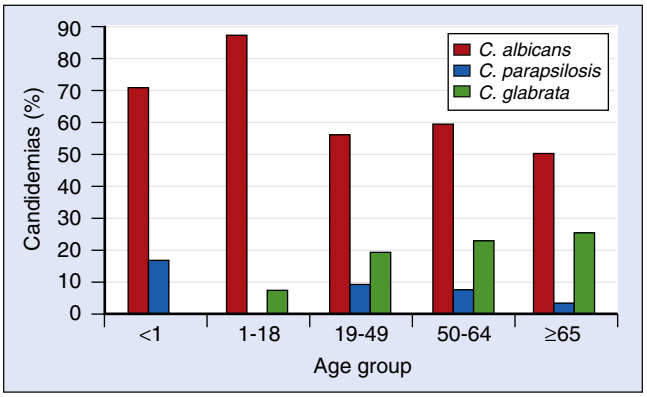

Fig. 65.3 Percentage of all candidemias caused by selected *Candida* species in each age group. Data are from the Emerging Infections and the Epidemiology of Iowa Organisms Survey, 1998-2001. (Data from Pfaller, M.A., Diekema, D.J., 2007. Epidemiology of invasive candidiasis: a persistent public health problem. Clin. Microbiol. Rev. 20, 133.)

The consequences of a *Candida* BSI in the hospitalized patient are severe. Hospitalized patients with candidemia have been shown to be at a twofold greater risk of death in hospital than those with noncandidal BSIs. Among all patients with nosocomial (hospital-acquired) BSIs, candidemia was found to be an independent predictor of death in hospital. Although estimates of mortality may be confounded by the serious nature of the underlying diseases in many of these patients, matched cohort studies have confirmed that the mortality directly attributable to the fungal infection is quite high (Table 65.5). Notably, the excess or attributable mortality resulting from candidemia has not decreased from that observed in the mid-1980s to that observed in the present day, despite the introduction of new antifungal agents with good activity against most species of *Candida*.

Clearly, more is known about the epidemiology of nosocomial candidemia than any other fungal infection. The accumulated evidence allows one to propose a general view of nosocomial candidemia (Fig. 65.4). Certain hospitalized individuals are clearly at increased risk of acquiring candidemia during hospitalization because of their underlying medical condition: patients with hematologic malignancies

and/or neutropenia, those undergoing GI surgery, premature infants, and patients older than 70 years (see Table 65.1 and Fig. 65.4). Compared with control subjects without the specific risk factors or exposures, the likelihood of these already high-risk patients contracting candidemia in hospital is approximately 2 times greater for each class of antibiotics they receive, 7 times greater if they have a central venous catheter, 10 times greater if *Candida* has been found to be colonizing other anatomic sites, and 18 times greater if the patient has undergone acute hemodialysis.

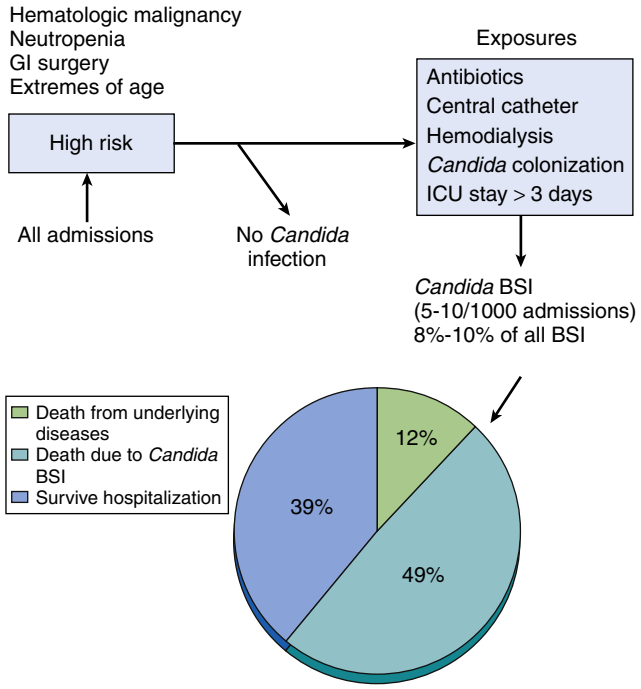

Fig. 65.4 Global view of hospital-acquired candidemia. *BSI,* Bloodstream infections; *GI,* gastrointestinal; *ICU,* intensive care unit. (Modified from Lockhart, S.R., Diekema D.J., Pfaller M.A., et al., 2009. The epidemiology of fungal infections. In: Anaissie, E.J., McGinnis, M.R., Pfaller, M.A. (Eds.), Clinical Mycology, second ed. Churchill Livingstone, New York.)

Hospitalization in the intensive care unit setting provides the opportunity for transmission of *Candida* among patients and has been shown to be an additional independent risk factor.

The available epidemiologic data indicate that between 20 and 40 of every 1000 high-risk patients exposed to the previously mentioned risk factors will contract a BSI caused by *Candida* spp. (8% to 10% of all nosocomial BSIs; see Table 65.2). Approximately 49% of these patients will die as a result of their infection, 12% will die of their underlying disease, and 39% will survive hospitalization (see Fig. 65.4). This picture has not changed, and may even be worse, from that seen in the mid-1980s. The outcome for almost half of those patients with candidemia could be improved by more effective means of prevention, diagnosis, and therapy. Clearly the most desirable of these is prevention, which is best approached by rigorous control of the exposures, especially limiting the use of broad-spectrum antibiotics, improving catheter care, and adhering to infection-control practices.

CLINICAL SYNDROMES

Given the right setting, *Candida* spp. can cause clinically apparent infection of virtually any organ system (Table 65.6; see Clinical Case 65.1). Infections range from superficial mucosal and cutaneous candidiasis to widespread hematogenous dissemination involving target organs, such as the liver, spleen, kidney, heart, and brain. In the latter situation, the mortality directly attributable to the infectious process approaches 50% (see Table 65.5 and Fig. 65.4).

Mucosal infections caused by *Candida* spp. (known as "thrush") may be limited to the oropharynx or extend to the esophagus and the entire GI tract. In women, the vaginal mucosa also is a common site of infection. These infections are generally seen in individuals with local or generalized immunosuppression or in those settings in which candidal overgrowth is favored (see Table 65.6). These infections usually present as white "cottage cheese"–like patches on the mucosal surface. Other presentations include the **pseudomembranous** type, which reveals a raw bleeding surface when scraped; the **erythematous** type, which has flat, red, and occasionally sore areas; candidal **leukoplakia,** which has nonremovable white thickening of epithelium caused by *Candida* spp.; and angular **cheilitis,** which has sore fissures at the corners of the mouth.

Candida spp. may cause localized skin infection in areas in which the skin surface is occluded and moist (e.g., groin, axillae, toe webs, breast folds). These infections present as a pruritic rash with erythematous vesiculopustular lesions.

Onychomycosis and paronychia may occur in the setting of a mixed microbial flora, including *Candida*. The species most commonly involved are *C. albicans*, *C. parapsilosis*, and *C. guilliermondii*.

Skin lesions may also appear during the course of hematogenous dissemination. These lesions are of major diagnostic importance; they can be directly biopsied and thus provide an etiologic diagnosis of a systemic process.

Chronic mucocutaneous candidiasis is a rare condition marked by a deficiency in T-lymphocyte responsiveness to *Candida* spp. These patients suffer from severe, unremitting mucocutaneous *Candida* lesions, including extensive nail

TABLE 65.6 Types of Candida Infection and Associated Predisposing Factors

Type of Disease	Predisposing Factors
Oropharyngeal infection	Age extremes Denture wearers Diabetes mellitus Antibiotic use Radiotherapy for head and neck cancer Inhaled and systemic steroids Cytotoxic chemotherapy HIV infection Hematologic malignancies Stem cell or solid organ transplantation

involvement and vaginitis. The lesions may become quite large, with a disfiguring granulomatous appearance.

Urinary tract involvement with *Candida* spp. ranges from asymptomatic bladder colonization to renal abscesses secondary to hematogenous seeding. Bladder colonization with *Candida* spp. is essentially not seen unless a patient requires an indwelling bladder catheter, has diabetes, suffers from urinary obstruction, or has had prior urinary procedures. Benign colonization of the bladder is most common in these settings, but urethritis and/or cystitis may occur. Hematogenous seeding of the kidney may result in renal abscess, papillary necrosis, or "fungus ball" of the ureter or renal pelvis.

Intraabdominal candidiasis in patients who have had recent abdominal surgery or intraabdominal events refers to a heterogeneous group of infections that includes peritonitis, abdominal abscess, and purulent or necrotic infection at sites of GI perforation or anastomotic leak. *Candida* peritonitis may be seen in the setting of chronic ambulatory peritoneal dialysis or after GI surgery, anastomotic leak, or intestinal perforation. These infections may remain localized to the abdomen, involve adjacent organs, or lead to hematogenous candidiasis. Up to 40% of patients with secondary or tertiary peritonitis, as defined by a multinational consensus panel, may develop intraabdominal candidiasis with a high mortality rate. A subset of postsurgical patients, particularly those with recurrent gastroduodenal perforation, anastomotic leaks, or acute necrotizing pancreatitis, are at uniquely high risk for invasive candidiasis. In other settings, such as perforated appendicitis, invasive candidiasis appears to be a rare complication. Infections are often polymicrobial, with yeast noted in as high as 20% of all cases and 40% in patients with a recent gastroduodenal perforation. Diagnosis is hampered by the lack of specific clinical signs and symptoms. Blood cultures are often negative. A laboratory report of yeast isolated from an abdominal specimen must be evaluated to distinguish between contamination, colonization, and invasive infection.

Hematogenous candidiasis may be acute or chronic and usually results in seeding of deep tissues, including the abdominal viscera, heart, eyes, bones and joints, and brain. Chronic hepatosplenic candidiasis may occur after overt or occult fungemia and presents as an indolent process marked by fever, elevated alkaline phosphatase, and multiple lesions in the liver and spleen.

Central nervous system (CNS) candidiasis may occur secondary to hematogenous disease or be associated with neurosurgical procedures and ventriculoperitoneal shunts. This process may mimic bacterial meningitis, or the course may be indolent or chronic.

Most cardiac involvement with *Candida* spp. is the result of hematogenous seeding of a prosthetic or damaged heart valve, the myocardium, or pericardial space. Implantation of heart valves contaminated with *C. parapsilosis* has been reported. The clinical presentation resembles bacterial endocarditis, with fever and a new or changing heart murmur. The vegetations are classically large and friable, and embolic events are more common with endocarditis caused by *Candida* spp. than with bacterial endocarditis.

The eye is frequently involved in patients with hematogenous candidiasis, presenting as chorioretinitis and endophthalmitis. For this reason, all patients at risk for candidemia should receive careful and frequent ophthalmologic examinations. Traumatic keratitis also may be seen.

Bone and joint infections caused by *Candida* spp. are almost always sequelae of candidemia. Often, these infections will present several months after successful treatment of candidemia. Similarly occult or "transient" candidemia may result in seeding of a skeletal focus that becomes clinically apparent at a later time. Vertebral osteomyelitis is a frequent presentation, with local pain and low-grade fever.

Although hematogenous candidiasis is most often an endogenous infection arising from the GI or genitourinary tract, it may also result from the contamination of an indwelling catheter. Organisms transferred to the hub or lumen of the catheter may form a biofilm within the lumen of the catheter and subsequently spread into the circulation. Although such infections are no less serious than those arising from an endogenous source, they may be dealt with somewhat more successfully because removal of the catheter essentially removes the nidus of infection. Of course, if the infected catheter resulted in the seeding of distant organs, the consequences and problems in treating the infection would be the same as those arising from an endogenous source.

LABORATORY DIAGNOSIS

The laboratory diagnosis of candidiasis involves the procurement of appropriate clinical material followed by direct microscopic examination and culture (see Chapter 60). Scrapings of mucosal or cutaneous lesions may be examined directly after treatment with 10% to 20% potassium hydroxide (KOH) containing calcofluor white. The budding yeastlike forms and pseudohyphae are easily detected on examination with a fluorescence microscope (see Fig. 60.1). Culture on standard mycologic medium will allow the isolation of the organism for subsequent identification to species. Increasingly, such specimens are plated directly on a selective chromogenic medium such as CHROMagar Candida, which allows the detection of mixed species of *Candida* within the specimen and the rapid identification of *C. albicans* (green colonies) and *C. tropicalis* (blue colonies) based on their morphologic appearance (Fig. 65.5).

All other types of infection require culture for diagnosis unless tissue can be obtained for histopathologic examination (see Chapter 60). Whenever possible, skin lesions should be biopsied and histologic sections stained with GMS or another fungal-specific stain. Visualization of characteristic budding yeasts and pseudohyphae is sufficient for the diagnosis of candidiasis (Fig. 65.6). Cultures of blood, tissue, and normally sterile body fluids also should be performed. Identification of *Candida* isolates to species level is important, given the differences in response to the various antifungal agents (see Chapter 61). This can be accomplished as described in Chapter 60, using the germ-tube test (*C. albicans*), various chromogenic media/tests (see Fig. 65.5), peptide nucleic acid–fluorescence in situ hybridization (PNA-FISH), and commercially available sugar assimilation panels. Alternatively the use of nucleic acid sequence–based methods or proteomics provides a rapid, accurate, and cost-effective means of species identification.

Immunologic, biochemical, and molecular markers for the diagnosis of candidiasis are described in Chapter 60. Although these methods are not widely available at the

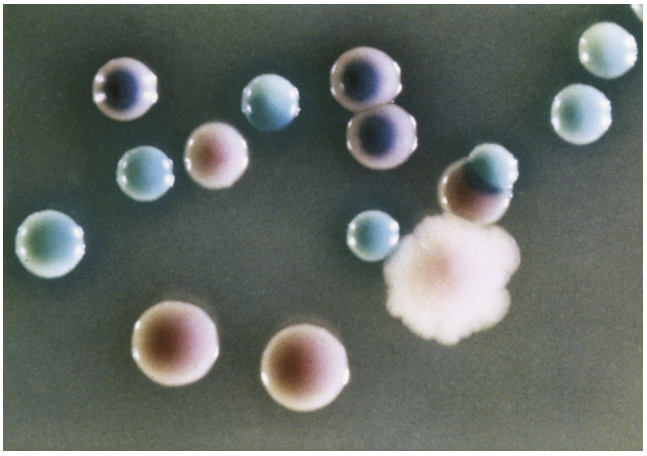

Fig. 65.5 Differentiation of *Candida* species by isolates on CHROMagar Candida. The green colonies are *C. albicans*; the blue-gray colonies are *C. tropicalis*; and the large, rough, pale pink colony is *C. krusei*. The smooth, pink or mauve colonies are another yeast species (only *C. albicans*, *C. tropicalis*, and *C. krusei* can be reliably recognized on this media; other species have colonies ranging from white to pink to mauve). (From Anaissie, E.J., McGinnis, M.R., Pfaller, M.A. (Eds.), 2009. Clinical Mycology, second ed. Churchill Livingstone, New York.)

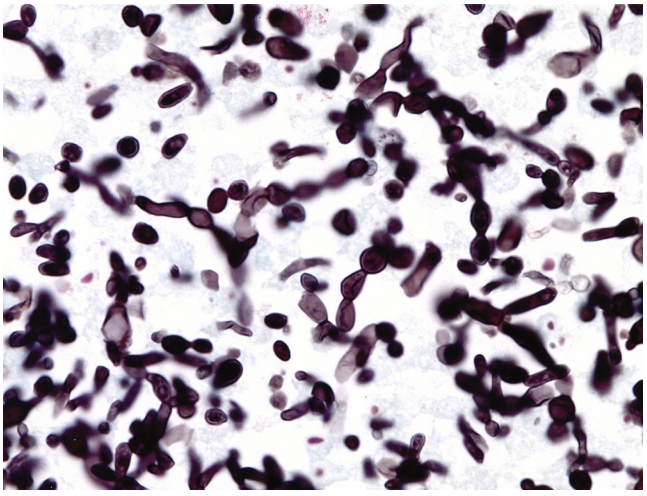

Fig. 65.6 *Candida* stained with Gomori methenamine silver demonstrating budding yeasts and pseudohyphae (×1000).

present time, recent breakthroughs in direct detection technology hold great promise for the rapid diagnosis of invasive candidiasis.

TREATMENT, PREVENTION, AND CONTROL

There are a wide variety of treatment options for candidiasis (see Chapter 61). Mucosal and cutaneous infections may be treated with a number of different topical creams, lotions, ointments, and suppositories containing various azole antifungal agents (see Table 61.1). Oral systemic therapy of these infections may also be accomplished with either fluconazole or itraconazole.

Bladder colonization or cystitis may be treated with either instillation of amphotericin B directly into the bladder (bladder wash) or by oral administration of fluconazole. Both of these measures will likely be unsuccessful if the bladder catheter cannot be removed.

More deep-seated infections require systemic therapy, the choice of which depends on the type of infection, the infecting species, and the overall status of the host. In many instances, oral fluconazole may be quite effective in treating candidiasis. It may be used in the treatment of peritonitis, as well as in more long-term maintenance therapy of invasive disease after an initial intravenous course of therapy. Fluconazole is efficacious when administered intravenously for the treatment of candidemia in nonneutropenic patients. Those patients who become candidemic while on fluconazole prophylaxis or those with documented infection caused by *C. auris*, *C. krusei*, or fluconazole-resistant *C. glabrata* require treatment with either amphotericin B (conventional or lipid formulation) or an echinocandin (anidulafungin, caspofungin, or micafungin). In those clinical settings in which *C. auris*, *C. glabrata*, or *C. krusei* are plausible etiologic agents (e.g., prior fluconazole therapy/prophylaxis or an endemic situation), initial therapy with either an echinocandin or an amphotericin B formulation is advised, with a switch to fluconazole (less toxic than amphotericin B, less expensive, and orally available versus echinocandins) based on final species identification and susceptibility test results. In every instance, care should be taken to remove the nidus of infection if possible. Thus vascular catheters should be removed or changed, abscesses should be drained, and other potentially infected implanted materials should be removed to the extent possible; likewise, efforts should be directed toward immune reconstitution.

As in most infectious diseases, prevention is clearly preferable to the treatment of an established candidal infection. Avoidance of broad-spectrum antimicrobial agents, meticulous catheter care, and rigorous adherence to infection-control precautions are a must. Decreased colonization achieved by fluconazole prophylaxis has been shown to be efficacious when used in **specific** high-risk groups, such as BMT patients and liver transplant patients. Such prophylaxis carries with it the potential for selecting or creating, strains or species that are resistant to the agent administered. This in fact has been seen with the emergence of fluconazole-resistant *C. glabrata, C. auris,* and *C. krusei* in certain institutions, but the overall benefit in the high-risk patient groups outweighs the risk. Transfer of this approach to other patient groups, however, is fraught with problems and should not be undertaken without careful study and risk stratification to identify those individuals most likely to benefit from antifungal prophylaxis.

Opportunistic Mycoses Caused by *Cryptococcus Neoformans* and Other Noncandidal Yeastlike Fungi

In the same manner that *Candida* species have taken advantage of immunocompromising conditions, indwelling devices, and broad-spectrum antibiotic use, so too have a number of non-*Candida* yeastlike fungi found an "opportunity" to colonize and infect immunocompromised patients. These organisms may occupy environmental niches or be found in food and water and can be normal human microbial flora. The list of these opportunistic yeasts is long, but

we will limit this discussion to two major pathogens, *C. neoformans* and *C. gattii,* and four genera that pose particular problems as opportunistic pathogens: *Malassezia* spp., *Trichosporon* spp., *Rhodotorula* spp., and *S. capitata* (formerly *B. capitatus*).

CRYPTOCOCCOSIS

Cryptococcosis is a systemic mycosis caused by the encapsulated, basidiomycetous, yeastlike fungi *C. neoformans* and *C. gattii*. *C. neoformans* is worldwide in distribution and is found as a ubiquitous saprophyte of soil, especially that which is enriched with pigeon droppings. *C. neoformans* includes capsular serotypes A and D, and *C. gattii* includes serotypes B and C. Recent phylogenetic studies have resulted in the proposal for a complete reorganization of the species complexes (SCs) designated previously as *C. neoformans* and *C. gattii. C. neoformans* was retained to describe species formerly referred to as *C. neoformans* var. *grubii*, *C. deneoformans* was erected to encompass serotype D isolates (formerly *C. neoformans* var *neoformans*), and at least five cryptic species are recognized in the *C. gattii* SC. For purposes of this chapter, we will limit our discussion to *C. neoformans* and *C. gattii*.

Morphology

Microscopically, *C. neoformans* and *C. gattii* are spheric to oval, encapsulated, yeastlike organisms, 2 to 20 μm in diameter. Replication is by budding from a relatively narrow base. Single buds are usually formed, but multiple buds and chains of budding cells are sometimes present (Fig. 65.7). Germ tubes, hyphae, and pseudohyphae are usually absent in clinical material.

In tissue and on staining with India ink, the cells are variable in size, spheric, oval, or elliptic, and are surrounded by optically clear, smoothly contoured, spheric zones or "halos" that represent the extracellular polysaccharide capsule (Fig. 65.8). The capsule is a distinctive marker, which may have a diameter of up to five times that of the fungal cell and is readily detected with a mucin stain, such as Mayer mucicarmine (Fig. 65.9). The organism stains poorly with H&E but is easily detected with PAS and GMS stains. The cell wall of *C. neoformans* contains melanin, which may be demonstrated by staining with the Fontana-Masson stain.

Epidemiology

Cryptococcosis is usually acquired by inhaling aerosolized cells of *C. neoformans* and *C. gattii* from the environment (Fig. 65.10). Subsequent dissemination from the lungs, usually to the CNS, produces clinical disease in susceptible individuals. Primary cutaneous cryptococcosis may occur after transcutaneous inoculation but is rare.

Although both *C. neoformans* and *C. gattii* are pathogenic for immunocompetent individuals, *C. neoformans* is most often encountered as an opportunistic pathogen. It is the most common cause of fungal meningitis and tends to occur in those patients with defective cellular immunity.

Whereas *C. neoformans* and *C. deneoformans* are found worldwide in association with soil contaminated with avian excreta, the environmental habitat of members of the *C. gattii* SC was originally identified as being the gum tree, *Eucalyptus camaldulensis*; however, several other plant families have been identified as sources. *C. gattii* SC isolates have been reported from subtropical areas and from temperate areas of Europe, Asia, Oceana, Africa, North America, and Central and South America. An endemic focus of *C. gattii* has been identified in Vancouver Island, British Columbia,

and in Oregon and Washington State extending down into California. Sporadic cases of *C. gattii* infection have been detected in several different areas of the United States. Both *C. neoformans* (var. *neoformans* and var. *grubii*) and *C. gattii* cause a similar disease, although *C. gattii* infection tends to occur in immunocompetent individuals and has a lower associated mortality but more severe neurologic sequelae because of CNS granuloma formation.

C. neoformans is a major opportunistic pathogen of patients with AIDS. Those individuals with $CD4^+$ lymphocyte counts of less than $100/mm^3$ (usually $<200/mm^3$) are at high risk for CNS and disseminated cryptococcosis. The incidence of cryptococcosis seems to have peaked in the United States in the early 1990s (65.5 infections per million per year) and has progressively declined since then because of the widespread use of fluconazole and, more importantly, successful treatment of the HIV infection with new antiretroviral drugs.

Clinical Syndromes

Cryptococcosis may present as a pneumonic process or, more commonly, as a CNS infection secondary to hematogenous and lymphatic spread from a primary pulmonary focus (Clinical Case 65.2). Less often, a more widely disseminated infection may be seen with cutaneous, mucocutaneous, osseous, and visceral forms of the disease.

Pulmonary cryptococcosis is variable in presentation, from an asymptomatic process to a more fulminant bilateral pneumonia. Nodular infiltrates may be either unilateral or bilateral, becoming more diffuse in severe infections. Cavitation is rare.

C. neoformans and *C. gattii* are highly neurotropic, and the most common form of disease is cerebromeningeal. The course of disease is variable and may be quite chronic; however, it is inevitably fatal if untreated. Both meninges and the underlying brain tissue are involved, and the clinical

Clinical Case 65.2 **Cryptococcosis**

Pappas and colleagues described a case of cryptococcosis in a heart transplant recipient. The 56-year-old patient, who underwent heart transplantation surgery 3 years earlier, presented with new-onset cellulitis of his left leg and a mild headache of 2 weeks' duration. The patient was on chronic immunosuppressive therapy with cyclosporine, azathioprine, and prednisone and was admitted for IV antibiotics. Despite 5 days of IV nafcillin, the patient failed to improve, and a skin biopsy of the cellulitic area was obtained for histopathologic studies and culture. Laboratory results revealed the presence of a yeast consistent with *Cryptococcus neoformans*. A lumbar puncture was also performed, and examination of the CSF disclosed cloudy fluid and an elevated opening pressure of 420 mm H_2O. Microscopic examination revealed encapsulated budding yeast forms. Cryptococcal antigen titers of CSF and blood were markedly elevated. Blood, CSF, and skin biopsy cultures grew *C. neoformans*. Systemic antifungal therapy with amphotericin B and flucytosine was initiated. Unfortunately, the patient suffered progressive mental status decline, despite aggressive management of intracranial pressure and maximizing doses of antifungals. He experienced slow, progressive decline, leading to death 13 days after initiation of antifungal therapy. CSF cultures obtained 2 days before death remained positive for *C. neoformans*.

The patient in this case was highly immunocompromised and presented with cellulitis and headache. Such a presentation should arouse suspicion of an atypical pathogen such as *C. neoformans*. Given the high mortality associated with cryptococcal infection, a rapid and accurate diagnosis is important. Unfortunately, despite these efforts and use of aggressive therapy, many such patients will succumb to the infection.

CSF, Cerebrospinal fluid; IV, intravenous.

presentation is that of fever, headache, meningismus, visual disturbances, abnormal mental status, and seizures. The clinical picture is highly dependent on the patient's immune status and tends to be dramatically severe in AIDS patients and other severely compromised patients treated with steroids or other immunosuppressive agents.

Parenchymal lesions, or cryptococcomas, are uncommon in infections caused by *C. neoformans* but are the most common presentation of CNS cryptococcosis in immunocompetent hosts infected with *C. gattii*.

Other manifestations of disseminated cryptococcosis include skin lesions, which occur in 10% to 15% of patients and may mimic those of molluscum contagiosum; ocular infections, including chorioretinitis, vitritis, and ocular nerve invasion; osseous lesions involving the vertebrae and bony prominences; and prostatic involvement, which may be an asymptomatic reservoir of infection.

Laboratory Diagnosis

The diagnosis of infection caused by *C. neoformans* and *C. gattii* may be made by culture of blood, cerebrospinal fluid (CSF), or other clinical material (see Chapter 60). Microscopic examination of CSF may reveal the characteristic encapsulated budding yeast cells. The cells of *C. neoformans*, when present in CSF or other clinical material, may be

AIDS, Acquired immunodeficiency syndrome.
Modified from Viviani, M.A., Tortorano, A.M., 2009. *Cryptococcus.* In: Anaissie, E.J., McGinnis, M.R., Pfaller, M.A. (Eds.), 2009. Clinical Mycology, second ed. Churchill Livingstone, New York.

visualized with Gram stain (see Chapter 60, Fig. 60.2), as well as with India ink (see Fig. 65.8) or other stains (see Fig. 65.7). Culture of clinical material on routine mycologic media will produce mucoid colonies composed of round, encapsulated, budding yeast cells that are urease-positive within 3 to 5 days. Species identification may be accomplished by carbohydrate assimilation testing, by growth on niger seed agar (*C. neoformans* colonies become brown to black in color), or by directly testing for phenoloxidase activity (positive).

Most commonly, however, the diagnosis of cryptococcal meningitis is made by direct detection of the capsular polysaccharide antigen in serum or CSF (Table 65.7). Detection of cryptococcal antigen is accomplished by using one of several commercially available latex agglutination or enzyme immunoassay kits. The development of a lateral flow antigen detection assay provides a potential point-of-care test for use in the field. These assays have been shown to be rapid, sensitive, and specific for the diagnosis of cryptococcal disease caused by both *C. neoformans* and *C. gattii* (see Table 65.7). Whereas the β-D-glucan test is not useful for diagnosis of cryptococcosis, molecular methods such as polymerase chain reaction (PCR) show great promise.

Treatment

Cryptococcal meningitis (and other disseminated forms of cryptococcosis) is universally fatal if left untreated. In addition to the prompt administration of appropriate antifungal therapy, effective management of CNS pressure and the immune reconstitution inflammatory syndrome (IRIS) is crucial to the successful treatment of cryptococcal meningitis. All patients should receive amphotericin B plus flucytosine acutely for 2 weeks (induction therapy), followed by an 8-week consolidation with either oral fluconazole (preferred) or itraconazole. AIDS patients generally require lifelong maintenance therapy with either fluconazole or itraconazole. In non-AIDS patients, treatment may be discontinued after the consolidation therapy; however, relapse may be seen in up to 26% of these patients within 3 to 6 months after discontinuation of therapy. Thus a prolonged consolidation treatment with an azole for up to 1 year may be advisable, even with patients without AIDS.

Treatment of these patients should be followed both clinically and mycologically. Mycologic follow-up requires repeat lumbar puncture to be performed (1) at the end of the 2-week induction therapy to ensure sterilization of the CSF, (2) at the end of the consolidation therapy, (3) whenever indicated by a change in clinical status during follow-up. CSF samples collected during follow-up must be cultured. Determination of CSF protein, glucose, cell count, and cryptococcal antigen titer are helpful in assessing the response to therapy but are not highly predictive of outcome. Failure to sterilize the CSF by day 14 of therapy is indicative of a much higher probability that the consolidation therapy will fail.

OTHER MYCOSES CAUSED BY YEASTLIKE FUNGI

Among the non-*Candida,* non-*Cryptococcus* yeastlike pathogens, nosocomial infections caused by *Malassezia* spp., *Trichosporon* spp., *Rhodotorula* spp., and *S. capitata* are most prominent, either because they are difficult to detect or because they may pose particular problems with respect to antifungal resistance.

Infections caused by *Malassezia* spp. (*M. furfur* and *M. pachydermatis*) are usually catheter related and tend to occur in premature infants or in other patients receiving lipid infusions. Both of these organisms are budding yeasts (Fig. 65.11; see also Chapter 62, Fig. 62.2). *M. furfur* is a common skin colonizer and is the etiologic agent of tinea (pityriasis) versicolor (see Chapter 62), whereas *M. pachydermatis* is a frequent cause of otitis in dogs, as well as a human skin commensal.

Among the *Malassezia* spp., *M. furfur* is known for its requirement for exogenous lipid for growth. This growth requirement, plus its ecologic niche on skin, explains some of the epidemiology of *M. furfur* because nosocomial infections caused by this organism are directly related to the administration of intravenous lipid supplements through a central venous catheter. Although *M. pachydermatis* does not require exogenous lipids for growth, fatty acids do stimulate its growth, and infections caused by this organism have been associated with parenteral nutrition and intravenous lipid administration. Although most infections with *Malassezia* spp. are sporadic, outbreaks of fungemia have been observed among infants receiving intravenous lipid supplementation. The growth of the organism is favored by the lipid-rich infusion, and the organism gains access to the bloodstream via the catheter. One notable outbreak of *M. pachydermatis* fungemia in a pediatric intensive care unit was linked to nurses who owned dogs with *M. pachydermatis* otitis. The outbreak strain was found on the hands of the nurses and at least one of the affected dogs.

Malassezia spp. should be considered when yeasts are seen microscopically in blood culture bottles or clinical material but no organisms are recovered on routine agar medium. To isolate *Malassezia* spp., especially *M. furfur*, on agar medium, the plates must be inoculated and then overlaid with sterile olive oil. Olive oil provides the lipid requirement, and growth should be detected in 3 to 5 days.

Treatment of fungemia caused by *Malassezia* spp. does not usually require the administration of antifungal agents. The infection subsides once the lipid infusion is stopped and the intravascular lines are removed.

The genus *Trichosporon* currently consists of six species that are of clinical significance: *T. asahii* and *T. mucoides* (now classified under the genus *Cutaneotrichosporon*) are known to cause deep invasive infections, *T. asteroides* and *T. cutaneum* (now classified under the genus *Cutaneotrichosporon*) cause superficial skin infections, *T. ovoides* causes white piedra of the scalp, and *T. inkin* causes white piedra of the pubic hair. Morphologically, these organisms are similar and appear in clinical material such as hyphae, arthroconidia, and budding yeast cells.

Trichosporon causes catheter-associated fungemia in neutropenic patients but also may gain entrance to the bloodstream via the respiratory or GI tract. Widespread hematogenous dissemination may manifest as positive blood cultures and multiple cutaneous lesions. Chronic hepatic trichosporonosis may mimic hepatic candidiasis and is seen on recovery from neutropenia. *Trichosporon* has been reported as the most common cause of noncandidal yeast infection in patients with hematologic malignancies and carries mortality in excess of 80%. Susceptibility to amphotericin B is variable, and this agent lacks fungicidal activity against *Trichosporon*. Clinical failures with amphotericin B, fluconazole, and combinations of the two have been reported, and the outcome is generally dismal in the absence of neutrophil recovery. *Trichosporon* species are resistant to the echinocandins but appear to respond clinically to treatment with voriconazole.

Rhodotorula spp. are characterized by the production of carotenoid pigments (produce pink to red colonies) and variably encapsulated, multilateral, budding yeast cells. The major clinically relevant species of *Rhodotorula* include *R. glutinis*, *R. mucilaginosa* (syn. *R. rubra)*, and *R. dariensis*. These yeastlike fungi are found as commensals on skin, nails, and mucous membranes, as well as in cheese and milk products and environmental sources, including air, soil, shower curtains, bathtub grout, and toothbrushes. *Rhodotorula* species are emerging as important human pathogens in immunocompromised patients and those with indwelling devices. *Rhodotorula* has been implicated as a cause of central venous catheter infection and fungemia, ocular infections, peritonitis, and meningitis. Amphotericin B has excellent activity against *Rhodotorula* and, coupled with catheter removal, is an optimal approach to infections with this organism. Flucytosine has excellent activity as well but should not be considered for monotherapy. Neither fluconazole nor the echinocandins should be used to treat infections caused by *Rhodotorula* species, and the role of the new extended-spectrum triazoles (e.g., voriconazole, isavuconazole, and posaconazole) is uncertain pending clinical data.

Among the emerging opportunistic yeastlike pathogens, *S. capitata* (formerly *B. capitatus*) is a rarely described fungus that produces severe systemic infection in immunocompromised patients, especially those with hematologic malignancies. This organism produces hyphae and arthroconidia, is widely distributed in nature, and may be found as part of the normal skin flora. Infection with *S. capitata* presents similar to that with *Trichosporon* in neutropenic patients, with frequent fungemia and multiorgan (including brain) dissemination and a mortality rate of 60% to 80%. Blood cultures are usually positive. As with *Trichosporon*, a chronic disseminated form similar to chronic disseminated candidiasis may be seen on resolution of neutropenia.

The optimal approach to therapy of infections caused by *S. capitata* is not yet defined. Some clinicians feel that *S. capitata* has decreased susceptibility to amphotericin B. The excellent in vitro activity of voriconazole suggests that it may be a useful agent for the treatment of infections caused by this organism. Rapid removal of central venous catheters, adjuvant immunotherapy, and novel antifungal therapies (e.g., voriconazole or high-dose fluconazole plus amphotericin B) are recommended for treatment of this rare but devastating infection.

Microsporidia

PHYSIOLOGY AND STRUCTURE

Microsporidia are nucleated, single-celled, obligately intracellular parasites that were considered to be primitive eukaryotic organisms based on the presence of prokaryote-like ribosomes and the apparent absence of true Golgi membranes, peroxisomes, and mitochondria. Genome-wide sequence and synteny analyses indicate that the organisms of the phylum Microsporidia belong to the kingdom of Fungi because they are derived from an endoparasitic chytrid ancestor on the earliest diverging branch of the fungal phylogenetic tree. Recently, Microsporidia were proposed to be linked to, or placed within, the novel phylum Cryptomycota, which phylogenetically represent intermediate fungal forms. Also, structural features of the organisms, such as the presence of chitin in the spore wall, diplokaryotic nuclei, and electron-dense spindle plaques associated with the nuclear envelope, suggest a possible relationship between fungi and microsporidia, whereas the life cycle of microsporidia is unique and dissimilar to that of other fungal species. The organisms are characterized by the structure of their spores, which have a complex tubular extrusion mechanism used for injecting the infective material (sporoplasm) into cells. Microsporidia have been detected in human tissues and implicated as participants in human disease. Fourteen microsporidian species have been identified as human pathogens: *Anncaliia* (formerly *Brachiola*) *algerae, A. (formerly Brachiola) connori, A. vesicularum, Encephalitozoon cuniculi, E. hellem, E. intestinalis (*syn. *Septata intestinalis), E. bieneusi, Microsporidium ceylonensis, M. africanum, Nosema ocularum, Pleistophora ronneafiei, Trachipleistophora hominis, T. anthropophthera, and Vittaforma corneae.* Unclassified microsporidia, assigned to the collective group Microsporidium, have also been implicated in human infections. *E. bieneusi* and *E. intestinalis* are the two most common causes

of enteric disease, whereas most of the species incriminated in extraintestinal and disseminated disease belong to the *Encephalitozoon* genera, such as *E. hellem, E. cuniculi, and E. intestinalis.* Other species, *A. connori, V. corneae, T. anthropophthera,* and *T. hominis,* have been described in rare cases of disseminated microsporidiosis.

PATHOGENESIS

Infection with microsporidia is initiated by the ingestion of spores. After ingestion, the spores pass into the duodenum, in which the sporoplasm, with its nuclear material, is injected into an adjacent cell in the small intestine. Once inside a suitable host cell, the microsporidia multiply extensively, either within a parasitophorous vacuole or free within the cytoplasm. The intracellular multiplication includes a phase of repeated divisions by binary fission (merogony) and a phase culminating in spore formation (sporogony). The parasites spread from cell to cell, causing cell death and local inflammation. Although some species are highly selective in the cell type they invade, collectively, the microsporidia are capable of infecting every organ of the body, and disseminated infections have been described in severely immunocompromised individuals. After sporogony, the mature spores containing the infective sporoplasm may be excreted into the environment, continuing the cycle.

EPIDEMIOLOGY

Microsporidia are distributed worldwide and have a wide host range among invertebrate and vertebrate animals. *E. bieneusi* and *E. intestinalis* have gained increasing attention as causes of chronic diarrhea in patients with AIDS. Both *Encephalitozoon*-like and *Enterocytozoon*-like organisms have been reported in the tissues of AIDS patients with hepatitis and peritonitis. *Trachipleistophora* and *Nosema* are known to cause myositis in immunocompromised patients. *Nosema* species has caused localized keratitis, as well as disseminated infection in a child with severe combined immunodeficiency. *Microsporidium* species and *E. hellem* have caused infection of the human cornea.

Although the reservoir for human infection is unknown, transmission is likely accomplished by ingestion of spores that have been shed in the urine and feces of infected animals or individuals. As with cryptosporidial infection, individuals with AIDS and other cellular immune defects appear to be at increased risk for infection with microsporidia.

CLINICAL SYNDROMES

Clinical signs and symptoms of microsporidiosis are quite variable in the human cases reported (Clinical Case 65.3). Intestinal infection caused by *E. bieneusi* in patients with AIDS is marked by persistent and debilitating diarrhea similar to that seen in patients with cryptosporidiosis, cyclosporiasis, and cystoisosporiasis. The clinical presentation of infection with other species of microsporidia depends on the organ system involved and ranges from localized ocular pain and loss of vision (*Microsporidium* and *Nosema* species) to neurologic disturbances and hepatitis (*E. cuniculi*) to a more generalized picture of dissemination with fever, vomiting, diarrhea, and malabsorption (*Nosema* species). In a report of disseminated infection with *A. connori,* the organism was observed involving the muscles of the stomach, bowel, arteries, diaphragm, and heart and the parenchymal cells of the liver, lungs, and adrenal glands.

Clinical Case 65.3 **Microsporidiosis**

Coyle and colleagues (*N Engl J Med* 351:42–47, 2004) described a case of fatal myositis caused by the microsporidian *Brachiola* (*Anncaliia*) *algerae.* The patient was a 57-year-old woman with rheumatoid arthritis and diabetes who presented with a 6-week history of increasing fatigue, generalized muscle and joint pain, profound weakness, and fever. She was taking immunosuppressive agents (prednisone, methotrexate, leflunomide) for rheumatoid arthritis and had no evidence of human immunodeficiency virus (HIV) infection. In the 6 months before admission, she began taking infliximab, which is a monoclonal antibody with high binding affinity for TNF-α. The patient resided in a small town in northeastern Pennsylvania and had no recent travel history. She had no contact with animals. On admission, her serum creatine kinase was elevated, and a test for HIV was negative. A muscle biopsy from the left anterior thigh contained microorganisms that were consistent with microsporidia. The morphologic appearance suggested *Brachiola (Anncaliia)* species, and the identity was confirmed by polymerase chain reaction with the use of primers specific for *B. (A.) algerae,* which is a mosquito pathogen.

The muscle pain worsened, and the patient became increasingly debilitated, requiring mechanical ventilation after respiratory insufficiency developed. Despite administration of albendazole and itraconazole, a repeat muscle biopsy from the right quadriceps muscle revealed microsporidia. Four weeks after admission, the patient died from a massive cerebrovascular infarction. A postmortem muscle biopsy revealed necrosis and persistent organisms.

B. (A.) algerae is a well-known microsporidian pathogen of mosquitoes but had not been reported previously to cause myositis in humans. The present case report illustrates that insect pathogens such as *B. (A.) algerae* are capable of causing disseminated disease in humans. Anti-TNF-α therapy (infliximab) may have predisposed the patient to infection with this agent.

TNF-α, Tumor necrosis factor-α.

LABORATORY DIAGNOSIS

Diagnosis of microsporidia infection may be made by detection of the organisms in biopsy material and by light-microscopic examination of CSF and urine. Spores measuring between 1.0 and 2.0 μm may be visualized by Gram (gram-positive), acid-fast, PAS, immunochemical, modified trichrome, and Giemsa staining techniques. A chromotrope-based staining technique for light-microscopic detection of *E. bieneusi* and *E. (S.) intestinalis* spores in stool and duodenal aspirates has also been described. Monoclonal antibodies against *Encephalitozoon* spp. and *E. bieneusi* have been generated, of which some have been evaluated for diagnostic purposes with stool specimens. Recently, a commercial immunofluorescence assay (IFA) became

available, but it is not approved by the U.S. Food and Drug Administration (FDA). Electron microscopy is considered the gold standard for diagnostic confirmation of microsporidiosis and for identification to the genus and species level; however, its sensitivity is unknown. Additional diagnostic techniques, including PCR, culture, and serologic testing, are under investigation. These techniques are not yet considered reliable enough for routine diagnosis. Molecular methods may also be used to identify the infecting organism to genus and species.

TREATMENT, PREVENTION, AND CONTROL

Management of microsporidial infection most often includes oral treatment with the drug albendazole. Clinical studies have demonstrated the efficacy of albendazole against species of the *Encephalitozoon* genus in HIV-infected patients for whom it is the treatment of choice for intestinal, ocular, and disseminated microsporidiosis, although it is only partially active against *E. bieneusi.* Fumagillin has been used successfully against species of the *Encephalitozoon* genus and against *V. corneae* in vitro and in humans for the treatment of *E. bieneusi* intestinal microsporidiosis. Nitazoxanide has activity against *E. intestinalis* and *V. corneae* and has been effective in treating infection caused by *E. bieneusi* in AIDS patients. As with most opportunistic infections, antiretroviral therapy plays a key role in eradicating microsporidia in HIV-infected patients, and effective antiretroviral therapy is likely to reduce the incidence of infections caused by microsporidia in the future.

As with *Cryptosporidium*, preventing microsporidian infection is difficult. The same methods of improved personal hygiene and sanitation used for other intestinal protozoa should be maintained with this disease.

Aspergillosis

Aspergillosis comprises a broad spectrum of diseases caused by members of the genus *Aspergillus* (Box 65.2). Exposure to *Aspergillus* in the environment may cause allergic reactions in hypersensitized hosts or destructive, invasive pulmonary and disseminated disease in highly immunosuppressed individuals. Although approximately 19 species of *Aspergillus* have been documented as agents of human disease, the majority of infections are caused by *A. fumigatus, A. flavus, A. niger,* and *A. terreus.* Molecular taxonomic studies have shown that all the previously mentioned species are actually SCs that contain morphologically indistinguishable cryptic species, some of which may exhibit important antifungal resistance profiles and pathogenic features.

MORPHOLOGY

Aspergillus spp. grow in culture as hyaline molds. On a gross level, the colonies of *Aspergillus* may be black, brown, green, yellow, white, or other colors, depending on the species and the growth conditions. Colonial appearance may provide an initial suggestion as to the species of *Aspergillus,* but definitive identification requires microscopic examination of the hyphae and the structure of the conidial head.

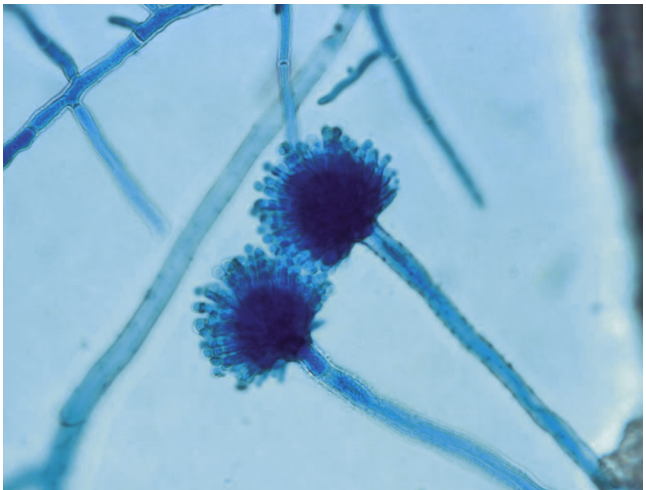

Fig. 65.12 *Aspergillus fumigatus*. Lactophenol cotton blue preparation showing conidial heads.

Aspergilli grow as branched, septate hyphae that produce conidial heads when exposed to air in culture and in tissue. A conidial head consists of a conidiophore with a terminal vesicle, on which are borne one or two layers of phialides, or sterigmata (see Chapter 57, Fig. 57.3B). The elongated phialides in turn produce columns of spheric conidia, which are the infectious propagules from which the mycelial phase of the fungus develops. Identification of individual species of *Aspergillus* depends in part on the difference in their conidial heads, including the arrangement and morphology of the conidia (Figs. 65.12 and 65.13). In many instances, the cryptic species within a SC can require molecular methods for identification.

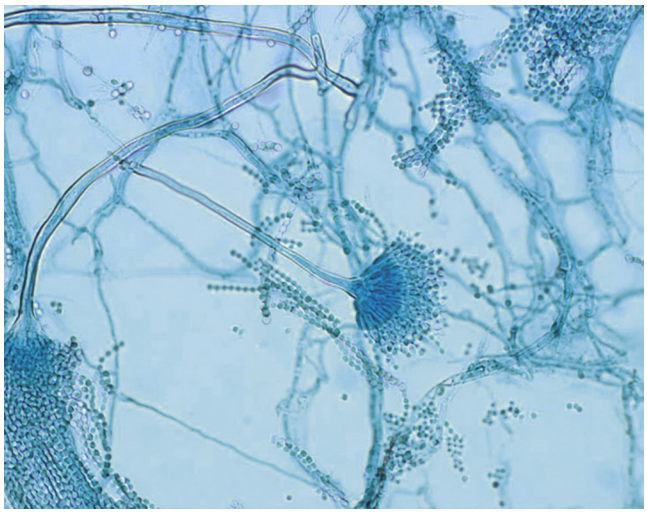

Fig. 65.13 *Aspergillus terreus*. Lactophenol cotton blue preparation showing conidial head.

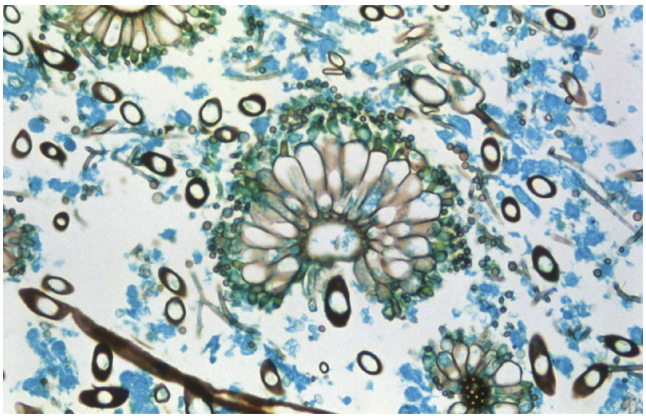

Fig. 65.15 *Aspergillus niger* in a cavitary lung lesion showing both hyphae and conidial head (Gomori methenamine silver, ×1000).

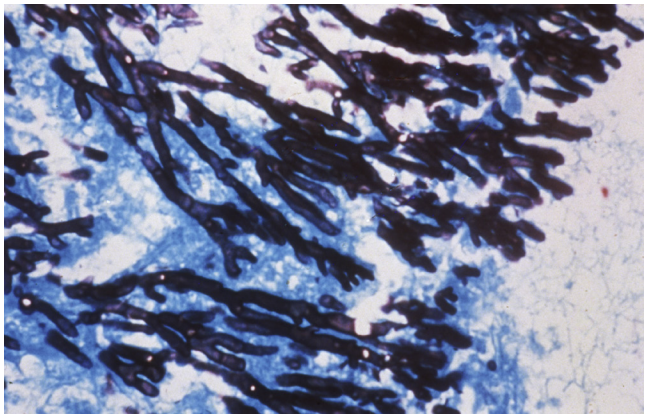

Fig. 65.14 *Aspergillus* in tissue showing acute-angle branching, septate hyphae (Gomori methenamine silver, ×1000).

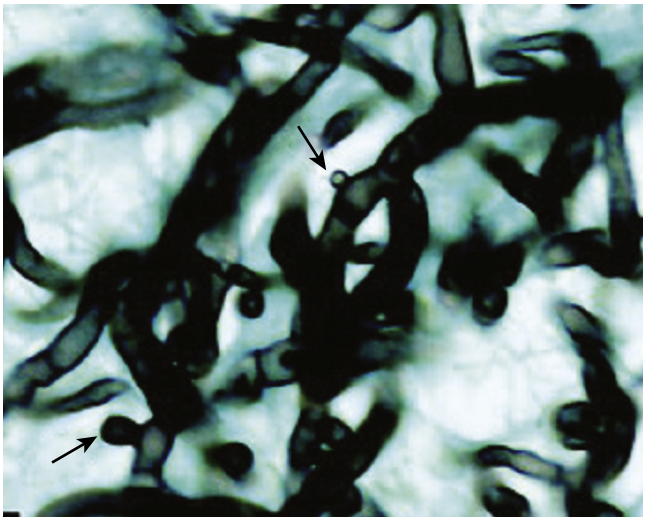

Fig. 65.16 *Aspergillus terreus* in tissue. Arrows point to aleurioconidia (Gomori methenamine silver, ×1000). (From Walsh, T.J., et al., 2003. Experimental pulmonary aspergillosis caused by *Aspergillus terreus:* pathogenesis and treatment of an emerging fungal pathogen resistant to amphotericin B. J. Infect. Dis. 188, 305–319.)

In tissue, the hyphae of *Aspergillus* spp. stain poorly with H&E but are well visualized by the PAS, GMS, and Gridley fungal stains (Fig. 65.14). The hyphae are homogeneous, uniform in width (3 to 6 μm), with parallel contours, regular septations, and a progressive, treelike pattern of branching (see Fig. 65.14). The branches are dichotomous and usually arise at acute (≈45 degree) angles. The hyphae may be seen within blood vessels (angioinvasion), causing thrombosis. The conidial heads are rarely seen in tissue but may arise within a cavity (Fig. 65.15). The important species *A. terreus* can be identified in tissue by its spheric or oval aleurioconidia that develop from the lateral walls of the mycelium (Fig. 65.16); otherwise, the hyphae of pathogenic *Aspergillus* spp. are morphologically indistinguishable from one another in tissue.

EPIDEMIOLOGY

Aspergillus spp. are common throughout the world. Their conidia are ubiquitous in air, soil, and decaying matter. Within the hospital environment, *Aspergillus* spp. may be found in air, showerheads, hospital water storage tanks, and potted plants. As a result, they are constantly being inhaled. The type of host reaction, the associated pathologic findings, and the ultimate outcome of infection depend more on host factors than on the virulence or pathogenesis of the individual *Aspergillus* spp. The respiratory tract is the most frequent, and most important, portal of entry.

CLINICAL SYNDROMES

The allergic manifestations of aspergillosis constitute a spectrum of presentations based on the degree of hypersensitivity to *Aspergillus* antigens (Clinical Case 65.4). In the bronchopulmonary form, asthma, pulmonary infiltrates, peripheral eosinophilia, elevated serum IgE, and evidence of hypersensitivity to *Aspergillus* antigens (skin test) may be seen. Allergic sinusitis shows laboratory evidence of hypersensitivity to go along with upper respiratory symptoms of nasal obstruction and discharge, headache, and facial pain.

Clinical Case 65.4 **Invasive Aspergillosis**

Guha and associates (*Infect Med* 24[Suppl 8]:8–11, 2007) described a case of invasive aspergillosis in a renal transplant recipient. The patient was a 34-year-old woman who presented with a 2-day history of weakness, dizziness, left calf pain, and black tarry stools. She denied chest pain, cough, or shortness of breath. Her past medical history was significant for diabetes leading to renal failure, for which she received a cadaveric renal transplant in 2002. Three weeks before presentation, acute graft rejection developed. She was placed on an immunosuppressive regimen of alemtuzumab, tacrolimus, sirolimus, and prednisone. On admission, she was tachycardic, hypotensive, and febrile. Physical examination revealed a tender venous cord palpable in the popliteal fossa. An initial chest radiograph showed no abnormalities. Laboratory studies showed anemia and azotemia. The white blood cell count was 4800/μL with 80% neutrophils. The patient was given four units of packed red blood cells, and empiric treatment with gatifloxacin was started. Blood cultures were positive for *Escherichia coli* susceptible to gatifloxacin. On hospital day 6, a vesicular rash developed on the buttocks and left calf, cultures of which were positive for herpes simplex virus, and she was placed on acyclovir. The patient's clinical condition stabilized, except for her renal function, and intermittent hemodialysis was started on hospital day 8. On hospital day 12, the patient exhibited decreased responsiveness, became obtunded, and was intubated for respiratory distress. A chest radiograph showed diffuse bilateral lung nodules. Culture of bronchoalveolar lavage fluid was positive for *Aspergillus* species, and viral inclusion bodies suggestive of cytomegalovirus were seen. Her immunosuppression was decreased, and liposomal amphotericin B was started. The patient experienced an acute myocardial infarction and became comatose. Multiple acute infarcts in the frontal lobe and cerebellum were seen on a magnetic resonance imaging scan of the brain. The patient's condition continued to deteriorate, and multiple skin nodules developed on her arms and trunk. Biopsy specimens of the skin nodules grew *A. flavus* on culture. The patient subsequently died on hospital day 23. At autopsy, *A. flavus* was detected in multiple organs, including heart, lung, adrenal gland, thyroid, kidney, and liver.

This case serves as an extreme example of disseminated aspergillosis in an immunocompromised host.

Both the paranasal sinuses and the lower airways may become colonized with *Aspergillus* spp., resulting in *Aspergillus* bronchitis and true aspergilloma ("fungus ball"). *Aspergillus* bronchitis usually occurs in the setting of underlying pulmonary disease, such as cystic fibrosis, chronic bronchitis, or bronchiectasis. The condition is marked by the formation of bronchial casts or plugs composed of hyphal elements and mucinous material. The symptoms remain those of the underlying disease; no tissue injury results, although antifungal therapy may be helpful. An aspergilloma can form either in the paranasal sinuses or in a preformed pulmonary cavity secondary to old tuberculosis or other chronic cavitary lung disease. Aspergillomas may be seen on radiographic examination but usually are asymptomatic. Treatment is generally not warranted unless pulmonary hemorrhage occurs. In the event of pulmonary hemorrhage, which may be severe and life-threatening, surgical excision of the cavity and fungus ball is indicated. Also, radical debridement of the paranasal sinuses may be necessary to alleviate any symptomatology or hemorrhage caused by a fungus ball of the sinuses. Oral antifungal therapy may help symptoms but rarely kills the fungus in the cavity or sinus.

Forms of invasive aspergillosis run the gamut from superficially invasive disease that may occur in the setting of mild immunosuppression (e.g., low-dose steroid therapy, collagen vascular disease, or diabetes) to destructive, locally invasive pulmonary or disseminated aspergillosis. The more limited forms of invasion generally include necrotizing pseudomembranous bronchial aspergillosis and chronic necrotizing pulmonary aspergillosis. Bronchial aspergillosis may cause wheezing, dyspnea, and hemoptysis. Most patients with chronic necrotizing pulmonary aspergillosis have underlying structural pulmonary disease, which may be treated with low-dose corticosteroids. This is a chronic infection that may be locally destructive, with the development of infiltrates and fungus balls seen on radiographic examination. It is not associated with vascular invasion or dissemination. Surgical resection of affected areas and administration of antifungal therapy are efficacious in treating this condition.

Invasive pulmonary aspergillosis and disseminated aspergillosis are devastating infections seen in severely neutropenic and immunodeficient patients. The major predisposing factors for this infectious complication include neutrophil count less than 500/mm^3, cytotoxic chemotherapy, and corticosteroid therapy. Patients present with fever and pulmonary infiltrates, often accompanied by pleuritic chest pain and hemoptysis. Definitive diagnosis is often delayed because sputum and blood cultures are usually negative. The mortality of this infection despite specific antifungal therapy is quite high, usually exceeding 70% (see Table 65.5). Hematogenous dissemination of infection to extrapulmonary sites is common because of the angioinvasive nature of the fungus. Sites most often involved include brain, heart, kidneys, GI tract, liver, and spleen.

LABORATORY DIAGNOSIS

As with other ubiquitous fungi, the diagnosis of aspergillosis necessitates caution when evaluating the isolation of an *Aspergillus* species from clinical specimens. Recovery from surgically removed tissue or sterile sites, accompanied by positive histopathology (moniliaceous, septate, dichotomously branching hyphae) should always be considered significant; isolation from normally contaminated (e.g., respiratory) sites requires closer scrutiny.

Most etiologic agents of aspergillosis grow readily on routine mycologic media lacking cycloheximide. Species-level identification of the major human pathogens can be made by observing cultural and microscopic characteristics from growth on potato dextrose agar. Microscopic morphology (conidiophores, vesicles, metulae, phialides, and conidia) is best observed with a slide culture and is necessary for species identification.

Invasive aspergillosis caused by *A. fumigatus* and most other species is rarely documented by positive blood cultures. In fact, most bloodstream isolates of *Aspergillus*

species have been shown to represent pseudofungemia or terminal events at autopsy. Notably, *A. terreus*, among all species of *Aspergillus*, has been shown to cause true aspergillemia. Similar to other angioinvasive filamentous fungi (e.g., *Fusarium*, *Scedosporium* spp.), *A. terreus* is capable of adventitious sporulation, in which yeastlike spores, or aleurioconidia, are formed in tissue and are more likely to be detected in blood obtained for culture (see Fig. 65.16). Recognition of these aleurioconidia on microscopic examination of tissue, fine-needle aspirates, or bronchoscopy specimens can allow a rapid, presumptive identification of *A. terreus*.

The rapid diagnosis of invasive aspergillosis has been advanced by the development of immunoassays for the *Aspergillus* galactomannan antigen in serum, bronchoalveolar lavage (BAL) fluid, and CSF. The most widely available form of this test uses an enzyme immunoassay format and is available as a commercial kit or from reference laboratories. This test appears to be reasonably specific but exhibits variable sensitivity. It is best used on serial specimens from high-risk (primarily neutropenic and BMT patients) patients as an early indication to begin empiric or preemptive antifungal therapy and to pursue a definitive diagnosis more aggressively. A lateral flow immunoassay (LFI) has been developed for detection of an extracellular glycoprotein of *Aspergillus*, which is present in cell walls of growing germ tubes and secreted at growing hyphal tips but absent from ungerminated conidia. The simplicity of the LFI test suggests the possibility for use as a point-of-care test on serum or BAL fluid. The β-D-glucan test has been applied to the diagnosis of invasive aspergillosis, but it suffers from a lack of specificity. In contrast, PCR-based assays have proven to be both sensitive and specific for the diagnosis of invasive aspergillosis, and efforts to standardize this method are ongoing. Several multiplex real-time PCR assays for the detection of *Aspergillus* deoxyribonucleic acid (DNA) are commercially available in Europe. One of the more successful approaches to the diagnosis of invasive aspergillosis is to use a combination of antigen detection (either galactomannan or β-D-glucan) and PCR. It is clear from numerous publications that the use of these tests in combination assists in the earlier diagnosis of invasive aspergillosis,

TREATMENT AND PREVENTION

Prevention of aspergillosis in high-risk patients is paramount. Neutropenic and other high-risk patients are generally housed in facilities in which the air is filtered to minimize exposure to *Aspergillus* conidia.

Specific antifungal therapy of aspergillosis usually involves the administration of voriconazole (isavuconazole and posaconazole are alternatives to voriconazole) or one of the lipid formulations of amphotericin B. It is important to realize that *A. terreus* is considered resistant to amphotericin B and should be treated with an alternative agent, such as voriconazole (or another mold-active triazole). The introduction of voriconazole provides a treatment option that is more efficacious and less toxic than amphotericin B (see Chapter 61). Concomitant efforts to decrease immunosuppression and/or reconstitute host immune defenses are important components of the treatment of aspergillosis. Likewise, surgical resection of involved areas is recommended if possible. Resistance to the mold-active triazoles (isavuconazole, itraconazole, posaconazole, and voriconazole) is uncommon but has been reported from numerous locations worldwide. A potential link to the use of azole fungicides in agriculture has been reported from the Netherlands.

Fig. 65.17 *Rhizopus* sp. showing sporangium and rhizoids.

Mucormycosis

Mucormycosis refers to diseases caused by fungi of the subphyla Mucoromycotina and Entomophthoromycotina. The principal human pathogens among the Mucormycetes are encompassed by two orders, the Mucorales and the Entomophthorales. The orders Entomophthorales and Basidiobolales contain two pathogenic genera, Conidiobolus and Basidiobolus, respectively. These agents generally incite a chronic, granulomatous infection of subcutaneous tissues and are discussed in Chapter 63.

In the order Mucorales, pathogenic genera include *Rhizopus*, *Mucor*, *Lichtheimia* (formerly *Absidia*), *Rhizomucor*, *Saksenaea*, *Cunninghamella*, *Syncephalastrum*, and *Apophysomyces*. Infections caused by Mucormycetes are rare, occurring at an annual rate of 1.7 to 3.4 infections per million population in the United States. Unfortunately, when they do occur, infections caused by these agents are generally acute and rapidly progressive, with mortality rates of 70% to 100%.

MORPHOLOGY

Macroscopically, the pathogenic Mucorales grow rapidly, producing gray-to-brown woolly colonies within 12 to 18 hours. Further identification of the genus and species level is based on microscopic morphology. Microscopically, the Mucormycetes are molds with broad, hyaline, sparsely septate, coenocytic hyphae. The asexual spores of the order Mucorales are contained within a sporangium and are referred to as sporangiospores. The sporangia are borne at the tips of stalklike sporangiophores that terminate in a bulbous swelling called the columella (Fig. 65.17; also see Chapter 57, Fig. 57.3A). The presence of rootlike structures, called rhizoids, is helpful in identifying specific genera within the Mucorales. As with the aspergilli, identification of the Mucorales is best accomplished by molecular methods.

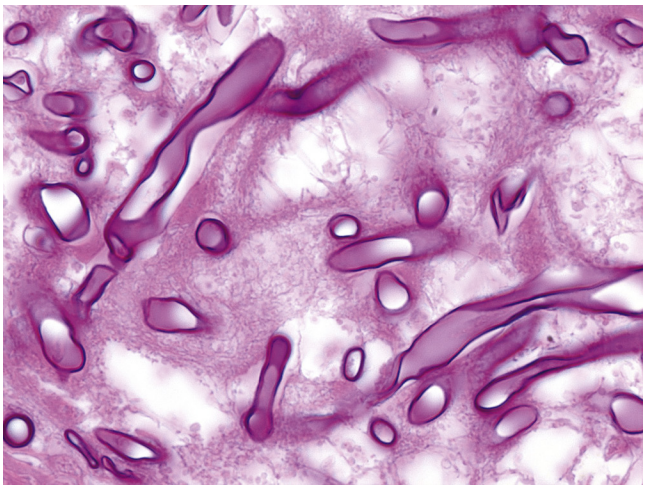

Fig. 65.18 *Rhizopus* sp. in tissue showing broad, ribbon-like, aseptate hyphae (hematoxylin and eosin, ×1000).

In tissue, Mucormycetes (order Mucorales) are seen as ribbon-like, aseptate or sparsely septate, moniliaceous (nonpigmented) hyphae (Fig. 65.18). In contrast to *Aspergillus* spp. and other hyaline molds, the width of the hyphae often exceeds 10 μm, and the hyphae are irregularly contoured and pleomorphic, often folding and twisting back on themselves. The pattern of hyphal branching is haphazard and nonprogressive, and branches typically arise from the parent hyphae at right angles. The walls of the hyphae are thin, stain weakly with GMS and other fungal stains, and are often more easily detected with H&E (see Fig. 65.18). The Mucormycetes are typically angioinvasive.

EPIDEMIOLOGY

Mucormycosis is a sporadic disease that occurs worldwide. *R. arrhizus* is the most common cause of human mucormycosis; however, additional species of *Rhizopus, Rhizomucor, Lichtheimia,* and *Cunninghamella* are known to cause invasive disease in hospitalized individuals. The organisms are ubiquitous in soil and decaying vegetation, and infection may be acquired by inhalation, ingestion, or contamination of wounds with sporangiospores from the environment. As with *Aspergillus* spp., nosocomial spread of Mucormycetes may occur by way of air-conditioning systems, particularly during construction. Focal outbreaks of mucormycosis also have been associated with the use of contaminated adhesive bandages or tape in surgical wound dressings, resulting in primary cutaneous mucormycosis. Notably, immunocompetent patients may develop posttrauma skin infections, representing up to 18% of all mucormycosis cases in a study of cases diagnosed in France. In addition, necrotizing cutaneous cases have been reported after a tornado in Joplin, Missouri, or as a cause of infections after combat-related injuries in Afghanistan.

Invasive mucormycosis occurs in immunocompromised patients and is similar clinically to aspergillosis. It is estimated that Mucormycetes may cause infection in 1% to 9% of solid organ transplants, especially those with underlying diabetes mellitus. Risk factors include corticosteroid and deferoxamine therapy, diabetic ketoacidosis, renal failure, hematologic malignancy, myelosuppression, and exposure to hospital construction activity. Mucormycosis has been seen after BMT in patients receiving antifungal prophylaxis with voriconazole, which is an agent that is not active against the Mucormycetes.

CLINICAL SYNDROMES

There are several clinical forms of mucormycosis caused by members of the order Mucorales. Sinus involvement (isolated sinusitis, rhinocerebral, and sinoorbital forms) is the most common presentation in diabetic patients and intravenous drug abusers, whereas pulmonary infection is the second most common presentation, and the reverse is true in hematology patients.

Rhinocerebral mucormycosis is an acute invasive infection of the nasal cavity, paranasal sinuses, and orbit that involves the facial structures and extends into the CNS, involving the meninges and the brain. Most of these infections occur in patients with metabolic acidosis, particularly diabetic ketoacidosis, and those with hematologic malignancies.

Pulmonary mucormycosis occurs as a primary infection in neutropenic patients and may be misdiagnosed as invasive aspergillosis. The pulmonary lesions are infarctive, secondary to hyphal invasion and subsequent thrombosis of pulmonary vessels. Chest radiographs show a rapidly progressive bronchopneumonia, segmented or lobar consolidation, and signs of cavitation. Fungus-ball formation mimicking aspergilloma may be seen. Pulmonary hemorrhage with fatal hemoptysis may occur as a result of vascular invasion by the fungus.

The angioinvasive nature of the mucoraceous mucormycetes often produces disseminated infection, with tissue infarction of various organs. Symptoms at presentation point to neurologic, pulmonary, or GI involvement. Involvement of the GI tract often results in massive hemorrhage or perforation.

Cutaneous mucormycosis may be a sign of hematogenous dissemination. Lesions tend to be nodular with an ecchymotic center. Primary cutaneous mucormycosis may occur after traumatic injury, in surgical dressings, or as colonization of burn wounds. The infection may be superficial or extend rapidly into the subcutaneous tissues. The aftermath of the devastating tornados of 2011 in the United States saw several cases of deeply invasive mucormycosis in non-immunocompromised individuals secondary to cutaneous inoculation by flying debris.

LABORATORY DIAGNOSIS

Because of the extremely poor prognosis of mucormycosis, every effort should be made to obtain tissue for direct microscopic examination, histologic study, and culture. The Mucormycetes are an extremely ubiquitous group of fungi, so demonstration of characteristic fungal elements in tissue merits considerably more importance than simple isolation in culture.

Appropriate specimens include scrapings of nasal mucosa, aspirates of sinus contents, bronchial alveolar lavage fluid, and biopsy of any and all necrotic infected tissue. Direct examination of material mounted in KOH with

calcofluor white may reveal the broad, aseptate hyphae. Histopathologic sections stained with H&E or PAS are most useful (see Fig. 65.18). Broad, irregularly branched, paucisseptate, twisted hyphae can be observed.

Tissue for culture should be minced, not homogenized, and placed on standard mycologic media without cycloheximide. Negative cultures are common, occurring about 40% of the time, despite the microscopic demonstration of hyphae in tissue. The diagnosis of mucormycosis cannot be established or rejected based on culture alone; it depends on a panel of evidence gathered by both the clinician and microbiologist. Unfortunately, no widely available serologic or molecular tests specific for the Mucormycetes are available yet (see Chapter 60).

TREATMENT

Amphotericin B remains the first-line therapy for mucormycosis, often supplemented by surgical debridement and immune reconstitution. Most Mucormycetes appear quite susceptible to amphotericin B and are generally not susceptible to the azoles or echinocandins (see Chapter 61). Among the extended-spectrum triazoles, however, posaconazole and isavuconazole stand out, in that both appear to be active against the Mucormycetes. Posaconazole and isavuconazole have documented efficacy in murine models of mucormycosis and in limited experience in the treatment of infections in humans. In contrast, voriconazole is inactive against these agents, and breakthrough mucormycosis has been reported in BMT patients receiving voriconazole prophylaxis.

Mycoses Caused by Other Hyaline Molds

The list of hyaline molds, also known as hyalohyphomycetes, is quite long, and it is well beyond the scope of this chapter to discuss them all (Clinical Case 65.5; see Box 65.1). The taxonomically diverse agents of hyalohyphomycosis (infection caused by nonpigmented molds) do share several characteristics, in that many agents exhibit decreased susceptibility to a number of antifungal agents, and when present in tissue, they appear as hyaline (nonpigmented), septate, branching, filamentous fungi that may be indistinguishable from *Aspergillus.* Culture is necessary to identify these agents and may be critical in determining the most appropriate therapy.

Although infections caused by most of these fungi are relatively uncommon, they appear to be increasing in incidence. Most disseminated infections are thought to be acquired by the inhalation of spores or by the progression of previously localized cutaneous lesions. In this chapter, the discussion of specific genera is limited to selected clinically important hyaline molds: *Fusarium* spp., *Sarocladium* spp., *Paecilomyces* spp., *Purpureocillium* spp., *Trichoderma* spp., and *Scopulariopsis* spp. These organisms tend to cause infections in neutropenic patients, are often disseminated in nature, and are almost uniformly fatal in the absence of immune reconstitution. Several of these organisms are capable of adventitious conidiation (generation of spores in tissue) with concomitant hematogenous dissemination, positive blood cultures, and multiple cutaneous lesions.

Clinical Case 65.5 **Fusariosis**

Badley and associates described a 38-year-old man, undergoing chemotherapy for recently diagnosed acute myeloid leukemia, who developed neutropenia and fever. He was placed on broad-spectrum antibacterial agents but remained febrile after 96 hours. A left internal jugular catheter was in place. Blood and urine cultures showed no growth. To combat a potential fungal infection, voriconazole was added to the therapeutic regimen. After 1 week of treatment, the patient was still febrile and neutropenic, and his antifungal therapy was changed to caspofungin. Four days later, the patient developed a mildly painful rash. Initially the rash developed on the upper extremities and consisted of papular, erythematous, plaquelike lesions with centers that became necrotic. Blood cultures and skin biopsy specimens were sent to the laboratory for analysis. The laboratory report indicated that the blood cultures were positive for "yeast" based on the presence of budding cells and pseudohyphae. The skin biopsy showed "mold" consistent with *Aspergillus*. However, serum galactomannan testing was negative. All cultures grew *Fusarium solani*. The patient's caspofungin was discontinued, and he was switched to a lipid preparation of amphotericin B and voriconazole. Despite the antifungal therapy, the lesions increased in number over the next 2 weeks and spread throughout his extremities, trunk, and face. The neutropenia and fever persisted, and he died approximately 3 weeks after the initial diagnosis.

The combination of skin lesions and positive blood cultures are typical findings in fusariosis. Although "yeast" was reported from the blood cultures, closer examination revealed the microconidia and hyphae of *Fusarium*; likewise, the appearance of septate hyphae in the skin biopsy could represent a number of different hyaline molds, including *Fusarium*.

Fusarium species have been recognized with increased frequency as causes of disseminated infection in immunocompromised patients. *Fusarium* also is an important cause of fungal keratitis, especially among contact lens wearers. There are numerous toxic secondary metabolites (mycotoxins) produced by *Fusarium* species that have been implicated in human disease, especially associated with the consumption of contaminated grain. Along with orally ingested mycotoxins, systemic effects of exposure to inhaled mycotoxins also have been attributed to *Fusarium*, although these effects have been much less characterized.

Several molecular phylogenetic studies have shown that fusaria, once considered individual species by morphologic features, are now known to represent SCs. The most common SCs (clinically relevant species shown in parenthesis) isolated from clinical specimens include *Fusarium fujikuroi* SC (*F. verticillioides, F. thapsinum,* and *F. proliferatum*), *F. solani* SC (*F. falciforme, F. petroliphilum, F. keratoplasticum, F. solani*), and *F. oxysporum* SC (*F. oxysporum*). For the purposes of this chapter, we will focus on these three SCs without further delineation. The hallmark of disseminated fusariosis is the appearance of multiple purpuric cutaneous nodules with central necrosis (see Clinical Case 65.5). Biopsy of these nodules generally reveals branching, hyaline, and septate hyphae invading dermal blood vessels (Fig. 65.19). Cultures of biopsy material and of blood are useful in establishing the diagnosis

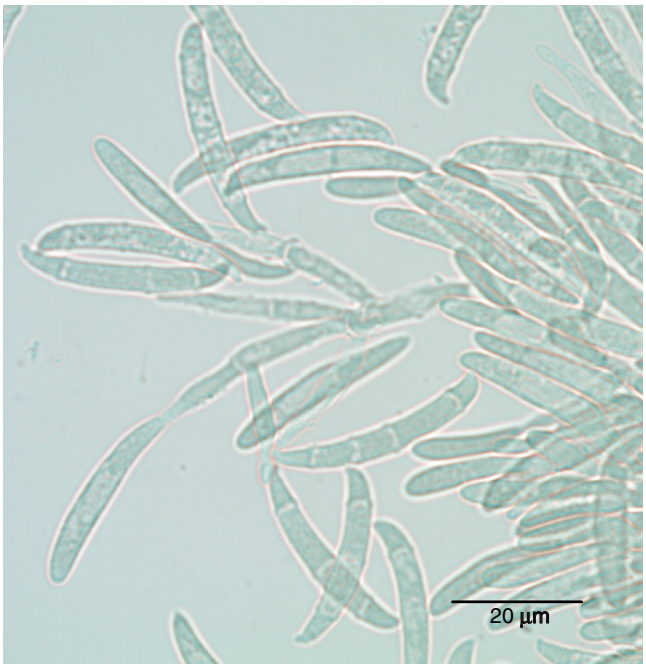

Fig. 65.19 *Fusarium* sp. in tissue showing acute-angle branching, septate hyphae that are indistinguishable from that of *Aspergillus* spp. (From Chandler, F.W., Watts, J.C., 1987. Pathologic Diagnosis of Fungal Infections. American Society for Clinical Pathology Press, Chicago, IL.)

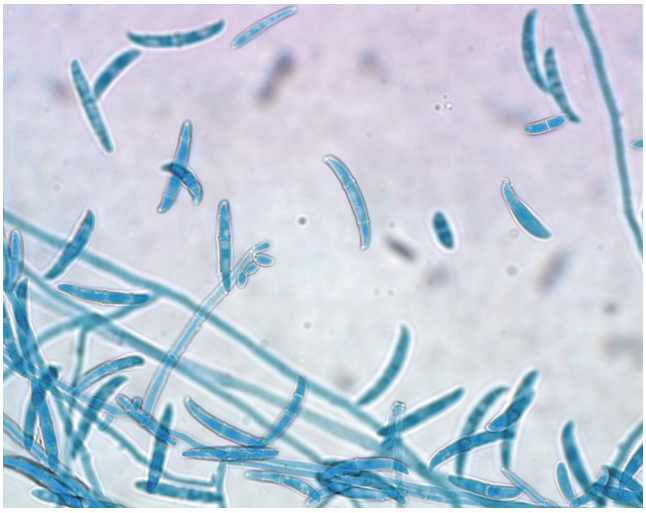

Fig. 65.20 *Fusarium oxysporum*, lactophenol cotton blue preparation.

of *Fusarium* infection. Although blood cultures are virtually always negative in invasive infections caused by *Aspergillus* spp., approximately 75% of patients with fusariosis will have positive blood cultures. In culture, colonies of *Fusarium* spp. are rapidly growing, cottony to woolly, flat, and spreading. Colors may include blue-green, beige, salmon, lavender, red, violet, and purple. Microscopically, *Fusarium* spp. are characterized by the production of both macroconidia and microconidia. Microconidia are single-celled or double-celled, ovoid to cylindric, and generally borne as mucous balls or short chains. Macroconidia are fusiform or sickle shaped and many celled (Fig. 65.20). *Fusarium* spp. often appear resistant to amphotericin B in vitro, and breakthrough infections occur frequently in patients treated with this agent. Voriconazole and posaconazole have been used successfully in some patients with amphotericin B–refractory fusariosis. Primary therapy with a lipid formulation of amphotericin B, voriconazole, or posaconazole, plus vigorous efforts at immune reconstitution, are recommended for treatment of fusariosis.

Invasive infections caused by *Sarocladium* (*Acremonium)* spp. are almost exclusively seen in patients with neutropenia, transplantation, or other immunodeficiency conditions and occur in a manner similar to that of *Fusarium*, with hematogenously disseminated skin lesions and positive blood cultures. Species of *Sarocladium* are commonly found in soil, decaying vegetation, and decaying food. Colonies are whitish gray or rose, with a velvety to cottony surface. The conidia may be single-celled in chains or a conidial mass arising from short, unbranched, tapered phialides. The optimal treatment for infections caused by *Sarocladium* spp. has not been established. Resistance is seen to amphotericin B, itraconazole, and the echinocandins. A recent report of successful treatment of a pulmonary infection caused by *S.* (formerly *Acremonium*) *strictum* with posaconazole suggests that the new triazoles may be useful in treatment of *Sarocladium*/*Acremonium* infections.

Although uncommon, *Paecilomyces* spp. may cause invasive disease in organ and hematopoietic stem cell recipients, individuals with AIDS, and other immunocompromised patients. The portal of infection is often through breaks in the skin or intravascular catheters. Dissemination of the infection may be aided by adventitious conidiation that takes place within the tissues. The two most common medically important species are *P. lilacinus* and *P. variotii*. In a recent taxonomic shuffle *P. lilacinus* has been assigned to the genus *Purpureocillium* (*Purpureocillium lilacinum*). Microscopically, the *Paecilomyces*/*Purpureocillium* species conidia are unicellular, ovoid to fusiform, and form chains. Phialides have a swollen base and a long, tapered neck. Susceptibility to amphotericin B is variable, with resistance seen with *P. (Paecilomyces) lilacinum*. Voriconazole has been used successfully to treat both severe cutaneous infection and disseminated disease.

Trichoderma spp. are excellent examples of fungi previously labeled as nonpathogenic that have emerged as important opportunistic pathogens in immunocompromised patients and in patients undergoing peritoneal dialysis. Fatal disseminated disease caused by *T. longibrachiatum* occurs in patients with hematologic malignancies, after BMT or solid organ transplantation. Most *Trichoderma* spp. show decreased susceptibility to amphotericin B, itraconazole, fluconazole, and flucytosine. Voriconazole appears to be active against the few isolates tested.

Scopulariopsis spp. are ubiquitous soil saprobes that have been rarely implicated in invasive human disease. *S. brevicaulis* is the most frequently isolated species. Infection is usually confined to the nails; however, serious deep infection has been noted in neutropenic leukemia patients and after BMT. Both local and disseminated infections have been described, with involvement of the nasal septum, skin and soft tissues, blood, lungs, and brain. Diagnosis is made by culture and histopathology. *Scopulariopsis* spp. grow moderately to rapidly on standard mycologic media. Colonies are initially smooth, becoming granular to powdery with age. Conidiophores are simple or branched; the conidiogenous cells are annelides that form singly or in clusters or may form a broomlike structure, or *scopula*, similar to that seen with *Penicillium* spp. The annelloconidia are smooth

initially, become rough at maturity, are shaped like light bulbs, and form basipetal chains. *Scopulariopsis* spp. are usually resistant to itraconazole and moderately susceptible to amphotericin B. Invasive infections may require surgical and medical treatment and are often fatal.

Phaeohyphomycosis

Phaeohyphomycosis is defined as a tissue infection caused by dematiaceous (pigmented) hyphae and/or yeasts. Infections caused by dematiaceous fungi constitute a significant and increasingly prevalent group of opportunistic fungal diseases and may take the form of disseminated disease or become localized to the lung, paranasal sinuses, or CNS. Primary inoculation, resulting in localized subcutaneous infection, occurs commonly in underdeveloped countries and has been discussed in Chapter 64.

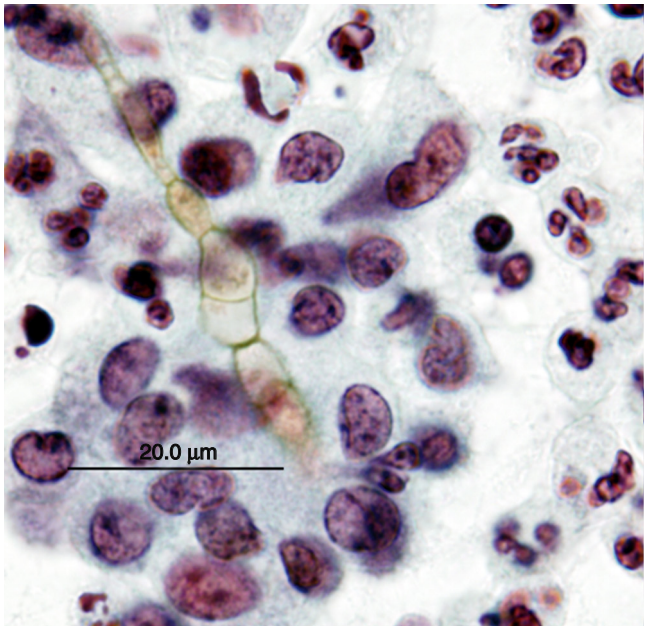

Fig. 65.21 *Scedosporium apiospermum*. Lactophenol cotton blue preparation showing melanized conidia and septate hyphae.

The dematiaceous fungi that have been documented to cause human infection encompass a large number of different genera; however, the more common causes of human infection include *Alternaria, Bipolaris, Cladosporium, Curvularia, Scedosporium*, *Lomentospora,* and *Exserohilum* species. In addition, several of the dematiaceous fungi appear to be neurotropic: *Curvularia* (formerly *Bipolaris*) *spicifera, Cladophialophora bantiana, Verruconis gallopava, Exophiala dermatitidis,* and *Rhinocladiella mackenziei.* Brain abscess is the most common CNS presentation. *Bipolaris* (*Curvularia*) spp. and *Exserohilum* spp. infections may present initially as sinusitis, which then extends into the CNS. *E. rostratum* was implicated in a large iatrogenic outbreak in the United States caused by contaminated methylprednisolone preparations, leading to numerous fatal cases of meningitis and CNS vasculitis in otherwise immunocompetent individuals. Notably both PCR and the β-D-glucan tests were quite useful in diagnosis and management of these patients.

In tissue, hyphae with or without yeast forms are present. Melanization of vegetative cells or conidia, which results in colony coloration ranging from olive or gray to black, is caused by the deposition of dihydroxynaphthalene melanin in cell walls. The amount of melanin expressed in host tissue may be very small and difficult to observe using traditional histologic stains. Most often, the pale brown to dark melanin-like pigment within the cell wall is apparent in H&E-stained or Papanicolaou-stained tissue (Fig. 65.21). Staining with the Fontana-Masson technique (a melanin-specific stain) may help visualize the dematiaceous elements. The use of the Fontana-Masson stain is therefore recommended as a

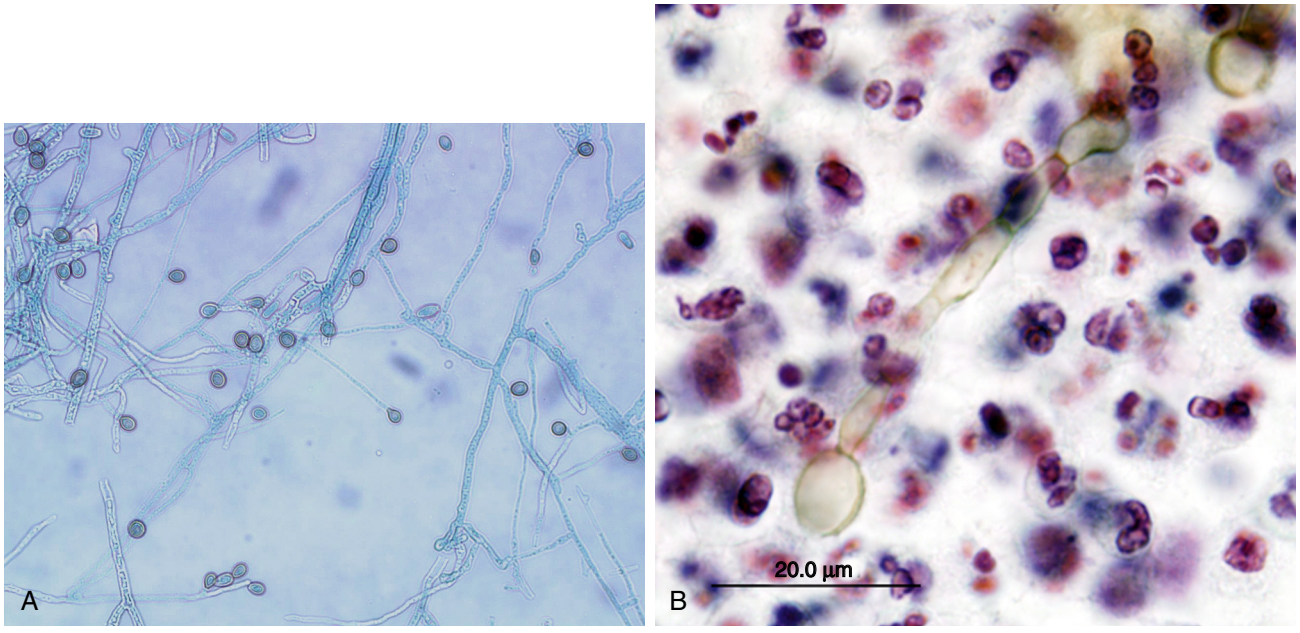

Fig. 65.22 (A and B) Fine-needle aspirate of a fluctuant mass showing the pigmented hyphae of *Phialophora verrucosa* (Papanicolaou). (From Anaissie, E.J., McGinnis, M.R., Pfaller, M.A. (Eds.), 2009. Clinical Mycology, second ed. Churchill Livingstone, New York.)

routine to distinguish fungi with melanized hyphae from those causing "hyalohyphomycosis," e.g., *Fusarium*. This does not apply for *Scedosporium or L. prolificans*, which do not produce melanized hyphae but are able to produce melanized conidia either *in vitro* or *in vivo* or both Fig. Fig. 65.22.

The dematiaceous fungi differ considerably in the clinical spectrum of infection and response to therapy. Furthermore, the different genera are not readily distinguished on histopathologic examination. Thus an accurate microbiologic diagnosis based on culture of the infected tissue is important for optimal clinical management of infections caused by these fungi.

Alternaria spp. are important causes of paranasal sinusitis in both healthy and immunocompromised individuals. Other sites of infection include skin and soft tissue, cornea, lower respiratory tract, and peritoneum. *A. alternata* is the best documented human pathogen in this genus. In culture, *Alternaria* colonies are rapidly growing, cottony, and gray to black. The conidiophores are usually solitary and simple or branched. The conidia develop in branching chains and are dematiaceous, muriform, and smooth or rough and taper toward the distal end with a short beak at their apices (Fig. 65.23).

Cladosporium spp. usually cause superficial cutaneous infections but may cause deep infections as well. These fungi are rapidly growing with a velvety, olive gray to black colony. The conidiophores arise from the hyphae and are dematiaceous, tall, and branching. The conidia may be smooth or rough and single celled to several celled and form branching chains at the apex of the conidiophore.

Curvularia spp. are ubiquitous inhabitants of the soil and have been implicated in both disseminated and local infections. Sites of infection include endocarditis, local catheter-site infections, nasal septum and paranasal sinuses, lower respiratory tract, skin and subcutaneous tissues, bones, and cornea. In tissue, the hyphae may appear nonpigmented. Common species found to be etiologic agents of human infection include *C. geniculata, C. lunata, C. pallescens,* and *C. senegalensis.* In culture, colonies are rapidly growing, woolly, and gray to grayish black. Microscopically, the conidia are dematiaceous, solitary or in groups, septate, simple or branched, sympodial, and geniculate.

Infections caused by the genera *Curvularia/Bipolaris* and *Exserohilum* present similarly to those of *Aspergillus* spp., except that the disease progresses more slowly. Clinical presentations include dissemination with vascular invasion and tissue necrosis, involvement of the CNS and paranasal sinuses, and association with allergic bronchopulmonary disease. These organisms cause sinusitis in "normal" (atopic or asthmatic) hosts and more invasive disease in immunocompromised hosts. In culture, both *Bipolaris* and *Exserohilum* form rapidly growing, woolly, gray to black colonies. Microscopically, the conidiophores are sympodial and geniculate. The conidia are dematiaceous, oblong to cylindric, and multicelled (Fig. 65.24). The preponderant *Bipolaris* species in human infections are *B. australiensis, B. hawaiiensis,* and *B. spicifera*. Recently these species have been transferred to the genus *Curvularia.*

Scedosporium spp. (*S. apiospermum*, *S. aurantiacum*, *S. boydii,* and *S. dehoogii*) and *Lomentospora* (formerly *Scedosporium*) *prolificans* represent two important antifungal-resistant, opportunistic pathogens. *S. apiospermum* may be readily isolated from soil and is an occasional cause of mycetoma worldwide; however, it is also the cause of serious disseminated and localized infection in immunocompromised patients. In addition to widespread disseminated disease, *S. apiospermum* has been reported to cause corneal ulcers, endophthalmitis, sinusitis, pneumonia, endocarditis, meningitis, arthritis, and osteomyelitis. *S. apiospermum* is indistinguishable from *Aspergillus* spp. and *Fusarium* spp. on histopathologic examination. Such distinction is important clinically because *S. apiospermum* is resistant to amphotericin B and susceptible to voriconazole, isavuconazole, and posaconazole. In culture, colonies are woolly to cottony and are initially white, becoming smoky brown to green. Microscopically, conidia are one-celled, elongate, and pale brown and are borne singly or in balls on either short or long conidiophores (Fig. 65.22).

Lomentospora prolificans is a potentially virulent and highly aggressive emerging agent of invasive mycosis. Although far less common than *Fusarium* or *S. apiospermum,* infections caused by *L. prolificans* are associated

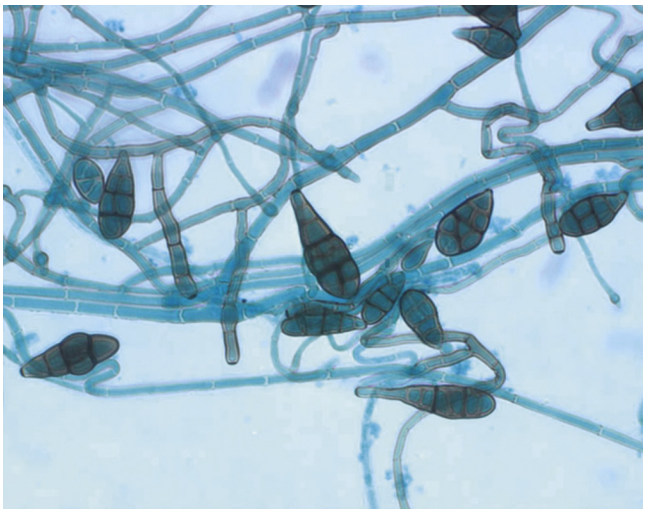

Fig. 65.23 *Alternaria* sp. Lactophenol cotton blue preparation showing darkly pigmented chains of muriform conidia.

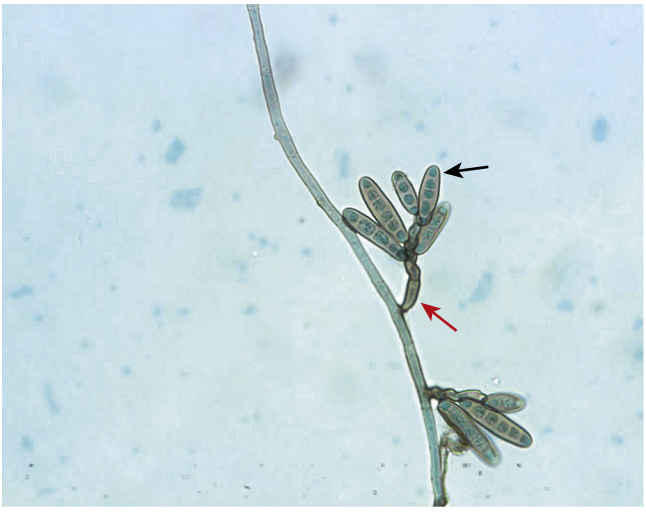

Fig. 65.24 *Bipolaris (Curvularia)* sp. Lactophenol cotton blue preparation showing pigmented conidia *(black arrow)* borne on geniculate conidiophores *(red arrow)*.

with soft-tissue trauma and are characterized by widespread local invasion, tissue necrosis, and osteomyelitis. *L. prolificans* resembles *S. apiospermum* in macroscopic and microscopic morphology. The formation by *L. prolificans* of annelloconidia in wet clumps at the apices of annellides with swollen bases is the most useful characteristic in differentiating this organism from *S. apiospermum*. *L. prolificans* is considered to be resistant to virtually all the systemically active antifungal agents, including the extended-spectrum triazoles and the echinocandins. Surgical resection remains the only definitive therapy for infection by *L. prolificans*.

The optimal treatment of deep-seated phaeohyphomycosis has not yet been established, although it most often includes early administration of amphotericin B and aggressive surgical excision. Despite these efforts, phaeohyphomycosis does not respond well to treatment and relapses are common. Posaconazole has been used successfully to treat disseminated infection caused by *E. spinifera.* In those patients with brain abscesses, complete excision of the lesion has been associated with improved survival. Long-term triazole (posaconazole or voriconazole) therapy coupled with repeated surgical excision may prevent recurrences. Treatment of the iatrogenic cases of infection caused by *E. rostratum* included lipid formulations of amphotericin B and voriconazole.

Pneumocystosis

Pneumocystis jirovecii (formerly *P. carinii*) is an organism that causes infection almost exclusively in debilitated and immunosuppressed patients, especially those with HIV infection. It is the most common opportunistic infection among individuals with AIDS; however, the incidence has decreased considerably in recent years with the use of highly active antiretroviral therapy. Although previously considered to be a protozoan parasite, recent molecular and genetic evidence place it among the fungi (see Chapter 57).

The life cycle of *P. jirovecii* includes both sexual and asexual components. During the course of human infection, *P. jirovecii* may exist as free trophic forms (1.5 to 5 μm in diameter), as a uninucleate sporocyst (4 to 5 μm), or as a cyst (5 μm) containing up to eight ovoid to fusiform intracystic bodies (Fig. 65.25). After rupture of the cyst, the cyst wall may be seen as an empty, collapsed structure (Fig. 65.26).

The reservoir for *P. jirovecii* in nature is unknown. Although airborne transmission has been documented experimentally among rodents, the rodent strains are genetically distinct from those of humans, making it unlikely that rodents serve as a zoonotic reservoir for human disease.

The respiratory tract is the main portal of entry for *P. jirovecii* in humans. Pneumonia is clearly the most common presentation of pneumocystosis, although extrapulmonary manifestations may be seen among AIDS patients. Involvement of lymph nodes, spleen, bone marrow, liver, small bowel, genitourinary tract, eyes, ears, skin, bone, and thyroid have been reported. Recent evidence suggests that both reactivation of quiescent old infection and primary infection can occur. Malnourished, debilitated, and immunosuppressed patients, especially AIDS patients with low CD4 counts (<200/μL), are at high risk of infection.

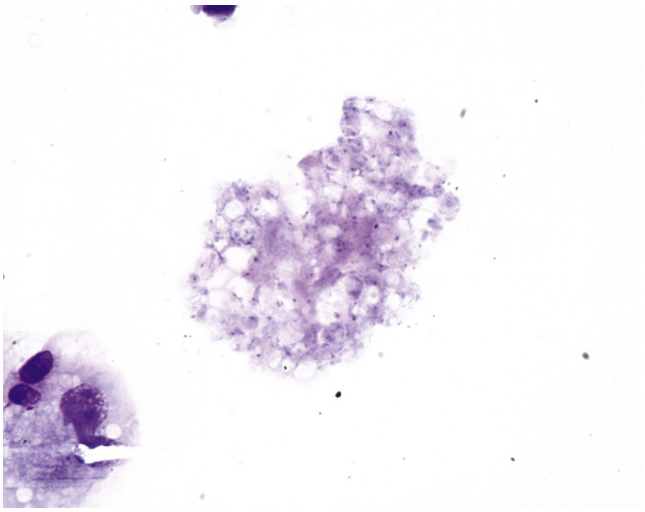

Fig. 65.25 *Pneumocystis jirovecii* in bronchoalveolar lavage fluid. Giemsa stain shows intracystic forms (×1000).

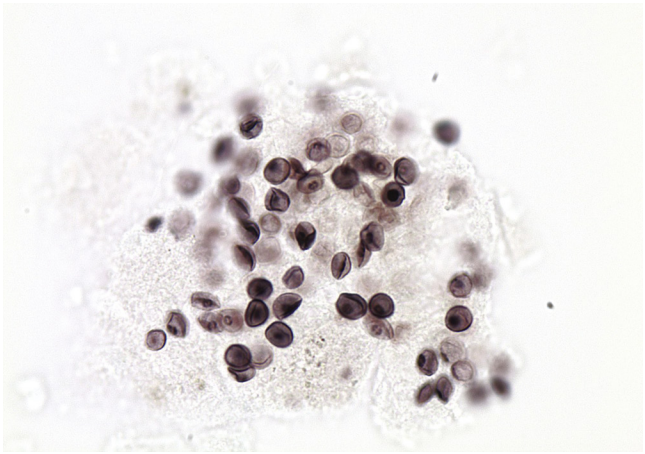

Fig. 65.26 *Pneumocystis jirovecii* in bronchoalveolar lavage fluid. Gomori methenamine silver stain shows typical intact and collapsed cysts (×1000).

The hallmark of *P. jirovecii* infection is an interstitial pneumonitis with a mononuclear infiltrate composed predominantly of plasma cells. The onset of disease is insidious, with signs and symptoms including dyspnea, cyanosis, tachypnea, nonproductive cough, and fever. The radiographic appearance is typically one of diffuse interstitial infiltrates with a ground-glass appearance extending from the hilar region, but radiographs may appear normal or show nodules or cavitation. The mortality rate is high among untreated patients, and death is caused by respiratory failure.

Histologically, a foamy exudate is seen within the alveolar spaces, with an intense interstitial infiltrate composed predominantly of plasma cells. Other patterns, including diffuse alveolar damage, noncaseating granulomatous inflammation, and infarct-like coagulative necrosis, also may be seen.

The diagnosis of *P. jirovecii* infection is almost entirely based on microscopic examination of clinical material, including BAL fluid, bronchial brushing, induced sputum, and transbronchial or open-lung biopsy specimens.

Examination of BAL fluid has been shown to have a sensitivity of 90% to 100% and usually precludes the need for transbronchial or open-lung biopsy. Microscopic examination of induced sputum may be useful in AIDS patients with a very high organism load; however, it has a 20% to 25% false-negative rate. A variety of histologic and cytologic stains have been used to detect *P. jirovecii*, including GMS, Giemsa, PAS, toluidine blue, calcofluor white, and immunofluorescence. The Giemsa stain demonstrates the trophic forms but does not stain the cyst wall (see Fig. 65.25), whereas the GMS stain is specific for the cyst wall (see Fig. 65.26). Immunofluorescent techniques stain both trophic forms and the cyst wall. The use of the β-D-glucan test has proven to be quite useful for the rapid diagnosis of *Pneumocystis* pneumonia with a high degree of sensitivity and specificity. Also, PCR is quite promising and is commercially available in Europe.

The cornerstone for both prophylaxis and treatment is trimethoprim-sulfamethoxazole. Alternative therapies have been used in AIDS patients, including pentamidine, trimethoprim-dapsone, clindamycin-primaquine, atovaquone, and trimetrexate.

Case Study and Questions

A 54-year-old man with chronic obstructive pulmonary disease (COPD) develops a new respiratory infection marked by blood-tinged sputum. A chest radiogram shows a ball-like mass in a preexisting right upper lobe cavity.

1. What is the most likely diagnosis?
   a. *Candida* pneumonia
   b. Aspergilloma
   c. Cryptococcoma
   d. *Pneumocystis* pneumonia
2. How would you confirm the diagnosis?
3. How would you treat this patient?

66 Fungal and Fungal-Like Infections of Unusual or Uncertain Etiology

Jim is a 50-year-old ex-smoker who went to his family physician for an annual physical examination. In the process, a chest radiograph was performed, which revealed a nodule in the left upper lobe of the lung. Because of his age and prior smoking history, Jim underwent a thoracotomy, and the nodule was excised. Pathologic examination revealed fibrosis and several large spheric structures but no evidence of cancer.

1. What is the differential diagnosis of a solitary lung nodule?
2. Describe how one can differentiate the spherules of *Rhinosporidium seeberi* from those of *Coccidioides immitis* and *Adiaspiromyces* spp.
3. Describe the disease process of adiaspiromycosis.
4. Which of the following agents can be identified using commercially available yeast identification systems?
   a. *Lacazia loboi*
   b. *Pythium insidiosum*
   c. *Rhinosporidium seeberi*
   d. *Prototheca wickerhamii*

Answers to these questions are available on www.StudentConsult.com.

Summaries Clinically Significant Organisms

CHLORELLOSIS

Trigger Words

Chloroplasts, green lesions, water exposure, alga

Biology, Virulence, and Disease

- Infection of humans and animals caused by a unicellular green alga of genus *Chlorella*
- *Chlorella:* unicellular, ovoid, spherical or polygonal, reproduce by endosporulation
- Fresh lesions in liver, lymph nodes, cutaneous tissue are green on gross examination; smears reveal organisms that contain green refractile granules (chloroplasts)
- A single human infection reported thus far; most infections occur in sheep and cattle

Epidemiology

- A single human infection in Nebraska; resulted from exposure of a surgical wound to river water
- Infections in domestic and wild animals range from lymph node and deep organ involvement to cutaneous and subcutaneous lesions, presumably related to exposure to water containing the organism

Diagnosis

- *Chlorella* spp. infections diagnosed by culture and histopathologic examination of infected tissue
- On culture, colonies are bright green
- Wet mounts of wound exudate or touch preparations of infected tissue reveal ovoid, endosporulating cells with characteristic green cytoplasmic granules
- In tissue, cells stain with GMS and PAS but not H&E stains

Treatment, Prevention, and Control

- Repeat debridement, irrigation with Dakin solution, gauze packing and removal for drainage and granulation
- Amphotericin B therapy combined with administration of tetracycline may be useful

LACAZIOSIS

Trigger Words

Cutaneous trauma, soil, vegetation, water, dolphins, cutaneous nodules, tropical

Biology, Virulence, and Disease

- Chronic fungal skin infection caused by *Lacazia loboi*
- *L. loboi:* ascomycete fungus, reproduces by sequential budding, forms chains of spherical to oval cells connected by narrow tubelike bridges
- Slowly developing cutaneous nodules of varying size and shape
- Nodular keloid-like lesions most common; occur on the face, ears, arms, legs, feet
- Lesions increase in size and number over a period of 40 to 50 years
- Most patients asymptomatic; no systemic manifestations of disease

Epidemiology

- Human disease endemic in tropical regions of Central and South America
- *L. loboi* considered a saprophyte of soil and vegetation
- Mode of infection: cutaneous trauma; occurs in individuals involved in farming and jungle clearing
- Lacaziosis occurs in both marine and fresh water dolphins, suggesting an aquatic reservoir

Diagnosis

- Based on demonstrating yeast cells in lesion exudate or tissue sections
- Biopsy reveals a dispersed granulomatous infiltrate and numerous fungal forms in dermis and subcutaneous tissue

Treatment, Prevention, and Control

- Surgical excision of localized lesions
- Does not respond to antifungal therapy

RHINOSPORIDIOSIS

Trigger Words

Polypoid lesions, oropharynx, sporangium, trophocyte, endoconidia, granulomatous

Biology, Virulence, and Disease

- Granulomatous disease of humans and animals caused by *Rhinosporidium seeberi*
- Characterized by development of nasopharyngeal and ocular conjunctival polyps
- Two developmental forms seen in tissue: a large spherical form (sporangia) and a smaller trophic form

Epidemiology

- ≈90% of all known cases of rhinosporidiosis occur in India and Sri Lanka
- Natural habitat unknown
- Occurs primarily in men aged 20 to 40
- Appears to be associated with both rural and aquatic environments
- No evidence rhinosporidiosis is contagious

Diagnosis

- Histopathologic examination of affected tissues; distinctive appearance of trophocytes and sporangia in routine H&E-stained tissue is diagnostic
- *R. seeberi* has not been grown in culture

Treatment, Prevention, and Control

- Only effective form of treatment is surgical excision of lesions
- Recurrences common

GMS, Gomori methenamine silver; *H&E,* hematoxylin and eosin; *PAS,* periodic acid–Schiff.

Thus far we have discussed mycotic processes caused by reasonably well-characterized fungi that may serve as colonizers, opportunistic pathogens, or true pathogens. Although many of these organisms have undergone minor taxonomic reclassification over time, they all share the characteristics of the kingdom Fungi (see Chapter 57). One notable exception to this statement is *Pneumocystis jirovecii* (formerly *P. carinii*), which is an organism formerly considered to be a protozoan and now classified as a fungus of the class Pneumocystidomycetes based on molecular evidence (see Chapters 57 and 65). The fact that *P. jirovecii* cannot be grown on artificial media has complicated its characterization and assignment to the proper taxonomic category. In this chapter, we will discuss several infections that historically have been considered to represent fungal or "fungal-like" processes based on clinical and histopathologic presentation but, similar to *P. jirovecii*, have been difficult to classify because they cannot be grown on artificial media. In one instance, recent molecular evidence has suggested that an organism previously thought to be a fungus (*Rhinosporidium seeberi*) is in fact a protistan parasite. We also discuss two algal infections and two unusual infections caused by the oomycetes *Pythium insidiosum* and *Lagenidium* spp. In addition to being unusual, as well as uncommon, these infections are all diagnosed based on detection of characteristic structures on histopathologic examination of tissue. A listing of the infections, the etiologic agents, and the typical morphology in tissue are provided in Table 66.1.

Adiaspiromycosis

In humans, adiaspiromycosis is a rare, self-limited, pulmonary infection caused by inhalation of the asexual conidia of the soil saprophytes *Adiaspiromyces* (formerly *Emmonsia*) *crescens* and *Blastomyces parvus* (formerly *Emmonsia parva*). Synonyms include **haplomycosis** or **adiaspirosis.**

MORPHOLOGY

The fungi, *A. crescens* and *B. parvus*, grow as molds in culture at room temperature and in nature. The hyphae are septate and branched. The small (2- to 4-μm) aleurioconidia are borne on conidiophores that arise at right angles to the vegetative hyphae. On incubation at 40° C in vitro, or when introduced into the lungs, the conidia transform into **adiaconidia**, which then undergo massive enlargement but show no evidence of replication (e.g., budding, endospore formation).

When mature, the adiaconidia are thick-walled spherules measuring 200 to 400 μm or more in diameter (Fig. 66.1; see Table 66.1). The walls of the spherule are refractile, 20 to 70 μm thick, and when stained with hematoxylin and eosin (H&E) stain, comprise two layers: a narrow, outer, eosinophilic layer containing periodic fenestrations and a broad, hyaline, inner layer composed predominantly of chitin (see Fig. 66.1). The conidial walls stain with Gomori methenamine silver (GMS), periodic acid–Schiff (PAS), and the Gridley fungus stains but not with mucicarmine (Table 66.2). In human lung tissue, the adiaconidia are usually empty but may contain small eosinophilic globules along the inner surface of the walls (see Fig. 66.1).

EPIDEMIOLOGY

Although human adiaspiromycosis is uncommon, the infection is prevalent in rodents worldwide. Likewise, the fungus may be found in nature, predominantly in temperate zones. Human disease has been reported in France, Czechoslovakia, Russia, Honduras, Guatemala, Venezuela, and Brazil. Rodents may serve as a zoonotic reservoir for the disease. The likely mode of infection is by inhalation of fungal conidia aerosolized by contaminated soil.

TABLE 66.1 Morphologic Features of Fungal and Fungal-Like Infections of Unusual or Uncertain Etiology

Disease	Etiologic Agent(s)	Typical Morphology in Tissue	Usual Host Reaction
Adiaspiromycosis	*Adiaspiromyces* (*Emmonsia*) *crescens* *Blastomyces parvus* (formerly, *Emmonsia parva*)	Large adiaconidia, 200- to 400-μm diameter with thick (20- to 70-μm) walls; see Fig. 66.1	Granulomatous fibrotic and noncaseating
Chlorellosis	*Chlorella* sp. (chlorophyllous green alga)	Unicellular, endosporulating, round organisms, 4- to 15-μm diameter, containing multiple cytoplasmic granules (chloroplasts); lesions are green pigmented; see Fig. 66.2	Pyogranulomatous
Lacaziosis (lobomycosis)	*Lacazia loboi*	Spheric, budding yeasts, 5- to 12-μm diameter, which form chains of cells connected by tubelike structures; secondary budding may be present; see Fig. 66.3	Granulomatous
Protothecosis	*Prototheca wickerhamii, P. zopfii* (achlorophyllous green algae)	Spheric, oval, or polyhedral spherules, 2- to 25-μm diameter, containing 2–20 endospores when mature; see Fig. 66.5	Variable; no reaction to granulomatous
Pythiosis insidiosi Lagenidiosis	*Pythium insidiosum Lagenidium* spp. (not true fungi; belong to the protistal kingdom Stramenopila)	Hyphae and short hyphal fragments that are hyaline, thin-walled, pauciseptate, irregularly branched, 5- to 7-μm (*Pythium*) to 9- to 18-μm (*Lagenidium*) wide with nonparallel contours; angioinvasive; see Fig. 66.6	Granulomatous, necrotizing, suppurative, arteritis
Rhinosporidiosis	*Rhinosporidium seeberi* (aquatic protistan parasite of the Mesomycetozoa clade)	Large sporangia (100- to 350-μm diameter) with thin walls (3–5 μm) that enclose numerous endospores (6- to 8-μm diameter) with a zonal distribution; see Figs. 66.7 and 66.8	Nonspecific chronic inflammatory or granulomatous

Data from Chandler, F.W., Watts, J.C., 1987. Pathologic Diagnosis of Fungal Infections. American Society for Clinical Pathology Press, Chicago, IL; Connor, D.H., et al., 1997. Pathology of Infectious Diseases, vol 2. Appleton & Lange, Stamford, CT.

CLINICAL SYNDROMES

As with many fungal infections, most cases of documented adiaspiromycosis have been asymptomatic. Pulmonary nodules may be detected radiographically or incidentally at autopsy or in surgical specimens of lung removed for another reason.

Three forms of human adiaspiromycosis have been recognized: solitary granuloma; localized granulomatous disease; and diffuse, disseminated granulomatous disease. Patients with the disseminated granulomatous form of pulmonary adiaspiromycosis may experience fever, cough, and progressive dyspnea caused by compression and displacement of distal airways and alveolar parenchyma by the expanding granulomas. Fungal replication in the lungs does not occur, and dissemination to extrapulmonary sites has not been reported. The severity of the disease appears to be entirely commensurate with the number of conidia inhaled.

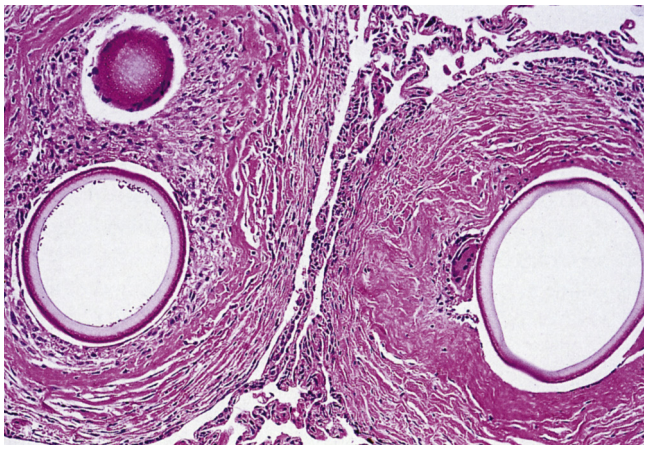

Fig. 66.1 Pulmonary adiaspiromycosis. The hematoxylin and eosin (H&E) stain defines two layers in the wall of the adiaconidium. Each adiaconidium has evoked a fibrogranulomatous response (H&E, ×40). (From Connor D.H., et al., 1997. Pathology of Infectious Diseases, vol 2. Appleton & Lange, Stamford, CT.)

LABORATORY DIAGNOSIS

The diagnosis of adiaspiromycosis is established by histopathologic examination of the affected lung and identification of the characteristic adiaconidia. Each adiaconidium is surrounded by an epithelioid and giant-cell granulomatous response, which is further encompassed by a dense capsule of fibrous tissue (see Fig. 66.1). All the granulomas are at a similar stage of development, reflecting a one-time exposure without subsequent replication within the lung.

The spherules represented by the adiaconidia should not be confused with those of *C. immitis* or *R. seeberi*, which are two other organisms that produce large spherules in tissue (see Table 66.2). In contrast to *C. immitis*, the adiaconidia of *A. crescens* and *B. parvus* are much larger, have a thicker wall, and do not contain endospores. The sporangia of *R. seeberi* are distinguished by the zonation of the sporangiospores and the distinctive eosinophilic globules seen within the mature sporangiospores (see Table 66.2). No other fungus of medical importance has walls as thick as those of the adiaconidia of *A. crescens* and *B. parvus*. Culture of infected tissue is not useful because the adiaconidia do not represent a replicative form of the fungus.

TREATMENT

Human pulmonary adiaspiromycosis is a self-limited infection. Specific antifungal therapy is not necessary.

TABLE 66.2 Comparative Morphologic Features of Fungi and Fungal-Like Organisms That Appear as Large Spherules in Tissue

	ORGANISMS		
Feature	***Coccidioides immitis***	***Rhinosporidium seeberi***[a]	***Adiaspiromyces crescens***[b]
External diameter of spherule (μm)	20-200	10-350	200-400
Thickness of spherule wall (μm)	1-2	3-5	20-70
Diameter of endospores (μm)	2-5	6-10[c]	None
Pigmentation	None	None	None
Hyphae or arthroconidia	Rare	None	None
Host reaction	Necrotic granulomas	Mucosal polyps with acute and chronic inflammation	Fibrotic granulomas
Growth in culture	+	–	±[d]
Special stain reactions	—	—	—
Gomori methenamine silver	+	+	+
Periodic acid–Schiff	+	+	+
Mucicarmine	–	+	–

[a]Not a fungus. Newly classified as an aquatic protistan parasite of the Mesomycetozoa clade.
[b]Adiaconidia.
[c]Endospores arranged in characteristic zonal distribution. Mature endospores contain distinctive eosinophilic globules.
[d]Grows as a mold on agar medium. Organism not recoverable from tissue.
Modified from Chandler, F.W., Watts, J.C., 1987. Pathologic Diagnosis of Fungal Infections. American Society for Clinical Pathology Press, Chicago, IL.

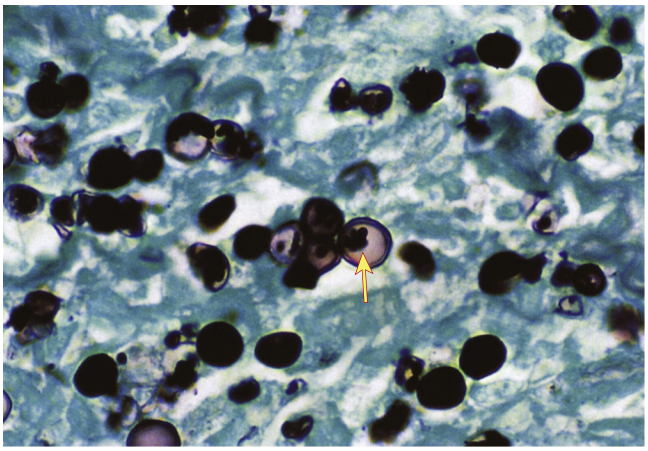

Fig. 66.2 *Chlorella* sp. showing intracellular chloroplasts and doubly contoured cell wall (Gomori methenamine silver, ×400). (From Connor. D.H., et al., 1997. Pathology of Infectious Diseases, vol 2. Appleton & Lange, Stamford, CT.)

Chlorellosis

Chlorellosis is an infection of humans and animals caused by a unicellular green alga of the genus *Chlorella*. In contrast to *Prototheca*, another alga that causes human infection, *Chlorella* contains chloroplasts, which give the lesions of chlorellosis a distinct green color. Most infections with this organism occur in sheep and cattle. A single human infection has been reported thus far.

MORPHOLOGY

Chlorella spp. are unicellular, ovoid, spheric, or polygonal, and 4 to 5 μm in diameter. They reproduce by endosporulation. The organisms contain numerous green chloroplasts that appear as cytoplasmic granules. The chloroplasts contain starch granules, which stain intensely with GMS, PAS, and Gridley fungal stains. The cell walls may appear doubly contoured (Fig. 66.2; see Table 66.1). *Chlorella* spp. reproduce asexually by internal septation and cytoplasmic cleavage, producing up to 20 daughter cells (sporangiospores) within the sporangium (parent cell). On maturation, the outer wall of the sporangium ruptures, releasing the sporangiospores, each of which goes on to produce sporangiospores of its own.

EPIDEMIOLOGY

The single human case took place in Nebraska and resulted from exposure of a surgical wound to river water. Infections in domestic (sheep and cattle) and wild animals (beaver) range from lymph node and deep organ involvement to cutaneous and subcutaneous lesions, presumably related to exposure to water containing the organism.

CLINICAL SYNDROMES

As noted previously, the human case of chlorellosis involved a healing surgical wound contaminated with river water. The wound subsequently drained a greenish yellow exudate. The infection was cured by repeated surgical debridement over a 10-month period. In animals, fresh lesions in liver, lymph nodes, and subcutaneous tissue are green on gross examination, and smears reveal organisms that contain green refractile granules (chloroplasts).

LABORATORY DIAGNOSIS

Infections caused by *Chlorella* spp. may be diagnosed by culture and by histopathologic examination of infected tissue. The organism grows well on most solid media, producing bright green colonies. Wet mounts of wound exudate or touch preparations of infected tissue reveal ovoid, endosporulating cells with characteristic green cytoplasmic granules representing chloroplasts. In tissue, the cells stain well with GMS and PAS but not H&E stains. They may be distinguished histopathologically from *Prototheca* by the intracellular chloroplasts.

TREATMENT

Treatment in the only human case of chlorellosis consisted of repeated debridement, irrigation with Dakin solution, and gauze packing and removal for drainage and granulation. Alternatively, amphotericin B therapy combined with administration of tetracycline has proven efficacious in the treatment of protothecosis and may be useful for chlorellosis as well.

Lacaziosis (Lobomycosis)

Lacaziosis is a chronic fungal infection of the skin caused by *Lacazia loboi* (formerly *Loboa loboi*). *L. loboi* is currently classified as an ascomycete fungus in the order Onygenales and the family Ajellomycetaceae. The disease is seen primarily in the South and Central American tropics. Natural infection occurs only in humans and dolphins, although it has been reproduced experimentally by injecting infected tissue into hamsters and armadillos. The organism has never been cultured in vitro.

MORPHOLOGY

L. loboi is spheric to oval and yeastlike in appearance. The fungi are 6 to 12 μm in diameter and have a thick, double-refractile cell wall. *L. loboi* reproduces by sequential budding and usually forms chains of cells connected by narrow, tubelike bridges (Fig. 66.3). Some of the cells may have one or two secondary buds and may be mistaken for the "pilot-wheel" form of *Paracoccidioides brasiliensis*. *L. loboi* is usually intracellular, although extracellular forms may be seen.

EPIDEMIOLOGY

The human disease is endemic in the tropical regions of Central and South America and has been reported in central and western Brazil, Bolivia, Columbia, Costa Rica, Ecuador, Guyana, French Guiana, Mexico, Panama, Peru, Surinam, and Venezuela. Isolated cases have been reported from Holland, and a single case has been reported in the United States in a patient with a history of travel to Venezuela.

L. loboi is believed to be a saprophyte of soil or vegetation, and lacaziosis predominates in tropical regions with thick vegetation, such as the Amazon rain forests. Cutaneous trauma is believed to be the mode of infection. A plant reservoir has not been identified.

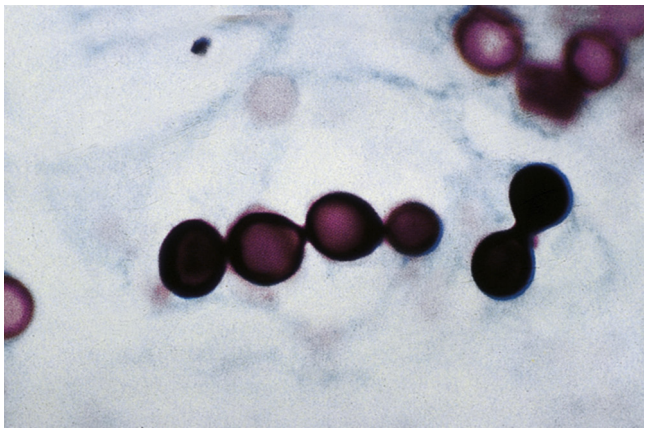

Fig. 66.3 *Lacazia loboi*. The fungi form a single chain with individual cells joined by tubelike bridges (Gridley, ×400). (From Chandler, F.W., Watts, J.C., 1987. Pathologic Diagnosis of Fungal Infections. American Society for Clinical Pathology Press, Chicago, IL.)

Fig. 66.4 Multiple keloid-like lesions of lacaziosis. (From Chandler, F.W., Watts, J.C., 1987. Pathologic Diagnosis of Fungal Infections. American Society for Clinical Pathology Press, Chicago, IL.)

Given the fact that lacaziosis occurs in marine dolphins and freshwater dolphins, an aquatic habitat is likely as well. Infection among dolphins has been reported for Florida, the Texas coast, the Spanish-French coast, the South Brazilian coast, and the Surinam River estuary. One instance of dolphin-to-human transmission has been reported; however, there is no evidence of human-to-human transmission.

Lacaziosis occurs primarily in men, or in women who are involved in farming and jungle clearing. Farmers, miners, hunters, and rubber plant workers have an increased incidence of disease. There is no racial predilection, and lobomycosis affects all age groups, with the peak age of onset being 20 to 40 years.

CLINICAL SYNDROMES

Lacaziosis is characterized by slowly developing cutaneous nodules of varying size and shape (Fig. 66.4 and Clinical Case 66.1). The dermal lesions are polymorphic, ranging from macules, papules, keloidal nodules, and plaques to verrucous and ulcerated lesions, all of which may be present in a single patient (see Fig. 66.4). The nodular keloid-like lesion is the most common lesion. The disease is characterized by a long dormancy period of months to years. The increase in the number and size of lesions also is a slow process, progressing over a period of 40 to 50 years. Lesions tend to arise on traumatized areas of skin, such as the face, ears, arms, legs, and feet. The disease does not involve mucous membranes or internal organs. Local cutaneous spread may occur through autoinoculation. Aside from occasional pruritus and hypesthesia or anesthesia of the affected area, patients are asymptomatic. There are no systemic manifestations of the disease.

LABORATORY DIAGNOSIS

Diagnosis is based on demonstrating the presence of the characteristic yeast cells in lesion exudate or tissue sections. Biopsy reveals a dispersed granulomatous infiltrate, along with numerous fungal forms in the dermis and subcutaneous tissue. The granuloma consists primarily of giant cells, macrophages, and epithelioid cells. Both the giant cells and macrophages contain fungi that have been phagocytosed.

Clinical Case 66.1 **Lacaziosis**

Elsayed and associates (*Emerg Infect Dis* 10:715–718, 2004) described a case of lacaziosis in a Canadian geologist. The patient presented to her dermatologist with a slowly growing, 1.5-cm diameter, dusky red, nontender, plaque-like lesion surrounded by keloidal scar on the posterior aspect of her right upper arm. It was located at the site of a scar from a previous excision attempt of a similar lesion 2 years earlier. The original lesion was first noticed while the patient was visiting Southeast Asia in 1996, although she did not seek medical attention until returning to Canada 1 year later. At that time, coccidioidomycosis was diagnosed, based on a history of travel to an endemic region and on the presence of oval, yeastlike organisms in histologic sections. However, *Coccidioides immitis* was never cultured from the lesion, and serologic studies for this infection remained negative. She remained well until a new lesion reappeared at the site of the scar and gradually increased in size. The patient had an extensive travel history, including prolonged stays in Mexico, Costa Rica, South America, Indonesia, and the Philippines. During her travels, she generally lived in rural camps and had extensive exposure to freshwater, soil, and underground caves. Her medical history included episodes of amoebic dysentery, dengue fever, and intestinal helminthiasis but was otherwise unremarkable. Biopsied specimens of the new lesion were obtained and submitted for pathologic and microbiologic examination. The hematoxylin and eosin–stained sections showed a diffuse, superficial and deep, granulomatous dermatitis with multinucleated giant cells. Intracellular and extracellular unstained fungal cells with thick refractile walls were seen. The fungal cells stained strongly with periodic acid–Schiff and Gomori methenamine silver stains; cells were spheric or lemon shaped, approximately 10 μm in diameter, and uniform in size. They were arranged as single cells or in short, budding chains joined by narrow, tubelike bridges. The organisms were not cultivatable. Fungal morphology was consistent with *Lacazia loboi*. The lesion was completely excised, with no subsequent recurrence. This disease should be suspected in patients with single or multiple keloidal skin lesions, particularly if they have traveled to remote areas of Latin America.

L. loboi stains intensely with both GMS and PAS stains. H&E stain reveals the thick, doubly contoured, hyaline cell wall and one or more hematoxylinophilic nuclei.

Although the lesions of lacaziosis resemble keloids on a gross level, microscopically, keloids have marked fibrosis, which is not the case with lacaziosis. Similarly, keloids lack granulomas and fungal elements. The morphology and pattern of budding of *L. loboi* are distinctive and should not be confused with that of *P. brasiliensis* (multiple buds, variable size), *B. dermatitidis,* and *Histoplasma capsulatum* var. *duboisii* (no chains of cells) or *Sporothrix schenckii* and *H. capsulatum* var. *capsulatum* (both smaller, 2 to 8 μm versus 5 to 12 μm). The latter fungi will also grow in culture, whereas *L. loboi* has never been cultured in vitro.

TREATMENT

Surgical excision of localized lesions is the optimal therapy. More widespread disease usually recurs when treated surgically and does not respond to antifungal therapy. Clofazimine has been used in these situations, but at this time medical treatment of lacaziosis is not satisfactory.

Protothecosis

Protothecosis is an infection of humans and animals caused by achlorophyllous algae of the genus *Prototheca*. These organisms belong to the same family as the green algae of the genus *Chlorella*. Two species, *P. wickerhamii* and *P. zopfii*, are known to cause infection. Three forms of human protothecosis have been described: (1) cutaneous, (2) olecranon bursitis, and (3) disseminated.

MORPHOLOGY

The protothecae are unicellular, oval or spheric organisms that reproduce asexually by internal septation and irregular cleavage within hyaline sporangia. Each sporangium contains between 2 and 20 sporangiospores arranged in a "morula" configuration (Fig. 66.5). The sporangiospores are released after rupture of the sporangium and in turn develop into mature endosporulating forms. The cells measure 3 to 30 μm in diameter and differ from those of *Chlorella* by the lack of chloroplasts. Protothecae differ from fungi by the lack of glucosamine in their cell walls. The two species of *Prototheca* that cause human disease differ from one another in size: *P. wickerhamii* measures 3 to 15 μm in diameter, whereas *P. zopfii* measures 7 to 30 μm in diameter. Both species are readily stained with PAS, GMS, and the Gridley fungus stain (see Fig. 66.5) and are gram-positive organisms.

EPIDEMIOLOGY

Prototheca spp. are ubiquitous environmental saprobes that have been isolated from grass, soil, water, and both wild and domestic animals. Human protothecosis has been reported on all continents with the exception of Antarctica.

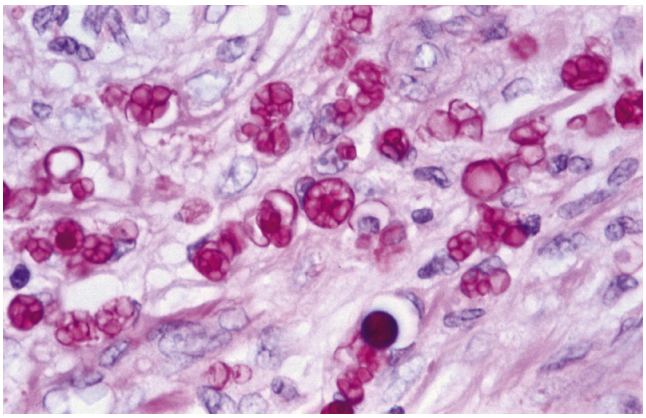

Fig. 66.5 *Prototheca wickerhamii*. Single and endosporulating algal cells that are readily demonstrated with the periodic acid–Schiff stain. A classic "morula" form is present (×1000).

CLINICAL SYNDROMES

At least half of all cases of protothecosis are simple cutaneous infections. For the most part, these infections occur in patients who are immunocompromised because of immunosuppressive therapy, acquired immunodeficiency syndrome (AIDS), malnutrition, renal or hepatic disease, cancer, or autoimmune disorders. Lesions usually arise in areas exposed to traumatic implantation and are present in an indolent fashion, such as nodules and papules, or as an eczematoid eruption.

Those individuals presenting with olecranon bursitis are usually not immunocompromised, but most report some sort of penetrating or nonpenetrating trauma to the affected elbow. Signs and symptoms of olecranon bursitis usually occur several weeks after the trauma and include mild induration of the bursa, tenderness, erythema, and production of a variable amount of serosanguineous fluid.

Disseminated protothecosis is rare but has been reported in individuals with no known immunologic deficiency. One patient with visceral protothecosis presented with abdominal pain and abnormal liver function studies that were initially considered to be the result of cholangitis. The patient had multiple peritoneal nodules that resembled metastatic cancer but were in fact manifestations of protothecosis. Another patient presented with protothecal lesions on the forehead and nose.

LABORATORY DIAGNOSIS

Prototheca spp. grow easily on a wide variety of solid media at 30° C to 37° C. Colonies are yeastlike, white, and creamy in appearance and consistency. A wet mount of the culture material may be stained with lactophenol cotton blue to reveal the characteristic sporangia and sporangiospores. The organisms are quite metabolically active and may be identified to species using one of several commercially available yeast identification panels to determine the carbohydrate assimilation profile.

On histopathologic examination of infected tissue, *Prototheca* spp. appear as sporangiospores that are wedge shaped and arranged in a radial or "morula" pattern within the

sporangium (see Fig. 66.5). The organisms are best visualized by stains used to demonstrate fungi in tissue: the GMS, PAS, and Gridley fungus procedures. In addition to the size differences noted previously, the two species of *Prototheca* differ in that *P. wickerhamii* tends to form very symmetric morula forms, whereas these forms are rare with *P. zopfii*, which exhibits more random internal divisions. The inflammatory response in protothecosis is predominantly granulomatous.

TREATMENT

Treatment of olecranon bursitis usually involves bursectomy. Repeated drainage has failed; however, drainage coupled with local instillation of amphotericin B was curative in one patient. Treatment of cutaneous protothecosis with a variety of topical and systemic antibacterial, antifungal, and antiprotozoal agents has been unsuccessful. Local excision coupled with topical amphotericin B, systemic tetracycline, and systemic ketoconazole has proven useful, despite ketoconazole-related hepatotoxicity. Disseminated protothecosis has been treated with systemic antifungal agents; both amphotericin B and ketoconazole have been used.

Pythiosis Insidiosi

Pythiosis insidiosi is a "fungal-like" infection of humans and animals caused by the plant pathogen *Pythium insidiosum*. Although described as an "aquatic fungus," this organism is not a true fungus; rather it is an oomycete that belongs to the protistal kingdom Stramenopila near the green algae and some lower plants in the evolutionary tree. In humans, pythiosis causes keratitis and orbital infections as well as a cutaneous and subcutaneous vascular process marked by rapidly developing granulomatous lesions, leading to progressive arterial insufficiency, tissue infarction, aneurysms, and occasionally death. In animals (cats, dogs, horses, cattle), it is an osseous, subcutaneous, or pulmonary infection. Dogs and horses may also present with intestinal infection.

MORPHOLOGY

P. insidiosum grows as white colonies with submerged vegetative hyphae and short aerial hyphae on solid culture medium. Because this organism is a plant pathogen, it requires water cultures containing the appropriate leaves to produce zoosporangia and zoospores in vitro. In nature, *P. insidiosum* produces biflagellate zoospores that attach and penetrate the leaves of various grasses and water lilies. The zoospores have a strong tropism for skin and hair, as well as water lily and grass leaves. If zoospores contact injured tissue, they encyst, form germ tubes that produce hyphae, and cause invasive disease.

In tissue, *P. insidiosum* exists as hyaline, pauciseptate, thin-walled hyphae or hyphal fragments that branch infrequently. The hyphal elements are 5 to 7 μm wide with nonparallel contours and superficially resemble those of Mucormycota (Fig. 66.6). Like the Mucormycetes, *P. insidiosum* is angioinvasive. In tissue, the hyphal elements of *P. insidiosum* stain with GMS but not with H&E or other fungal stains.

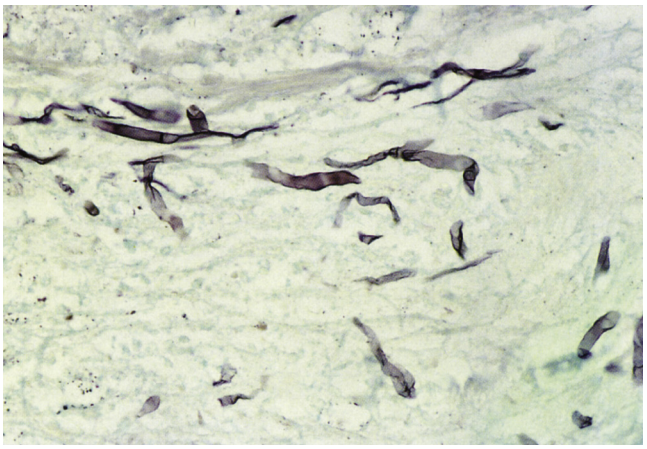

Fig. 66.6 *Pythium insidiosum* invading an arterial wall. Infrequently septate, weakly stained hyphae, and hyphal fragments resemble those of Mucormycetes (Gomori methenamine silver, ×160). (From Connor. D.H., et al., 1997. Pathology of Infectious Diseases, vol 2. Appleton & Lange, Stamford, CT.)

EPIDEMIOLOGY

P. insidiosum grows in aquatic to wet environments in tropical to subtropical regions. Infections caused by this hydrophilic pathogen have been recorded in tropical, subtropical, and some temperate areas of the world. In the Americas, pythiosis is common in tropical Central, North, and South America, with most cases reported in Brazil, Colombia, Costa Rica, the United States, and Venezuela. In the United States, infections are more prevalent in animals and humans inhabiting southern states, such as Alabama, Georgia, Florida, Louisiana, Mississippi, North Carolina, South Carolina, and Texas. However, cases of the disease have also been reported in northern states, including California, Illinois, Indiana, Kansas, New Jersey, Missouri, Tennessee, Virginia, and as far north as Wisconsin and New York. In Asia, pythiosis has been reported in Japan, India, Indonesia, the Pacific islands, South Korea, and Thailand and in nearby areas such as Australia, New Guinea, and New Zealand.

CLINICAL SYNDROMES

Human disease caused by *P. insidiosum* has occurred in patients with thalassemia who developed pythiosis insidiosi of the lower limbs (Clinical Case 66.2). The disease process was marked by progressive ischemia of the lower limbs, necrosis, thrombosis of major arteries caused by hyphal invasion, gangrene, aneurism formation, and ultimately fatal hemorrhage. Orbital pythiosis has been misdiagnosed as a mucormycotic fungal infection. Less serious forms of the infection include keratitis and localized cutaneous infections after injury.

In horses, pythiosis presents as localized inflammation and necrotic sores of the legs and lower abdomen with necrotic cores. Septic arthritis, osteitis, and tenosynovitis are also common.

Clinical Case 66.2 **Pythiosis**

Bosco and associates (*Emerg Infect Dis* 11:715–718, 2005) described a case of pythiosis in a 49-year-old Brazilian man. The patient was admitted to the hospital for the treatment of a skin lesion on his leg, initially diagnosed as cutaneous mucormycosis. The patient stated that a small pustule developed on his left leg 3 months earlier, 1 week after he fished in a lake with standing water. The pustule was initially diagnosed as bacterial cellulitis; it was treated with intravenous antibiotics, with no improvement. A biopsy of the lesion showed a suppurative granulomatous inflammation associated with several nonseptate hyphae (shown by Gomori methenamine silver stain), a finding that led to the diagnosis of mucormycosis. The treatment was changed to amphotericin B. After receiving 575 mg (cumulative dosage) of amphotericin B plus two surgical debridements, the patient showed only slight improvement; he was then transferred to another hospital. At admission, the physical examination showed a pretibial ulcer 15 cm in diameter, with an infiltrating and nodular proximal border. Serum chemistries showed azotemia, hypokalemia, and anemia as adverse effects of the amphotericin B treatment. His white blood cell count was 4200/mm^3 with 9% eosinophils. His blood glucose was normal and an human immunodeficiency virus (HIV) serology was negative. Results of a second biopsy again suggested mucormycosis. The patient received itraconazole and potassium iodide with no significant improvement. Attempts to isolate the organism in the laboratory failed. With progression of the disease, an extensive surgical debridement was considered. A course of amphotericin B was begun, and the lesion was debrided down to and including the fascia lata. A skin graft was placed and produced an acceptable recovery. Tissue was submitted for culture and molecular testing, using the generic primers for fungal internal transcribed spacer (ITS) regions of ribosomal DNA. Cultures grew colorless colonies, which on microscopic examination showed broad, branched, and sparsely septate hyphae without fruiting bodies were later identified as *Pythium insidiosum*. Use of the polymerase chain reaction, followed by sequencing of the ITS amplicons, gave results showing 100% identity with *P. insidiosum*. This case illustrates the clinical and diagnostic issues surrounding human pythiosis.

LABORATORY DIAGNOSIS

The organism may be isolated from fresh clinical material seeded onto mycologic medium, such as Sabouraud glucose agar. Demonstration of biflagellate zoospores may be accomplished using water cultures with grass or lily bait incubated at 37° C for 1 hour. Serologic assays using either the enzyme-linked immunosorbent assay (ELISA) or Western blot technologies have been useful in the early detection of the disease in humans and animals.

Histopathologic examination of infected tissue shows a necrotizing arteritis and thrombosis. Vascular invasion by sparsely septate, irregularly branched hyphae is seen (see Fig. 66.6). The acute perivascular inflammatory reaction is eventually replaced by granulomas that contain sparse hyphae and hyphal fragments. The hyphal elements of *P. insidiosum* may be surrounded by the eosinophilic Splendore-Hoeppli phenomenon. Pythiosis insidiosi in humans must be differentiated from cutaneous and subcutaneous mucormycosis, sporotrichosis, mycetoma, and neoplasms.

TREATMENT

Although potassium iodide has been used to treat cutaneous infections, medical treatment of pythiosis insidiosi is generally not effective. Surgical debridement and excision of infected tissue has been used with some success. There is some evidence that azole antifungal agents, such as fluconazole, ketoconazole, itraconazole, and miconazole, exhibit in vitro activity against this organism. A case of orbital pythiosis responded well to a combination of itraconazole and terbinafine, although this combination has not been useful in other cases of pythiosis. Immunotherapy has been useful in the treatment of equine pythiosis and has a 55% cure rate in human disease.

Lagenidiosis

Like *P. insidiosum, Lagenidium* spp. is an oomycete that causes infections in other mammals but rarely in humans. Members of the genus *Lagenidium* also cause infections in lower animals, including crabs, nematodes, and mosquito larvae, among others. In mammals, the infection presents with involvement of the skin and subsequently disseminates to blood vessels. These organisms are currently classified within the Kingdom Stramenopila, Phylum Heterokonta, Class Oomycota, Order Lagenidiales, and Family Lagenidiaceae. At least three species were recently reported: *L. giganteum,* affecting American dogs; *L. deciduum (L. vilelae),* affecting an American cat; and *L. albertoi,* causing keratitis in a Thai man.

MORPHOLOGY

In contrast to other pathogens covered in this chapter, *Lagenidium* spp. grow readily on routine fungal isolation media. On agar media, these organisms grow readily at 37° C as white to yellow submerged colonies without aerial mycelia. Similar to *P. insidiosum*, *Lagenidium* spp. produce 9- to 18-μm ribbon-like hyphae with spherical structures 20 to 45 μm in diameter. In liquid media, vesicles may be seen at the tips of the undifferentiated hyphae. The presence of sexual structures (oogonia) has not yet been described.

EPIDEMIOLOGY

At the present time, most of the cases of lagenidiosis in mammals have been reported in the United States and in the same areas as *P. insidiosum* infections: the States bordering the Gulf of Mexico as well as Arkansas, Georgia, Illinois, Indiana, Maryland, North and South Carolina, Tennessee, and Virginia, among others. *Lagenidium* completes its life cycle in aquatic environments, possibly using plants or lower animal hosts. In addition to the regions noted previously, a case of human keratitis caused by *Lagenidium* has been reported in Thailand, and lagenidiosis in a dog has been reported in Australia. It is thought that infection is initiated when zoospores present in a contaminated

environment gain entry through open skin injuries. Lagenidiosis does not appear to be transmitted from one infected host to another, and attempts to establish infection in mice have been unsuccessful.

CLINICAL SYNDROME

As with *P. insidiosum*, *Lagenidium* spp. cause infections ranging from superficial cutaneous to subcutaneous and arterial involvement. Systemic infection appears to be rare. In humans and animals, the sites of infection are cornea, gastrointestinal tract, and limbs.

LABORATORY DIAGNOSIS

The diagnosis of infection with *Lagenidium* spp. may be made by direct microscopy and culture of material taken from the site of infection. On microscopic examination of cytologic specimens stained with Giemsa, *Lagenidium* spp. appear as broad-branched hyphae. In culture on Sabouraud dextrose agar, white to yellowish, flat, glabrous colonies submerged in the agar may be seen after incubation at 37° C for 24 to 48 hours. Microscopically the hyphae are coenocytic, broad (9 to 18 μm) with large spherical structures connected by short segments of hyphae. Observation of spherical structures connected by small tubules may be used to differentiate *Lagenidium* spp. from *P. insidiosum*; however, molecular studies have often been required to make this distinction. Detection of antibodies using both ELISA and Western Blot assays have been used for both diagnosis and monitoring of response to therapy. A strong cross-reaction with *P. insidiosum* antigens has been observed with ELISA testing.

TREATMENT

In contrast to fungi, the oomycetes lack ergosterol in their cytoplasmic membranes, thus precluding efficacy with antifungal agents directed at this sterol pathway. Despite this feature, several antifungal agents have been used both clinically and in vitro with mixed results. As with pythiosis, early surgical resection is recommended as the treatment of choice.

Rhinosporidiosis

Rhinosporidiosis is a granulomatous disease of humans and animals that is characterized by the development of polyps that primarily affect the nasopharynx and the ocular conjunctiva of infected individuals. The disease is caused by *Rhinosporidium seeberi*, which is an organism with a confusing taxonomic history. This organism has been considered to be a protozoan and a fungus, and most recently it has been placed in a novel clade of aquatic protistan parasites, the Mesomycetozoa. Because *R. seeberi* will not grow in synthetic media, this reclassification was based on sequence analysis of the 18S small-subunit ribosomal deoxyribonucleic acid (rDNA) of this organism. This analysis placed *R. seeberi* among the Mesomycetozoa (formerly DRIP: *Dermocystidium*, Rosette agent, *Ichthyophonus*, and *Psorospermium*), which is a clade of fish parasites that form a branch of the evolutionary tree near the animal-fungal divergence.

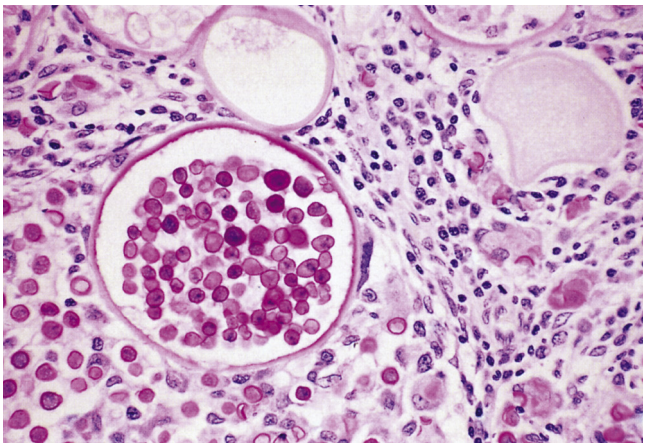

Fig. 66.7 Mature sporangium of *R. seeberi*. The walls of the mature endoconidia are carminophilic (Mayer mucicarmine, ×100). (From Connor. D.H., et al., 1997. Pathology of Infectious Diseases, vol 2. Appleton & Lange, Stamford, CT.)

MORPHOLOGY

Given that *R. seeberi* will not grow on artificial media, the morphologic descriptions are entirely based on the organism as it appears in infected tissue. Two developmental forms of *R. seeberi* are seen in tissue: the large spheric form, or sporangia, and the smaller trophocyte. The sporangium is considered the mature form of the organism and measures 100 to 350 μm in diameter. The sporangial wall is 3 to 5 μm thick and is composed of an inner hyaline layer and a thin outer eosinophilic layer. The sporangium contains numerous endoconidia arranged in a characteristic zonal formation, in which the small, flattened, uninucleate immature endoconidia (1 to 2 μm) form a crescentic mass at the periphery of one wall of the sporangium, with the larger maturing and mature endoconidia arranged sequentially toward the center. The mature endoconidia range in size from 5 to 20 μm in diameter and contain multiple refractile cytoplasmic globules. This zonal arrangement of immature, maturing, and fully mature endoconidia is diagnostic of this pathogen and distinguishes it from other spheric endosporulating organisms in the tissue (see Table 66.2).

The trophocytes are considered to develop directly from endoconidia that have been released from the sporangium. The trophocytes range in size from 10 to 100 μm in diameter and have refractile eosinophilic walls (2 to 3 μm thick), granular cytoplasm, and a round, pale nucleus with a prominent nucleolus. Ultimately, the trophocytes enlarge and transform into mature sporangia through a process of endosporulation.

The walls of both the sporangia and endoconidia stain with both GMS and PAS fungal stains. In addition, the walls of the endoconidia and the inner wall of the sporangium stain positively with the mucin stain, mucicarmine (Fig. 66.7; see Table 66.2).

EPIDEMIOLOGY

Approximately 90% of all known cases of rhinosporidiosis occur in India and Sri Lanka. The disease also occurs in the Americas, Europe, and Africa. The natural habitat and the extent of distribution of *R. seeberi* in nature are unknown. The disease occurs primarily in young men 20 to 40 years

Clinical Case 66.3 **Rhinosporidiosis**

Gaines and Clay (*South Med J* 89:65–67, 1996) described three cases of rhinosporidiosis in young boys who had not traveled outside of the United States. In fact, there was no history of their having traveled outside of the state of Georgia. All of the patients lived in rural areas in the northeast portion of the state. One had a polypoid conjunctival lesion, and the other two had nasal polyps. In each case, the lesions were excised, and histopathologic examination revealed structures morphologically typical of *Rhinosporidium seeberi*. No other treatment was given, and follow-up showed no evidence of recurrence. Despite the very rare nature of these cases, the distinctive appearance of the developmental forms of *R. seeberi* in histopathologic sections is diagnostic.

old and appears to be associated with both rural and aquatic environments. There is no evidence that rhinosporidiosis is contagious.

CLINICAL SYNDROME

Rhinosporidiosis manifests as slow-growing polypoid or tumor-like masses, usually of the nasal mucosa or conjunctiva (Clinical Case 66.3). Lesions may also be seen in the paranasal sinuses, larynx, and external genitalia. Secondary spread to surrounding skin is thought to result from autoinoculation by scratching. In most patients, the disease remains localized, and symptoms are primarily nasal obstruction and bleeding resulting from polyp formation. Limited systemic dissemination has been reported, but it is rare.

LABORATORY DIAGNOSIS

The diagnosis of rhinosporidiosis is made by histopathologic examination of the affected tissue. The distinctive appearance of the trophocytes and sporangia in routine H&E-stained sections is diagnostic. Although other organisms that occur in tissue in the form of large spherules may be mistaken for *R. seeberi*, they are usually easily differentiated from this organism by consideration of the tissue involved and the morphologic and staining characteristics of the spherule and the endoconidia (see Table 66.2).

TREATMENT

The only effective form of treatment is surgical excision of the lesions. Recurrences are common, especially in mucosal sites such as the oropharynx and paranasal sinuses, in which complete excision is often difficult to achieve.

For a case study and questions see StudentConsult.com.

Case Study and Questions

A 71-year-old farmer presented with a 1-month history of an erythematous scaling plaque and scattered papules over her left forearm. The patient denied any history of trauma. Pathology of the skin lesion revealed a moderately dense perivascular lymphocytic infiltrate and a few multinucleated giant cells containing endospores arranged in a morula-like pattern. Culture of skin tissue yielded white, pasty, smooth yeastlike colonies on potato dextrose agar.

1. What is the most likely pathogen involved in this infection?
   a. *Lacazia loboi*
   b. *Pythium insidiosum*
   c. *Prototheca wickerhamii*
   d. Chlorella *spp.*

2. How would you identify this organism?

3. How would you treat this infection?

SECTION 7

Parasitology

SECTION OUTLINE

67 Parasitic Classification, Structure, and Replication

This chapter provides an introduction to parasite classification and physiology. This brief review is intended to enhance the reader's comprehension of the interrelationships among parasitic organisms, their epidemiology and transmission of disease, the specific disease processes involved, and the possibilities for prevention and control of maladies. We have deliberately attempted to simplify the taxonomy by using it to address the major divisions involved in medical parasitology: specifically, intestinal and urogenital protozoa, blood and tissue protozoa, nematodes, trematodes, cestodes, and arthropods.

Importance of Parasites

Medical parasitology is the study of invertebrate animals capable of causing disease in humans and other animals. Although parasitic diseases are frequently considered "tropical" and thus of little importance to physicians practicing in the more temperate, developed countries of the world, it is clear that the world has become a very small place and that physicians' knowledge of parasitic diseases is essential. The global effect of parasitic infections and the number of parasite-associated deaths is staggering and must be of concern to all health care workers (Table 67.1). Increasingly tourists, missionaries, Peace Corps volunteers, and others are visiting and working for extended periods of time in exotic, remote parts of the world. Thus they are at risk for parasitic and other infections that are rare in the United States and other more developed countries. Another source of infected patients is the ever-increasing number of refugees from developing countries. Finally, the profound immunosuppression problems that accompany advances in medical therapy (e.g., organ transplantation), as well as those associated with persons infected with the human immunodeficiency virus (HIV), place a growing number of individuals at risk for developing infections caused by certain parasites. Given these considerations, clinicians and laboratory workers should be aware of the possibility of parasitic disease and should be trained in ordering, performing, and interpreting the appropriate laboratory tests to aid in the diagnosis and therapy.

Classification and Structure

The eukaryotic parasites of humans are now divided into five monophyletic lineages called supergroups, of which four include human parasites: the SAR, Excavata, Amoebozoa, and Opisthokonta (Table 67.2). Traditionally, parasite classification has taken into account the morphology of intracytoplasmic structures, such as the nucleus, the type of locomotive organelles, and the mode of reproduction (Table 67.3). More recently, the new taxonomic consensus has emerged based mainly on advances in our understanding of the biochemistry and molecular biology of lower organisms (e.g., Protists and Stramenopila). Comparisons of small subunit ribosomal ribonucleic acid (SSU rRNA) and protein sequences have made it possible to arrange organisms within groups based on evolutionary distances. Furthermore, the identification of certain organelles found in eukaryotic cells with their prokaryote origins has made it possible to organize all living organisms within a realistic and evolutionarily sound overall taxonomic scheme. The Protists and Stramenopila are animals whose life functions occur in a single cell. The members of the Animalia clade, also known as metazoans, are multicellular animals in which life functions occur in cellular structures organized as tissue and organ systems.

PROTISTS (PROTOZOA)

Protists, or protozoa, are simple microorganisms that range in size from 2 to 100 μm. Their protoplasm is enclosed by a cell membrane and contains numerous organelles, including a membrane-bound nucleus, an endoplasmic reticulum, food-storage granules, and contractile and digestive vacuoles. The nucleus contains clumped or dispersed chromatin and a central karyosome. Organs of motility vary from simple cytoplasmic extrusions or pseudopods to more complex structures, such as cilia. Reproduction is generally by binary fission, and these organisms are facultative anaerobes.

TABLE 67.1 Estimated Worldwide Disease Burden of Parasitic Infections

Infection	Estimated Number Infected	Deaths (Annual)[a]
Malaria	>500 million	2.5 million
Lymphatic filariasis	44 million	0
Leishmaniasis	4 million	62,500
Hookworm	400 million	—
Schistosomiasis	290 million	5500
Trichuriasis	400 million	0
African trypanosomiasis	20,000	6900
Ascariasis	800 million	4500
Onchocerciasis	17.7 million (270,000 blind)	0
Chagas disease	9.4 million	10,600

[a]Mortality data included where available.

Modified from Herricks, J.R., et al., 2017. The global burden of disease study 2013: what does it mean for the NTDs? PLoS Neglected Tropical Diseases 11, e0005424.

TABLE 67.2 Medically Important Parasites

Supergroup	Clade	Organisms
Excavata	Metamonada: Fornicata	*Giardia, Chilomastix*
	Metamonada: Parabasala	*Dientamoeba, Trichomonas*
	Discicristata: Heterolobosea	*Naegleria*
	Discicristata: Euglenozoa	*Leishmania, Trypanosoma*
Amoebozoa	Centramoebida	*Acanthamoeba, Balamuthia*
	Entamoebida	*Entamoeba*
SAR	Apicomplexa (sporozoans)	*Cryptosporidium, Cyclospora, Toxoplasma, Babesia, Plasmodium*
	Ciliophora	*Neobalantidium coli*
	Stramenopila	*Blastocystis* spp.
Opisthokonta	Animalia: Nematoda (roundworms)	*Trichinella, Trichuris, Ancylostoma, Necator, Ascaris, Dracunculus, Enterobius, Strongyloides*
	Animalia: Platyhelminthes	Trematodes, Cestodes
	Animalia: Arthropoda	Crustaceans, spiders, insects, true bugs

The Protists encompasses five supergroups, four of which contain parasites of human hosts: the Opisthokonta, the Amoebozoa, the Excavata, the Archaeplastida, and the SAR supergroups. The **Opisthokonta** include the fungi, the animals, and several protist clades that are key to understanding the origin of animal and fungal metabolism, and of the origin of multicellularity in animals. The **Amoebozoa** include primarily genera with amoeboid locomotion but some include ciliated stages in their life cycle. Important examples in this supergroup are the *Entamoeba, Endolimax, Iodamoeba, Acanthamoeba, Balamuthia,* and *Sappinia* genera. The **Excavata** include many parasitic lineages. Many are well known to clinical microbiologists such as *Giardia*, *Trichomonas*, trypanosomes, and *Leishmania*. The **Archaeplastida** include the green algae and the red algae and do not contain any human parasites; they will not be discussed further here. Finally, the **SAR** supergroup includes three very diverse monophyletic clades, the Stramenopiles, the Alveolata, and the Rhizaria. The Stramenopiles include *Blastocystis,* along with the brown algae and a variety of plant parasites. The Alveolata include the Ciliophora (e.g., *Balantidium*), the Dinoflagellata, and the Apicomplexa (parasitic genera historically called the Sporozoa). Important apicomplexan parasites include *Cryptosporidium, Toxoplasma, Cyclospora, Sarcocystis, Babesia,* and *Plasmodium.* The last lineage in the SAR supergroup are the Rhizaria, and it does not include any human parasites.

Metamonada: *Giardia, Enteromonas, Chilomastix, Retortamonas, Dientamoeba, Trichomonas, Pentatrichomonas*

These genera belong to the supergroup Excavata and are placed in the Metamonada clade. They are anaerobic or microaerophilic. Previously described by the obsolete term "flagellates," these organisms contain reduced mitochondria, feed by pinocytosis, and are responsible for intestinal infections, except *Trichomonas vaginalis* (a genitourinary tract parasite) and *T. tenax* (an oral parasite). *Dientamoeba* and *Trichomonas* spp. do not form cysts and *Dientamoeba* is without cilia: all other members of this group possess cilia for motility and form cysts as a means of surviving adverse environmental conditions and to aid in transmission. The number and position of the cilia vary a great deal in different species. In addition, specialized structures associated with the cilia may produce a characteristic morphologic appearance that may be useful in species identification.

Discicristata: *Naegleria, Leishmania, Trypanosoma*

These genera belong to the supergroup Excavata and are placed in the Discicristata clade. In addition to many shared traits in the arrangement of the cytoskeleton, they have mitochondria with flat or disc-shaped cristae.

Naegleria is a free-living bacteria-feeding amoeba typically found in soil or encysted in fresh water sediments and disturbed resuspended sediment. Some strains of *N. fowleri* are opportunistic parasites that cause primary amoebic meningoencephalitis.

Leishmania and *Trypanosoma* infect vertebrate hosts and are transmitted by sanguivorous (hematophagous) insect vector species (with very few exceptions). There are about 53 species of *Leishmania* with about 20 infective to humans. The promastigote infective form has a cilium and occurs in the intestinal tract of the sandfly. The amastigote form (without cilia) is found as an intracellular parasite of blood mononuclear phagocytes and in the circulatory system.

In humans, *T. brucei* species complex are responsible for "sleeping sickness" and are transmitted by the tsetse fly (*Glossina* spp.) through the salivary glands. The causative agents are *T. brucei rhodesiense* (Tbr) and *T. b. gambiense* (Tbg). *T. cruzi* causes Chagas disease and is transmitted by insects from the subfamily Triatominae (kissing bugs); the insect feces on the host skin contain infective cells that can penetrate host tissues.

Amoebozoa: *Acanthamoeba, Balamuthia, Entamoeba, Endolimax, Iodamoeba*

These genera of amoeboid protists belong to the Amoebozoa supergroup. Locomotion of amebae is accomplished by the extrusion of pseudopodia ("false feet"). Amebae are phagocytic and contain mitochondria with tubular cristae.

Acanthamoeba and *Balamuthia* amebae belong to the Centramoebida clade and are flat and elongated, with pseudopodia and characteristic subpseudopodia. They feed on bacteria by phagocytosis in the soil, forming resistant cysts for quiescence and dispersal. Both genera have species that can be opportunistic parasites in humans causing granulomatous amoebic encephalitis.

The *Entamoeba* genus contains the major human parasite *Entamoeba histolytica* and belongs to the Entamoebida clade. These species feed on gut bacteria by phagocytosis. Dispersal is by cysts that form in stools.

Endolimax and *Iodamoeba* are related to the Entamoebidae and similarly have reduced nonaerobic mitochondria, with cyst dispersal. The genus *Endolimax* is known from intestinal samples of various animals in which it feeds on bacteria

TABLE 67.3 Biologic, Morphologic, and Physiologic Characteristics of Pathogenic Parasites

Organism Class	Morphology	Reproduction	Organelles of Locomotion	Respiration	Nutrition
PROTOZOA					
Amoeba	Unicellular; cyst and trophocyte forms	Binary fission	Pseudopods	Facultative anaerobe	Assimilation by pinocytosis or phagocytosis
Ciliates	Unicellular; cyst and trophozoite forms; possibly intracellular	Binary fission or conjugation	Cilia	Facultative anaerobe	Simple diffusion or ingestion via cytostome, pinocytosis, or phagocytosis Food vacuole
Sporozoa	Unicellular, frequently intracellular; multiple forms, including trophozoites, sporozoites, cysts (oocysts), gametes	Schizogony and sporogony	None	Facultative anaerobe	Simple diffusion
HELMINTHS					
Nematodes	Multicellular; round, smooth, spindle-shaped, tubular alimentary tract; possibility of teeth or plates for attachment	Separate sexes	No single organelle; active muscular motility	Adults: usually anaerobic Larvae: possibly aerobic	Ingestion or absorption of body fluids, tissue, or digestive contents
Trematodes	Multicellular; leaf shaped with oral and ventral suckers, blind alimentary tract	Hermaphroditic (*Schistosoma* group has separate sexes)	No single organelle; muscle-directed motility	Adults: usually anaerobic	Ingestion or absorption of body fluids, tissue, or digestive contents
Cestodes	Multicellular; head with segmented body (proglottids); lack of alimentary tract; head equipped with hooks and/or suckers for attachment	Hermaphroditic	No single organelle; usually attachment to mucosa; possible muscular motility (proglottids)	Adults: usually anaerobic	Absorption of nutrients from intestine
ARTHROPODS					
Myriapoda	Elongated; many legs; distinctive head and trunk; poison claws on first segment	Separate sexes	Legs	Aerobic	Carnivore
Crustacea: Pentastomida	Wormlike; cylindric or flattened; two distinct body regions; digestive and reproductive organs; lack of circulatory and respiratory systems	Separate sexes	Muscle-directed motility	Aerobic	Ingestion of body fluids and tissue
Crustacea: Copepoda (copepods) and Decapoda (crabs and crayfish)	Hard external carapace; one pair of maxillae; five pairs of biramous legs	Separate sexes	Legs	Aerobic	Ingestion of body fluids and tissue, carnivorous
Chelicerata: Arachnida	Body divided into cephalothorax and abdomen; eight legs and venomous fangs	Separate sexes	Legs	Aerobic	Carnivore
Hexapoda: Insecta	Body: head, thorax, and abdomen; one pair of antennae; three pairs of appendages, up to two pairs of wings	Separate sexes	Legs, wings	Aerobic	Ingestion of fluids and tissues

by phagocytosis, with one species, *E. nana*, found in human samples. *Iodamoeba buetschlii* occurs in human intestines and feeds by phagocytosis on bacteria and yeasts.

Apicomplexa: *Babesia, Plasmodium, Cryptosporidium, Cyclospora, Cystoisospora, Sarcocystis, Toxoplasma*

These genera belong to the Apicomplexa clade in the SAR supergroup. Apicomplexa organisms are often referred to as **Sporozoa** or Coccidia. The Apicomplexa are a lineage of genera that are parasites of vertebrate and invertebrate animals. Key characteristics are flattened vesicles against the cell membrane at least in one life cycle stage, and an apical complex for host cell penetration. Locomotion is typically by gliding and body flexion. Nutrition is by pinocytosis.

Ciliophora: *Neobalantidium* (Formerly *Balantidium*) *coli*

Neobalantidium, previously known as *Balantidium*, belongs to the Ciliophora clade in the SAR supergroup. *Neobalantidium* occurs in several mammals in which it is an intestinal endosymbiont that is often nonpathogenic and asymptomatic. *N. coli* is the only ciliate (i.e., Ciliophora) known to be a human parasite. It forms cysts in excreted feces, and it is normally transmitted through the oral-fecal route. Excystment occurs in the intestines in which the trophozoite ingests bacteria by phagocytosis. *N. coli* contains two nuclei: a large macronucleus and a small micronucleus. Ciliate locomotion involves the coordinated movement of rows of hairlike structures, or cilia.

Stramenopila (Formerly *Chromista*): *Blastocystis*

Blastocystis belongs to the Stramenopiles in the SAR supergroup. *Blastocystis* stands alone without further classification in the Stramenopiles as a genus of anaerobic commensals or parasites of the intestinal tract of many vertebrates and some invertebrates. Cells lack morphology and appear yeastlike, although slightly amoeboid forms have been observed. The remnant of the mitochondrion retains a small number of genes, and its metabolism has received considerable attention. Trophozoites feed on intestinal fluids and a cyst form also exists. The Stramenopila was created to accommodate a number of plantlike organisms, mainly algae, that were originally chimeras between eukaryotic biflagellate hosts and symbiotic red algae that had lost their chloroplasts over evolutionary time yet still retain elements of their red algae ancestry. Although previously shuffled between the Fungi and Protozoa, *Blastocystis* spp. is now placed within the Stramenopila based on analysis of 18S rRNA and other molecular evidence.

ANIMALIA (METAZOA)

Within the supergroup Opisthokonta, the parasites of human interest fall under the Metazoa in the Animalia clade. The Animalia clade includes all eukaryotic organisms that are not Protozoa, Stramenopila, or Fungi. This chapter discusses two broad groups of organisms of major importance: the helminths ("worms") and the arthropods (crabs, insects, ticks, and others).

Helminths

The helminths are complex multicellular organisms that are elongated and bilaterally symmetric. They are considerably larger than the protozoan parasites and generally are macroscopic, ranging in size from less than 1 mm to 1 m or larger. The external surface of some worms is covered with a protective cuticle, which is acellular and may be smooth or possess ridges, spines, or tubercles. The protective covering of flatworms is known as a **tegument.** Often helminths possess elaborate attachment structures, such as hooks, suckers, teeth, or plates. These structures are usually located anteriorly and may be useful in classifying and identifying the organisms (see Table 67.3). Helminths typically have primitive nervous and excretory systems. Some have alimentary tracts; however, none have a circulatory system. The helminths of human interest are separated into two groups of parasites, the Nematoda and the Platyhelminthes.

Nematoda. The Nematoda clade consists of the roundworms, which have cylindric bodies. The sexes of roundworms are separate, and these organisms have a complete digestive system. The Nematoda may be intestinal parasites or may infect the blood and tissue.

Platyhelminthes. The Platyhelminthes clade consists of the flatworms, which have flattened bodies that are leaflike or resemble ribbon segments. Platyhelminthes can be further divided into trematodes and cestodes.

Trematodes, or flukes, have leaf-shaped bodies. Most are hermaphroditic, with male and female sex organs in a single body. Their digestive systems are incomplete and only have saclike tubes. Their life cycle is complex; snails serve as first intermediate hosts, and other aquatic animals or plants serve as second intermediate hosts.

Cestodes, or tapeworms, have bodies composed of ribbons of proglottids, or segments. All are hermaphroditic, and all lack digestive systems, with nutrition absorbed through the body walls. The life cycles of some cestodes are simple and direct, whereas those of others are complex and require one or more intermediate hosts.

Arthropoda

The Arthropoda is the largest group of animals in the Animalia clade. Arthropods are complex multicellular organisms that may be involved directly in causing invasive or superficial (infestation) disease processes or indirectly as intermediate hosts and vectors of many infectious agents, including protozoan and helminthic parasites (Table 67.4). In addition, envenomization by biting and stinging arthropods can result in adverse reactions in humans that range from local allergic and hypersensitivity reactions to severe anaphylactic shock and death. There are four major categories of arthropods of interest in human medicine.

Myriapoda. The Myriapoda consist of two classes of medical importance: Chilopoda (centipedes) and Diplopoda (millipedes). Some centipedes can have venomous bites. Millipedes produce toxic defensive secretions.

TABLE 67.4 Transmission and Distribution of Pathogenic Parasites

Organism	Infective Form	Mechanism of Spread	Distribution
INTESTINAL PROTOZOA			
Entamoeba histolytica	Cyst/trophozoite	Indirect (fecal-oral) Direct (venereal)	Worldwide
Giardia duodenalis/intestinalis	Cyst	Fecal-oral route	Worldwide
Dientamoeba fragilis	Trophozoite ? Cyst	Fecal-oral route	Worldwide
Neobalantidium coli	Cyst	Fecal-oral route	Worldwide
Cystoisospora belli	Oocyst	Fecal-oral route	Worldwide
Cryptosporidium spp.	Oocyst	Fecal-oral route	Worldwide
Cyclospora spp.	Oocyst	Fecal-oral route	Worldwide
UROGENITAL PROTOZOA			
Trichomonas vaginalis	Trophozoite	Direct (venereal) route	Worldwide
BLOOD AND TISSUE PROTOZOA			
Naegleria and Acanthamoeba spp.	Cyst/trophozoite	Direct inoculation, inhalation	Worldwide
Plasmodium spp.	Sporozoite	*Anopheles* mosquito	Tropical and subtropical areas
Babesia spp.	Pyriform body	*Ixodes* tick	North America, Europe
Toxoplasma gondii	Oocysts and tissue cysts	Fecal-oral route, carnivorism	Worldwide
Leishmania spp.	Promastigote	*Phlebotomus* sandfly	Tropical and subtropical areas
Trypanosoma cruzi	Trypomastigote	Reduviid bug	North, Central, and South America
T. brucei	Trypomastigote	Tsetse fly	Africa
NEMATODES			
Enterobius vermicularis	Egg	Fecal-oral route	Worldwide
Ascaris lumbricoides	Egg	Fecal-oral route	Areas of poor sanitation
Toxocara spp.	Egg	Fecal-oral route	Worldwide
Trichuris trichiura	Egg	Fecal-oral route	Worldwide
Ancylostoma duodenale	Filariform larva	Direct skin penetration from contaminated soil	Tropical and subtropical areas
Necator americanus	Filariform larva	Direct skin penetration, autoinfection	Tropical and subtropical areas
Strongyloides stercoralis	Filariform larva	Direct skin penetration, autoinfection	Tropical and subtropical areas
Trichinella spiralis	Encysted larva in tissue	Carnivorism	Worldwide
Wuchereria bancrofti	Third-stage larva	Mosquito	Tropical and subtropical areas
Brugia malayi	Third-stage larva	Mosquito	Tropical and subtropical areas
Loa loa	Filariform larva	*Chrysops* fly	Africa
Mansonella spp.	Third-stage larva	Biting midges or blackflies	Africa, Central and South America
Onchocerca volvulus	Third-stage larva	*Simulium* blackfly	Africa, Central and South America
Dracunculus medinensis	Third-stage larva	Ingestion of infected *Cyclops*	Africa, Asia
Dirofilaria immitis	Third-stage larva	Mosquito	Japan, Australia, United States
TREMATODES			
Fasciolopsis buski	Metacercaria	Ingestion of metacercaria encysted on aquatic plants	China, Southeast Asia, India
Fasciola hepatica	Metacercaria	Metacercaria on water plants	Worldwide
Opisthorchis (Clonorchis) sinensis	Metacercaria	Metacercaria encysted in freshwater fish	China, Japan, Korea, Vietnam
Paragonimus westermani	Metacercaria	Metacercaria encysted in freshwater crustaceans	Asia, Africa, India, Latin America
Schistosoma spp.	Cercaria	Direct penetration of skin by free-swimming cercaria	Africa, Asia, India, Latin America

TABLE 67.4 Transmission and Distribution of Pathogenic Parasites—cont'd

Organism	Infective Form	Mechanism of Spread	Distribution
CESTODES			
Taenia solium	Cysticercus, embryonated egg or proglottid	Ingestion of infected pork; ingestion of egg (cysticercosis)	Pork-eating countries: Africa, Southeast Asia, China, Latin America
T. saginata	Cysticercus	Ingestion of cysticercus in meat	Worldwide
Diphyllobothrium latum	Sparganum	Ingestion of sparganum in fish	Worldwide
Echinococcus granulosus	Embryonated egg	Ingestion of eggs from infected canines	Sheep-raising countries: Europe, Asia, Africa, Australia, United States
E. multilocularis	Embryonated egg	Ingestion of eggs from infected animals, fecal-oral route	Canada, Northern United States, Central Europe
Hymenolepis nana	Embryonated egg	Ingestion of eggs, fecal-oral route	Worldwide
H. diminuta	Cysticercus	Ingestion of infected beetle larvae in contaminated grain products	Worldwide
Dipylidium caninum	Cysticercoid	Ingestion of infected fleas	Worldwide

Crustacea. The crustaceans include familiar aquatic forms, such as crabs, crayfish, shrimp, copepods, and pentastomids. Several are involved as intermediate hosts in life cycles of various intestinal or blood and tissue helminths. The pentastomids, or tongue worms, are bloodsucking endoparasites of reptiles, birds, and mammals. Adult pentastomids are white and cylindric or flattened parasites that possess two distinct body regions: an anterior cephalothorax and an abdomen. Humans may serve as intermediate hosts for these parasites.

Chelicerata. Within the Chelicerata only the class Arachnida contains medically important species, such as mites, ticks, spiders, and scorpions. Unlike insects, these animals have no wings or antennae, and adults have four pairs of legs, as opposed to three pairs for insects. Of medical importance are those serving as vectors for microbial diseases (mites and ticks) or as venomous animals that bite (spiders) or sting (scorpions).

Hexapoda. The Hexapoda of medical importance are contained in the class Insecta and consist of familiar aquatic and terrestrial forms, such as mosquitoes, flies, midges, fleas, lice, bugs, wasps, and ants. Wings and antennae are present, and adult forms have three pairs of legs. Of medical importance are the many insects that serve as vectors for microbial diseases (mosquitoes, fleas, lice, and bugs) or as venomous animals that sting (bees, wasps, and ants).

Physiology and Replication

PROTOZOA

The nutritional requirements of the parasitic protozoa are generally simple and require the assimilation of organic nutrients. The amebae and certain other protozoa accomplish this assimilation by the rather primitive process of pinocytosis or phagocytosis of soluble or particulate matter (see Table 67.3). The engulfed material is enclosed in digestive vacuoles. The Metamonada and ciliates generally ingest food at a definitive site or structure, the peristome or cytostome. Other unicellular parasites assimilate nutrients by simple diffusion. The ingested food material may be retained in intracytoplasmic granules or in vacuoles. The undigested particles and waste may be eliminated from the cell by extrusion of the material at the cell surface. Respiration in most parasitic protozoa is accomplished by facultatively anaerobic processes.

To ensure survival under harsh or unfavorable environmental conditions, many parasitic protozoa develop into a cyst form that is less metabolically active. This cyst is surrounded by a thick external cell wall capable of protecting the organism from otherwise lethal physical and chemical insults. The cyst form is an integral part of the life cycle of many protozoan parasites and facilitates the transmission of the organism from host to host in the external environment (see Table 67.4). Parasites that cannot form cysts must rely on direct transmission from host to host or require an arthropod vector to complete their life cycles (see Table 67.4).

In addition to cyst formation, many protozoan parasites have developed elaborate immunoevasive mechanisms that allow them to respond to attack by the host immune system by continuously changing their surface antigens, ensuring continued survival within the host. Reproduction among the protozoa is generally by simple binary fission (merogony), although the life cycle of some protozoa, such as the sporozoans, includes cycles of multiple fission (schizogony) alternating with a period of sexual reproduction (sporogony or gametogony).

ANIMALIA (METAZOA)

Helminths

The nutritional requirements of helminthic parasites are met by active ingestion of host tissue, fluids, or both, with resultant tissue destruction, or by more passive absorption

of nutrients from the surrounding fluids and intestinal contents (see Table 67.3). The muscular motility of many helminths expends considerable energy, and the worms rapidly metabolize carbohydrates. Nutrients are stored in the form of glycogen, the content of which is high in most helminths. Similar to respiration in protozoa, respiration in helminths is primarily anaerobic, although the larval forms may require oxygen.

A significant proportion of the energy requirement of helminths is dedicated to supporting the reproductive process. Many worms are quite prolific, producing as many as 200,000 offspring each day. In general, helminthic parasites lay eggs (oviparous), although a few species may bear live young (viviparous). The resulting larvae are always morphologically distinct from the adult parasites and must undergo several developmental stages or molts before attaining adulthood.

The major protective barrier for most helminths is the tough external layer (cuticle or tegument). Worms may also secrete enzymes that destroy host cells and neutralize immunologic and cellular defense mechanisms. Similar to protozoan parasites, some helminths possess the ability to alter the antigenic properties of their external surfaces and thus evade the host immune response. This is accomplished in part by incorporating host antigens into their external cuticular layer. In this way the worm avoids immunologic recognition, and in some diseases (e.g., schistosomiasis), it allows the parasite to survive within the host for decades.

Arthropods

Arthropods have segmented bodies, paired jointed appendages, and well-developed digestive and nervous systems. Sexes are separate. Respiration by aquatic forms is via gills and by terrestrial forms is via tubular body structures. All have a hard chitin covering as an exoskeleton.

Summary

Physician awareness of parasitic diseases is undoubtedly more critical now than at any time in the history of medical practice. Physicians today must be prepared to answer questions from patients about protection from malaria and the risks of drinking water and eating fresh fruits and vegetables in remote areas where they may be traveling. With this knowledge of parasitic diseases, the physician also can evaluate signs, symptoms, and incubation periods in returning travelers, make a diagnosis, and begin treatment for a patient with a possible parasitic disease. The risks of parasitic diseases in immunosuppressed individuals and those with acquired immunodeficiency syndrome (AIDS) must also be understood and taken into account.

Proper education regarding parasitic diseases in medical curricula cannot be overemphasized as a requirement for physicians whose practice includes travelers to foreign countries and refugee populations. Many of the important parasites responsible for human diseases are transmitted by arthropod vectors or are acquired by the consumption of contaminated food or water. The various modes of transmission and distribution of parasitic diseases are presented in appropriate detail in the following chapters; however, the data in Table 67.4 are provided as an outline.

Questions

1. How do protozoa adapt to harsh environmental conditions?
2. Which morphologic form is important in the transmission of protozoa from host to host?
3. How do helminths, such as schistosomes, avoid the host immune response?
4. How do arthropods cause human disease?

68 Pathogenesis of Parasitic Diseases

Given the wide diversity that exists among human parasites, it is not surprising that the pathogenesis of protozoan and helminthic disease is highly variable. Although the various human parasites exhibit a wide range of direct pathogenic mechanisms, in most instances, the organisms themselves are not highly virulent, are unable to replicate within the host, or have both characteristics. Thus the severity of illness caused by many parasites is related to the infecting dose and the number of organisms acquired over time. Unlike many bacterial and viral infections, parasitic infections are often chronic, lasting months to years. Repeated exposures result in an ever-increasing parasite burden. When infection with a particular organism is associated with a strong immune response, there is undoubtedly a considerable immunopathologic contribution to the disease manifestations attributed to the infection.

Important factors to consider when discussing parasite pathogenicity are listed in Box 68.1. Parasites are almost always exogenous to the human host and thus must enter the body through ingestion or direct penetration of anatomic barriers. Inoculum size and duration of exposure greatly influence the disease-causing potential of an organism; likewise, the route of exposure is critical for most organisms. For example, pathogenic strains of *Entamoeba histolytica* are unlikely to cause disease on exposure to intact skin but may cause severe dysentery after oral ingestion. Many parasites have active, self-directed means of invading the human host. Once they have invaded, parasites attach to specific host cells or organs, avoid immunodetection, replicate (most protozoa and some helminths), produce toxic substances that destroy tissue, and cause disease secondary to the host's own immunologic response (see Box 68.1). In addition, some parasites physically obstruct and damage organs and tissues because of their size alone. This chapter discusses factors that are important for parasite pathogenicity and provides examples of organisms and disease processes related to each factor.

Exposure and Entry

Although many infectious diseases are caused by **endogenous** organisms that are part of the normal flora of the human host, this is not the case with most diseases caused by protozoan and helminthic parasites. These organisms are virtually always acquired from an **exogenous** source and as such have evolved numerous ways to enter the body of the human host. The most common modes of entry are oral ingestion or direct penetration through the skin or other surfaces (Table 68.1). Transmission of parasitic diseases is frequently facilitated by environmental contamination with human and animal wastes. This is most applicable to diseases transmitted by the fecal-oral route but also applies to helminthic infections, such as hookworm disease and strongyloidiasis, which rely on larval penetration of the skin.

Many parasitic diseases are acquired via the bites of **arthropod** vectors. Transmission of disease in this manner is extraordinarily effective, as evidenced by the widespread distribution of diseases such as malaria, trypanosomiasis, and filariasis. Examples of parasites and their ports of entry are listed in Table 68.1. This compilation should not be considered exhaustive; rather, the list provides examples of some of the more common parasites and the means by which they enter the human body.

Additional factors that determine the outcome of the interaction between parasite and host are route of **exposure** and **inoculum** size. Most human parasites have a limited range of organs or tissues in which they can replicate or survive. For example, simple skin contact with most intestinal protozoa does not result in disease; rather, the organisms must be ingested for the disease process to be initiated. Also, a minimum number of organisms is required to establish infection. Although some parasitic diseases may be acquired by the ingestion or inoculation of only a few organisms, a sizable inoculum is usually required. Whereas an individual may acquire malaria by a single bite of an infected female mosquito, large inocula are usually necessary to produce diseases such as amebiasis in humans.

BOX 68.1 Factors Associated with Parasite Pathogenicity

Infective dose and exposure
Penetration of anatomic barriers
Attachment
Replication
Cell and tissue damage
Disruption, evasion, and inactivation of host defenses

TABLE 68.1 Parasite Ports of Entry

Route	Examples
Ingestion	*Giardia* spp., *Entamoeba histolytica*, *Cryptosporidium* spp., cestodes, nematodes
Direct penetration	
Arthropod bite	Malaria, *Babesia* spp., filaria, *Leishmania* spp., trypanosomes
Transplacental penetration	*Toxoplasma gondii*
Organism-directed penetration	Hookworm, *Strongyloides* spp., schistosomes

TABLE 68.2 Examples of Parasitic Adherence Mechanisms

Organism	Disease	Target	Mechanism of Attachment and Receptor
Plasmodium vivax	Malaria	Red blood cell	Merozoite (non–complement-mediated attachment), Duffy antigen
P. falciparum	Malaria	Red blood cell	Merozoite and glycophorin A and B
Babesia spp.	Babesiosis	Red blood cell	Complement-mediated C3b receptor
Giardia duodenalis	Diarrhea	Duodenal and jejunal epithelium	Mechanical suction; microtubules and lectin-mediated attachment
Entamoeba histolytica	Dysentery	Colonic epithelium	Lectin and *N*-acetylglucosamine conjugates
Trypanosoma cruzi	Chagas disease	Fibroblast	Penetrin, fibronectin, and fibronectin receptor
Leishmania major	Leishmaniasis	Macrophage	Adsorbed C3bi and CR3
L. mexicana	Leishmaniasis	Macrophage	Surface glycoprotein (gp63) and CR2
Necator americanus Ancylostoma duodenale	Hookworm	Intestinal epithelium	Mechanical and biting mouthparts

Adherence and Replication

Most infections are initiated by the attachment of the organism to host tissues, followed by replication to establish colonization. The life cycle of a parasite is based on species and **tissue tropisms,** which determine the organs or tissues of the host in which a parasite can survive. The attachment of the parasite to host cells or tissue can be relatively nonspecific, can be mediated by mechanical or biting mouthparts, or can result from the interaction between structures on the parasite surface known as **adhesins** and specific glycoprotein or glycolipid receptors found on some cell types but not on others. Specific surface structures that facilitate parasite adhesion include surface **glycoproteins,** such as glycophorin A and B, complement receptors, adsorbed components of the complement cascade, fibronectin, and *N*-acetylglucosamine conjugates. Examples of some of the adherence mechanisms identified in human parasites are listed in Table 68.2.

E. histolytica is a good model for the importance of **adhesins** in virulence. The pathogenesis of invasive amebiasis requires adherence of amebae to the colonic mucosal layer, parasite attachment to and lysis of colonic epithelium and acute inflammatory cells, and resistance of the amebic trophozoites to host humoral and cell-mediated immune defense mechanisms. Amebic adherence to colonic mucins, epithelial cells, and leukocytes is mediated by a surface lectin inhibitable by galactose (gal) or *N*-acetyl-D-galactosamine (GalNAc). Binding of the galactose-inhibitable adherence lectin to carbohydrates on the host cell surface is required for *E. histolytica* trophozoites to exert their cytolytic activity. The presence of the galactose-inhibitable adherence lectin is one feature that distinguishes pathogenic from nonpathogenic strains of *E. histolytica*.

Various attachment mechanisms have been associated with specific infections. For example, the **Duffy blood group antigen** acts as an attachment site for *Plasmodium vivax*. Red blood cells from most West Africans, in contrast to those from Europeans, lack the Duffy antigen. Accordingly, malaria resulting from *P. vivax* is almost unknown in West Africa. Notably, however, clinical vivax malaria has been reported in Duffy-negative individuals in Madagascar. The parasite and host molecules that enable this Duffy-independent invasion of human red blood cells have not yet been identified.

The physical structures of parasites may act with adhesion molecules to promote attachment to host cells. *Giardia duodenalis* (formerly *lamblia*) is a protozoan parasite that uses a ventral disk to attach to the intestinal epithelium by a clasping or suction-like mechanism. Contractile and/or suction forces generated by the ventral disk, which is a unique microtubule-based structure, may play a dominant role in attachment. Molecular binding and/or adhesion likely serves as a secondary mechanism that aids in the recognition of more suitable orientation of the parasite cell for attachment. This lectin interaction provides for correct orientation during attachment and may contribute to cell specificity.

After attachment to the specific cell or tissue type, the parasite may undergo replication as the next step in establishing infection. Most protozoan parasites replicate intracellularly or extracellularly in the human host, whereas replication is generally not observed with the helminths capable of establishing human infection.

Temperature also may play an important role in the ability of parasites to infect a host and cause disease. This is well illustrated by the *Leishmania* species. *L. donovani* replicates well at 37° C and causes visceral leishmaniasis, involving the bone marrow, liver, and spleen. In contrast, *L. tropica* grows well at 25° C to 30° C but poorly at 37° C and causes an infection of the skin without involvement of deeper organs.

Cell and Tissue Damage

Although some microorganisms may cause disease by localized multiplication and elaboration of potent microbial **toxins,** most organisms initiate the disease process by invading normally sterile tissue, with subsequent replication and destruction. Parasitic protozoa and helminths are generally not known to produce toxins with potencies comparable to those of classic bacterial toxins, such as anthrax toxin and botulinum toxin; however, parasitic disease

can be established by the elaboration of toxic products, mechanical tissue damage, and immunopathologic reactions (Table 68.3).

Numerous authors have suggested that toxic products elaborated by parasitic protozoa are responsible for at least some aspects of pathology (see Table 68.3). **Proteases** and **phospholipases** may be secreted and are released on the destruction of the parasites. These enzymes can cause host cell destruction, inflammatory responses, and gross tissue pathology. For example, the intestinal parasite *E. histolytica* produces proteinases that can degrade epithelial basement membrane and cell-anchoring proteins, disrupting epithelial cell layers. Furthermore, the amebae produce phospholipases and an ionophore-like protein that lyse the responding host neutrophils, resulting in the release of neutrophil constituents that are toxic to host tissues. The expression of certain proteinases increases relative to the virulence of the strain of *E. histolytica*. In contrast to the protozoan parasites, many of the pathogenic consequences of helminthic infections are related to the size, movement, and longevity of the parasites. The host is exposed to long-term damage and immune stimulation, as well as the sheer physical consequences of being inhabited by large foreign bodies. The most obvious forms of direct damage from helminthic parasites are those resulting from mechanical blockage of internal organs or from the effects of pressure exerted by growing parasites. Large adult *Ascaris* organisms can physically block the intestine and the bile ducts, and blockage of lymph flow, leading to elephantiasis, is associated with the presence of adult *Wuchereria* organisms in the lymphatic system. Some neurologic manifestations of cysticercosis are caused by the pressure exerted by the slowly expanding larval cysts of *Taenia solium* on the central nervous system (CNS) and eyes. Migration of helminths (usually larval forms) through body tissues, such as the skin, lungs, liver, intestines, eyes, and CNS, can damage the tissues directly and initiate hypersensitivity reactions.

As with many infectious agents, the manifestations of parasitic disease are caused not only by the mechanical or chemical tissue damage produced by the parasite, but they are also caused by the host responses to the presence of the parasite. Cellular hypersensitivity is observed in protozoan and helminthic disease (Table 68.4). During a parasitic infection, host cell products such as cytokines and lymphokines are released from activated cells. These mediators influence the action of other cells and may contribute directly to the pathogenesis of parasite infections. **Immunopathologic reactions** range from acute anaphylactic reactions to cell-mediated delayed hypersensitivity reactions (see Table 68.4). The fact that many parasites are long-lived means that many inflammatory changes become irreversible, producing functional changes in tissues. Examples include hyperplasia of the bile ducts secondary to the presence of liver flukes and extensive fibrosis leading to genitourinary and hepatic dysfunction in chronic schistosomiasis. Migration of larval helminths through tissues, such as the skin, lungs, liver, intestine, CNS, and eyes, produces immune-mediated inflammatory changes in these structures. Finally, chronic inflammatory changes around parasites such as *Clonorchis* (*Opisthorchis*) *sinensis* and *Schistosoma haematobium* have been linked to the induction of carcinomatous changes in the bile ducts and the bladder, respectively.

TABLE 68.3 Some Pathologic Mechanisms in Parasitic Diseases

Mechanism	Examples
TOXIC PARASITE PRODUCTS	
Hydrolytic enzymes, proteinases, collagenase, elastase	Schistosomes (cercariae), *Strongyloides* spp., hookworm, *Entamoeba histolytica*, African trypanosomes, *Plasmodium falciparum*
Amebic ionophore	*E. histolytica*
Endotoxins	African trypanosomes, *P. falciparum*
Indole catabolites	Trypanosomes
MECHANICAL TISSUE DAMAGE	
Blockage of internal organs	*Ascaris* spp., tapeworms, schistosomes, filaria
Pressure atrophy	*Echinococcus* spp., *Cysticercus* spp.
Migration through tissue	Helminthic larvae
IMMUNOPATHOLOGY	
Hypersensitivity	See Table 68.4
Autoimmunity	See Table 68.4
Protein-losing enteropathies	Hookworm, tapeworm, *Giardia* spp., *Strongyloides* spp.
Metaplastic changes	*Opisthorchis* spp. (liver flukes), schistosomes

TABLE 68.4 Immunopathologic Reactions to Parasitic Disease

Reaction	Mechanism	Result	Example
Type 1: anaphylactic	Antigen + immunoglobulin E antibody attached to most cells: histamine release	Anaphylactic shock; bronchospasm; local inflammation	Helminth infection, African trypanosomiasis
Type 2: cytotoxic	Antibody + antigen on cell surface: complement activation or antibody-dependent cellular cytotoxicity	Lysis of cell-bearing microbial antigens	*Trypanosoma cruzi* infection
Type 3: immune complex	Antibody + extracellular antigen complex	Inflammation and tissue damage; complex deposition in glomeruli, joints, skin vessels, brain; glomerulonephritis, and vasculitis	Malaria, schistosomiasis, trypanosomiasis
Type 4: cell-mediated (delayed)	Sensitized T-cell reaction with antigen, liberation of lymphokines, triggered cytotoxicity	Inflammation, mononuclear accumulation, macrophage activation Tissue damage	Leishmaniasis, schistosomiasis, trypanosomiasis

Modified from Mims, C, et al., 1995. Mims Pathogenesis of Infectious Disease, fourth ed. Academic, London.

TABLE 68.5 Microbial Interference with or Avoidance of Immune Defenses

Type of Interference or Avoidance	Mechanism	Examples
Antigenic variation	Variation of surface antigens within the host	African trypanosomes, *Plasmodium* spp., *Babesia* spp., *Giardia* spp.
Molecular mimicry	Microbial antigens mimicking host antigens, leading to poor antibody response	*Plasmodium* spp., trypanosomes, schistosomes
Concealment of antigenic site (masking)	Acquisition of coating of host molecules	Hydatid cyst, filaria, schistosomes, trypanosomes
Intracellular location	Failure to display microbial antigen on host cell surface	*Plasmodium* spp. (red blood cells), trypanosomes, *Leishmania* spp., *Toxoplasma* spp.
	Inhibition of phagolysosomal fusion	*Toxoplasma* spp.
	Escape from phagosome into cytoplasm, with subsequent replication	*Leishmania* spp., *Trypanosoma cruzi*
Immunosuppression	Suppression of parasite-specific B-cell and T-cell responses	Trypanosomes, *Plasmodium* spp.
	Degradation of immunoglobulins	Schistosomes

Disruption, Evasion, and Inactivation of Host Defenses

Although the processes of cell and tissue destruction are often sufficient to initiate clinical disease, the parasite must be able to evade the host's immune defense system for the disease process to be maintained. Similar to other organisms, parasites elicit humoral and cell-mediated immune responses; however, parasites are particularly adept at interfering with or avoiding these defense mechanisms (Table 68.5).

Organisms can shift antigenic expression, such as that observed with the African trypanosomes. Rapid variation of expression of antigens in the glycocalyces of these organisms occurs each time the host exhibits a new humoral response. Similar changes have been observed with *Plasmodium*, *Babesia*, and *Giardia* species. Some organisms may produce antigens that mimic host antigens **(mimicry)** or acquire host molecules that conceal the antigenic site **(masking)**, preventing immune recognition by the host.

Many protozoan parasites evade the immune response by assuming an intracellular location in the host. The organisms that reside in macrophages have developed a variety of mechanisms to avoid intracellular killing. These include prevention of phagolysosome fusion, resistance to killing after exposure to lysosomal enzymes, and escape of phagocytosed cells from the phagosome into the cytoplasm, with subsequent replication of the organism (see Table 68.5).

Immunosuppression of the host is often observed during parasitic infections. The immunosuppression may be parasite specific or generalized, involving a response to various nonparasite and parasite antigens. Proposed mechanisms include antigen overload, antigenic competition, induction of suppressor cells, and production of lymphocyte-specific suppressor factors. Certain helminths, such as *S. mansoni*, may also produce proteinases that can degrade immunoglobulins.

Finally, it is becoming apparent that the host microbiome may play a distinct role in the pathogenesis of parasitic infections. This has been especially true for the gut microbiome and enteric parasites such as *E. histolytica*, *Giardia* spp., and *Cryptosporidium* spp.

Questions

1. What are the most common modes of entry of parasites into the human host?

2. Name two factors that determine the outcome of the interaction between parasite and host.

3. Give an example of an adhesin that is directly related to the virulence of a parasite.

4. Name three pathologic mechanisms thought to be important in parasitic diseases.

5. How can parasites resist immunologic clearance? Give at least one example of each mechanism.

6. Name the four types of immunopathologic reactions that occur in parasitic diseases and provide examples of each.

69 Role of Parasites in Disease

A summary of the parasites (protozoan and helminths) most commonly associated with human disease is presented in this chapter. Although many parasites are associated with a single-organ system (e.g., gastrointestinal tract) and therefore cause a disease process involving that system, some of the most dramatic manifestations of parasitic disease occur when the parasite leaves its "normal" location in the human body. Also, several different parasites may produce a similar disease syndrome. The management of a specific parasitic infection may differ tremendously depending on the etiologic agent, and many antiparasitic treatment regimens are quite toxic. So, to guide both diagnostic and therapeutic efforts, it is useful to generate a differential diagnosis that includes the most likely parasites.

The development and prognosis of a parasitic infection often depend on factors aside from the innate virulence of the organism. In determining the possibility of a parasitic infection, the meaning of any microbiologic data and the necessity to treat and with what agent, one must take into account numerous factors such as exposure history (e.g., travel to an endemic area), the potential infectious dose and/or organism burden, the use of prophylaxis (e.g., antimalarial prophylaxis), and the immunologic status of the host. The presentation of a given parasitic infection may be quite different in a nonimmune traveler to an endemic region versus a semi-immune resident of that same region. The treatment and prevention strategies will be different as well.

This chapter provides a very broad listing of the various parasitic agents commonly associated with infections at specific body sites and/or specific clinical manifestations (Table 69.1). This information is meant to be used in conjunction with Table 70.1 as an aid in establishing a differential diagnosis and selecting the most likely clinical specimens that will help establish a specific etiologic diagnosis. Other factors that may be important in determining the relative frequency with which specific parasites cause disease (e.g., travel and exposure history, specific clinical presentations) are covered in the individual chapters in this text or in the more comprehensive infectious disease texts cited in this and other chapters.

TABLE 69.1 Summary of Parasites Associated with Human Disease

System Affected and Disease	Pathogens
BLOOD	
Malaria	*Plasmodium falciparum, P. knowlesi, P. malariae, P. ovale, P. vivax*
Babesiosis	*Babesia* spp.
Filariasis	*Wuchereria bancrofti, Brugia malayi, Mansonella* spp., *Loa loa*
BONE MARROW	
Leishmaniasis	*Leishmania donovani, L. tropica*
CENTRAL NERVOUS SYSTEM	
Meningoencephalitis	*Naegleria fowleri, Trypanosoma brucei gambiense, T. b. rhodesiense, T. cruzi, Toxoplasma gondii*
Granulomatous encephalitis	*Acanthamoeba* spp., *Balamuthia mandrillaris*
Mass lesion Brain abscess	*T. gondii, Taenia solium, Schistosoma japonicum, Acanthamoeba* spp., *B. mandrillaris*
Eosinophilic meningitis Cerebral malaria	*Angiostrongylus cantonensis, Toxocara* spp., *Baylisascaris* (neural larva migrans), *P. falciparum*
Cerebral paragonimiasis	*Paragonimus westermani*
EYE	
Keratitis	*Acanthamoeba spp., Onchocerca volvulus*
Chorioretinitis Conjunctivitis	*T. gondii, O. volvulus, L. loa*
Ocular cysticercosis (mass lesion)	*T. solium*
Toxocariasis	*Toxocara* spp. (ocular larva migrans; mimics retinoblastoma)

70 Laboratory Diagnosis of Parasitic Disease

The diagnosis of parasitic infections may be very difficult, particularly in the nonendemic setting. The clinical manifestations of parasitic diseases are seldom specific enough to raise the possibility of these processes in the mind of the clinician, and routine laboratory tests are seldom helpful. Although peripheral eosinophilia is widely recognized as a useful indicator of parasitic disease, this phenomenon is characteristic only of helminthic infection and even in these cases is frequently absent. Thus the physician must maintain a heightened index of suspicion and must rely on detailed travel, food intake, transfusion, and socioeconomic history to raise the possibility of parasitic disease. Proper diagnosis requires that (1) the physician consider the possibility of parasitic infection and communicates the possibility to the diagnostic laboratory, (2) appropriate specimens are obtained and transported to the laboratory in a timely fashion, (3) the laboratory competently performs the appropriate procedures for the recovery and identification of the etiologic agent, (4) the laboratory results are effectively communicated to the physician, and (5) the results are correctly interpreted by the physician and applied to the care of the patient. In addition, for most parasitic diseases, appropriate test selection and interpretation is based on an understanding of the **life cycle** of the parasite and the **pathogenesis** of the disease process in humans.

Numerous methods for diagnosing parasitic diseases have been described (Box 70.1). Some are useful in detecting a wide variety of parasites, whereas others are particularly useful for one or a few parasites. Although the mainstay of diagnostic clinical microbiology is the isolation of the causative pathogen in culture, the diagnosis of parasitic diseases is accomplished almost entirely by morphologic (usually microscopic) demonstration of parasites in clinical material. Occasionally, demonstration of a specific antibody response (serodiagnosis) helps in establishing the diagnosis. The detection of parasite antigens in serum, urine, or stool now provides a rapid and sensitive means of diagnosing infection with certain organisms; the development of nucleic acid–based assays has proven to be an excellent means of detecting and identifying a number of parasites in biologic samples, such as blood, stool, urine, sputum, and tissue biopsies obtained from infected patients. In general, it is better for the laboratory to offer a limited number of competently performed procedures than to offer a wide variety of infrequently and poorly performed tests.

This chapter provides a general description of the principles of specimen collection and processing necessary to diagnose most parasitic infections. Specific details of these and other procedures of general and limited usefulness may be found in several reference texts listed in the Bibliography.

Parasite Life Cycle as an Aid in Diagnosis

Parasites may have complex life cycles involving single or multiple hosts. Understanding the life cycle of parasitic organisms is a key to understanding important features of geographic distribution, transmission, and pathogenesis of many parasitic diseases. The life cycles of parasites often suggest useful clues for diagnosis as well. For example, in the life cycle of filariae that infect humans, certain species, such as *Wuchereria bancrofti,* have a **"nocturnal periodicity"** in which greater numbers of microfilariae are found in the peripheral blood at night. Sampling the blood of such patients during daytime hours may fail to detect the microfilariae, whereas blood specimens collected between 10 p.m. and 4 a.m. may demonstrate many microfilariae. Also, intestinal nematodes such as *Ascaris lumbricoides* and hookworm, which reside in the lumen of the intestine, produce large numbers of eggs that can be detected easily in the stool of an infected patient. In contrast, another intestinal nematode, *Strongyloides stercoralis*, lays its eggs in the bowel wall rather than in the intestinal lumen. As a result, the eggs are rarely seen on stool examination; to make the diagnosis, the parasitologist must be alert for the presence of larvae. Finally, parasites may cause clinical symptoms at a time when diagnostic forms are not yet present in the usual site. For example, in certain intestinal nematode infections, the **migration** of larvae through the tissues may cause intense symptomatology weeks before the characteristic eggs are present in the feces.

General Diagnostic Considerations

The importance of appropriate specimen collection, the number and timing of specimens, timely transport to the laboratory, and prompt examination by an experienced microscopist cannot be overemphasized. Because the majority of parasitologic examinations and identifications are based entirely on recognizing the characteristic morphology of the organisms, any condition that may obscure or distort the morphologic appearance of the parasite may result in an erroneous identification or missed diagnosis. As noted previously and in Box 70.1, there may be alternatives to microscopy for the detection and identification

of certain parasites. These tests (e.g., antigen detection, nucleic acid amplification/detection), are becoming more widely used (especially antigen and nucleic acid–based detection). They offer the promise of more rapid, sensitive, and specific diagnostic testing for parasitic diseases. These diagnostic test options may expand the testing capabilities of many laboratories, allowing laboratories with limited proficiency in parasitology to offer diagnostic testing for certain parasitic diseases. A list of common and uncommon diagnostic procedures and specimens to be collected for selected parasitic infections is provided in Table 70.1.

BOX 70.1 Laboratory Methods for Diagnosing Parasitic Disease

Macroscopic examination
Microscopic examination
- Wet mount
- Permanent stains
- Stool concentrates

Serologic examination
- Antibody response
- Antigen detection

Nucleic acid hybridization
- Probes and amplification techniques
- Detection
- Identification

Parasitic Infections of the Intestinal and Urogenital Tracts

Protozoa and helminths may colonize or infect the intestinal and urogenital tracts of humans. Most commonly, these parasites are amebae, ciliates, or nematodes (Table 70.2). However, infection with trematodes, cestodes, or coccidian parasites may also be encountered.

In intestinal and urogenital infections, a simple wet mount or stained smear is often inadequate. Repeated specimen collection and testing are often necessary to optimize the detection of organisms that are shed intermittently or in fluctuating numbers. Concentration of specimens by sedimentation or flotation techniques may be required to detect low numbers of ova (of worms) or cysts (of protozoa) in fecal specimens. Whereas routine microscopic examination of stool for ova and parasites (O&P) is useful for detecting infections caused by helminths and amebae, physicians often (inappropriately) favor this approach as a screening method for intestinal parasites and underutilize immunoassays for *Giardia* and *Cryptosporidium* despite their epidemiologic and performance superiority among patients at low risk for other parasites (e.g., helminths and *Entamoeba histolytica*).

Occasionally, specimens other than stool or urine must be examined (see Table 70.1). Optimal detection of small bowel pathogens, such as *Giardia duodenalis* and *S. stercoralis,* may require the aspiration of duodenal contents or even small bowel biopsy. Also, the detection of colonic parasites, such as *E. histolytica* and *Schistosoma mansoni,* may necessitate proctoscopic or sigmoidoscopic examination with aspiration or biopsy of mucosal lesions. Sampling of the perianal skin is a useful means of recovering the eggs of *Enterobius vermicularis* (pinworm) or *Taenia* species (tapeworm).

Physician use of parasite tests in the United States from 1997 to 2006 and in a Utah *Cryptosporidium* outbreak in 2007. J. Clin. Microbiol. 49, 591–596.

FECAL SPECIMEN COLLECTION

Patients, clinicians, and laboratory personnel must be properly instructed on collection and handling of specimens. Fecal specimens should be collected in clean, wide-mouthed, waterproof containers with a tight-fitting lid to

ensure and maintain adequate moisture. Specimens must not be contaminated with water, soil, or urine because water and soil may contain free-living organisms that can be mistaken for human parasites, and urine can destroy motile trophozoites and may cause helminth eggs to hatch. Stool specimens should not contain barium, bismuth, or medications containing mineral oil, antibiotics, antimalarials, or other chemical substances, because such specimens compromise the detection of intestinal parasites. Specimen collection should be delayed for 5 to 10 days to allow barium to clear and for at least 2 weeks after antibiotics, such as tetracycline, to allow intestinal parasites to recover from the toxic (but not curative) effects of the drugs.

Purged specimens may be collected when organisms are not detected in normally passed fecal specimens; however, only certain purgatives (sodium sulfate and buffered sodium biphosphate [Phospho-Soda]) are satisfactory. One series of purged specimens may be examined in place of, or in addition to, a series of normally passed specimens.

Unpreserved formed fecal specimens should arrive in the laboratory within 2 hours after passage. If the stool is liquid and thus more likely to contain trophozoites, it should reach the laboratory for examination within 30 minutes. Soft or loose stools should be examined within 1 hour of passage. If examination is not possible within the recommended time limits, all fresh fecal samples should be placed into preservatives, such as 10% formalin, polyvinyl alcohol (PVA), merthiolate-iodine-formalin (MIF), or sodium acetate formalin (SAF). Fecal specimens may be stored at 4° C but should not be incubated or frozen.

The number of specimens required to demonstrate intestinal parasites varies, depending on the quality of the specimen submitted, the accuracy of the examination performed, the severity of the infection, and the purpose for which the examination is made. If the physician is interested only in determining the presence or absence of helminths, one or two examinations may suffice, provided that concentration methods are used. For a routine parasitic examination, a total of three fecal specimens is recommended. The examination of three specimens using a combination of techniques ensures detection of more than 99% of infections. In a survey conducted in the United States, examination of three specimens was required to detect 100% of infected patients (Table 70.3).

It is inappropriate for multiple specimens to be collected from the same patient on the same day. It also is not recommended for the three specimens to be submitted one each day for 3 consecutive days. The series of three specimens should be collected within no more than 10 days. Many parasites do not appear in fecal specimens in consistent numbers on a daily basis; therefore collection of specimens on alternate days tends to yield a higher percentage of positive findings.

It has become apparent that, in the United States, submission of stool for parasitologic examination from patients with hospital-acquired diarrhea (onset more than 3 days after admission) is usually inappropriate because the frequency of acquisition of protozoan or helminthic parasites in a hospital is vanishingly rare. A request for stool examination for O&P in a hospitalized patient should be accompanied by a clear statement of clinical indications and only after the more common causes of hospital-acquired diarrhea (e.g., antibiotic induced) have been ruled out.

TECHNIQUES OF STOOL EXAMINATION

Specimens should be examined systematically by a competent microscopist for helminth eggs and larvae, as well as for intestinal protozoa. For optimal detection of these various infectious agents, a combination of several techniques of examination is required.

Macroscopic Examination

The fecal specimen should be examined for consistency and for the presence of blood, mucus, worms, and proglottids.

Direct Wet Mount

Fresh stools should be examined under the microscope with the saline and iodine wet-mount technique to detect motile trophozoites or larvae *(Strongyloides)*. The saline and iodine wet mounts also are used to detect helminth eggs, protozoan cysts, and host cells such as leukocytes and red blood cells. This approach also is useful in examining material from sputum, urine, vaginal swabs, duodenal aspirates, sigmoidoscopy, abscesses, and tissue biopsies.

Concentration

All fecal specimens should be placed in 10% formalin to preserve parasite morphology and should be concentrated using a procedure such as formalin ethyl acetate (or formalin ether) sedimentation or zinc sulfate flotation. These methods separate protozoan cysts and helminth eggs from the bulk of fecal material and thus enhance the ability to detect small numbers of organisms usually missed by the use of only a direct smear. After concentration, the material is stained with iodine and examined microscopically.

Permanently Stained Slides

The detection and correct identification of intestinal protozoa often depend on the examination of the permanently stained smear. These slides provide a permanent record of the protozoan organisms that are identified. The cytologic detail revealed by one of the permanent staining methods is essential for accurate identification, and most identification should be considered tentative until confirmed by the permanently stained slide. The common permanent stains used are trichrome, iron hematoxylin, and phosphotungstic acid–hematoxylin. Slides are made either by preparing smears of fresh fecal material and placing them in Schaudinn fixative solution or by fixing a small amount of fecal material in PVA fixative. It should be noted that an order for a routine microscopic examination of stool for

O&P does not necessarily include special stains required to detect organisms such as *Cryptosporidium* or *Cyclospora*. If these organisms are considered in the differential diagnosis, the order for stool examination must state this explicitly so that the necessary special stains (acid-fast [*Cryptosporidium, Cyclospora*]) and procedures (immunoassay [*Cryptosporidium*]) can be performed.

COLLECTION AND EXAMINATION OF SPECIMENS OTHER THAN STOOL

Frequently, specimens other than fecal material must be collected and examined to diagnose infections caused by intestinal pathogens. These specimens include perianal samples; sigmoidoscopic material; aspirates of duodenal contents; liver abscesses; and sputum, urine, and urogenital specimens.

Perianal Specimens

The collection of perianal specimens is frequently necessary to diagnose pinworm *(E. vermicularis)* and occasionally *Taenia* (tapeworm) infections. The methods include the preparation of a clear cellulose tape slide or an anal swab. The cellulose tape slide preparation is the method of choice for the detection of pinworm eggs. Specimens collected by either method should be obtained in the morning before the patient bathes or goes to the bathroom. The tape method requires that the adhesive surface of the tape be pressed firmly against the right and left perianal folds and then spread onto the surface of a microscope slide; the anal swab should be rubbed gently over the perianal area and transported to the laboratory for microscopic examination. With either collection method, the slides or swabs should be kept at 4° C if transport to the laboratory is to be delayed.

Sigmoidoscopic Material

Material from sigmoidoscopy can be helpful in the diagnosis of *E. histolytica* infection that has not been detected by routine fecal examinations. The specimens consist of scraped or aspirated material from the mucosal surface. At least six areas should be sampled. After collection, the material should be placed in a tube containing 0.85% saline and should be kept warm during transport to the laboratory. The specimens should be examined immediately for motile trophozoites.

Duodenal Aspirates

Sampling and examination of duodenal contents is a means of recovering *Strongyloides* larvae; the eggs of *Clonorchis*, *Opisthorchis*, and *Fasciola* species; and other small bowel parasites, such as *Giardia*, *Cystoisospora*, and *Cryptosporidium* organisms. Specimens may be obtained by endoscopic intubation or by the use of the enteric capsule or string test (Entero-Test). Endoscopic biopsy of the small intestinal mucosa may reveal *Giardia* and *Cryptosporidium* organisms, as well as *Strongyloides* larvae. Specimens should be collected in saline and transported directly to the laboratory for microscopic examination.

Liver Abscess Aspirate

Suppurative lesions of the liver and subphrenic spaces may be caused by *E. histolytica* (extraintestinal amebiasis). Extraintestinal amebiasis may occur in the absence of any history of symptomatic intestinal infection. The specimen should be collected from the liver abscess margin instead of the necrotic center. The first portion removed is usually yellowish white in appearance and seldom contains amebae. Later portions, which are reddish, are more likely to contain organisms. A minimum of two separate portions of exudative material should be removed. After aspiration, the collapse of the abscess and the subsequent inflowing of blood often release amebae from the tissue. Subsequent aspirations may have a greater chance of revealing organisms. The aspirated material should be transported immediately to the laboratory.

Sputum

Occasionally, intestinal parasites may be detected in sputum. These organisms include the larvae of *Ascaris*, *Strongyloides*, and hookworm; cestode hooklets; and intestinal protozoa such as *E. histolytica* and *Cryptosporidium* species. The specimen should be a deep sputum rather than primarily saliva, and it should be delivered immediately to the laboratory. Microscopic examination should include saline wet-mount and permanently stained preparations.

Urine

Examination of urine specimens may be useful in diagnosing infections caused by *Schistosoma haematobium* (occasionally other species as well) and *Trichomonas vaginalis*. Detection of eggs in urine can be accomplished using direct detection or concentration using the sedimentation centrifugation technique. Eggs may be trapped in mucus or pus and are more frequently present in the last few drops of the specimen rather than the first portion. The production of *Schistosoma* eggs fluctuates; therefore examinations should be performed over several days. *T. vaginalis* may be found in the urinary sediment of male and female patients.

Urogenital Specimens

Urogenital specimens are collected if infection with *T. vaginalis* is suspected. Identification is based on wet-mount preparation examinations of vaginal and urethral discharges, prostatic secretions, or urine sediment. Specimens should be placed in a container with a small amount of 0.85% saline and sent immediately to the laboratory for examination. If no organisms are detected by direct wet mounts, culture may be used.

Parasitic Infections of Blood and Tissue

Parasites localized within the blood or tissues of the host are more difficult to detect than intestinal and urogenital parasites. Microscopic examination of blood films is a direct and useful means of detecting malarial parasites, trypanosomes, and microfilariae. Unfortunately, the concentration of organisms often fluctuates; thus the collection of multiple specimens over several days is required. The preparation of both wet mounts (microfilariae and trypanosomes) and permanently stained thick and thin blood films is the mainstay of diagnosis. Examination of sputum may reveal helminth ova (lung flukes) or larvae (*Ascaris* and *Strongyloides*

species) after appropriate concentration techniques. Biopsy of skin (onchocerciasis) or muscle (trichinosis) may be required for the diagnosis of certain nematode infections (see Table 70.1).

BLOOD FILMS

The clinical diagnosis of parasitic diseases such as malaria, leishmaniasis, trypanosomiasis, and filariasis largely rests on the collection of appropriately timed blood samples and the expert microscopic examination of properly prepared and stained thick and thin blood films. The optimal time for obtaining blood for parasitologic examination varies with the particular parasite expected.

Because malaria is one of the few parasitic infections that can be acutely life-threatening, blood collection and examination of blood films should be performed immediately if the diagnosis is suspected. Laboratories offering this service should be prepared to do so on a 24-hour basis, 7 days a week. Because the levels of parasitemia may be low or fluctuating, it is recommended that repeat blood films be obtained and examined at 6, 12, and 24 hours after the initial sample. Detection of trypanosomes in blood is occasionally possible during the early acute phase of the disease. *Trypanosoma cruzi* (Chagas disease) may also be detected during subsequent febrile periods. After several months to a year, the trypomastigotes of African trypanosomiasis (*T. brucei rhodesiense* and *T. b. gambiense*) are better demonstrated in spinal fluid than blood. Blood samples for the detection of nocturnal microfilariae (*W. bancrofti* and *Brugia malayi*) should be obtained between 10 p.m. and 4 a.m., whereas for the diurnal *Loa loa*, samples are obtained around noon.

Two types of blood films are prepared for the diagnosis of blood parasite infections, thin and thick. Although wet-mount preparations of blood films can be examined for motile parasites (microfilariae and trypanosomes), most laboratories proceed directly to the preparation of thick and thin films for staining. In the thin film, the blood is spread over the slide in a thin (single cell) layer, and the red blood cells remain intact after fixation and staining. In the thick film, the red cells are lysed before staining, and only the white blood cells, platelets, and parasites (if present) are visible. Thick films allow a larger amount of blood to be examined, which increases the possibility of detecting light infections. Unfortunately, increased distortion of the parasites makes species identification using the thick film particularly difficult. Proper use of this technique usually requires a great deal of expertise and experience.

Occasionally, other blood-concentration procedures may be used to detect light infections. Alternative concentration methods for detecting blood parasites include the use of microhematocrit centrifugation, the examination of buffy coat preparations, a triple centrifugation technique for the detection of low numbers of trypanosomes, and a membrane filtration technique for the detection of microfilariae.

Once prepared, blood films must be stained. The most dependable staining of blood parasites is obtained with Giemsa stain buffered to pH 7.0 to 7.2, although special stains may be occasionally used to identify species of microfilariae. Giemsa stain is particularly useful for the staining of protozoa (malaria and trypanosomes); however, the sheath of microfilariae may not always stain with Giemsa. In this case, hematoxylin-based stains may be used.

SPECIMENS OTHER THAN BLOOD

Examination of tissue and body fluids other than blood may be necessary, based on clinical presentation and epidemiologic considerations. Smears and concentrates of cerebrospinal fluid are necessary to detect trophozoites of *Naegleria fowleri*, trypanosomes, and larvae of the nematode *Angiostrongylus cantonensis* within the central nervous system. Cerebrospinal fluid must be promptly examined because the trophozoite forms of the protozoan parasites are very labile (trypanosomes) or tend to round up and become nonmotile (*N. fowleri*). Examination of tissue impression smears of lymph nodes, liver biopsy material, spleen, or bone marrow stained with Giemsa stain is very useful in detecting **intracellular** parasites such as *Leishmania* species and *Toxoplasma gondii*. Also, biopsies of various tissues are an excellent means of detecting localized or disseminated infections caused by protozoan and helminthic parasites. Saline mounts of superficial skin snips are very useful in detecting the microfilariae of *Onchocerca volvulus*. Examination of sputum (induced) is indicated when there is a question of pulmonary paragonimiasis (lung fluke) or abscess formation with *E. histolytica*. *Strongyloides* larvae may be detected in sputum in hyperinfection syndrome.

Alternatives to Microscopy

In the majority of cases, the diagnosis of parasitic disease is made in the laboratory by microscopic detection and morphologic identification of the parasite in clinical specimens. In some cases, the parasite cannot be detected despite a careful search because of low or absent levels of organisms in readily available clinical material. In such cases, the clinician may need to rely on alternative methods based on the detection of parasite-derived material (antigens or nucleic acids) or by the host response to parasitic invasion (antibodies). Additional approaches used in selected infections include culture, animal inoculation, and xenodiagnosis.

IMMUNODIAGNOSTICS

Immunodiagnostic methods have long been used as aids in the diagnosis of parasitic diseases. The majority of these serologic tests are based on the detection of specific antibody responses to the presence of the parasite. The analytical approaches include the use of classic agglutination, complement fixation, and gel diffusion methods, as well as the more modern immunofluorescence assays (IFAs), enzyme immunoassay (EIA), lateral flow immunoassay (LIFA), and Western blot assays. Antibody detection is useful and indicated in the diagnosis of many protozoan diseases (e.g., extraintestinal amebiasis, South American trypanosomiasis, leishmaniasis, transfusion-acquired malaria and babesiosis, and toxoplasmosis) and helminthic diseases (e.g., clonorchiasis, cysticercosis, hydatidosis, lymphatic filariasis, schistosomiasis, trichinellosis, and toxocariasis). There is a problem with the detection of antibody as a means of diagnosis: because of the persistence of antibody for months

to years after the acute infection, demonstration of antibody can rarely differentiate between acute and chronic infection.

In contrast to antibody detection, the measurement of circulating **parasite antigen** in serum, urine, or feces may provide a more appropriate marker for the presence of active infection and also may indicate parasite load. Also, demonstrations of specific parasite antigen in lesion fluid, such as material from an amebic abscess or fluid from a hydatid cyst, may provide a definitive diagnosis of the infecting organism. Most common antigen-detection assays use an EIA format; however, immunofluorescence, radioimmunoassay, immunochromatographic, and immunoblot methods have also proved useful. Several commercial assays for the detection of parasite antigens are now available in kits. These include EIA and immunochromatographic assays for the detection of *Giardia*, *E. histolytica*, *Entamoeba dispar*, and *Cryptosporidium* species in stool, EIA for the detection of *T. vaginalis* in urogenital specimens, and IFA for the detection of *Giardia*, *Cryptosporidium*, and *Trichomonas* species. Several antigen detection tests also are available for detection of **blood parasites** (malaria, filariasis) in conjunction with microscopic examination of thick and thin blood smears. The reported sensitivity and specificity for most of these kits are quite good. The advantages to these approaches are labor savings and a potential increase in sensitivity. Indeed, numerous studies have shown that immunoassays are more sensitive than microscopic examination in detecting infections caused by *Giardia* and *Cryptosporidium*. Also, rapid diagnostic tests for detecting antigens of *Plasmodium* spp. may outperform microscopy in certain situations and are being considered for use in the field, especially because the use of the more expensive artemisinin combination therapies makes a laboratory diagnosis of malaria more cost-effective than empiric therapy in the era of chloroquine resistance. The disadvantages are the loss of parasitologic expertise and the fact that, in some instances, the available assay tests are for only a single organism, whereas conventional microscopic examination provides the opportunity to recognize many different parasites. Although antigen-detection assays have been described for many other parasites, they are not widely available. The availability of a broad panel of antigen-detection assays potentially would make the use of an antigen screen a viable alternative to tedious microscopic examination.

MOLECULAR DIAGNOSTIC APPROACHES

In addition to immunodiagnostic methods, the diagnosis of parasitic diseases has been enhanced considerably by the application of molecular diagnostic methods based on **nucleic acid hybridization, amplification, and sequencing.** This approach takes advantage of the fact that all organisms contain nucleic acid sequences that may be used in a hybridization assay to distinguish among strains, species, and genera. Thus parasites may be simultaneously detected and identified in clinical material depending on the specificity of the molecular method used. Another advantage of nucleic acid–based detection systems is that they are independent of the patient's immunologic status or previous infection history, identifying active infection. Finally, the use of target nucleic acid amplification tests (NAATs), such as the polymerase chain reaction (PCR), loop-mediated amplification (LAMP), and nucleic acid sequence–based amplification (NASBA), provides exquisite sensitivity, allowing the detection of as little as one organism in a biologic sample (Table 70.4). It should be noted that when applying NAAT to the detection of intestinal parasites, stool fixatives or preservatives may inhibit amplification and fresh stool without preservatives is recommended for testing to avoid false-negative results.

Nucleic acid–based methods can be used to detect parasites not only in clinical samples of blood, stool, or tissue from infected patients but also in their natural vector. The application of deoxyribonucleic acid (DNA) "fingerprinting" or strain typing allows precise identification of the parasite to the subspecies or strain level and has considerable value in epidemiologic studies. Assay formats using nucleic acid probes range from dot blot and Southern hybridization methods to in situ hybridization in tissue to PCR or other target amplification methods coupled with rapid amplicon detection and characterization. The use of nonisotopic DNA labeling techniques greatly expands the potential applicability of these assays worldwide.

Molecular testing is becoming more readily available for most diagnostic laboratories. Assays for *Trichomonas vaginalis*, *E. histolytica, E. histolytica* complex, *Giardia* spp., *Cyclospora* spp., and *Cryptosporidium* spp. are commercially available and approved by the U.S. Food and Drug Administration. Intestinal gastrointestinal panels are available that can test simultaneously for multiple gastrointestinal pathogens, including bacterial, viral, and parasitic pathogens. As with antigen detection, only select pathogens can be detected, and other pathogens may be missed. Additional panels for *Blastocystis* spp., *Dientamoeba fragilis,* microsporidia, and *S. stercoralis* are under development.

Irrespective of the assay format, nucleic acid probes and amplification techniques are now used on a routine basis for the detection and identification of numerous species and strains, including *Plasmodium* species, *Leishmania* species, *T. cruzi*, and *T. gondii* (see Table 70.4). The widespread use of these techniques requires further development of simple procedures for sample handling and preparation and will require extensive clinical and field testing before they can be applied broadly to aid in clinical diagnosis.

CULTURE

Although culture is the standard for the diagnosis of most infectious diseases, it is not commonly used in the parasitology laboratory. Certain protozoan parasites, such as *T. vaginalis*, *E. histolytica*, *Acanthamoeba* species, *N. fowleri*, *Leishmania* species, *Plasmodium falciparum*, *T. cruzi*, and *T. gondii,* can be cultured with relative ease. However, culture of other parasites has not been successful or is too difficult or cumbersome to be of practical value in routine diagnostic efforts.

ANIMAL INOCULATION

Animal inoculation is a sensitive means of detecting infection caused by blood and tissue parasites, such as *T. b. gambiense*, *T. b. rhodesiense*, *T. cruzi*, *Leishmania* species, and *T. gondii*. Although useful, this approach is not practical for most diagnostic laboratories and is largely confined to research settings.

TABLE 70.4 Examples of Techniques for Detection of Parasitic Infections Based on Polymerase Chain Reaction Analysis

Organism	Gene	Target Sensitivity (%)	Comment
Plasmodium vivax	Circumsporozoite gene	91-96	Dried blood-spotted filter paper samples are used
Leishmania species	kDNA minicircle sequence	87-100	Results are compared with culture and microscopy of biopsy specimens
Trypanosoma cruzi	kDNA minicircle sequence	100	Results are compared with serology and xenodiagnosis of blood samples
Toxoplasma gondii	B1 gene Repetitive element sequence gene P30 major surface antigen Recombinant DNA sequences	46-99	PCR of BAL, blood, cerebrospinal fluid, and amniotic fluid show great potential for diagnosis of toxoplasmosis
Entamoeba histolytica	P145 tandem repeat sequence SSU rRNA	96 >90	Results are compared with microscopic diagnosis of stool samples Test may distinguish pathogenic from nonpathogenic *(E. dispar)* strains

BAL, Bronchoalveolar lavage; *kDNA,* kinetoplast deoxyribonucleic acid; *PCR,* polymerase chain reaction; *SSU rRNA,* small subunit ribosomal ribonucleic acid.

XENODIAGNOSIS

The technique of xenodiagnosis uses laboratory-raised arthropod vectors to detect low levels of parasites in infected individuals. Classically, this approach was used to diagnose Chagas disease by allowing an uninfected reduviid bug to feed on an individual suspected of having the disease. Subsequently, the bug was dissected and examined microscopically for evidence of developmental stages of *T. cruzi*. Although this technique may be used in endemic areas, it is obviously not practical for most diagnostic laboratories.

Questions

1. Why is it important to understand the life cycle of parasites when diagnosing parasitic diseases?
2. What factors may confound the use of microscopy in the diagnosis of parasitic disease?
3. Describe the important considerations in collecting and submitting a fecal specimen for parasitologic examination.
4. Which parasites can be detected in blood?
5. What are the alternatives to microscopy for the diagnosis of parasitic infections?

71 Antiparasitic Agents

The chemotherapeutic approach to the management of infectious diseases has clearly changed the face of medicine. Unfortunately, few of the antiinfective agents that have proved so successful against bacterial pathogens have been effective against parasites. In many instances, clinicians continue to rely on antiparasitic agents from the preantibiotic era. These and some newer agents remain limited in effectiveness and are relatively toxic. Many antiparasitic agents require prolonged or parenteral administration and may be effective only in certain disease states. Fortunately, in the last several years, new agents have appeared that constitute significant advances in the treatment of parasitic diseases. In each case, the previously available drugs were toxic and often ineffective.

In large part, the difficulties in the treatment of parasitic diseases stem from the fact that parasites are **eukaryotic** organisms and thus are more similar to the human host than the more successfully treated prokaryotic bacterial pathogens. Furthermore, the chronic and prolonged course of infection, the complex life cycles, and multiple developmental stages of many parasites add to the difficulties of effective chemotherapeutic intervention. Additional complicating factors in resource-poor countries, in which the majority of parasitic diseases occur, include (1) the presence of multiple infections and the high probability of reinfection; (2) lack of access to diagnostic testing methods; (3) the large number of persons immunocompromised by malnutrition and human immunodeficiency virus (HIV) infection; and (4) the overwhelming influence of poverty and poor sanitation, which facilitate the transmission of many parasitic infections. Although chemotherapeutic approaches may be used effectively to treat and prevent many parasitic infections, some agents have adverse effects or eventually meet with resistance (microbial and social). Most antiparasitic agents are too expensive for widespread use in resource-poor countries. Thus the global approach to the prevention and treatment of parasitic diseases must involve several strategies, including improved hygiene and sanitation, control of the disease vector, access to point-of-care diagnostic testing, use of **vaccinations** if available (largely unavailable for parasitic diseases), and prophylactic and therapeutic administration of safe and effective chemotherapy. Of note, large-scale chemotherapy administered one to three times per year in endemic regions has reduced transmission of, and morbidity and mortality from, certain infections, including lymphatic filariasis, onchocerciasis, schistosomiasis, and intestinal nematodes. These strategies also must include efforts to decrease the transmission of infection due to HIV.

Targets for Antiparasite Drug Action

As mentioned previously, parasites are eukaryotic organisms and thus have more similarities than differences with the human host. Consequently, many antiparasitic agents act on pathways (nucleic acid synthesis, carbohydrate metabolism) or targets (neuromuscular function) shared by both the parasite and the host. For this reason, developing safe and effective antiparasitic drugs based on **biochemical differences** between the parasite and host has been difficult. **Differential toxicity** is commonly achieved by preferential uptake, metabolic alteration of the drug by the parasite, or differences in the susceptibility of functionally equivalent sites in the parasite and host. Fortunately, as our understanding of the basic biology and biochemistry of parasites and the mechanism of action of antimicrobial agents has improved, so has our recognition of potential parasite-specific targets for chemotherapeutic attack. Increasingly, investigators are exploiting newly completed genome projects for protozoan parasites to identify potential drug targets for high-throughput screening. Examples of the chemotherapeutic strategies that exploit the differences between parasite and host are provided in Table 71.1. These are discussed in greater detail as we deal with the specific agents.

Drug Resistance

Resistance to antimicrobial agents is an important consideration in the treatment of infections resulting from bacterial and fungal pathogens and certainly plays a role in the chemotherapy of parasitic diseases. Unfortunately, our understanding of the molecular and genetic basis for resistance to most antiparasitic agents is quite limited. Greater understanding of the epidemiology and mechanisms of drug resistance can provide valuable guidance for a better use of existing compounds and for the development of novel agents. The use of molecular markers of drug resistance has added another dimension to surveillance efforts and generated insights into the global spread of drug resistance in both protozoa and helminthes. Molecular markers have been identified for *Plasmodium falciparum* resistance to chloroquine, sulfadoxine-pyrimethamine, atovaquone-proguanil, and, to a limited degree, other antimalarials. For chloroquine and sulfadoxine-pyrimethamine, the molecular markers involve single nucleotide polymorphisms in genes

TABLE 71.1 Chemotherapeutic Strategies That Exploit Differences between Parasite and Host

Unique Site of Attack	Drug	Organism
Drug-concentrating mechanism unique to parasite	Chloroquine	*Plasmodium* spp.
Folic acid pathway (parasite unable to use exogenous folate)	Pyrimethamine or trimethoprim-sulfamethoxazole	*Plasmodium* or *Toxoplasma* spp.
Inhibitor of trypanothione-dependent mechanisms for reducing oxidized thiol groups	Arsenicals, difluoromethylornithine	Trypanosomes
Interference with neuromediators unique to parasites	Pyrantel pamoate, diethylcarbamazine	*Ascaris* spp.
Interacts with chloride channels, resulting in hyperpolarization of cells, paralysis, and death of parasites	Ivermectin	Filaria
Interaction with tubulin unique to parasites	Benzimidazoles	Many helminths
Inhibition of topoisomerase II	Pentamidine	Trypanosomes
Inhibition of pyruvate ferredoxin oxidoreductase	Nitazoxanide	*Cryptosporidium* and *Giardia*

encoding a vacuolar membrane transporter protein and enzymes involved in folate synthesis, respectively. Parasites that have developed both chloroquine and sulfadoxine-pyrimethamine resistance and subsequently develop resistance to a third operational drug are termed "multidrug resistant" (MDR). Patients infected with plasmodia containing an increased copy number of *pfmdr1* (*P. falciparum* MDR 1 gene), which encodes PfPGH-1, a purported transporter pump, were found to have reduced responses to mefloquine, quinine, lumefantrine, and artemisinin-based combinations containing these drugs. More recently, the *pfcrt* (chloroquine-resistant transporter) gene was associated with drug efflux in cultured parasites, and single nucleotide polymorphisms in the *pfcrt* gene were observed in recurrent infections after treatment with artemether-lumefantrine. Resistance in *P. falciparum* to the atovaquone component of atovaquone-proguanil maps to the same locus that determines atovaquone resistance in *Pneumocystis jirovecii*. These efforts have led to further studies and improved understanding of mechanisms of drug resistance in *Trichomonas* (metronidazole), *Leishmania* (pentavalent antimonials), African trypanosomes (melarsoprol, pentamidine), and schistosomes (oxamniquine). Further insights into the mechanisms of action and resistance to antiparasitic agents are necessary to optimize the effectiveness of antiparasite chemotherapy.

Antiparasitic Agents

Although the number of effective antiparasitic agents is small relative to the vast array of antibacterial agents, the list is expanding (Table 71.2). Certainly, a primary goal of antiparasitic therapy is similar to that of antibacterial therapy, which is to eradicate the organism rapidly and completely. In many cases, however, the agents and treatment regimens used for parasitic diseases are designed simply to decrease the parasite burden, to prevent the systemic complications of chronic infection, or to carry out both actions. Thus the goals of antiparasitic therapy, particularly as applied in endemic areas, may be quite different from those usually considered for therapy of microbial infection in the United States or other developed countries. Given the significant toxicity of many of these agents, in every case, the need for treatment must be weighed against the toxicity of the drug. A decision to withhold therapy may often be correct, particularly when the drug can cause severe adverse effects.

Immunocompromised individuals pose a particular problem with respect to antiparasitic chemotherapy. On the one hand, **prophylaxis,** such as that administered for toxoplasmosis, may be effective in preventing infection. However, once infection is established, radical cure may not be possible, and long-term **suppressive therapy** may be indicated. In some diseases, such as cryptosporidiosis and microsporidiosis, effective (curative) therapy is not readily available, and care must be taken to avoid unnecessary toxicity while providing supportive care for the patient.

The remainder of this chapter provides an overview of the major classes of antiprotozoal and anthelmintic agents. These and additional antiparasitic agents, their mechanisms of action, and their clinical indications are listed in Table 71.2. Treatment of specific infections is discussed in the chapters that deal with the parasites. The Bibliography in this chapter lists several excellent reviews for more complete information and for discussions of the antiparasitic agents that are available.

ANTIPROTOZOAL AGENTS

Similar to antibacterial and antifungal agents, the antiprotozoal agents are generally targeted at relatively rapidly proliferating, young, growing cells. Most commonly, these agents target nucleic acid synthesis, protein synthesis, or specific metabolic pathways (e.g., folate metabolism) unique to the protozoan parasites.

Heavy Metals

The heavy metals used for the treatment of parasitic infections include arsenical (melarsoprol) and antimonial compounds (sodium stibogluconate, meglumine antimonate). These agents are thought to oxidize sulfhydryl groups of enzymes that are essential catalysts in carbohydrate metabolism. Melarsoprol inhibits parasite pyruvate kinase, causing decreased concentrations of adenosine triphosphate (ATP), pyruvate, and phosphoenolpyruvate. Arsenicals also inhibit *sn*-glycerol-3-phosphate oxidase, which is

TABLE 71.2 Mechanisms of Action and Clinical Indications for the Major Antiparasitic Agents

Drug Class	Mechanism of Action	Examples	Clinical Indications
ANTIPROTOZOAL AGENTS			
Heavy metals: arsenicals and antimonials	Inactivate sulfhydryl groups Disrupt glycolysis	Melarsoprol, sodium stibogluconate, meglumine antimonate	Trypanosomiasis, leishmaniasis
Aminoquinoline analogs	Accumulate in parasitized cells Interfere with DNA replication Bind to ferriprotoporphyrin IX Raise intravesicular pH Interfere with hemoglobin digestion	Chloroquine, mefloquine, quinine, primaquine, halofantrine, lumefantrine	Malaria prophylaxis and therapy Radical cure (exoerythrocytic-primaquine only)
Folic acid antagonists	Inhibit dihydropteroate synthetase and dihydrofolate reductase	Sulfonamides, pyrimethamine, trimethoprim	Toxoplasmosis, malaria, cyclosporiasis
Inhibitors of protein synthesis	Block peptide synthesis at level of ribosome	Clindamycin, spiramycin, paromomycin, tetracycline, doxycycline	Malaria, babesiosis, amebiasis, cryptosporidiosis, leishmaniasis
Diamidines	Unclear Bind DNA Inhibit dihydrofolate reductase, DNA, RNA, and protein synthesis Interfere with amino acid transport	Pentamidine	Pneumocystosis, leishmaniasis, trypanosomiasis
Nitroimidazoles	Unclear Inhibit protein and RNA synthesis Inhibit metabolism of glucose and interfere with mitochondrial function	Metronidazole, benznidazole, tinidazole	Amebiasis, giardiasis, trichomoniasis, American trypanosomiasis (Chagas disease)
Nitrofurans	Depletion of glutathione, trypanothione, and metallothionein Oxidative stress	Nifurtimox	Chagas disease, late-stage African trypanosomiasis *(Trypanosoma brucei gambiense)*
Sesquiterpenes	React with heme, causing free-radical damage to parasite membranes (artemisinins) Inhibit methionine aminopeptidase type 2 (fumagillin) Inhibit RNA and DNA synthesis (fumagillin)	Artemisinin, artemether, artesunate Fumagillin	Malaria (artemisinins)
Ornithine analog	Inhibits ornithine decarboxylase Interferes with polyamine metabolism	Difluoromethylornithine	African trypanosomiasis
Phosphocholine analog	Disrupts cell-signaling pathways and lipid metabolism; induces apoptotic cell death	Miltefosine	Leishmaniasis
Acetanilide	Unknown	Diloxanide furoate	Intestinal amebiasis
Sulfated naphthylamine	Inhibits *sn*-glycerol-3- phosphate oxidase and glycerol-3-phosphate dehydrogenase, causing decreased ATP synthesis	Suramin	African trypanosomiasis
Thiazolides	Inhibit pyruvate-ferredoxin oxidoreductase	Nitazoxanide	Cryptosporidiosis, giardiasis
ANTHELMINTIC AGENTS			
Benzimidazoles	Inhibit fumarate reductase Inhibit glucose transport Disrupt microtubular function	Mebendazole, thiabendazole, albendazole	Broad-spectrum anthelmintic: nematodes, cestodes
Tetrahydropyrimidine	Blocks neuromuscular action Inhibits fumarate reductase	Pyrantel pamoate	Ascariasis, pinworm, hookworm
Piperazines	Cause neuromuscular paralysis Stimulate phagocytic cells	Piperazine, diethylcarbamazine	Lymphatic filariasis Visceral larva migrans
Avermectins	Block neuromuscular action Hyperpolarize nerve and muscle cells Inhibit filarial reproduction	Ivermectin	Filarial infections, strongyloidiasis, ascariasis, scabies
Pyrazinoisoquinoline	Calcium agonist Causes tetanic muscular contractions Causes tegmental disruption Provides synergy with host defenses	Praziquantel	Broad-spectrum anthelmintic: cestodes, trematodes
Phenol	Uncouples oxidative phosphorylation	Niclosamide	Intestinal tapeworm
Quinolone	Alkylates DNA Inhibits DNA, RNA, and protein synthesis	Bithionol, oxamniquine	Paragonimiasis, schistosomiasis

Continued

TABLE 71.2 Mechanisms of Action and Clinical Indications for the Major Antiparasitic Agents—cont'd

Drug Class	Mechanism of Action	Examples	Clinical Indications
Organophosphate	Anticholinesterase Blocks neuromuscular action	Metrifonate	Schistosomiasis
Sulfated naphthylamidine	Inhibits glycerophosphate oxidase and dehydrogenase	Suramin	Onchocerciasis

ATP, Adenosine triphosphate; *DNA,* deoxyribonucleic acid; *RNA,* ribonucleic acid.

needed for the regeneration of nicotinamide adenine dinucleotide in trypanosomes but is not found in mammalian cells. The antimonials, sodium stibogluconate and meglumine antimonate, inhibit the glycolytic enzyme phosphofructokinase and certain Krebs cycle enzymes in *Leishmania* organisms. They also have been shown to interfere with the metabolism of glutathione and trypanothione, resulting in an increased sensitivity of the organisms to oxidant stress. In each instance, the inhibition of parasite metabolism is **parasiticidal.** Unfortunately, the heavy metal compounds are toxic to the host and the parasite. The toxicity is greatest on cells that are most metabolically active, such as neuronal, renal tubular, intestinal, and bone marrow stem cells. Their differential toxicity and therapeutic value are largely related to enhanced uptake by the parasite and its intense metabolic activity.

Melarsoprol is the drug of choice for trypanosomiasis involving the central nervous system. It can penetrate the blood-brain barrier and is effective in all stages of trypanosomiasis. The antimonial compounds are restricted to the management of leishmaniasis. Meglumine antimonate and sodium stibogluconate are important agents for the treatment of leishmaniasis and are active against all forms of the disease. Prolonged therapy is usually required for disseminated leishmaniasis, and relapses are common. Despite the use of antimonials worldwide for the treatment of leishmaniasis for more than six decades with little evidence of resistance, acquired resistance has become a clinical threat within recent years. Thus far this resistance is unique to *Leishmania donovani,* which causes visceral leishmaniasis in the hyperendemic region of Bihar, India. Many of the proposed mechanisms of resistance across the different *Leishmania* spp. involve a reduced intracellular concentration of the active drug, either by decreased uptake or increased efflux from the cell.

Quinoline Derivatives

The quinoline derivatives include the 4-aminoquinolines (chloroquine, hydroxychloroquine, and amodiaquine), the cinchona alkaloids (quinine, quinidine), the 8-aminoquinolines (primaquine), and the synthetic quinoline compounds (mefloquine, halofantrine, lumefantrine). These compounds all have antimalarial activity and accumulate preferentially in parasitized red blood cells. Several potential mechanisms of action have been proposed, including (1) binding to deoxyribonucleic acid (DNA) and interfering with DNA replication; (2) binding to ferriprotoporphyrin IX released from hemoglobin in infected erythrocytes, producing a toxic complex; and (3) raising the pH of the parasite's intracellular acid vesicles, thus interfering with its ability to degrade hemoglobin. Quinine, quinidine, the 4-aminoquinolines, and the synthetic quinolines rapidly destroy the erythrocytic stage of malaria; thus they may be used **prophylactically** to prevent clinical illness or **therapeutically** to terminate an acute attack. The 8-aminoquinolines (e.g., primaquine) accumulate in tissue cells and destroy the extraerythrocytic (hepatic) stages of malaria, resulting in a radical cure of the infection.

Chloroquine remains the drug of choice for the prophylaxis and treatment of susceptible malaria strains. Chloroquine is active against all five *Plasmodium* species that infect humans *(P. falciparum, P. knowlesi, P. vivax, P. ovale, P. malariae)* and is well tolerated, inexpensive, and effective orally. Unfortunately, resistance of *P. falciparum* to chloroquine is widespread in Asia, Africa, and South America, greatly limiting the use of this agent. Resistance of *P. vivax* to chloroquine has also been reported in Papua New Guinea, the Solomon Islands, Indonesia, and Brazil.

Quinine and quinidine are used primarily to treat chloroquine-resistant *P. falciparum* infection. Presumably, they are active against the chloroquine-resistant strains of *P. vivax* as well. Quinine is used orally only to treat mild attacks and by the intravenous route to treat acute attacks of MDR *P. falciparum*. Both quinine and quinidine are quite toxic and not rapidly parasiticidal; thus they should not be used alone but rather in combination with a sulfonamide or tetracycline antibiotic with antimalarial activity.

Mefloquine is a 4-quinolinemethanol antimalarial agent used for the prophylaxis and treatment of falciparum malaria. It displays a high level of activity against most chloroquine-resistant parasites. Unfortunately, mefloquine-resistant strains of falciparum malaria have been reported in Southeast Asia and Africa.

Halofantrine is a synthetic phenanthrene-methanol compound with proven efficacy in the treatment of *P. vivax* and *P. falciparum* malaria. It is not recommended for prophylaxis of malaria because of its toxicity. Halofantrine is more active than mefloquine; however, cross-resistance between these drugs occurs. It is considered a second-line agent for the treatment of malaria because of its expense and toxicity.

Lumefantrine is also a phenanthrene-methanol compound that is available only as a fixed formulation, combined with artemether. Studies in Cambodia have raised the possibility of declining efficacy to artemether-lumefantrine, with failure rates for the treatment of *P. falciparum* infection between 15% and 30%. Wild-type and various mutant *pfcrt* alleles have been associated with altered susceptibility to lumefantrine and artemisinin.

Folic Acid Antagonists

Similar to other organisms, protozoan parasites require folic acid for the synthesis of nucleic acids and ultimately DNA. Protozoa are unable to absorb exogenous folate, so they are susceptible to drugs that inhibit folate synthesis. The folic acid **antagonists** that are useful in treating protozoan

infections include the diaminopyrimidines (pyrimethamine and trimethoprim) and the sulfonamides. These compounds block separate steps in the folic acid pathway. The sulfonamides inhibit the conversion of aminobenzoic acid to dihydropteroic acid. The diaminopyrimidines inhibit dihydrofolate reductase, which effectively blocks the synthesis of tetrahydrofolate, which is a precursor necessary for the formation of purines, pyrimidines, and certain amino acids. These agents are effective at concentrations far below those needed to inhibit the mammalian enzyme, so selectivity can be attained. When a diaminopyrimidine is used with a sulfonamide, a **synergistic effect** is achieved via the blockade of two steps in the same metabolic pathway, resulting in very effective inhibition of protozoan growth.

The diaminopyrimidine trimethoprim is used with sulfamethoxazole to treat toxoplasmosis. Another diaminopyrimidine, pyrimethamine, has a high affinity for sporozoan dihydrofolate reductase and has been very effective when combined with a sulfonamide in the treatment of malaria and toxoplasmosis. Resistance to antifolates is caused by specific point mutations at the active site of the parasite's dihydrofolate reductase and has been largely confined to species of plasmodia.

Inhibitors of Protein Synthesis

Several antibiotics that inhibit protein synthesis in bacteria also exhibit antiparasitic activity in vitro and in vivo. These agents include clindamycin, spiramycin, tetracycline, and doxycycline.

Clindamycin and the tetracyclines are active against *Plasmodium* species, *Babesia* species, and amebae. Doxycycline is used for the chemoprophylaxis of chloroquine-resistant *P. falciparum* malaria, and tetracycline may be used with quinine for the treatment of chloroquine-resistant *P. falciparum* infection. Clindamycin may be useful in the treatment of central nervous system toxoplasmosis. Spiramycin is recommended as an alternative to the antifolates in the treatment of toxoplasmosis. Although spiramycin appears active against *Cryptosporidium* species in vitro, it has not been shown to be effective clinically for human cryptosporidiosis. Recent studies suggest that paromomycin, an older aminoglycoside, may be at least partially effective in treating cryptosporidiosis. Paromomycin, which is not systemically absorbed, also is used as a secondary drug in amebiasis and giardiasis. It has been shown that treatment of the filarial parasite *Onchocerca volvulus* with doxycycline causes inhibition of worm development, blocks embryogenesis and fertility, and reduces viability. The activity of doxycycline in this organism is caused by its action on the *Wolbachia* bacterial symbiont that is integral to the biology of the parasite and the disease pathogenesis.

Diamidines

Pentamidine, a diamidine, is a relatively toxic agent. Its mechanism of action has not been clearly defined and may not be uniform against different organisms. It may inhibit dihydrofolate reductase and interfere with aerobic glycolysis in protozoa. It also may interfere with amino acid transport, precipitate nucleotides and nucleotide-containing coenzymes, and inhibit DNA, ribonucleic acid (RNA), and protein synthesis.

Pentamidine is effective in treating the tissue forms of leishmania and the early (pre–central nervous system) forms of African trypanosomiasis. Pentamidine does not penetrate the central nervous system; therefore it is not useful in the late stages of infection with *Trypanosoma brucei gambiense*. Pentamidine may also inhibit kinetoplast topoisomerase II activity and may act against trypanosomes in part by this mechanism.

Nitroimidazoles

The nitroimidazoles include the well-known antibacterial agent metronidazole, as well as benznidazole and tinidazole. The mechanism of action of these compounds is unclear. It has been suggested that they inhibit DNA and RNA synthesis and also inhibit the metabolism of glucose and interfere with mitochondrial function. Metronidazole binds to parasite guanine and cytosine residues, causing the loss of helical structure and breakage of DNA strands.

The nitroimidazoles have excellent penetration into body tissues and therefore are particularly effective for the treatment of disseminated amebiasis. Metronidazole is the drug of choice for trichomoniasis and is effective in the treatment of giardiasis. Benznidazole is used for the treatment of acute Chagas disease and may have benefits in chronic disease as well. Tinidazole appears to be more effective and less mutagenic than metronidazole. Tinidazole has recently been approved by the U.S. Food and Drug Administration (FDA) for the treatment of amebiasis, giardiasis, and vaginal trichomoniasis.

Sesquiterpenes

The sesquiterpenes are antimicrobial agents that are represented by the artemisinins, artemether, dihydroartemisinin, arteether, and artesunate. These agents react with the heme moiety, causing **free-radical damage** to parasite membranes. The artemisinins are the most active of the available antimalarial compounds and produce a fractional reduction in parasite biomass of approximately 10^4 per asexual cycle. Artemisinins are efficacious against small-ring forms, as well as maturing schizonts of both *P. vivax* and *P. falciparum*, which are stages that are less susceptible to quinolines or quinine. The earlier stage ring forms are immediately cleared (within 6 to 12 hours) after exposure to artemisinins. The artemisinin derivatives also have the advantage of reducing gametocyte carriage and thus transmission. These agents are highly effective when used in combination with mefloquine, halofantrine, or lumefantrine in the treatment of severe malaria, including that caused by MDR *P. falciparum*. Artemisinin-based combination treatments are now considered the best therapy for falciparum malaria, combining unrelated compounds with different molecular targets (and thus different potential mechanisms of resistance), delaying the emergence of resistances. Resistance to artemisinins has been associated with single amino acid changes in the kelch domain of the K13 protein, resulting in alterations in cell development and proteostasis. Of interest is the apparent efficacy of mefloquine-artesunate in the treatment of a helminth infection such as schistosomiasis.

Atovaquone-Proguanil (Malarone)

Atovaquone is a hydroxynaphthoquinone, and proguanil is an antifolate. The combination of these two agents, Malarone, is used for the prophylaxis and treatment of malaria. Atovaquone inhibits the electron transport system in the

mitochondria of parasites, blocking nucleic acid synthesis and inhibiting replication. Proguanil selectively inhibits plasmodial dihydrofolate reductase; however, in combination with atovaquone, it directly lowers the effective concentration at which atovaquone causes collapse of the mitochondrial membrane potential. Malarone is effective against all stages of development of *P. falciparum* and is recommended for prophylaxis and treatment of falciparum malaria. It also is active against the erythrocytic stages of *P. vivax* and *P. ovale* and shows good efficacy in the treatment of *P. malariae* infections. There are reports of clinical failure and resistance of *P. falciparum* isolates to Malarone associated with single-gene mutations in the cytochrome b gene.

Miltefosine

Miltefosine is an oral phosphocholine analog used for the treatment of visceral leishmaniasis. It is becoming increasingly important because of the growing resistance of *Leishmania* strains to the pentavalent antimonials. Miltefosine interferes with cell-signaling, appears to act on key enzymes involved in the metabolism of ether lipids present on the surface of parasites, and induces apoptotic cell death, but the exact mechanisms of its parasiticidal activity are unknown. Miltefosine is active against both pentavalent antimonial-resistant and antimonial-susceptible strains of *L. donovani* and has been found to have a cure rate of 94% to 97% at 6 months in patients with visceral leishmaniasis. Resistance is caused by decreased uptake and/or increased efflux of the drug. In addition to *Leishmania* spp., miltefosine has activity against *Trypanosoma cruzi*, *T. brucei*, *Entamoeba histolytica*, and *Acanthamoeba* spp. Miltefosine was approved in 2014 by the FDA for the treatment of visceral, mucocutaneous, and cutaneous forms of leishmaniasis.

Nitazoxanide

Nitazoxanide is a novel 5-nitrothiazole derivative with broad-spectrum activity against numerous intestinal protozoa and helminths. Nitazoxanide inhibits pyruvate-ferredoxin oxidoreductase, which is an enzyme essential to anaerobic energy metabolism in protozoa, as well as anaerobic bacteria. The mechanism of action of this agent against helminths is unknown. Nitazoxanide is licensed in the United States for the treatment of cryptosporidiosis and giardiasis in immunocompetent individuals older than 12 months. It also has been shown to be effective in vitro and/or in vivo against infections caused by many enteric protozoa and helminths, including *Ascaris lumbricoides*, *Neobalantidium coli*, *Blastocystis*, *Cyclospora cayetanensis*, *Echinococcus* spp., *E. histolytica*, *Fasciola hepatica*, hookworms, *Hymenolepis nana*, *Cystoisospora belli*, *Taenia saginata*, *Trichomonas vaginalis*, and *Trichuris trichiura*.

Other Antiprotozoal Agents

A number of additional agents used in therapy, their mechanisms of action (if known), and clinical use are listed in Table 71.2.

ANTHELMINTIC AGENTS

The strategy for the use of anthelmintic drugs is quite different from that for the use of drugs for treating most protozoal infections. Most anthelmintic drugs are targeted at **nonproliferating** adult organisms, whereas with protozoa the targets are generally younger, more rapidly proliferating cells. The helminthic life cycle is frequently quite complex, and the adaptation to survival in the human host depends strongly on (1) neuromuscular coordination for feeding movements and for maintenance of a favorable location of the worm within the host; (2) carbohydrate metabolism as the major source of energy, with glucose the primary substrate; and (3) microtubular integrity because egg laying and hatching, larval development, glucose transport, and enzyme activity and secretion are impaired when microtubules are modified. Most anthelmintic agents are targeted at one of these biochemical functions in the adult organism.

The mechanisms of action and clinical indications for common anthelmintic agents are listed in Table 71.2.

Benzimidazoles

The benzimidazoles are broad-spectrum anthelmintic agents and include mebendazole, flubendazole, thiabendazole, triclabendazole, and albendazole. The basic structure of these agents consists of linked imidazole and benzene rings. Three mechanisms of action have been proposed for the benzimidazoles: (1) inhibition of fumarate reductase; (2) inhibition of glucose transport, resulting in glycogen depletion, cessation of ATP formation, and paralysis or death; and (3) disruption of microtubular function. Benzimidazoles block the assembly of tubulin dimers into tubulin polymers in a process mimicked by colchicine, which is a powerful antimitotic and embryotoxic drug. Because tubulin is important for parasite motility, drugs such as the benzimidazoles, which bind to parasite tubulin, are thought to act against nematode parasites by reducing or eliminating their motility.

The benzimidazoles have a wide spectrum of activity, including intestinal nematodes (*Ascaris*, *Trichuris*, *Necator*, and *Ancylostoma* species; *Enterobius vermicularis*), as well as a number of cestodes (*Taenia*, *Hymenolepis*, and *Echinococcus* species). Triclabendazole is the agent of choice for fascioliasis and is an alternative to praziquantel for therapy of paragonimiasis and intestinal flukes. Mebendazole is active against the intestinal nematodes and the cestodes previously listed. Thiabendazole is active against a variety of nematodes, but frequent and severe side effects have limited its primary systemic use to the treatment of strongyloidiasis. Albendazole has a spectrum similar to that of mebendazole and may have greater activity against *Echinococcus* species. In addition to its broad-spectrum anthelmintic activity, albendazole is also active against *Giardia* species. Albendazole is increasingly used in combination with either diethylcarbamazine (DEC) or ivermectin for the treatment of filariasis and loiasis; it is especially useful for these infections as part of a single-dose regimen for mass chemotherapy programs.

Tetrahydropyrimidines

Pyrantel pamoate, a tetrahydropyrimidine, is a cholinergic agonist that has a powerful effect on nematode muscle cells by binding to cholinergic receptors, which results in cell depolarization and muscle contraction. This **paralytic action** on intestinal nematodes leads to expulsion of the worm from the host's intestinal tract.

Pyrantel pamoate is not readily absorbed from the intestine and is active against *Ascaris* species, pinworm, and hookworm. Oxantel, an analog of pyrantel, may be used with pyrantel to provide effective therapy for the three major soil-transmitted nematodes: *Ascaris* species, hookworm, and *Trichuris* species.

Piperazines

The piperazine anthelmintic used most commonly is diethylcarbamazine (DEC). DEC is predominantly a microfilaricidal agent that is thought to act by stimulating cholinergic receptors and depolarizing muscle cells, with subsequent paralysis of the worms. However, additional evidence suggests that it enhances the adherence of leukocytes to microfilariae and thus may act by altering the parasite surface membrane or by directly stimulating phagocytic cells.

DEC is active against the filariae that produce river blindness *(O. volvulus)* and lymphatic filariasis (*Wuchereria bancrofti* and *Brugia malayi*). Unfortunately, destruction of the microfilariae in the tissues may increase the pathology to the host because of the inflammatory response to the parasite antigens and *Wolbachia* endosymbionts released on exposure to DEC. Recent information suggests that single-dose treatment with DEC may produce antiparasitic effects similar to those obtained with 14- to 21-day courses without the severe side effects observed with the multidose regimens. In addition to its use as individual therapy for filarial infections, DEC is also used for mass community chemotherapy programs either alone or in combination with ivermectin or albendazole.

Avermectins

Ivermectin, an avermectin, acts by interacting with the chloride channel in nerve and muscle cell membranes, resulting in hyperpolarization of the affected cells and consequent paralysis and death of the parasites. The drug also inhibits the reproductive function of the adult female *O. volvulus* and alters the ability of the *O. volvulus* microfilariae to evade the host's immune system.

Although ivermectin is used extensively to control gut-dwelling nematode infections in domestic and farm animals, its use in humans is limited primarily to treating ocular and lymphatic filariasis. Ivermectin is effective in the treatment of strongyloidiasis, as well as several common intestinal parasitic nematodes, including *Ascaris*, *Trichuris*, and *Enterobius* species. When used to treat filariasis, ivermectin has fewer side effects than DEC, and a single dose can eliminate microfilariae for up to 6 months. Ivermectin has a dramatic effect on the tissue-dwelling microfilariae of *O. volvulus* and reduces the severity of the ocular pathology seen in onchocerciasis. Because of its ability to markedly reduce the number of microfilariae in the skin of people with onchocerciasis, ivermectin has been effective in reducing the transmission of onchocerciasis in endemic areas.

Pyrazinoisoquinolines

Praziquantel, a pyrazinoisoquinoline, is an anthelmintic active against a broad spectrum of trematodes and cestodes. The drug is rapidly taken up by susceptible helminths, in which it acts as a **calcium agonist.** The entry of calcium into various cells results in elevated intracellular calcium levels, tetanic muscular contraction, and destruction of the tegument. Praziquantel appears to act with the host's immune system to produce a synergistic anthelmintic effect. The drug causes disruption of the parasite surface and tegument, allowing antibodies to attack parasite antigens not normally exposed on the surface (Fig. 71.1). Irreversible damage to the parasite probably occurs when complement or host leukocytes are recruited to the sites in which antibody is bound.

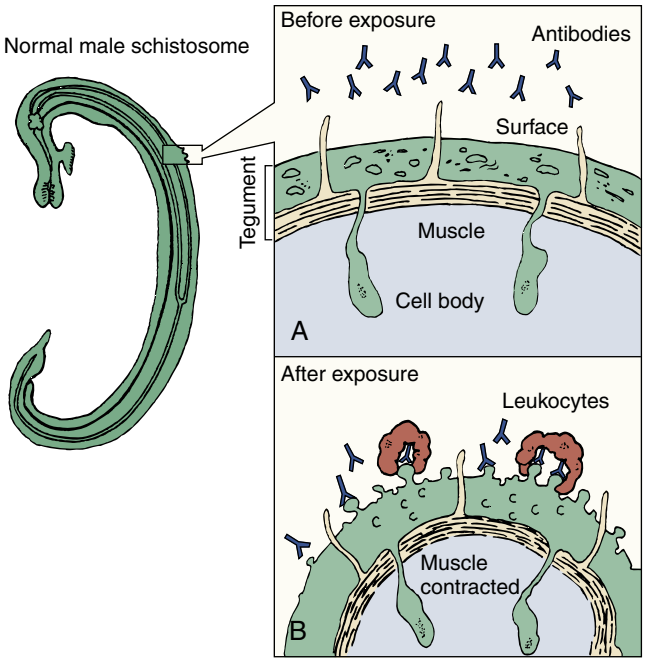

Fig. 71.1 Before exposure to praziquantel, the schistosome is capable of avoiding the numerous antibodies directed toward surface and internally located antigens. (A) Cross section of the dorsal surface of a normal male schistosome. Within 1 to 2 seconds after exposure to praziquantel, the muscles of the schistosome contract because of a drug-induced influx of calcium ions into the schistosome tegument. (B) The change in permeability of the schistosome surface toward external ions initiates the appearance of small holes and balloon-like structures, making the parasite vulnerable to antibody-mediated adherence of host leukocytes that kill the helminth. (From Wingard Jr., L.B., et al., 1991. Human Pharmacology: Molecular to Clinical. Mosby, St Louis, MO.)

Praziquantel has extremely broad-spectrum activity against trematodes, including *Fasciolopsis*, *Clonorchis*, *Opisthorchis*, *Paragonimus*, and *Schistosoma* species. It also is active against cestodes, including *Echinococcus*, *Taenia*, and *Dipylidium* species. Praziquantel is the drug of choice for the treatment of schistosomiasis, clonorchiasis, opisthorchiasis, and intestinal fluke infections. There is now reliable evidence that praziquantel reduces hepatosplenomegaly and portal hypertension in schistosomiasis. Most tapeworm infections respond to praziquantel. Praziquantel is also used in the treatment of neurocysticercosis and echinococcal infections, either alone or in combination with albendazole.

Phenols

The phenol niclosamide is a nonabsorbable anthelmintic with selective activity against intestinal tapeworms. The drug is absorbed by gut-dwelling cestodes but not by nematodes. It acts by uncoupling oxidative phosphorylation in mitochondria, resulting in a loss of helminth ATP that ultimately immobilizes the parasite so that it is expelled with feces. Niclosamide is effective in the treatment of intestinal tapeworms in humans and animals.

Other Anthelmintic Agents

Additional anthelmintic agents, including oxamniquine, metrifonate, and suramin, are described in Table 71.2. These agents are generally considered secondary agents for the treatment of trematode (oxamniquine and metrifonate) and filarial (suramin) infections.

Questions

1. What are the obstacles to effective treatment and prophylaxis of parasitic diseases in resource-poor countries?
2. What are the goals of antiparasitic therapy, and how are they different from antibacterial therapy?
3. What is the importance of aminoquinoline analogs?
4. How does the strategy for the use of anthelmintic agents differ from that for the use of drugs for protozoal infections?

72 Intestinal and Urogenital Protozoa

A 31-year-old female veterinarian complained of diarrhea that she had experienced for 2 weeks. The diarrhea was described as thin, watery, and nonbloody. The patient described 10 to 14 diarrheal stools per day, the frequency of which was not influenced by a variety of over-the-counter antidiarrheal medications. Physical examination revealed a well-developed, well-nourished woman who appeared somewhat fatigued and mildly dehydrated. The workup included a negative human immunodeficiency virus (HIV) serologic test, a normal flexible sigmoidoscope examination, and a negative stool culture for bacterial pathogens. A microscopic examination of the stool for white blood cells was negative, as was a test for Clostridium difficile toxin. A stool specimen was sent for ova and parasite examination and, after appropriate concentration measures, demonstrated acid-fast oocysts.

1. Which parasite was found in the patient's stool?
2. What was the likely source of this individual's infection?
3. If this individual were HIV positive, what other intestinal pathogens would have been considered?
4. Other than conventional microscopy, what other methods could have been used to diagnose this infection?
5. Should this patient have received specific antimicrobial therapy? If so, what would have been prescribed? If not, why not?

Answers to these questions are available on www.StudentConsult.com.

Summaries Clinically Significant Organisms

AMEBAE (AMOEBOZOA)

Trigger Words

Protozoa, amebae, trophozoite, cyst, intestinal amebiasis, extraintestinal amebiasis, hepatic amebiasis, flask-shaped ulcer, *Entamoeba*

Biology, Virulence, and Disease

- Primitive unicellular organisms with a simple two-stage life cycle
- Motility accomplished by extension of a pseudopod (false foot)
- Most amebae found in humans are commensal organisms
- Human pathogens: *Entamoeba histolytica* (most important), *E. polecki*

Epidemiology

- *E. histolytica* has worldwide distribution, with highest incidence in tropical and subtropical regions
- As many as 50% of the population in some areas are infected (average prevalence, 10% to 15%); U.S. prevalence is 4% to 5%
- Many carriers asymptomatic; pass cysts in stool (reservoir)
- Main source of food and water contamination is asymptomatic carrier who passes cysts

Diagnosis

- Microscopic examination of stool allows identification of cysts and trophozoites of *E. histolytica*
- Must differentiate from nonpathogenic and commensal species of amebae
- Specific serologic tests can confirm diagnosis
- Examination of stool samples may be negative in extraintestinal amebiasis
- Newer diagnostic approaches: fecal antigen, PCR, DNA probe

Treatment, Prevention, and Control

- Acute amebiasis treated with metronidazole, followed by iodoquinol, diloxanide furoate, or paromomycin
- Carrier state may be eradicated with iodoquinol, diloxanide furoate, or paromomycin
- Elimination of cycle of infection requires introduction of adequate sanitation measures, education about routes of transmission, chlorination, and filtration of water supplies
- Travelers to developing countries should avoid consumption of water (including ice cubes), avoid unpeeled fruits and raw vegetables, boil water, and thoroughly clean fruits and vegetables before consumption

CILIATES (METAMONADA [FORMERLY FLAGELLATES])

Trigger Words

Giardiasis, trichomoniasis, worm egg, contaminated stream, stool antigen test, cilia, wet mount, diarrhea, IgA deficiency

Biology, Virulence, and Disease

- Clinically important Metamonada: *Giardia duodenalis (lamblia/intestinalis), Dientamoeba fragilis, Trichomonas vaginalis*
- *G. duodenalis* life cycle has both cyst and trophozoite stages; *D. fragilis* has a trophozoite stage (cyst stage in mice); *T. vaginalis* has only a trophozoite stage
- Most flagellates move by lashing of cilia that pull organism through fluid environments
- Infection with *G. duodenalis* initiated by ingestion of cysts; asymptomatic carriage (50% of infected individuals); symptomatic disease ranges from mild diarrhea to a severe malabsorption syndrome
- Most infections with *D. fragilis* asymptomatic
- *T. vaginalis* causes urogenital infections
- Diseases produced by Metamonada result from mechanical irritation, inflammation of gastrointestinal and genitourinary (*Trichomonas*) mucosa

Epidemiology

- *G. duodenalis* has a worldwide distribution
- Giardiasis acquired by fecal-oral route
- Risk factors for giardiasis: poor sanitary conditions, travel to known endemic areas, consumption of inadequately treated water, day-care centers, oral-anal sexual practices
- *D. fragilis* has a worldwide distribution; transmission by fecal-oral and oral-anal routes
- *T. vaginalis* has a worldwide distribution; transmission primarily by sexual intercourse

Diagnosis

- *Giardia* may be detected by microscopic examination of fecal samples or duodenal aspirates
- Detection of *Giardia* fecal antigen by enzyme immunoassay, immunofluorescent microscopy
- Infection with *D. fragilis* diagnosed by microscopic examination of fecal specimens
- Trichomoniasis: microscopic examination of vaginal or urethral discharge

Continued

Summaries Clinically Significant Organisms—cont'd

Treatment, Prevention, and Control

- Drug of choice for treatment of giardiasis (both symptomatic patients and carriers): metronidazole or nitazoxanide; alternatives: furazolidone, tinidazole, paromomycin, albendazole, quinacrine
- Prevention and control of giardiasis involves avoidance of contaminated water and food
- No consensus on best approach for treating *D. fragilis* infections; infection can be avoided by adequate sanitary conditions
- Drug of choice for trichomoniasis is metronidazole; personal hygiene, avoidance of shared toilet articles and clothing, and safe sexual practices are important preventive actions

CILIATES (CILIOPHORA)

Trigger Words

Macronucleus, pig feces, cytostome, cilia, intestinal ulceration

Biology, Virulence, and Disease

- Protozoan organisms whose locomotion involves coordinated movement of rows of hairlike structures (cilia)
- *Neobalantidium coli:* only Ciliophora parasite of humans
- *N. coli* has a funnel-like primitive mouth called a cytostome, a large and small nucleus involved in reproduction, food vacuoles, and two contractile vacuoles
- Disease produced by *N. coli* is similar to amebiasis; symptoms include abdominal pain, tenderness, tenesmus, nausea, anorexia, watery stools with blood and pus, ulceration of intestinal mucosa; extraintestinal infection very rare

Epidemiology

- *N. coli* distributed worldwide; swine and monkeys most important reservoirs
- Infections transmitted by fecal-oral route
- Outbreaks associated with contamination of water supplies with pig feces
- Person-to person spread has been implicated in outbreaks
- Risk factors include contact with swine and substandard hygienic conditions

Diagnosis

- Microscopic examination of feces for trophozoites and cysts

Treatment, Prevention, and Control

- Drug of choice is tetracycline; iodoquinol and metronidazole are alternatives
- Important preventive measures: personal hygiene, maintenance of sanitary conditions, careful monitoring of pig feces

SPOROZOA

Trigger Words

Coccidia, oocyst, chronic diarrhea, acid-fast, fecal antigen, waterborne transmission, contaminated fruits and vegetables

Biology, Virulence, and Disease

- Sporozoa constitute a very large group of protozoa called Apicomplexa or Coccidia
- All sporozoans demonstrate typical characteristics: asexual (schizogony) and sexual (gametogony) reproduction; share alternative hosts
- Intestinal sporozoan: *Cystoisospora belli, Sarcocystis spp., Cryptosporidium spp., Cyclospora cayetanensis*
- *C. belli:* coccidian parasite of intestinal epithelium; causes malabsorption syndrome
- *Sarcocystis* spp. can be detected in stool samples; nausea, abdominal pain, and diarrhea after ingestion of infected meat; muscular infections can occur if sporocysts ingested
- *Cryptosporidium* spp. cause intestinal disease, usually self-limited enterocolitis characterized by watery diarrhea without blood
- *Cyclospora:* illness self-limited in immunocompetent hosts, prolonged in HIV-infected individuals

Epidemiology

- *Cystoisospora* organisms distributed worldwide; disease frequent in patients with AIDS; infection reported with increasing frequency in both healthy and immunocompromised patients
- *Sarcocystis* spp. are isolated from pigs and cattle
- *Cryptosporidium* spp. are distributed worldwide
- *C. hominis* and *C. parvum* cause most human infections; *C. ubiquitum* and *C. felis* are emerging human pathogens
- *Cyclospora:* worldwide distribution; infection acquired through contaminated water; U.S. outbreaks correlated with consumption of contaminated fruits and vegetables

Diagnosis

- *C. belli* infection best diagnosed by careful examination of concentrated stool sediment
- *Sarcocystis* spp. sporocysts may be detected in human stool specimens
- *Cryptosporidium* spp. may be detected in unconcentrated stool specimens from immunocompromised patients with diarrhea
- Diagnosis of cyclosporiasis is based on microscopic detection of oocysts in stool
- Both *Cryptosporidium* and *Cyclospora* infections may be diagnosed by PCR

Treatment, Prevention, and Control

- *C. belli:* treatment of choice is trimethoprim-sulfamethoxazole; prevention and control effected by maintaining personal hygiene and sanitation, avoiding oral-anal sexual contact
- No known treatment for intestinal or muscular sarcocystosis in humans
- No broadly effective therapy has been developed for managing *Cryptosporidium* infections in immunocompromised patients; nitazoxanide is approved by the FDA for the treatment of cryptosporidiosis in nonimmunocompromised individuals older than 12 months
- Cyclosporiasis has been treated with modest success using trimethoprim-sulfamethoxazole

FDA, U.S. Food and Drug Administration; *PCR,* polymerase chain reaction.

Protozoa may colonize and infect the oropharynx, duodenum and small bowel, colon, and urogenital tract of humans. The majority of these parasites belong to the amebae and ciliates; however, infection with sporozoan/coccidian parasites may also be encountered (see Tables 67.4 and 70.2). These organisms are transmitted by the **fecal-oral route.** In the United States, transmission of intestinal protozoa is particularly problematic in day-care centers, in which several outbreaks of diarrhea caused by *Giardia* or *Cryptosporidium* species have been documented. In other parts of the world, the spread of enteric protozoal infections may be controlled in part by improved sanitation and by chlorination and filtration of water supplies; however, this may be difficult or impossible in many developing countries.

Amebae (Amoebozoa)

The amebae are primitive **unicellular** microorganisms. Their life cycle is relatively simple and divided into two stages: the actively motile feeding stage (trophozoite) and the quiescent, resistant, infective stage (cyst). Replication is accomplished by binary fission (splitting the trophozoite) or by the development of numerous trophozoites within the mature multinucleated cyst. Motility is

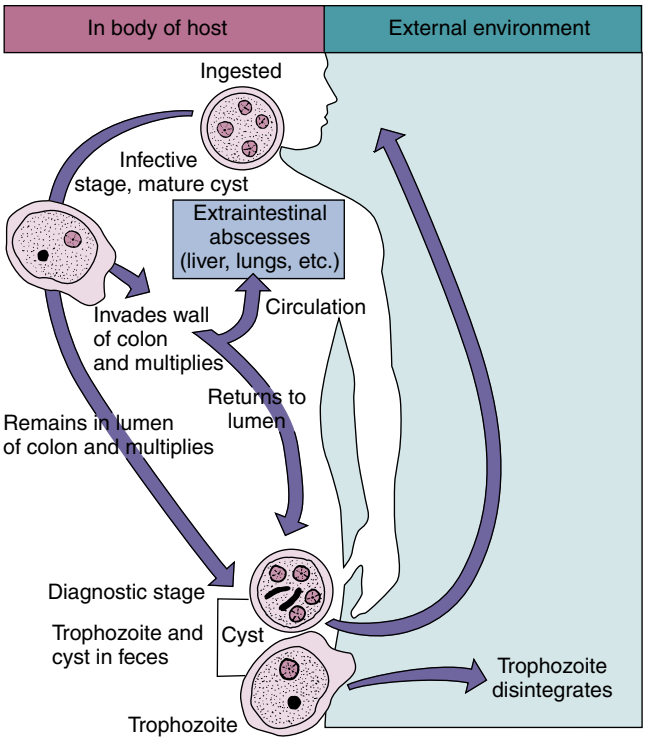

Fig. 72.1 Life cycle of *Entamoeba histolytica.*

accomplished by extension of a **pseudopod** ("false foot"), with extrusion of the cellular ectoplasm and then drawing up of the rest of the cell in a snail-like movement to meet this pseudopod. The amebic trophozoites remain actively motile as long as the environment is favorable. The cyst form develops when the environmental temperature or moisture level drops.

Most amebae found in humans are **commensal** organisms (*Entamoeba coli, E. hartmanni, E. dispar, E, moshkovskii, E. gingivalis, Endolimax nana, Iodamoeba buetschlii*). However, *E. histolytica* is an important human pathogen. Other amebae, particularly *E. polecki,* can cause human disease but are rarely isolated. Some free-living amebae (*Naegleria* spp., *Balamuthia* spp., *Acanthamoeba* spp.) are present in soil and in warm freshwater ponds or swimming pools and can be opportunistic human pathogens, causing meningoencephalitis or keratitis (see Chapter 73).

ENTAMOEBA HISTOLYTICA

Physiology and Structure

Cyst and trophozoite forms of *E. histolytica* are detected in fecal specimens from infected patients (Fig. 72.1). Trophozoites can also be found in the crypts of the large intestine. In freshly passed stools, actively motile trophozoites can be seen, whereas in formed stools, the cysts are usually the only form recognized. For the diagnosis of amebiasis, distinguishing between the *E. histolytica* trophozoites and cysts and those of commensal amebae, such as *E. coli,* is important (Table 72.1).

Pathogenesis

After ingestion, the cysts pass through the stomach, in which exposure to gastric acid stimulates the release of the pathogenic trophozoite in the duodenum. The trophozoites divide and produce extensive local necrosis in the large intestine. The basis for this tissue destruction is incompletely understood, although it is attributed to production of a **cytotoxin.** Attachment of *E. histolytica* trophozoites to host cells via a galactose-inhibitable adherence protein is required for cytolysis and tissue necrosis to occur. The lysis of colonic epithelial cells, human neutrophils, lymphocytes, and monocytes by trophozoites is associated with a lethal alteration of host cell membrane permeability, resulting in an irreversible increase in intracellular calcium levels. The release of toxic neutrophil constituents after the lysis of neutrophils may contribute to the tissue destruction. Flask-shaped ulcerations of the intestinal mucosa are present with inflammation, hemorrhage, and secondary bacterial infection. Invasion into the deeper mucosa with extension into the peritoneal cavity may occur. This can lead to secondary involvement of other organs, primarily the liver but also the lungs, brain, and heart. Extraintestinal amebiasis is associated with trophozoites. Amebae are found only in environments that have a low oxygen pressure because the protozoa are killed by ambient oxygen concentrations.

Lectin binding, zymodeme analysis, genome deoxyribonucleic acid (DNA) analysis, and staining with specific monoclonal antibodies have been used as markers to identify invasive strains of *E. histolytica*. It is now recognized that the ameba morphologically identified as *E. histolytica* is actually four distinct species. The pathogenic species is *E. histolytica*, and the nonpathogenic species are *E. dispar, E. moshkovskii,* and *E. bangladeshi*. The zymodeme profiles and biochemical, molecular, and immunologic differences are stable and support the existence of four species. Of note, these four species are morphologically indistinguishable from one another.

TABLE 72.1 Morphologic Identification of *Entamoeba histolytica* and *Entamoeba coli*

	E. histolytica[a]	*E. coli*
SIZE (DIAMETER, μM)		
Trophozoite	12-50 μm	20-30 μm
Cyst	10-20 μm	10-30 μm
Pattern of peripheral nuclear chromatin	Fine, dispersed ring	Coarse, clumped
Karyosome	Central, sharp	Eccentric, coarse
Ingested erythrocytes	Present	Absent
CYST STRUCTURE		
Number of nuclei	1-4	1-8
Chromatoidal bars	Rounded ends	Splintered, frayed ends

[a]*E. histolytica* is morphologically indistinguishable from the commensal species *E. dispar, E. moshkovskii, and E. bangladeshi.*

Epidemiology

E. histolytica has a worldwide distribution. Although it is found in cold areas such as Alaska, Canada, and Eastern Europe, its incidence is highest in tropical and subtropical regions that have poor sanitation and contaminated water. The average prevalence of infection in these areas is 10% to 15%, with as

many as 50% of the population infected in some areas. Many of the infected individuals are asymptomatic carriers who represent a reservoir for the spread of *E. histolytica* to others. The prevalence of infection in the United States is 4% to 5%.

Patients infected with *E. histolytica* pass noninfectious trophozoites and the infectious cysts in their stools. The trophozoites cannot survive in the external environment or in transport through the stomach if ingested. Therefore the main source of water and food contamination is the asymptomatic carrier who passes cysts. This is a particular problem in hospitals for the mentally ill, military and refugee camps, prisons, and crowded day-care centers. Flies and cockroaches also can serve as mechanical vectors for the transmission of *E. histolytica* cysts. Sewage containing cysts can contaminate water systems, wells, springs, and agricultural areas in which human waste is used as fertilizer. Finally, cysts can be transmitted by oral-anal sexual practices, with amebiasis prevalent in homosexual populations. Direct trophozoite transmission in sexual encounters can produce cutaneous amebiasis.

Clinical Syndromes

The outcome of infection may result in a carrier state, intestinal amebiasis, or extraintestinal amebiasis. If the strain of *E. histolytica* has a low virulence, if the inoculum is low, or if the patient's immune system is intact, the organisms may reproduce, and cysts may be passed in stool specimens with no clinical symptoms. Although infections with *E. histolytica* may be asymptomatic, most asymptomatic individuals are infected with the noninvasive *E. dispar* or *E. moshkovskii*, as characterized by specific isoenzyme profiles (zymodemes), DNA-based assays, their susceptibility to complement-mediated lysis, and their failure to agglutinate in the presence of the lectin concanavalin A. Detection of carriers of *E. histolytica* in areas with a low endemicity is important for epidemiologic purposes.

Patients with intestinal amebiasis develop clinical symptoms related to the localized tissue destruction in the large intestine. These include abdominal pain, cramping, and colitis with diarrhea. More severe disease is characterized by numerous bloody stools per day. Systemic signs of infection (fever, leukocytosis, rigors) are present in patients with extraintestinal amebiasis. The liver is primarily involved because trophozoites in the blood are removed as they pass through this organ. Abscess formation is common (Clinical Case 72.1). The right lobe is most commonly involved. Pain over the liver with hepatomegaly and elevation of the diaphragm is observed.

Laboratory Diagnosis

The identification of *E. histolytica* trophozoites (Fig. 72.2) and cysts in stools and trophozoites in tissue is diagnostic of amebic infection (see Table 72.1). Care must be taken to distinguish between these amebae and commensal amebae, as well as between these amebae and polymorphonuclear leukocytes. Microscopic examination of stool specimens is inherently insensitive because the protozoa are not usually distributed homogeneously in the specimen, and the parasites are concentrated in the intestinal ulcers and at the margins of the abscess, not in the stool or the necrotic center of the abscess. For this reason, multiple stool specimens should be collected. Extraintestinal amebiasis is sometimes diagnosed using scanning procedures for the liver and other organs. Specific serologic tests, together with microscopic examination of the abscess material, can confirm the diagnosis. Virtually all patients with hepatic amebiasis and most patients (more than 80%) with intestinal disease have positive serologic findings at the time of clinical presentation. This may be less useful in endemic areas in which the prevalence of positive serologic results is higher. Examinations of stool specimens are frequently negative in extraintestinal disease. In addition to conventional microscopic and serologic tests, researchers have developed several immunologic tests for the detection of fecal antigen, as well as polymerase chain reaction (PCR) and DNA-probe assays for the detection of pathogenic strains of *E. histolytica* (versus nonpathogenic *E. dispar* and *E. moshkovskii*). These newer diagnostic approaches are now commercially available (see Chapter 70).

Treatment, Prevention, and Control

Acute, fulminating amebiasis is treated with metronidazole, followed by iodoquinol, diloxanide furoate, or paromomycin. Asymptomatic carriage can be eradicated

Clinical Case 72.1 **Human Immunodeficiency Virus and Amebic Liver Abscess**

Liu and colleagues (*J Clin Gastroenterol* 33:64–68, 2001) described a 45-year-old homosexual man who developed intestinal and hepatic amebiasis. The patient initially presented with intermittent fever, followed by right upper quadrant pain and diarrhea. On admission to the hospital, he was afebrile with an elevated white blood count and abnormal liver function tests. Stool examinations were positive for occult blood and white blood cells. He underwent colonoscopy, and multiple discrete ulcers were detected in the rectum and colon. The diagnosis of amebic colitis was confirmed by the demonstration of numerous trophozoites on histopathologic examination of colon biopsy specimens. Ultrasonic examination of the abdomen revealed a large heterogeneous mass within the liver, consistent with an abscess. Percutaneous drainage of the abscess obtained chocolate-like pus, and examination of a biopsy from the margin of the abscess revealed only necrotic material without evidence of amebae. Polymerase chain reaction amplification of amebic 16S ribosomal RNA from the aspirate was positive, indicating infection with *Entamoeba histolytica*. The patient was treated with metronidazole, followed by iodoquinol to eradicate the luminal amebae. Subsequent history revealed a history of travel to Thailand 2 months before the onset of the present illness. HIV serology was positive as well. The patient improved rapidly on antiamebic therapy and was discharged on antiretroviral therapy.

Although amebic cysts are frequently detected in the stools of homosexual men, previous studies in Western countries suggested that almost all isolates belonged to the nonpathogenic species, *Entamoeba dispar*, and invasive amebiasis was considered rare in HIV-positive individuals. This case illustrates that invasive amebiasis, such as amebic liver abscess and colitis, can accompany HIV infection. The possible association of invasive amebiasis with HIV infection should be kept in mind in patients living in or with a history of travel to areas endemic with *E. histolytica*.

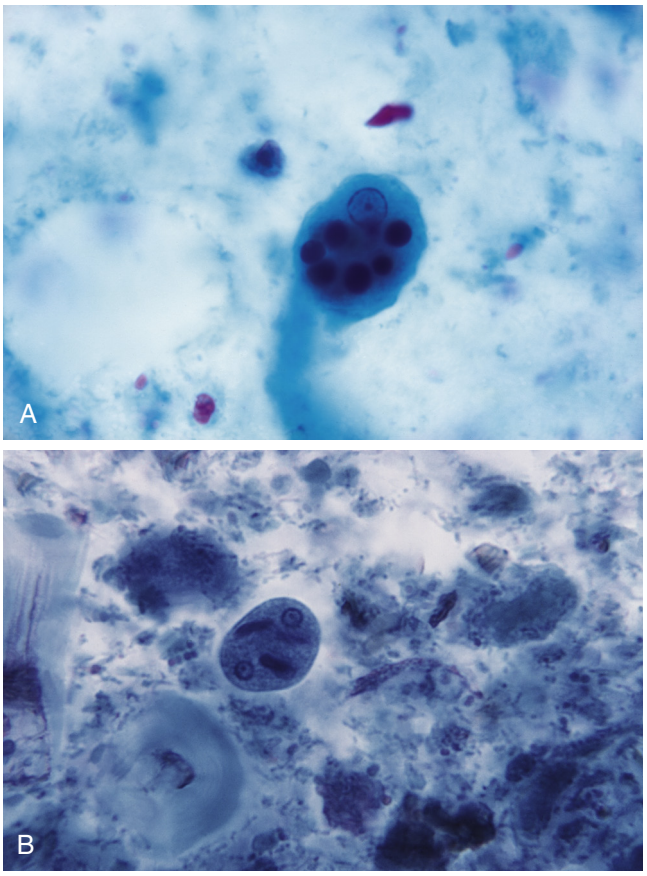

Fig. 72.2 *Entamoeba histolytica* (A) **trophozoite** and (B) **cyst. Trophozoites** are motile and vary in size from 12 to 60 μm (average, 15 to 30 μm). The single nucleus in the cell is round with a central dot (karyosome) and an even distribution of chromatin granules around the nuclear membrane. Ingested erythrocytes may be in the cytoplasm. The cysts are smaller (10 to 20 μm, with an average size of 15 to 20 μm) and contain one to four nuclei (usually four). Round chromatoidal bars may be in the cytoplasm. (From CDC Public Health Image Library.)

with iodoquinol, diloxanide furoate, or paromomycin. As already noted, human infection results from the ingestion of food or water contaminated with human feces or as a result of specific sexual practices. The elimination of the cycle of infection requires the introduction of adequate sanitation measures and education about the routes of transmission. The chlorination and filtration of water supplies may limit the spread of these and other enteric protozoal infections but are not possible in many developing countries. Physicians should alert travelers to developing countries about the risks associated with the consumption of water (including ice cubes), unpeeled fruits, and raw vegetables. Water should be boiled and fruits and vegetables thoroughly cleaned before consumption.

OTHER INTESTINAL AMEBAE

Other amebae that can parasitize the human gastrointestinal tract include *E. coli*, *E. hartmanni*, *E. polecki*, *E. nana*, *I. buetschlii*, and *Blastocystis* spp. *E. polecki*, which is primarily a parasite of pigs and monkeys, can cause human disease, which includes a mild, transient diarrhea. The diagnosis of *E. polecki* infection is confirmed by the microscopic detection of cysts in stool specimens. Treatment is the same as for *E. histolytica* infections.

Blastocystis spp., previously regarded as a nonpathogenic yeast, is now the center of considerable controversy concerning its taxonomic position and its pathogenicity. *Blastocystis* has recently been placed in the Kingdom Stramenopila (formerly Chromista), based on analysis of 18S ribosomal ribonucleic acid (rRNA) and other molecular evidence. Clinically, there are at least 17 subtypes (genotypes) within *Blastocystis*, nine of which have been detected in human stool. Human isolates of *Blastocystis* that in the past were referred to as *B. hominis* should be called *Blastocystis* spp. because there is not a single subtype specific to humans. The organism is found in stool specimens from asymptomatic individuals, as well as from persons with persistent diarrhea. It has been suggested that the presence of large numbers of these parasites (five or more per oil-immersion microscopic field) in the absence of other intestinal pathogens indicates disease. Other investigators have concluded that "symptomatic blastocystosis" is attributable to an undetected pathogen or functional bowel problems. The organism may be detected in wet mounts or trichrome-stained smears of fecal specimens. Treatment with iodoquinol or metronidazole has been successful in eradicating the organisms from the intestine and alleviating symptoms. However, the definitive role of this organism in disease remains to be demonstrated.

The nonpathogenic intestinal amebae are important because they must be differentiated from *E. histolytica*, *E. polecki*, and *Blastocystis* spp. This is particularly true for *E. coli*, which is frequently detected in stool specimens collected from patients exposed to contaminated food or water. Accurate identification of intestinal amebae requires careful microscopic examination of the cyst and trophozoite forms present in stained and unstained stool specimens (see Table 72.1). Also, differentiation of *E. dispar* and *E. moshkovskii* from *E. histolytica* is now possible using specific immunologic reagents.

Ciliates (Metamonada [Formerly Flagellates] and Ciliophora)

The Metamonada of clinical significance include *Giardia duodenalis* (*lamblia*/*intestinalis*), *Dientamoeba fragilis*, and *Trichomonas vaginalis*. Nonpathogenic commensal ciliates, such as *Chilomastix mesnili* (enteric) and *T. tenax* (oral), also may be observed. *Giardia* organisms, similar to *E. histolytica*, have cyst and trophozoite stages in their life cycles. In contrast, no cyst stage has been observed for *Trichomonas* species. A cyst stage of *D. fragilis* has been observed (rarely) in humans, although the role of the cyst form in transmission of *D. fragilis* infection is unclear. Unlike the amebae, most ciliates move by the lashing of cilia that propel the organisms through fluid environments. Diseases produced by the Metamonada are primarily the result of mechanical irritation and inflammation. For example, *G. duodenalis* (*lamblia*/*intestinalis*) attaches to the intestinal villi with an adhesive disk, resulting in localized tissue damage. The tissue invasion with extensive tissue destruction, as seen with *E. histolytica*, is rare with ciliates.

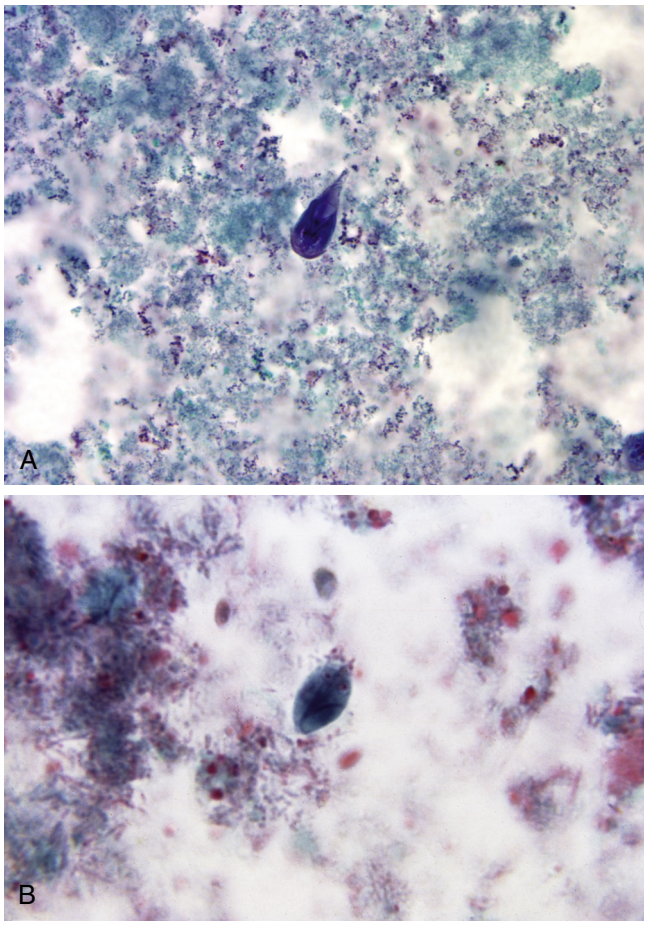

Fig. 72.3 (A) *Giardia duodenalis* trophozoite and (B) cyst. Trophozoites are 9 to 12 μm long and 5 to 15 μm wide. Flagella are present, as are two nuclei with large central karyosomes, a large ventral sucking disk for attachment of the flagellate to the intestinal villi, and two oblong parabasal bodies below the nuclei. The morphology gives the appearance that the trophozoites are looking back at the viewer. Cysts are smaller, 8 to 12 μm long and 7 to 10 μm wide. Nuclei and parabasal bodies are present. (From CDC Public Health Image Library.)

GIARDIA DUODENALIS (G. LAMBLIA; G. INTESTINALIS)

The literature refers to this organism as *G. duodenalis, G. lamblia,* and *G. intestinalis,* reflecting the ambiguity surrounding the classification and nomenclature of this parasite. Further studies are necessary to determine species designations or groupings; however, *G. duodenalis* is now the accepted species designation and will be used in this chapter.

Physiology and Structure

Both cyst and trophozoite forms of *G. duodenalis* are detected in fecal specimens from infected patients (Fig. 72.3).

Pathogenesis

Infection with *G. duodenalis* is initiated by ingestion of cysts (Fig. 72.4). The minimum infective dose for humans is estimated to be 10 to 25 cysts. Gastric acid stimulates excystation with the release of trophozoites in the duodenum and jejunum, in which the organisms multiply by **binary fission.** The trophozoites can attach to the intestinal villi by a

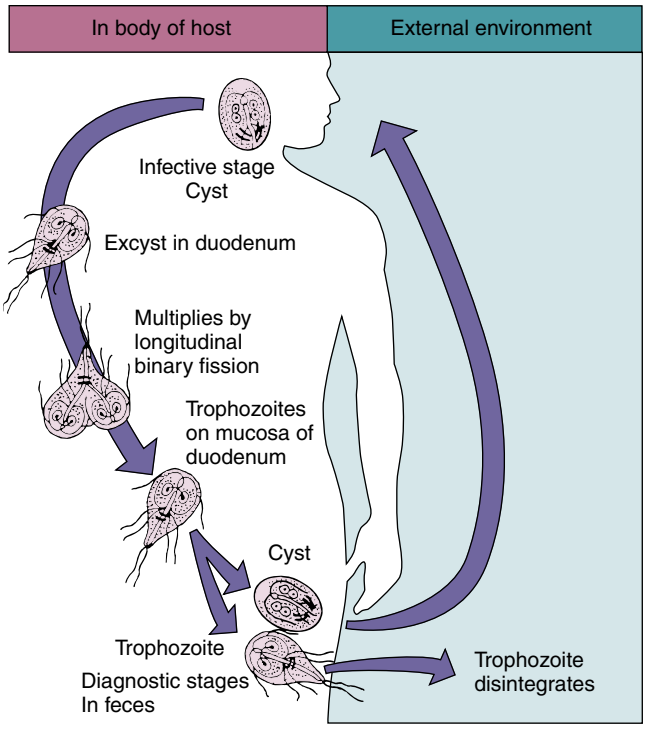

Fig. 72.4 Life cycle of *Giardia duodenalis.*

prominent ventral sucking disk. Although the tips of the villi may appear flattened, and inflammation of the mucosa with hyperplasia of lymphoid follicles may be observed, frank tissue necrosis does not occur. In addition, metastatic spread of disease beyond the gastrointestinal tract is very rare.

Epidemiology

The *Giardia* species has a worldwide distribution, and this organism has a sylvatic or "wilderness" distribution in many streams, lakes, and mountain resorts. This sylvatic distribution is maintained in reservoir animals such as beavers and muskrats. Giardiasis is acquired by the consumption of inadequately treated contaminated water, ingestion of contaminated uncooked vegetables or fruits, or person-to-person spread by the fecal-oral or oral-anal route. The cyst stage is resistant to chlorine concentrations (1 to 2 parts per million) used in most water-treatment facilities. Thus adequate water treatment should include chemicals plus filtration.

Risk factors associated with *Giardia* infections include poor sanitary conditions, travel to known endemic areas, consumption of inadequately treated water (e.g., from contaminated mountain streams), day-care centers, and oral-anal sexual practices. Infections may occur in outbreak and endemic forms within day-care centers and other institutional settings and among family members of infected children. Scrupulous attention to handwashing and treatment of all infected individuals are important in controlling the spread of infection in these settings.

Clinical Syndromes

Giardia infection can result in either asymptomatic carriage (observed in approximately 50% of infected individuals) or symptomatic disease, ranging from mild diarrhea to a severe malabsorption syndrome (Clinical Case 72.2). The incubation

Clinical Case 72.2 **Drug-Resistant Giardiasis**

Abboud and colleagues (*Clin Infect Dis* 32:1792–1794, 2001) described a case of metronidazole-resistant and albendazole-resistant giardiasis that was successfully treated with nitazoxanide. The patient was a 32-year-old homosexual man with AIDS who was admitted to the hospital because of intractable diarrhea. Examination of stool revealed the presence of numerous cysts of *Giardia duodenalis (G. lamblia)*. The patient was treated unsuccessfully five times with metronidazole and albendazole without improvement in diarrhea or cyst shedding. Although combined antiretroviral therapy also was administered, it was ineffective, and viral (HIV) genotypic analysis found mutations associated with high resistance to most antiretroviral drugs. The patient was subsequently treated for giardiasis with nitazoxanide, which resulted in resolution of the diarrhea and negative results of tests for stool cyst shedding. Resistance of the infecting strain of *G. duodenalis* to both metronidazole and albendazole was confirmed by in vivo and in vitro studies. Nitazoxanide may be considered a useful alternative therapy for resistant giardiasis.

period before symptomatic disease develops ranges from 1 to 4 weeks (average, 10 days). The onset of disease is sudden, with foul-smelling, watery diarrhea, abdominal cramps, flatulence, and steatorrhea. Blood and pus are rarely present in stool specimens, which is consistent with the absence of tissue destruction. Spontaneous recovery generally occurs after 10 to 14 days, although a more chronic disease with multiple relapses may develop. This is particularly a problem for patients with immunoglobulin A deficiency or intestinal diverticula.

Laboratory Diagnosis

With the onset of diarrhea and abdominal discomfort, stool specimens should be examined for cysts and trophozoites (see Fig. 72.3). The excretion of *Giardia* species may occur in "showers," with many organisms present in the stool on a given day and few or none detected the next day. For this reason, the physician should never accept the results of a single negative stool specimen as evidence that the patient is free of intestinal parasites. One stool specimen per day for 3 days should be examined. If stools remain persistently negative in a patient in whom giardiasis is highly suspected, additional specimens can be collected by duodenal aspiration, Entero-Test or string test, or biopsy of the upper small intestine. In addition to conventional microscopy, several immunologic tests for the detection of **fecal antigen** are available commercially. These tests include countercurrent immunoelectrophoresis, enzyme immunoassay, an immunochromatographic assay, and immunofluorescent staining. Reported sensitivities range from 88% to 98% and specificities from 87% to 100%. Numerous publications have documented the superior sensitivity of the immunoassay methods over that of routine microscopic examination of stool for the detection of *Giardia*. More recently, several molecular assays have been developed for the detection of *G. duodenalis* in clinical samples. Multiplex nucleic acid amplification test (NAAT) panels have been approved by the U.S. Food and Drug Administration (FDA) with reported sensitivities and specificities of 98% to 100% and 99%, respectively.

Treatment, Prevention, and Control

It is important to eradicate *Giardia* species from asymptomatic carriers and diseased patients. The drug of choice is metronidazole or nitazoxanide with furazolidone, tinidazole, paromomycin, albendazole, or quinacrine all acceptable alternatives. The prevention and control of giardiasis involves the avoidance of contaminated water and food, especially by the traveler and outdoorsman. Protection is afforded by boiling drinking water from streams and lakes or in countries with a high incidence of endemic disease. Maintenance of properly functioning filtration systems in municipal water supplies also is required because cysts are resistant to standard chlorination procedures. Public health efforts should be made to identify the reservoir of infection to prevent spread of disease. In addition, high-risk sexual behavior should be avoided.

DIENTAMOEBA FRAGILIS

Physiology and Structure

D. fragilis was initially classified as an ameba; however, the internal structures of the trophozoite are typical of a ciliate (Metamonada). A cyst stage has been detected in humans, but its role in transmission is unclear.

Epidemiology

D. fragilis has a worldwide distribution. The mode of transmission of *D. fragilis* is not completely understood. Some observers believe the organism can be transported from person to person inside the protective shell of worm eggs, such as those of *Enterobius vermicularis*, the pinworm. Transmission by the fecal-oral and oral-anal routes does occur.

Clinical Syndromes

Most infections with *D. fragilis* are asymptomatic, with colonization of the cecum and upper colon. However, some patients may develop symptomatic disease with abdominal discomfort, flatulence, intermittent diarrhea, anorexia, and weight loss. There is no evidence of tissue invasion with this organism, although irritation of the intestinal mucosa occurs.

Laboratory Diagnosis

Infection is confirmed by the microscopic examination of stool specimens in which typical trophozoites can be seen. The trophozoite is small (5 to 12 μm), with one or two nuclei. The central karyosome consists of four to six discrete granules. The excretion of the parasite may fluctuate markedly from day to day, thus collection of several stool samples may be necessary. Examination of a purged stool sample may also be useful. Several PCR assays are available for the detection of *D. fragilis,* although none are approved by the FDA in the United States.

Treatment, Prevention, and Control

Multiple differing antimicrobial agents have been used for treatment of *D. fragilis* infection with varying success. These include doxycycline, iodoquinol, metronidazole, paromomycin, and secnidazole. However, there is no consensus on the best approach for treating infections with this organism. The reservoir for *D. fragilis* and the organism's life cycle are unknown. Thus specific recommendations for prevention

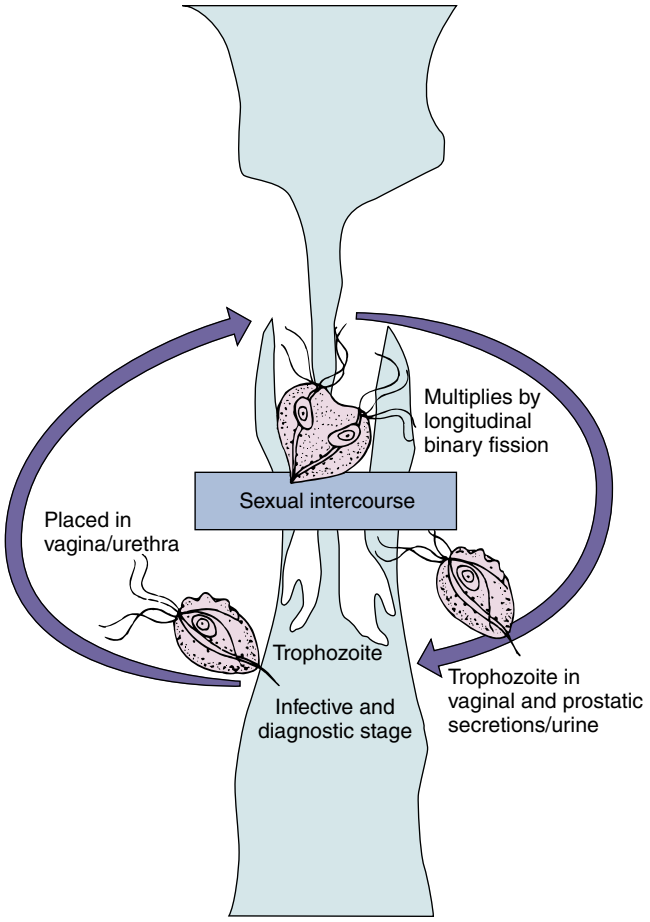

Fig. 72.5 Life cycle of *Trichomonas vaginalis.*

and control are difficult. However, infections can be avoided by maintaining adequate sanitary conditions. The eradication of infections with *Enterobius* organisms also may reduce the transmission of *Dientamoeba* infection.

TRICHOMONAS VAGINALIS

Physiology and Structure

T. vaginalis is not an intestinal protozoan; rather, it is the cause of urogenital infections. The organism's four cilia and short, undulating membrane are responsible for motility. *T. vaginalis* exists only as a trophozoite and is found in the urethras and vaginas of women and the urethras and prostate glands of men.

Epidemiology

This parasite has worldwide distribution, with sexual intercourse as the primary mode of transmission (Fig. 72.5). Occasionally, infections have been transmitted by fomites (toilet articles, clothing), although this transmission is limited by the lability of the trophozoite form. Infants may be infected by passage through the mother's infected birth canal. The prevalence of *T. vaginalis* in developed countries is reported to be 5% to 20% in women and 2% to 10% in men.

Clinical Syndromes

Most infected women are asymptomatic or have a scant, watery vaginal discharge. Vaginitis may occur with more extensive inflammation and erosion of the epithelial lining

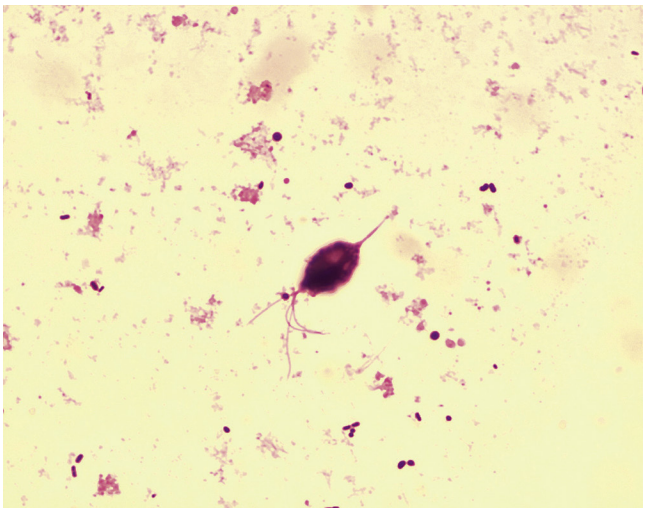

Fig. 72.6 *Trichomonas vaginalis* trophozoite. The trophozoite is 7 to 23 μm long and 6 to 8 μm wide (average, 13 × 7 μm). The flagella and a short, undulating membrane are present at one side, and an axostyle extends through the center of the parasite.

that is associated with itching, burning, and painful urination. Infection has also been associated with premature rupture of membranes, premature birth, other adverse pregnancy outcomes, and posthysterectomy cuff infections. Men are primarily asymptomatic carriers who serve as a reservoir for infections in women. However, men occasionally experience urethritis, prostatitis, and other urinary tract problems. Neonates can acquire the organism via passage through the birth canal and reports have documented *T. vaginalis* as a cause of neonatal pneumonia and conjunctivitis.

Laboratory Diagnosis

The microscopic examination of vaginal or urethral discharge for characteristic trophozoites is the diagnostic method of choice (Fig. 72.6). Stained (Giemsa, Papanicolaou) or unstained smears can be examined. The diagnostic yield may be improved by culturing the organism (93% sensitivity) or using monoclonal fluorescent antibody staining (86% sensitivity). A nucleic acid probe assay also is available commercially. Serologic tests may be useful in epidemiologic surveillance.

Treatment, Prevention, and Control

The drug of choice is metronidazole. Both male and female sex partners must be treated to avoid reinfection. Resistance to metronidazole has been reported and may require retreatment with higher doses. More recently, tinidazole has received FDA approval for treatment of trichomoniasis in adults and may be used as a first-line agent or for cases refractory to metronidazole. Personal hygiene, avoidance of shared toilet articles and clothing, and safe sexual practices are important preventive actions. Elimination of carriage in men is critical for the eradication of disease.

NEOBALANTIDIUM COLI

The intestinal protozoan *N. coli* is the only member of the Ciliophora group that is pathogenic for humans. Disease produced by *N. coli* is similar to amebiasis because the organisms elaborate proteolytic and cytotoxic substances that mediate tissue invasion and intestinal ulceration.

Physiology and Structure

The life cycle of *N. coli* is simple, involving ingestion of infectious cysts, excystation, and invasion of trophozoites into the mucosal lining of the large intestine, cecum, and terminal ileum (Fig. 72.7). The trophozoite is covered with rows of hairlike cilia that aid in motility. Morphologically more complex than amebae, *N. coli* has a funnel-like primitive mouth called a **cytostome,** which is a large and small nucleus involved in reproduction, food vacuoles, and two contractile vacuoles.

Epidemiology

N. coli is distributed worldwide. Swine and (less commonly) monkeys are the most important reservoirs. Infections are transmitted by the fecal-oral route; outbreaks are associated with contamination of water supplies with pig feces. Person-to-person spread, including through food handlers, has been implicated in outbreaks. Risk factors associated with human disease include contact with swine and substandard hygienic conditions.

Clinical Syndromes

As with other protozoan parasites, asymptomatic carriage of *N. coli* can exist. Symptomatic disease is characterized by abdominal pain and tenderness, tenesmus, nausea, anorexia, and watery stools with blood and pus. Ulceration of the intestinal mucosa, as with amebiasis, can be seen; a secondary complication caused by bacterial invasion into the eroded intestinal mucosa can occur. Extraintestinal invasion of other organs is extremely rare in neobalantidiasis.

Laboratory Diagnosis

Microscopic examination of feces for trophozoites and cysts is performed. The trophozoite is very large, varying in length from 50 to 200 μm and in width from 40 to 70 μm. The surface is covered with cilia, and the prominent internal structure is a **macronucleus.** A **micronucleus** also is present. Two pulsating, contractile vacuoles also are seen in fresh preparations of the trophozoites. The cyst is smaller (40 to 60 μm in diameter), is surrounded by a clear refractile wall, and has a single nucleus in the cytoplasm. *N. coli* is a large organism compared with other intestinal protozoa and is readily detected in fresh, wet microscopic preparations.

Treatment, Prevention, and Control

The drug of choice is tetracycline; iodoquinol and metronidazole are alternative antimicrobials. Actions for prevention and control are similar to those for amebiasis. Appropriate personal hygiene, maintenance of sanitary conditions, and the careful monitoring of pig feces are all important preventive measures.

Sporozoa (Apicomplexa)

Sporozoa constitute a very large group called **Apicomplexa** or **Coccidia,** some members of which are discussed in this section with the intestinal parasites and others with the blood and tissue parasites. All sporozoans demonstrate typical characteristics, especially the existence of asexual **(schizogony)** and sexual **(gametogony)** reproduction.

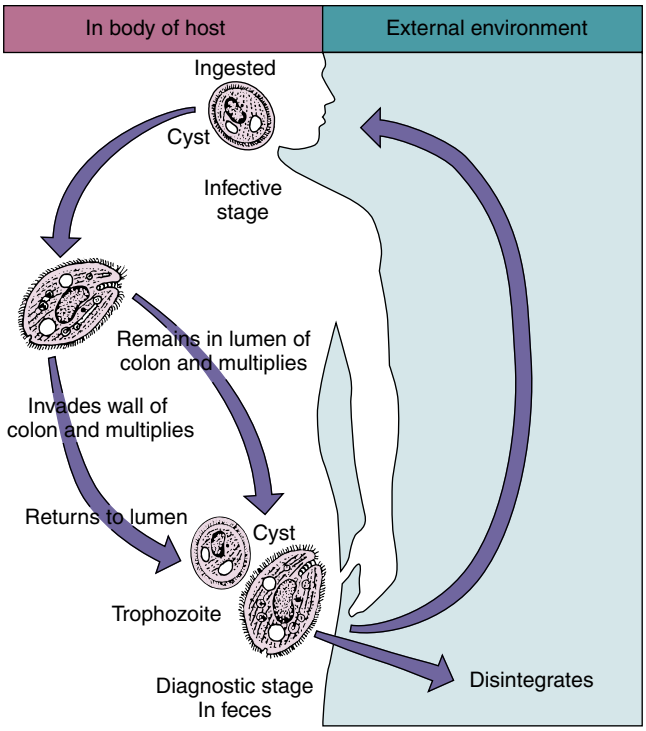

Fig. 72.7 Life cycle of *Neobalantidium coli.*

Most members of the group also share alternative hosts; for example, in malaria, mosquitoes harbor the sexual cycle and humans the asexual cycle. The intestinal Sporozoa discussed in this chapter are *Cystoisospora* (formerly *Isospora*), *Sarcocystis, Cryptosporidium*, and *Cyclospora* species.

CYSTOISOSPORA (FORMERLY *ISOSPORA*) *BELLI*

Physiology and Structure

C. belli is a coccidian parasite of the intestinal epithelium. Both sexual and asexual reproduction in the intestinal epithelium can occur, resulting in tissue damage (Fig. 72.8). The end product of gametogenesis is the oocyst, which is the diagnostic stage present in fecal specimens.

Epidemiology

Cystoisospora organisms are distributed worldwide but are infrequently detected in stool specimens. This parasite has been reported with increasing frequency in healthy and immunocompromised patients. This is probably because of the increased awareness of disease caused by *Cystoisospora* species in patients with acquired immunodeficiency syndrome (AIDS). Infection with this organism follows ingestion of contaminated food or water or oral-anal sexual contact.

Clinical Syndromes

Infected individuals may be asymptomatic carriers or suffer mild to severe gastrointestinal disease. Disease most commonly mimics giardiasis, with a malabsorption syndrome characterized by loose, foul-smelling stools. Chronic diarrhea with weight loss, anorexia, malaise, and fatigue can be seen, although it is difficult to separate this presentation from the patient's underlying disease.

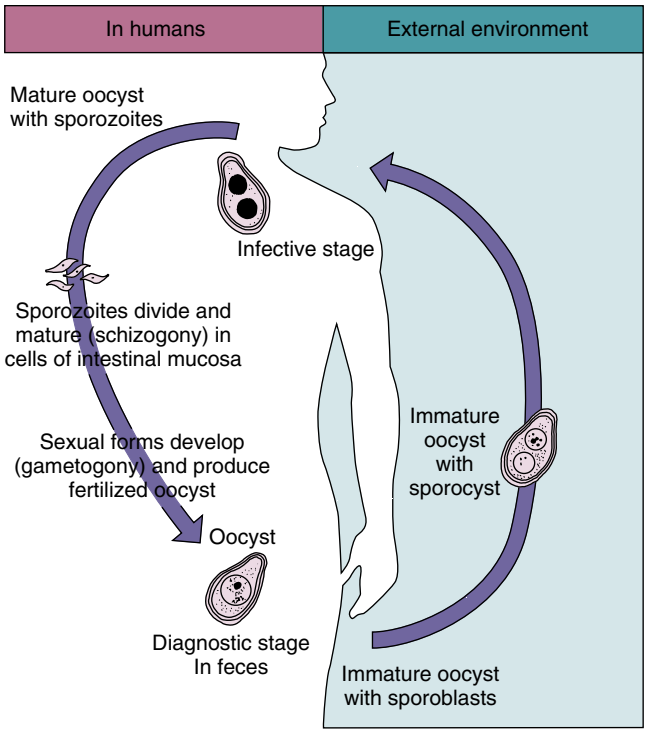

Fig. 72.8 Life cycle of *Cystoisospora* (formerly *Isospora*) species.

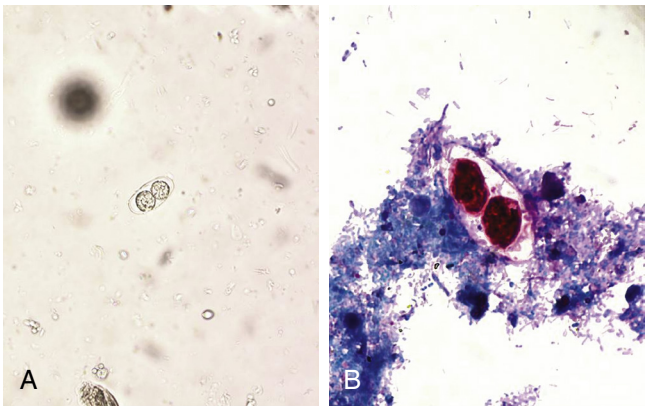

Fig. 72.9 Oocyst of *Cystoisospora belli* containing two sporoblasts. (A) Wet mount. (B) Acid-fast stain. Oocysts are ovoid (approximately 25 μm long and 15 μm wide) with tapering ends.

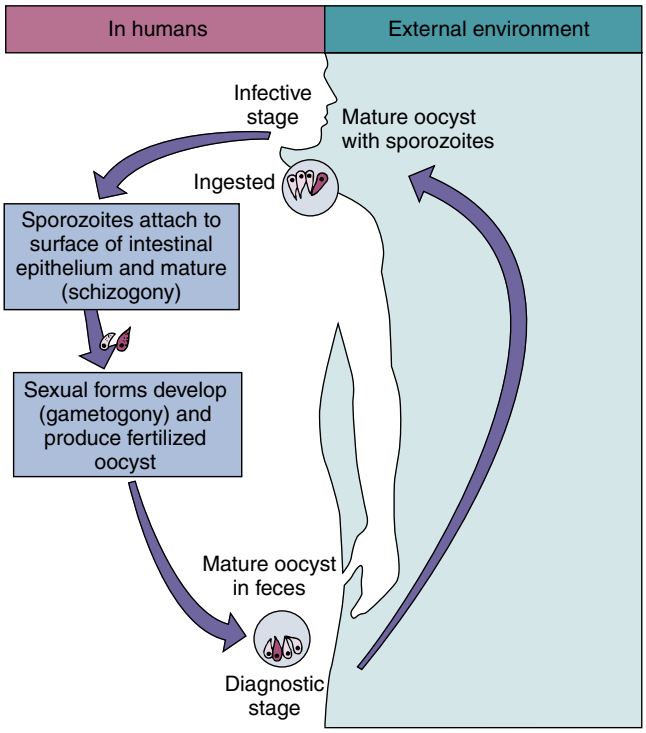

Fig. 72.10 Life cycle of *Cryptosporidium* species.

Laboratory Diagnosis

Careful examination of concentrated stool sediment and special staining with iodine or a modified acid-fast procedure reveal the parasite (Fig. 72.9). Small bowel biopsy has been used to establish the diagnosis when the results of tests on stool specimens are negative.

Treatment, Prevention, and Control

The drug of choice is trimethoprim-sulfamethoxazole, with the combination of pyrimethamine and sulfadiazine an acceptable alternative. Prevention and control are effected by maintaining personal hygiene and highly sanitary conditions and by avoiding oral-anal sexual contact.

SARCOCYSTIS SPECIES

Sarcocystis species can be isolated from pigs and cattle and are identical in all aspects to *Cystoisospora* species, with one exception: *Sarcocystis* oocysts rupture before passage in stool specimens, and only sporocysts are present. Clinical *Sarcocystis* infections in humans can manifest either as intestinal disease if infected meat is ingested or as muscular disease if sporocysts are ingested. Intestinal disease is characterized by nausea, abdominal pain, and diarrhea. Some individuals can be infected and show no clinical signs. Muscle sarcocysts in humans are associated with fever and muscle pain. Recent findings indicate that foodborne outbreaks of diarrhea can occur in humans that eat raw horse meat containing sarcocysts of *S. fayeri*. These sarcocysts produce a 15-kDa actin-depolymerizing factor protein that induces diarrhea in model systems. There is no known treatment for intestinal or muscular sarcocystosis in humans. There are no published attempts to treat patients with *S. fayeri* food poisoning. It most likely can be prevented by cooking horse meat prior to consumption based on the toxin structure.

CRYPTOSPORIDIUM SPECIES

Physiology and Structure

The life cycle of *Cryptosporidium* species is typical of coccidians, as is the intestinal disease, but this species differs in the intracellular location of the organism in the epithelial cells (Fig. 72.10). In contrast to the deep intracellular invasion observed with *Cystoisospora* species, *Cryptosporidium* organisms are found just within the brush border of the intestinal epithelium. The coccidia attach to the surface of the cells and replicate by a series of processes (merogony, gametogony, sporogony) leading to the production of new

Clinical Case 72.3 **Cryptosporidiosis**

Quiroz and colleagues (*J Infect Dis* 181:685–700, 2000) described an outbreak of cryptosporidiosis that was linked to a food handler. In the fall of 1998, an outbreak of gastroenteritis among university students was reported to the Department of Health. Preliminary findings suggested that the illness was associated with eating at one of the campus cafeterias; four employees of this cafeteria had a similar illness. The outbreak was thought to be caused by a viral agent until *Cryptosporidium parvum* was detected in the stool specimen of several cafeteria employees. In a case-control study of 88 case patients and 67 control subjects, eating in one of two cafeterias was associated with diarrheal illness. *C. parvum* was detected in stool samples of 16 (70%) of 23 ill students and 2 of 4 ill employees. One ill food handler with laboratory-confirmed cryptosporidiosis prepared raw produce on the days surrounding the outbreak. All 25 *C. parvum* isolates submitted for DNA analysis, including three from the ill food handler, were genotype 1. This outbreak illustrates the potential for cryptosporidiosis to cause foodborne illness. Epidemiologic and molecular evidence indicate that an ill food handler was the likely outbreak source.

infectious oocysts. After sporogony, the mature oocysts may either excyst within the digestive tract of the host, leading to the infection of new cells, or may be excreted into the environment.

Epidemiology

Cryptosporidium species are distributed worldwide. Infection is reported in a wide variety of animals, including mammals, reptiles, and fish. There are over 30 different species of *Cryptosporidium*; however, *C. hominis* and *C. parvum* are the species most commonly infecting humans. Waterborne transmission of cryptosporidiosis is now well documented as an important route of infection. The massive outbreak of cryptosporidiosis in Milwaukee in 1993 (approximately 300,000 individuals infected) was linked to contamination of the municipal water supply. Cryptosporidia are resistant to the usual water-purification procedures (chlorination and ozone), and it is believed that runoff of local waste and surface water into municipal water supplies is an important source of contamination. Zoonotic spread from animal reservoirs to humans, as well as person-to-person spread by fecal-oral and oral-anal routes, also are common means of infection. Veterinary personnel, animal handlers, children, homosexual men, and immunocompromised individuals (the elderly, AIDS patients, persons with primary immunodeficiency, and cancer and transplant patients undergoing immunosuppressive therapy) are at particularly high risk for infection. Many outbreaks have now been described in municipal swimming pools and day-care centers, in which fecal-oral transmission is common.

Clinical Syndromes

As with other protozoan infections, exposure to *Cryptosporidium* organisms may result in asymptomatic carriage (Clinical Case 72.3). Disease in previously healthy individuals is usually a mild, self-limiting **enterocolitis** characterized by watery diarrhea without blood. Spontaneous remission after an average of 10 days is characteristic. In contrast, disease in immunocompromised patients (e.g., patients with AIDS), characterized by 50 or more stools per day and tremendous fluid loss, can be severe and last for months to years. In some patients with AIDS, disseminated *Cryptosporidium* infections have been reported.

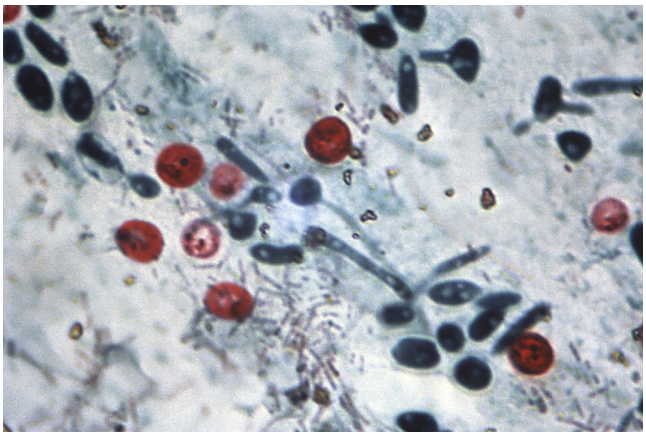

Fig. 72.11 Acid-fast–stained *Cryptosporidium* oocysts (approximately 5 to 7 μm in diameter). (From CDC Public Health Image Library.)

Laboratory Diagnosis

Cryptosporidium may be detected in large numbers in unconcentrated stool specimens obtained from immunocompromised individuals with diarrhea. Oocysts generally measure 5 to 7 μm and may be concentrated with the modified zinc sulfate centrifugal flotation technique or the Sheather sugar flotation procedure. Specimens may be stained using the modified **acid-fast** method (Fig. 72.11) or by a direct immunofluorescence assay. Both an enzyme immunoassay and an immunochromatographic assay for detecting fecal antigen are commercially available. It should be noted that *Cryptosporidium* will not be detected on routine microscopic examination for ova and parasites (need to specify acid-fast staining) and that data now suggest that the immunoassays are superior to microscopic methods for detection of this organism in fecal samples. The number of oocysts shed in stool may fluctuate; therefore a minimum of three specimens should be examined. Serologic procedures are used in epidemiologic and seroprevalence studies but are not yet widely available for diagnosing and monitoring infections. PCR assays for *Cryptosporidium* spp. are commercially available as part of gastrointestinal or multiplex enteric panel assays targeting major diarrheal pathogens. They offer high sensitivity, specificity, and the ability to detect co-infections, and may lead to more frequent detection of *Cryptosporidium*, which is not commonly ordered in tests of diarrheal pathogens

Treatment, Prevention, and Control

Nitazoxanide is approved by the FDA for the treatment of cryptosporidiosis in nonimmunocompromised individuals older than 12 months, but it is not yet approved for treatment of cryptosporidiosis in immunocompromised individuals. Unfortunately, no broadly effective therapy has been developed for managing *Cryptosporidium* infections in immunocompromised patients. The drugs paromomycin

and azithromycin have been used to treat cryptosporidiosis in HIV-infected patients and have been shown to reduce the parasite load. There is also evidence to suggest that some antiretroviral compounds may have a direct inhibitory effect on *Cryptosporidium*. Spiramycin may help control the diarrhea in some patients in the early stages of AIDS who have cryptosporidiosis, but it is ineffective in patients who have progressed to the later stages of AIDS. Spiramycin was no more effective than placebo in treating cryptosporidial diarrhea in infants. Therapy consists primarily of supportive measures to restore the tremendous fluid loss from the watery diarrhea.

Because of the widespread distribution of this organism in humans and other animals, preventing infection is difficult. The same methods of improved personal hygiene and sanitation used for other intestinal protozoa should be maintained for this disease. Contaminated water supplies should be treated with chlorination and filtration. In addition, avoidance of high-risk sexual activities is critical.

CYCLOSPORA SPECIES

Physiology and Structure

Cyclospora is a coccidian parasite that is taxonomically related to *Cystoisospora* species, *Cryptosporidium parvum*, and *Toxoplasma gondii*. A single species infecting humans, *C. cayetanensis*, has been identified thus far.

Cyclospora organisms are similar to *Cystoisospora* in that oocysts are excreted unsporulated and require a period of time outside the host for maturation to occur. On ingestion, the sporulated oocyst undergoes the excystation process in the lumen of the small intestine, releasing sporozoites. Sporozoites infect cells to form type I merozoites, and these form type II merozoites. The type II merozoites differentiate within the mucosal cells into sexual stages, the microgametocytes and macrogametocytes. The macrogametocyte is fertilized by the microgametocyte and produces a zygote. Oocysts are then formed and excreted into the environment as unsporulated oocysts. The pathogenic mechanisms by which *Cyclospora* species cause clinical illness are unknown; however, the organism usually infects the upper small bowel and causes pronounced histopathologic changes. The organism is found within vacuoles in the cytoplasm of jejunal epithelial cells, and its presence is associated with inflammatory changes, villous atrophy, and crypt hyperplasia.

The morphologic characteristics of *Cyclospora* species are similar to those of *Cystoisospora* species and *C. parvum* with a few exceptions. The oocysts of *Cyclospora* species are spheric and are 8 to 10 μm in diameter, as opposed to the smaller oocysts of *C. parvum* (5 to 7 μm) and the much larger elliptic oocysts of *Cystoisospora* species (15 to 25 μm). The oocysts of *Cyclospora* species contain two sporocysts, each of which contains two sporozoites, which in turn contain a membrane-bound nucleus and micronemes characteristic of the sporozoans. In contrast, the *Cryptosporidium* oocyst contains four naked, or nonencysted, sporozoites, whereas the *Cystoisospora* oocyst contains two sporocysts, each containing four sporozoites.

Epidemiology

As with *Cryptosporidium*, *Cyclospora* is widely distributed throughout the world and infects a variety of reptiles, birds, and mammals. Although direct animal-to-human or person-to-person transmission has not been documented, there is now compelling evidence that *Cyclospora* infection is acquired through contaminated water. In areas of endemicity, such as Nepal, studies have documented an annual surge of cyclosporiasis that coincides with the rainy season. The prevalence of infection (symptomatic and asymptomatic) ranges from 2% to 18% in endemic areas and is estimated at 0.1% to 0.5% in developed countries. Outbreaks in the United States have occurred during the summer months and have been correlated with the consumption of contaminated fruits and vegetables; transmission via contaminated water has also been documented. Similar to *Cryptosporidium*, *Cyclospora* species are resistant to chlorination and not readily detected by methods used currently to ensure the safety of supplies of drinking water.

Clinical Syndromes

The clinical manifestations of cyclosporiasis resemble those of cryptosporidiosis and include mild nausea, anorexia, abdominal cramping, and watery diarrhea. Fatigue, malaise, flatulence, and bloating also have been reported. In immunocompetent hosts, diarrhea is self-limited but may be prolonged and last for weeks. Among immunocompromised people (specifically, patients infected with HIV) clinical illness is typically prolonged and severe and is associated with a high rate of recurrence. Biliary tract infection with *Cyclospora* infection has been reported in patients with AIDS.

Laboratory Diagnosis

The diagnosis of cyclosporiasis is based on the microscopic detection of oocysts in stool. Oocysts may be detected by light microscopic examination of unstained fecal material (wet mount), in which they appear as nonrefractile, spheric to oval, slightly wrinkled bodies measuring 8 to 10 μm in diameter; they have an internal cluster of membrane-bound globules (Fig. 72.12). In fresh specimens, *Cyclospora* organisms fluoresce when examined with an ultraviolet fluorescence microscope fitted with a 365-nm excitation filter.

Cyclospora oocysts may be concentrated with the modified zinc sulfate centrifugal flotation technique or the Sheather sugar flotation procedure. Organisms are acid-fast, so they can be detected using one of the many acid-fast staining techniques, including the modified Ziehl-Neelsen stain or the Kinyoun acid-fast stain (Fig. 72.13). A distinguishing feature of *Cyclospora* species is its variable appearance on acid-fast staining, which ranges from unstained to mottled pink to deep red.

The relative sensitivity, specificity, and predictive value of the various methods for diagnosing *Cyclospora* infection are not known. Currently, there are no immunodiagnostic techniques to aid in the diagnosis and monitoring of these infections. Much attention has been placed on molecular methods to detect *C. cayetanensis* oocysts in stools, in water samples, and on produce because of the numerous outbreaks of *C. cayetanensis* infections. Gastrointestinal panels are available that can test simultaneously for multiple enteric pathogens, including bacterial, viral, and parasitic pathogens. A multiplex assay for *Giardia* spp., *E. histolytica*, *Cyclospora* spp., and *Cryptosporidium* spp. is commercially available and approved by the FDA.

Fig. 72.12 Sporulated oocyst of *Cyclospora cayetanensis*. The oocysts measure 8 to 10 μm in diameter and contain two sporocysts, each with two sporozoites (saline wet mount, ×900). (Courtesy Mr. J. Williams; from Peters, W., Giles, H.M., 1995. Color Atlas of Tropical Medicine and Parasitology, fourth ed. Mosby, London.)

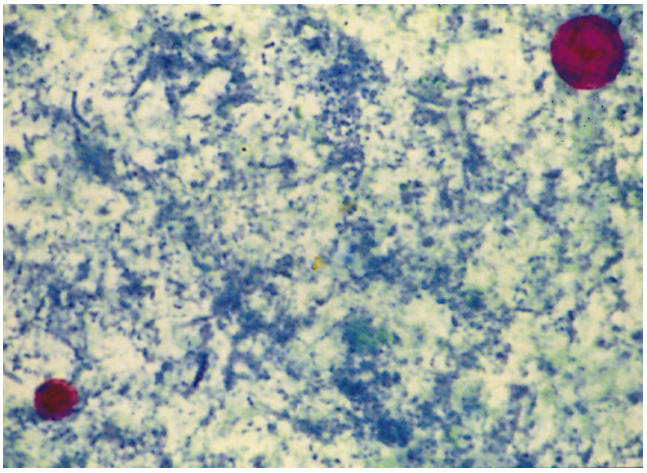

Fig. 72.13 Oocysts of *Cryptosporidium parvum (lower left)* and *Cyclospora cayetanensis (upper right)*. Both parasites stain red with Ziehl-Neelsen stain; however, *Cyclospora* organisms typically take up variable amounts of the stain, and the oocysts are larger (8 to 10 μm compared with 5 to 7 μm). (Courtesy Mr. J. Williams; from Peters, W., Giles, H.M., 1995. Color Atlas of Tropical Medicine and Parasitology, fourth ed. Mosby, London.)

Treatment, Prevention, and Control

The drug of choice for the treatment of *C. cayetanensis* infection is trimethoprim (160 mg)-sulfamethoxazole (800 mg) given twice daily for 7 days. The effectiveness of trimethoprim-sulfamethoxazole has been demonstrated in anecdotal reports, in a large, open-label study of patients infected with HIV and in a placebo-controlled trial. In HIV-infected patients, it appears that the high rate of recurrence can be attenuated with long-term suppressive therapy with trimethoprim-sulfamethoxazole. Although numerous additional agents, including metronidazole, nitazoxanide, ciprofloxacin, norfloxacin, quinacrine, nalidixic acid, tinidazole, and diloxanide furoate, have been used in various trials, the effectiveness of any one of these agents has not been proved.

As with *Cryptosporidium* species, prevention of *Cyclospora* infection is difficult. Although *Cyclospora* organisms appear resistant to chlorination, the treatment of water supplies with chlorination and filtration remains a reasonable practice. In addition, the same methods of improved personal hygiene and sanitation used for other intestinal protozoa should be used as preventive measures for this disease.

Case Study and Questions

A 25-year-old man has profuse watery, nonbloody diarrhea but has no fever. He is HIV-positive, and his current CD4 T-cell count is 50.

1. Which of the following is least likely to be the cause of his symptoms?
   a. *Cyclospora cayetanensis*
   b. *Entamoeba histolytica*
   c. *Enterocytozoon bieneusi*
   d. *Cryptosporidium parvum*

2. How would you make the diagnosis?

3. What is the mode of transmission of the possible etiologic agents?
   a. Aerosol
   b. Percutaneous
   c. Fecal-oral
   d. Vector

73 Blood and Tissue Protozoa

The patient, a 44-year-old heart transplant patient, complained to her primary physician about headache, nausea, and vomiting approximately 1 year after transplant. She had no skin lesions. A computed tomography (CT) scan of the head demonstrated ring-enhancing lesions. A biopsy of the lesions was performed. All cultures (bacterial, fungal, viral) were negative. Special stains of the tissue revealed multiple cystlike structures of varying size.

1. What was the differential diagnosis of infectious agents in this patient? What was the most likely etiologic agent?
2. What other tests would have been done to confirm the diagnosis?
3. What aspects of the medical history might suggest a risk for infection with this agent?
4. What were the therapeutic options and the likelihood that therapy would be successful?

Answers to these questions are available on www.StudentConsult.com.

- Five species that infect humans share a common life cycle
- Routes of acquisition: mosquito, transfusion, needle sharing, congenital
- *P. falciparum* produces daily (quotidian) chills and fever with nausea, vomiting, diarrhea progressing to tertian (36 to 48 hours) periodicity with fulminating disease (malignant tertian); no persistent liver stage
- *P. knowlesi* produces daily (quotidian) fever, chills, headache, rigors, abdominal pain, cough (severe symptoms in 7% of cases; respiratory distress and hepatorenal failure); no persistent liver stage
- *P. vivax* causes "benign tertian malaria" with paroxysms of fever and chills every 48 hours; a spectrum of severe, life-threatening syndromes similar to that with *P. falciparum* may be seen; a liver stage may cause relapses and recrudescences
- *P. ovale* causes benign tertian malaria similar to that of *P. vivax* with both relapses and recrudescence
- *P. malariae* has a long (18 to 40 days) incubation period and causes a moderate to severe disease with a 72-hour (quartan or malarial malaria) periodicity; no persistent liver stage

Epidemiology

- Infection with *Plasmodium* spp. accounts for 216 million episodes with approximately 500,000 deaths annually, 90% of which are in Africa
- Vector is the *Anopheles* mosquito, which is widely distributed in tropical, subtropical, and temperate regions
- *P. falciparum:* occurs almost exclusively in tropical and subtropical regions
- *P. knowlesi:* infects Old World Monkeys, and increasingly humans, in Malaysia and neighboring countries throughout Southeast Asia
- *P. vivax:* widest geographic distribution (tropics, subtropics, temperate regions); 80% of cases occur in South America and Southeast Asia
- *P. ovale:* distributed primarily in tropical Africa; also found in Asia and South America
- *P. malariae:* occurs in same tropical and subtropical areas as other malarial parasites but less prevalent

Diagnosis

- Most widely used method: detection of parasites in thick and thin blood films stained with Giemsa or Wright stain
- Antigen detection using an RDT; used in both the field and diagnostic laboratories as an adjunct to microscopic examination of blood films

Treatment, Prevention, and Control

- Treatment of malaria is based on history regarding travel to endemic areas, prompt clinical review and differential diagnosis, accurate and rapid laboratory work, and correct use of antimalarial drugs
- Chloroquine or parenteral quinine is drug of choice for susceptible strains of *Plasmodium;* widespread resistance to chloroquine seen with *P. falciparum* and *P. vivax*
- Chemoprophylaxis with chloroquine, doxycycline, Malarone, or mefloquine coupled with avoiding mosquito bites (netting, insect repellents, clothing) required for prevention
- Elimination of mosquito breeding places

BABESIA

Trigger Words

Babesia, zoonosis, ticks, tetrad forms, splenectomy, intracellular, RBC

Biology, Virulence, and Disease

- Intracellular sporozoan parasites, morphologically resemble plasmodia
- Zoonosis infecting a variety of animals
- *Babesia microti:* usual cause of babesiosis in United States; transmitted by *Ixodes* ticks
- Incubation period of 1 to 4 weeks
- Symptoms: general malaise, fever without periodicity, headache, chills, sweating, fatigue, weakness
- Hemolytic anemia coupled with renal failure can occur
- Splenectomy or functional asplenia, immunosuppression, HIV infection, advanced age increase susceptibility to infections and more severe disease

Epidemiology

- >70 different species of *Babesia* found in Africa, Asia, Europe, North America
- *Ixodes dammini:* tick vector along U.S. northeastern seaboard
- Natural reservoir hosts: field mice, voles, other small rodents
- Disease may be severe in HIV-infected individuals
- *B. microti* increasingly transmitted by blood transfusions

Diagnosis

- Examination of blood smears is diagnostic method of choice
- Serologic tests and PCR also used to diagnose babesiosis

Treatment, Prevention, and Control

- Treatment of choice for mild to moderate illness: combination of atovaquone and azithromycin

Continued

Summaries Clinically Significant Organisms—cont'd

- Treatment for severe disease: clindamycin, quinine, exchange transfusion
- Protective clothing, insect repellents can minimize tick exposure
- Prompt removal of ticks can be protective

TOXOPLASMA GONDII

Trigger Words

Cat feces, raw meat, lymphadenitis, CNS lesion, encephalomyelitis, cat litter, congenital infection, AIDS

Biology, Virulence, and Disease

- Typical coccidian intracellular parasite found in a wide variety of animals, including birds and humans
- Essential reservoir host: common house cat and other felines
- Most *T. gondii* infections asymptomatic
- Symptoms occur when parasite moves from blood to tissues; include fever, chills, headaches, myalgia, lymphadenitis, fatigue
- Chronic disease marked by hepatitis, encephalomyelitis, and myocarditis
- Chorioretinitis may lead to blindness
- Congenital infection has serious sequelae
- Reactivation of cerebral toxoplasmosis is a major cause of encephalitis in patients with AIDS

Epidemiology

- Human infections ubiquitous
- Infection from ingestion of improperly cooked meat from intermediate-host animals or ingestion of infective oocysts from contaminated cat feces
- Transplacental infection can occur during pregnancy
- Rate of severe infection affected by patient's immune status
- Illness in immunocompromised host believed to be caused by reactivation of previously latent infection rather than new exposure to organism

Diagnosis

- Increasing antibody titers documented in serially collected blood specimens
- Panel of tests (TSP) is used to determine recent versus past acquisition of infection
- Diagnosis of *Toxoplasma* encephalitis usually involves imaging study of brain
- Microscopy, serologic, and molecular techniques may be required for definitive diagnosis

Treatment, Prevention, and Control

- Treatment of choice: initial high-dose regimen of pyrimethamine plus sulfadiazine followed by lower doses of both drugs indefinitely (AIDS patients and other immunocompromised patients)
- Clindamycin or spiramycin may be used in first trimester of pregnancy
- High-risk patients may be considered for prophylaxis
- Additional preventive measures: avoid consumption and handling of raw or undercooked meat, avoid exposure to cat feces

LEISHMANIA

Trigger Words

Kala-azar, Dumdum fever, cutaneous and mucocutaneous disease, visceral leishmaniasis, sand fly, post–kala-azar dermal leishmaniasis

Biology, Virulence, and Disease

- *Leishmania:* obligate intracellular parasites transmitted from animal to human or human to human by bites from infected female sand fly
- Many different species can infect humans, producing a variety of diseases (cutaneous, diffuse cutaneous, mucocutaneous, visceral)
- Clinical syndromes depend on species involved; most common species: cutaneous *(L. tropica),* mucocutaneous *(L. braziliensis),* visceral *(L. donovani, L. infantum),* post–kala-azar dermal leishmaniasis *(L. donovani)*

Epidemiology

- Natural reservoirs: rodents, possums, anteaters, sloths, dogs, cats
- Infection may be transmitted by animal-vector-human or human-vector-human cycle, by direct contact with infected lesion, or mechanically by flies
- Mucocutaneous leishmaniasis most often occurs in Bolivia, Brazil, Peru; cutaneous leishmaniasis much more widespread throughout Middle East and in focal areas of South America
- Visceral leishmaniasis (kala-azar, Dumdum fever): ≈50,000 cases per year, 90% localized to Bangladesh, Brazil, India, Nepal, Sudan

Diagnosis

- Diagnosis of visceral, cutaneous, or mucocutaneous leishmaniasis made on clinical grounds in endemic areas
- Definitive diagnosis depends on detecting amastigotes in clinical samples or promastigotes in culture; molecular techniques have been used for diagnosis, prognosis, and species identification

Treatment, Prevention, and Control

- Drug of choice for all forms of leishmaniasis is the pentavalent antimonial compound sodium stibogluconate (Pentostam)
- Fluconazole and miltefosine efficacious in cutaneous disease
- Stibogluconate remains drug of choice for mucocutaneous leishmaniasis
- Prevention involves prompt treatment of human infections and control of reservoir hosts, along with vector control

TRYPANOSOMES

Trigger Words

Sleeping sickness, tsetse fly, reduviid bugs, chagoma, Romaña sign, megaesophagus, Winterbottom sign, Chagas disease

Biology, Virulence, and Disease

- *Trypanosoma*, a hemoflagellate, causes two distinctly different forms of disease: African trypanosomiasis and American trypanosomiasis
- African trypanosomiasis (sleeping sickness): chronic disease of several years' duration, transmitted by tsetse flies, fatal without treatment
- American trypanosomiasis (Chagas disease): asymptomatic, acute, or chronic forms, transmitted by reduviid bugs

Epidemiology

- *T. brucei gambiense* limited to tropical West and Central Africa, correlating to range of tsetse fly vector
- *T. b. rhodesiense* found in East Africa, especially cattle-raising countries
- Domestic and wild game animals act as reservoir hosts for *T. b. rhodesiense*
- *T. cruzi* occurs widely in both reduviid bugs and a wide variety of reservoir animals in North, Central, and South America
- Because of the chronic nature of infection, screening of solid organ and blood donors for Chagas disease has become important

Diagnosis

- Agents of sleeping sickness can be demonstrated in blood films, aspirations from lymph nodes, and concentrated spinal fluid
- *T. cruzi* can be demonstrated in blood films early in acute stage of disease

Treatment, Prevention, and Control

- Suramin: drug of choice for treating acute blood and lymphatic stages of both Gambian and Rhodesian forms of sleeping sickness; pentamidine is an alternative
- Melarsoprol: drug of choice for CNS disease
- Effective control measures: integrated approach to reduce human reservoir of infection, use of fly traps and insecticide
- Drugs of choice for treatment of Chagas disease: benznidazole and nifurtimox
- Vector control important: insecticide, eradication of nests, construction of homes to prevent nesting of bugs

CNS, Central nervous system; *PCR,* polymerase chain reaction; *RBC,* red blood cell; *RDT,* rapid diagnostic test; TSP, *T. gondii* serologic profile.

BOX 73.1 Medically Important Blood and Tissue Protozoa

Plasmodium species
Babesia species
Toxoplasma species
Sarcocystis species
Acanthamoeba species
Balamuthia species
Naegleria species
Leishmania species
Trypanosoma species

TABLE 73.1 Human Malarial Parasites

Parasite	Disease
Plasmodium vivax	Benign tertian malaria
P. ovale	Benign tertian or ovale malaria
P. malariae	Quartan or malarial malaria
P. falciparum	Malignant tertian malaria
P. knowlesi	Simian malaria or quotidian malaria

The protozoa of blood and tissues are closely related to the intestinal protozoan parasites in practically all aspects, except for their sites of infection (Box 73.1). The malaria parasites (*Plasmodium* species) infect both blood and tissues.

Plasmodium Species

Plasmodia are coccidian or sporozoan (Apicomplexa) parasites of blood cells, and as seen with other coccidia, they require two hosts: the mosquito for the sexual reproductive stages and humans and other animals for the asexual reproductive stages. Infection with *Plasmodium* spp. (i.e., malaria) accounts for 216 million episodes with approximately 500,000 deaths annually, 90% of which are in Africa.

The five species of plasmodia that infect humans are *P. falciparum, P. knowlesi, P. vivax, P. ovale,* and *P. malariae* (Table 73.1). These species share a common life cycle, as illustrated in Fig. 73.1. Human infection is initiated by the bite of an *Anopheles* mosquito, which introduces infectious plasmodia **sporozoites** via its saliva into the circulatory system. The sporozoites are carried to the parenchymal cells of the liver, in which asexual reproduction **(schizogony)** occurs. This phase of growth is termed the **exoerythrocytic cycle** and lasts 8 to 25 days, depending on the plasmodial species. Some species (e.g., *P. vivax, P. ovale*) can establish a dormant hepatic phase in which the sporozoites (called **hypnozoites** or **sleeping forms**) do not divide. The presence of these viable plasmodia can lead to the relapse of infections months to years after the initial clinical disease (relapsing malaria). The hepatocytes eventually rupture, liberating the plasmodia (termed **merozoites** at this stage), which in turn attach to specific receptors on the surface of erythrocytes and enter the cells, initiating the erythrocytic cycle.

Asexual replication progresses through a series of stages (ring, trophozoite, schizont) that culminates in the rupture

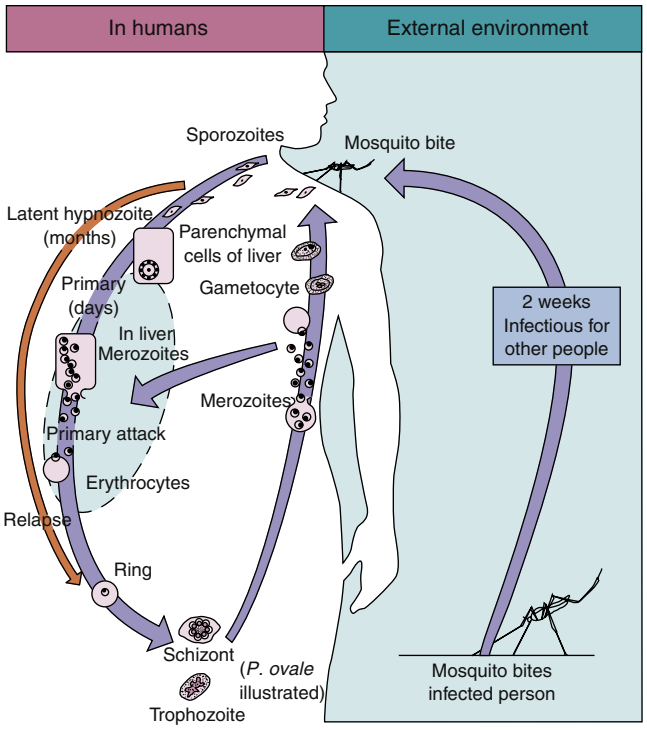

Fig. 73.1 Life cycle of *Plasmodium* species.

of the erythrocyte, releasing up to 24 merozoites, which initiates another cycle of replication by infecting other erythrocytes. Some merozoites also develop within erythrocytes into male and female **gametocytes.** If a mosquito ingests mature male and female gametocytes during a blood meal, the sexual reproductive cycle of malaria can be initiated, with the eventual production of sporozoites infectious for humans. This sexual reproductive stage within the mosquito is necessary for the maintenance of malaria within a population.

Most malaria seen in the United States is acquired by visitors or residents of countries with endemic disease (imported malaria). However, the appropriate vector, the *Anopheles* mosquito, is found in several sections of the United States, and domestic transmission of disease has been observed (introduced malaria). In addition to transmission by mosquitos, malaria can be acquired by blood transfusions from an infected donor (transfusion malaria). This type of transmission can also occur among narcotic addicts who share needles and syringes ("mainline" malaria). Congenital acquisition, although rare, also is a possible mode of transmission (congenital malaria).

PLASMODIUM FALCIPARUM

Physiology and Structure

P. falciparum demonstrates no selectivity in host erythrocytes and invades any red blood cell (RBC) at any stage in its existence. Also, multiple merozoites can infect a single erythrocyte; thus three or even four small rings may be seen in an infected cell (Fig. 73.2). *P. falciparum* is often seen in the host cell at the very edge or periphery of the cell membrane, appearing almost as if it were "stuck" on the outside of the cell (see Fig. 73.2). This is called the

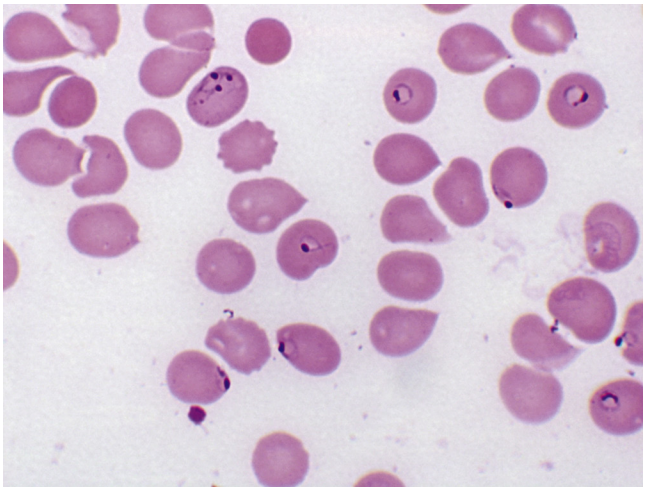

Fig. 73.2 Ring forms of *Plasmodium falciparum*. Note the multiple ring forms and appliqué (accolé) forms within the individual erythrocytes, which is characteristic of this organism.

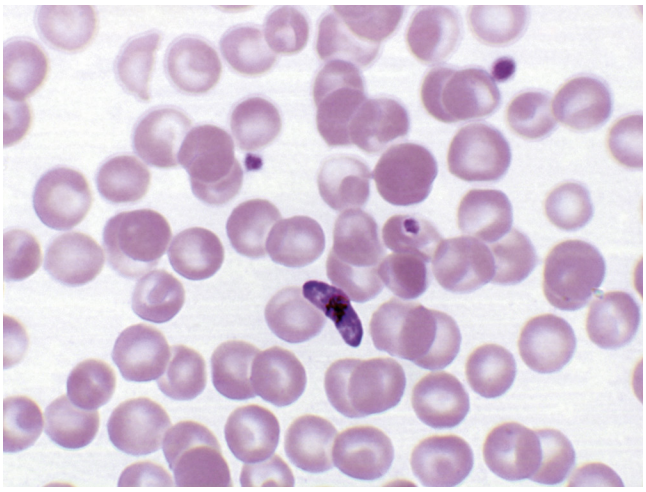

Fig. 73.3 Mature gametocyte of *Plasmodium falciparum*. The presence of this sausage-shaped form is diagnostic of *P. falciparum* malaria.

appliqué or **accolé** position and is distinctive for this species.

Growing trophozoite stages and schizonts of *P. falciparum* are rarely seen in blood films because their forms are sequestered in the liver and spleen. Only in very heavy infections are they found in the peripheral circulation. Thus peripheral blood smears from patients with *P. falciparum* malaria characteristically contain only young ring forms and occasionally gametocytes. The typical crescentic gametocytes are diagnostic for the species (Fig. 73.3). Infected RBCs do not enlarge and become distorted as they do with *P. vivax* and *P. ovale*. Occasionally, reddish granules known as **Maurer dots** are observed in *P. falciparum*.

P. falciparum, similar to *P. knowlesi* and *P. malariae*, does not produce hypnozoites in the liver. Relapses from the liver are not known to occur.

Epidemiology

P. falciparum occurs almost exclusively in tropical and subtropical regions. Co-infection with human immunodeficiency virus (HIV) is common in these regions and may pose a risk factor for severe malaria.

Clinical Syndromes

The incubation period of *P. falciparum* is the shortest of all the plasmodia, ranging from 7 to 10 days, and does not extend for months to years. After the early influenza-like symptoms, *P. falciparum* rapidly produces daily **(quotidian)** chills and fever and severe nausea, vomiting, and diarrhea. The periodicity of the attacks then becomes **tertian (36 to 48 hours),** and fulminating disease develops. The term **malignant tertian malaria** is appropriate for this infection. Because the symptoms of this type of malaria are similar to those of intestinal infections, the nausea, vomiting, and diarrhea have led to the observation that malaria is "the malignant mimic."

Although any malaria infection may be fatal, *P. falciparum* is the most likely to result in death if left untreated. The increased numbers of erythrocytes infected and destroyed result in toxic cellular debris, adherence of RBCs to vascular endothelium and to adjacent RBCs, and formation of capillary plugging by masses of RBCs, platelets, leukocytes, and malarial pigment.

Involvement of the brain (cerebral malaria) is most often seen in *P. falciparum* infection. Capillary plugging from an accumulation of malarial pigment and masses of cells can result in coma and death.

Kidney damage is also associated with *P. falciparum* malaria, resulting in an illness called **blackwater fever.** Intravascular hemolysis with rapid destruction of RBCs produces a marked hemoglobinuria and can result in acute renal failure, tubular necrosis, nephrotic syndrome, and death. Liver involvement is characterized by abdominal pain, vomiting of bile, severe diarrhea, and rapid dehydration.

Laboratory Diagnosis

Thick and thin blood films are searched for the characteristic rings of *P. falciparum*, which frequently occur in multiples within a single cell, as well as in the accolé position (see Fig. 73.2). The distinctive crescentic gametocytes also are diagnostic (see Fig. 73.3). A high-grade parasitemia (>10% of RBCs infected) consisting only of ring forms is suggestive of *P. falciparum* infection, even if no gametocytes are observed.

Laboratory personnel must perform a thorough search of the blood films because mixed infections can occur with any combination of the five species, but most often the combination is *P. falciparum* and *P. vivax*. The detection and proper reporting of a mixed infection directly affect the treatment chosen.

Increasingly antigen detection using a **rapid diagnostic test (RDT)** is being used both in the field and in diagnostic laboratories as an adjunct to conventional microscopic diagnosis. RDTs use immunochromatographic lateral-flow strip technology and use monoclonal antibodies directed at either species-specific or pan-*Plasmodium* targets. These tests are simple, rapid (results in <20 minutes), and inexpensive. *P. falciparum*–specific monoclonal antibodies have been developed for **histidine-rich protein 2 (HRP-2)** and *P. falciparum* lactate dehydrogenase. Targets conserved across all human malarias **(pan-malarial antigens)** have been identified on ***Plasmodium* lactate dehydrogenase**

(PLDH) and **aldolase** enzymes. Thus far, one RDT has been approved by the U.S. Food and Drug Administration (FDA). It is the BinaxNOW (Binax, Scarborough, Maine) Malaria test kit, based on the antigens HRP-2 and PLDH with high sensitivity and specificity for *P. falciparum* (94% to 100% and 94.2%, respectively) but much lower for non-*falciparum* species (67% to 86%), particularly for *P. knowlesi, P. malariae,* and *P. ovale.*

A variety of nucleic acid detection methods have been described for the diagnosis of malaria, including deoxyribonucleic acid (DNA)/ribonucleic acid (RNA) hybridization, polymerase chain reaction (PCR), nucleic acid sequence-based amplification (NASBA), and loop-mediated amplification (LAMP). Of these, the most commonly used method is PCR, in which the 18S small subunit ribosomal RNA gene is the most common target. Numerous conventional and real-time PCR formats have been described for *Plasmodium* detection, species/subspecies differentiation, and identification of parasite resistance markers to antimalarial drugs. Several nucleic acid amplification tests (NAATs) are commercially available outside the United States for detection of malaria parasites; unfortunately no NAATs have been approved or cleared by the FDA for in vitro diagnostic use.

Treatment, Prevention, and Control

The treatment of malaria is based on the history regarding travel to endemic areas, prompt clinical review and differential diagnosis, accurate and rapid laboratory work, and correct use of antimalarial drugs.

Because chloroquine-resistant strains of *P. falciparum* are present in all areas of endemicity (Africa, Southeast Asia, and South America), with the exception of Central America and the Caribbean, physicians must review all current protocols for the proper treatment of *P. falciparum* infections, noting particularly where **chloroquine resistance** is known to occur. If the patient's history indicates that the origin is not from a chloroquine-resistant area, then the drug of choice is either chloroquine or parenteral quinine. Patients infected with chloroquine-resistant *P. falciparum* (or *P. vivax*) may be treated with other agents, including mefloquine ± artesunate, artemether-lumefantrine, atovaquone-proguanil (Malarone), quinine, quinidine, pyrimethamine-sulfadoxine (Fansidar), and doxycycline. Because quinine and pyrimethamine-sulfadoxine are potentially toxic, they are used more often for treatment than prophylaxis. Amodiaquine, an analog of chloroquine, is effective against chloroquine-resistant *P. falciparum;* however, toxicity limits its use. Newer agents with excellent activity against multidrug-resistant strains of *P. falciparum* include the phenanthrene methanols, halofantrine and lumefantrine, and the artemisinins, artemether and artesunate, both sesquiterpene derivatives (see Chapter 71).

Combinations of the rapid-acting artemisinins with an existing or newly introduced antimalarial compound have been shown to be highly effective in both treatment and control of malaria caused by *P. falciparum.* The rapid reduction in parasite biomass (approximately 10^8-fold within 3 days) produced by the artemisinins leaves a relatively small number of organisms for the second agent (usually mefloquine or lumefantrine) to clear. This reduces considerably the exposure of the parasite population to mefloquine or lumefantrine, reducing the chance of an escape-resistant mutant arising from the infection. Combinations of artesunate and mefloquine and of artemether and lumefantrine have both been well tolerated and highly efficacious in the treatment of multidrug-resistant falciparum malaria in semi-immune and nonimmune individuals. Recently, decreased in vivo susceptibility to artemisinin compounds has been detected in *P. falciparum* strains along the Thai-Cambodian border (greater Mekong subregion), which is a historic site for emerging resistance to antimalarial agents. Outside of the greater Mekong subregion, significant levels of artemisinin combination therapy failure are primarily caused by resistance to the partner drug rather than the artemisinin component. High-level artemisinin resistance has not yet been documented.

Although the rationale for red cell exchange transfusion in severe malaria is compelling, there are no prospective clinical trials comparing this therapy with others. Nonetheless, red cell exchange (or whole-blood exchange), if available, should be considered in cases of severe malaria complicated by clinical signs of cerebral malaria, acute lung injury, severe hemolysis with acidemia, shock, or a high or rising level of parasitemia despite adequate intravenous antimicrobial therapy. The use of anticonvulsants (phenobarbitone) and dexamethasone in cerebral malaria is likely to be ineffective or harmful and is not recommended.

When there is uncertainty whether the *P. falciparum* is chloroquine resistant, it is advisable to assume that the strain is resistant and treat the patient accordingly. If the laboratory reports a mixed infection involving *P. falciparum* and *P. vivax,* the treatment must eradicate not only *P. falciparum* from the erythrocytes but also the liver stages of *P. vivax* to avoid relapses. Failure on the part of the laboratory to detect and report such a mixed infection can result in inappropriate treatment and unnecessary delay in accomplishing a complete cure.

Chemoprophylaxis and prompt eradication of infections are critical in breaking the mosquito-human transmission cycle. Control of mosquito breeding and protection of individuals by screening, netting, protective clothing, and insect repellents also are essential. Chloroquine resistance complicates the management of these patients but can be overcome by the physician's awareness of appropriate regimens. Immigrants from and travelers to endemic areas must be carefully screened, using blood films or serologic tests to detect possible infection. The development of vaccines to protect persons living in or traveling to endemic areas is under investigation.

PLASMODIUM KNOWLESI

Physiology and Structure

P. knowlesi is a malaria parasite of **Old World monkeys** (long-tailed *[Macaca fascicularis]* and pig-tailed *[M. nemestrina]* macaques). *P. knowlesi* is transmitted by members of the *A. leucosphyrus* group of mosquitoes that resides in the upper canopy of the forests and has infrequent contact with humans. Unlike other primate malarias, *P. knowlesi* exhibits a relaxed host specificity and is permissive in humans under natural and experimental conditions and in nonhuman primates. Similar to *P. falciparum,* the erythrocyte invasion by *P. knowlesi* is not restricted to young or old RBCs, which allows the development of high levels of parasitemia. It has a short

life cycle of 24 hours **(quotidian),** and the development of the parasite in RBCs is not synchronous. *P. knowlesi* infection is usually misidentified as *P. falciparum* or *P. malariae* because its early trophozoites resemble the ring forms of *P. falciparum* and its later stages mimic those of *P. malariae.* In contrast to *P. falciparum, P. knowlesi* does not appear to sequester in the microvasculature, and the neurologic complications seen with *P. falciparum* infection have not been described.

RBCs infected with *P. knowlesi* exhibit a normal morphology, and all developmental stages may be seen in peripheral blood.

P. knowlesi, similar to *P. falciparum* and *P. malariae,* does not appear to produce hypnozoites in the liver. Relapses from the liver are not known to occur.

Epidemiology

Thus far, human *P. knowlesi* infections have been described in high numbers only in Malaysia; however, because of reports of infection in the neighboring countries of Thailand, Singapore, Brunei, Indonesia, Myanmar, Vietnam, and the Philippines, it appears that *P. knowlesi* is a natural parasite of macaques throughout the Southeast Asia region.

Clinical Syndromes

The clinical and laboratory profiles of *P. knowlesi* infection are similar to those of patients infected with the other malaria parasites. Patients typically present with a nonspecific febrile illness with daily fever and chills. Other frequent symptoms include headache, rigors, malaise, abdominal pain, breathlessness, and productive cough. Tachypnea, pyrexia, and tachycardia are common clinical signs. Thrombocytopenia and mild hepatic dysfunction on hospital admission are common.

Approximately 7% of the cases of *P. knowlesi* infection thus far have been judged as severe, using the criteria of the World Health Organization, and the most frequent complication is respiratory distress with pulmonary rather than metabolic etiology. Deaths and severe disease result from pulmonary and hepatorenal failure. Severity of infection is related to high parasitemia levels produced by its rapid and unique 24-hour erythrocyte cycle and its ability to infect all stages of RBCs. It is strongly recommended that infection with *P. knowlesi* be considered in cases in which the microscopic examination suggests *P. malariae* but in which the patient has either severe disease, hyperparasitemia (>0.1%; i.e., >5000 parasites/μl), or a recent history of visiting woods or their vicinity in Southeast Asia.

Laboratory Diagnosis

Whereas the ring forms of *P. knowlesi* are morphologically similar to those of *P. falciparum,* the trophozoite, schizont, and gametocyte stages are indistinguishable from those of *P. malariae* by light microscopy. Clues to the identification of *P. knowlesi* by microscopy that are useful, if present, include early trophozoites with fine ring forms, double chromatin dots, and two to three parasites per RBC (resembling *P. falciparum*); trophozoites with a bird's-eye appearance and/or mature trophozoites with a band appearance resembling *P. malariae;* and mature schizonts with a higher average merozoite count (16 per RBC) than in *P. malariae* (10 to 12 per RBC). *P. knowlesi*–specific PCR is the only reliable means of identifying this emerging species of *Plasmodium.*

At present, no commercially available RDTs are designed to specifically detect *P. knowlesi.* Performance of these mainly *P. falciparum*–targeted and *P. vivax*–targeted RDTs in *P. knowlesi* infection has been reported in a few cases. PLDH produced by the four other *Plasmodium* species that cause human malaria is also present in *P. knowlesi.* Antibodies to the pan-malaria targets PLDH and aldolase also cross-react with those of *P. knowlesi.* At this time, the RDTs are not recommended because of the unreliable results and low sensitivity in detecting *P. knowlesi.*

Treatment, Prevention, and Control

Given the potential severity of *P. knowlesi* infection, it should be managed like *P. falciparum* malaria if the species identification is based on microscopy alone or if co-infection with *P. falciparum* cannot be excluded with certainty using PCR. *P. knowlesi* alone appears to be susceptible to numerous therapeutic alternatives, with the majority of patients responding promptly to chloroquine.

Prevention of *P. knowlesi* infection is based on avoiding mosquito bites and taking preventive medication when indicated. Although general precautions for avoiding the bites of *Anopheles* mosquitoes probably apply, it should be recognized that current indoor control measures for malaria do not prevent zoonotic transmission of malaria by vectors that feed mainly in the forest. Zoonotic *P. knowlesi* infection is likely to pose a problem for malaria control.

PLASMODIUM VIVAX

Physiology and Structure

P. vivax (Fig. 73.4) is selective in that it invades only young, immature erythrocytes. Whereas the **Duffy blood group antigen** on the RBC surface has long been considered to be the primary receptor for *P. vivax* (see Chapter 68), clinical vivax malaria has recently been reported in Duffy-negative individuals in Madagascar. The parasite and host molecules that enable this Duffy-independent *P. vivax* invasion of human RBCs are as yet unknown. In infections caused by *P. vivax,* infected RBCs are usually enlarged and contain numerous pink granules or **Schüffner dots,** the trophozoite is ring shaped but ameboid in appearance, more mature trophozoites and erythrocytic schizonts containing up to 24 merozoites are present, and the gametocytes are round. The mature schizonts often contain golden-brown **hemozoin** pigment granules **(malarial pigment).**

Epidemiology

P. vivax is the most prevalent of the human plasmodia, with the widest geographic distribution, including the tropics, subtropics, and temperate regions. The overwhelming majority (>80%) of clinical cases of vivax malaria occur in South America and Southeast Asia.

Clinical Syndromes

After an incubation period (usually 10 to 17 days), the patient experiences vague influenza-like symptoms with headache, muscle pains, photophobia, anorexia, nausea, and vomiting (Clinical Case 73.1).

As the infection progresses, increased numbers of rupturing erythrocytes liberate merozoites, toxic cellular debris and hemoglobin into the circulation. Together these

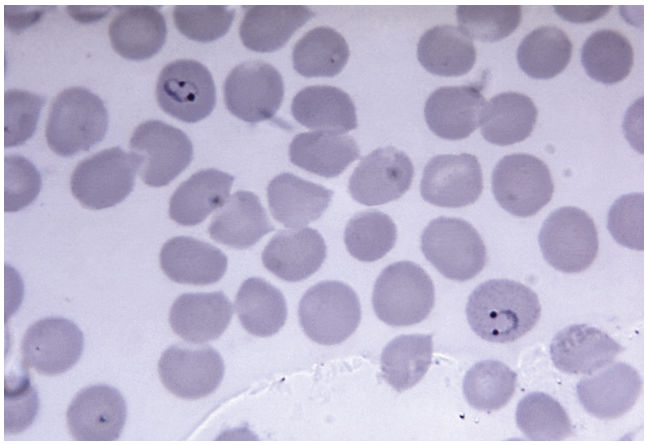

Fig. 73.4 *Plasmodium vivax* ring forms with double chromatin dots. This feature is more reminiscent of *P. falciparum* than *P. vivax*. *P. vivax* rings have a large quantity of cytoplasm and a large chromatin dot and occasional pseudopods. The red blood cells are normal, up to 1.5 times normal size, round, and contain fine Schüffner dots. (From CDC Public Health Image Library.)

produce the typical pattern of chills, fever, and malarial rigors. These **paroxysms** usually reappear periodically (generally every 48 hours) as the cycle of infection, replication, and cell lysis progresses. The paroxysms may remain relatively mild or progress to severe attacks, with hours of sweating, chills, shaking, persistently high temperatures (103° F to 106° F), and exhaustion.

P. vivax causes **"benign tertian malaria,"** which refers to the cycle of paroxysms every 48 hours (in untreated patients) and the belief that most patients tolerate the attacks and can survive for years without treatment. Recent evidence, however, suggests that *P. vivax* can cause a **spectrum of severe, life-threatening syndromes** that are strikingly similar to those caused by *P. falciparum*. Reports of vivax malaria marked by delirium, seizures, renal failure, shock, hepatic dysfunction, severe anemia, lung injury, pulmonary edema, and acute respiratory distress have come from Southeast Asia, the Middle East, and South America. Also, if left untreated, chronic *P. vivax* infections can lead to brain, kidney, and liver damage as a result of the malarial pigment, cellular debris, and capillary plugging of these organs by masses of adherent erythrocytes.

Laboratory Diagnosis

Microscopic examination of thick and thin films of blood is the method of choice for confirming the clinical diagnosis of malaria and identifying the specific species responsible for disease. The thick film is a concentration method and may be used to detect the presence of organisms. With training, thick films may be used to diagnose the species as well. The thin film is most useful for establishing species identification. Blood films can be taken at any time over the course of the infection, but the best time is midway between paroxysms of chills and fever, when the greatest number of intracellular organisms is present. It may be necessary to take repeated films at intervals of 4 to 6 hours.

Serologic procedures are available, but they are used primarily for epidemiologic surveys or for screening blood donors. Serologic findings usually remain positive for approximately a year, even after complete treatment of the infection. RDTs may be used as an adjunct to microscopy in the diagnosis of malaria caused by *P. vivax;* however, the sensitivity is generally much lower than that for detection of *P. falciparum:* 69% to 85% versus 94% to 100%, respectively.

Clinical Case 73.1 **Malaria**

Mohin and Gupta (*Infect Dis Clin Pract* 15:209–212, 2007) described a case of severe malaria caused by *Plasmodium vivax*. The patient was a 59-year-old man who presented with a 1-day history of high-grade fever after recently returning from Guyana in South America. He did not take any medications before, during, or after the trip. He noted that his symptoms were similar to those of a malaria infection 5 years previously, which also was acquired in Guyana. A peripheral blood smear as part of the initial workup showed numerous red blood cells with schizonts consistent with *Plasmodium* infection, with more than 5% parasitemia. Several blood tests, including a DNA PCR, were sent for parasite species determination. The patient was started on quinine and doxycycline oral therapy because of concerns regarding chloroquine-resistant malaria. Subsequently, during the next 4 days, the patient developed severe thrombocytopenia and nonoliguric renal, acute respiratory, and circulatory failure despite a decrease in parasitemia to less than 0.5%. He received intravenous quinidine and an exchange transfusion to treat *P. falciparum* infection, suspected at the time because of the severity of his symptoms. The next day, however, the results of the PCR of the blood revealed the parasite to be *P. vivax* and not *P. falciparum*. The patient gradually improved and was treated with primaquine to prevent relapse.

This case shows that although unusual, severe respiratory and circulatory compromise may complicate *P. vivax* malaria. *P. vivax* should be considered if the patient's condition deteriorates despite the presence of relatively low parasite levels. As opposed to *P. falciparum, P. vivax* infections carry the additional risk of relapse, which warrants appropriate and adequate treatment. This case also emphasizes the importance of chemoprophylaxis and personal protective measures for anyone planning a trip to a malaria-infested region.

PCR, Polymerase chain reaction.

Treatment, Prevention, and Control

The treatment of *P. vivax* infection involves a combination of supportive measures and chemotherapy. Bed rest, relief of fever and headache, regulation of fluid balance, and in some cases blood transfusion are supportive therapies.

The chemotherapeutic regimens are as follows:

1. Suppressive: aimed at avoiding infection and clinical symptoms (i.e., a form of prophylaxis)
2. Therapeutic: aimed at eradicating the erythrocytic cycle
3. Radical cure: aimed at eradicating the exoerythrocytic cycle in the liver
4. Gametocidal: aimed at destroying erythrocytic gametocytes to prevent mosquito transmission

Chloroquine is the drug of choice for the suppression and therapeutic treatment of *P. vivax,* followed by primaquine for radical cure and elimination of gametocytes. Chloroquine-resistant forms of *P. vivax* have emerged in Indonesia, the

Solomon Islands, New Guinea, and Brazil. Patients infected with chloroquine-resistant *P. vivax* may be treated with other agents, including mefloquine ± artesunate, quinine, pyrimethamine-sulfadoxine (Fansidar), and doxycycline. Primaquine is especially effective in preventing a relapse from the latent forms of *P. vivax* in the liver. Because antimalarial drugs are potentially toxic, it is imperative that physicians carefully review the recommended therapeutic regimens.

PLASMODIUM OVALE

Physiology and Structure

P. ovale is similar to *P. vivax* in many respects, including its selectivity for young, pliable erythrocytes. As a consequence, the host cell becomes enlarged and distorted, usually in an oval form. Schüffner dots appear as pale pink granules, and the cell border is frequently fimbriated or ragged. The schizont of *P. ovale,* when mature, contains about half the number of merozoites seen in *P. vivax,* and the malarial pigment is a darker brown. Recently, multilocus genetic analysis identified the presence of polymorphisms in *P. ovale,* leading to the description of classic and variant strains. It is now widely accepted that *P. ovale* comprises two closely related subspecies that co-exist in the same geographic regions without interbreeding, *P. ovale curtisi* (classic strain) and *P. ovale wallikeri* (variant strain). These two subspecies are morphologically indistinguishable, but have been reported to differ in duration of latency.

Epidemiology

P. ovale is distributed primarily in tropical Africa, in which it is often more prevalent than *P. vivax.* It is also found in Asia and South America.

Clinical Syndromes

The clinical picture of tertian attacks for *P. ovale* (benign tertian or ovale malaria) infection is similar to that for *P. vivax.* Untreated infections last only about 1 year, instead of the several years for *P. vivax.* Both relapse and recrudescence phases are similar to *P. vivax.*

Laboratory Diagnosis

As with *P. vivax,* thick and thin blood films are examined for the typical oval host cell with Schüffner dots and a ragged cell wall. Serologic tests reveal cross-reaction with *P. vivax* and other plasmodia. RDTs are not recommended for the diagnosis of *P. ovale* infection.

Treatment, Prevention, and Control

The treatment regimen, including the use of primaquine to prevent relapse from latent liver forms, is similar to that used for *P. vivax* infections. Preventing *P. ovale* infection involves the same measures as for *P. vivax* and other plasmodia.

PLASMODIUM MALARIAE

Physiology and Structure

In contrast with *P. vivax* and *P. ovale, P. malariae* can infect only mature erythrocytes with relatively rigid cell membranes. As a result, the parasite's growth must conform to the size and shape of the RBC. This produces no red cell enlargement or distortion, as seen in *P. vivax* and *P. ovale,* but it does result in distinctive shapes of the parasite seen in the host cell: "band and bar forms," as well as very compact, dark-staining forms. The schizont of *P. malariae* shows no red cell enlargement or distortion and is usually composed of eight merozoites appearing in a rosette surrounding a dark brown central pigment granule. Occasionally reddish granules called **Ziemann dots** appear in the host cell.

Unlike for *P. vivax* and *P. ovale,* hypnozoites for *P. malariae* are not found in the liver, and relapse does not occur. Recrudescence does occur, and attacks may develop after apparent abatement of symptoms.

Epidemiology

P. malariae infection occurs primarily in the same subtropical and temperate regions as the other plasmodia but is less prevalent.

Clinical Syndromes

The incubation period for *P. malariae* is the longest of the plasmodia, usually 18 to 40 days but possibly several months to years. The early symptoms are influenza like, with fever patterns of 72 hours (quartan or malarial malaria) in periodicity. Attacks are moderate to severe and last several hours. Untreated infections may last as long as 20 years.

Laboratory Diagnosis

Observing the characteristic **bar and band forms and the rosette schizont** in thick and thin films of blood establishes the diagnosis of *P. malariae* infection. As noted, serologic tests cross-react with other plasmodia. RDTs are not recommended for the diagnosis of infections with *P. malariae.*

Treatment, Prevention, and Control

Treatment is similar to that for *P. vivax* and *P. ovale* infections and must be undertaken to prevent recrudescent infections. Treatment to prevent relapse caused by latent liver forms is not required because these forms do not develop with *P. malariae.* Preventive and controlling mechanisms are as discussed for *P. vivax* and *P. ovale.*

Babesia Species

Babesia are intracellular sporozoan parasites that morphologically resemble plasmodia. Babesiosis is a zoonosis infecting a variety of animals, such as deer, cattle, and rodents; humans are accidental hosts. Infection is transmitted by *Ixodes* ticks. *B. microti* is the usual cause of babesiosis in the United States.

PHYSIOLOGY AND STRUCTURE

Human infection follows contact with an infected tick (Fig. 73.5). The infectious **pyriform bodies** are introduced into the bloodstream and infect erythrocytes. The intraerythrocytic trophozoites multiply by **binary fission,** forming tetrads, and then lyse the erythrocyte, releasing the merozoites; these can reinfect other cells to maintain the infection. Infected cells also can be ingested by feeding ticks, in which

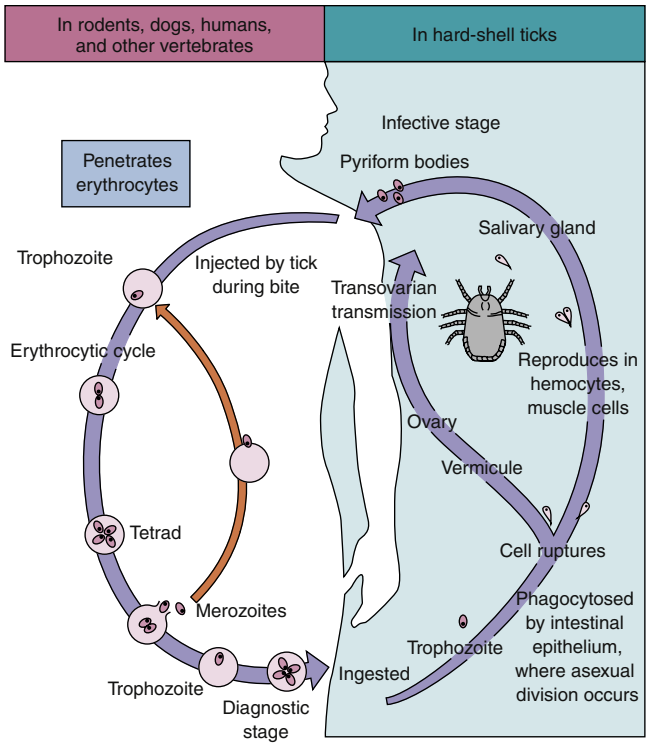

Fig. 73.5 Life cycle of *Babesia* species.

additional replication can take place. Infection in the tick population can also be maintained by transovarian transmission. The infected cells in humans resemble the ring forms of *P. falciparum,* but malarial pigment or other stages of growth characteristically seen with plasmodial infections are not seen with careful examination of blood smears (Fig. 73.6).

EPIDEMIOLOGY

More than 70 different species of *Babesia* are found in Africa, Asia, Europe, and North America, with *B. microti* responsible for disease along the northeastern seaboard of the United States (e.g., Nantucket Island, Martha's Vineyard, Shelter Island). *I. dammini* is the tick vector responsible for transmitting babesiosis in this area, and the natural reservoir hosts are field mice, voles, and other small rodents. Serologic studies in endemic areas have demonstrated a high incidence of past exposure to *Babesia.* Presumably, most infections are asymptomatic or mild. *B. divergens,* which has been reported more frequently from Europe, causes severe, often fatal infections in people who have undergone splenectomies. Severe, persistent *B. microti* parasitemia has occurred in immunosuppressed HIV-infected patients with intact spleens. Although most infections follow tick bites, *B. microti* is increasingly transmitted by blood transfusions in the United States. A recent upsurge in transfusion-transmitted babesiosis (TTB) cases attributed to *B. microti,* coupled with at least 12 fatalities in transfusion recipients diagnosed with babesiosis, has elevated TTB to a key policy issue in transfusion medicine. Prevention of transfusion-related cases is mostly through blood donor questionnaire screening; those with a history of babesiosis are deferred indefinitely from donating blood.

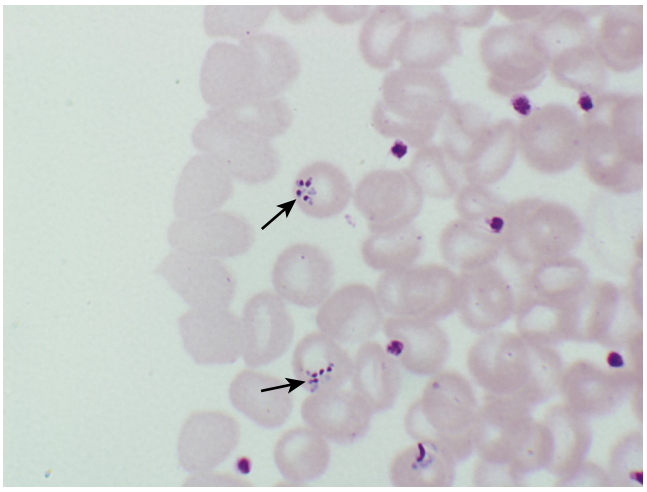

Fig. 73.6 Ring forms of *Babesia microti.* Note the multiple ring forms *(arrows)* within the individual erythrocytes and the similarity to those of *Plasmodium falciparum* in Fig. 73.2.

There is a need for a viable and cost-effective screening method for blood products. Presently, there is no FDA-approved test for this purpose.

CLINICAL SYNDROMES

After an incubation period of 1 to 4 weeks, symptomatic patients experience general malaise, fever without periodicity, headache, chills, sweating, fatigue, and weakness. As the infection progresses with increased destruction of erythrocytes, hemolytic anemia develops, and the patient may experience renal failure. Hepatomegaly and splenomegaly can develop in advanced disease. Low-grade parasitemia may persist for weeks. Splenectomy or functional asplenia, immunosuppression, HIV infection, and advanced age increase a person's susceptibility to infections and to more severe disease.

LABORATORY DIAGNOSIS

Examination of blood smears is the diagnostic method of choice. Laboratory personnel must be experienced in differentiating *Babesia* and *Plasmodium* species. *Babesia* may mimic *P. falciparum,* with RBCs infected with multiple small ring forms (see Fig. 73.6). Infected patients may have negative smears because of the low-grade parasitemia. These infections can be diagnosed by inoculating samples of blood into hamsters, which are highly susceptible to infection. Serologic tests and amplification of babesial DNA by PCR are also available for diagnostic use.

TREATMENT, PREVENTION, AND CONTROL

The treatment of choice for mild to moderate illness is the combination of atovaquone and azithromycin, whereas clindamycin and quinine and exchange transfusion are indicated for severe disease. Other antiprotozoal regimens, including chloroquine and pentamidine, have been used with variable results. However, most patients with mild disease recover without specific therapy. Exchange blood transfusion also has been successful in patients who have

had splenectomies and who have severe infections caused by *B. microti* or *B. divergens.* The use of protective clothing and insect repellents can minimize tick exposure in endemic areas, which is critical for the prevention of disease. Ticks must feed on humans for several hours before the organisms are transmitted, so prompt removal of ticks can be protective.

Toxoplasma gondii

T. gondii is a typical coccidian parasite related to *Plasmodium, Cystoisospora,* and other members of the Apicomplexa clade. *T. gondii* is an intracellular parasite, and it is found in a wide variety of animals, including birds and humans. Only one species exists, and there appears to be little strain-to-strain variation. The essential reservoir host of *T. gondii* is the common house cat and other felines.

PHYSIOLOGY AND STRUCTURE

Organisms develop in the intestinal cells of the cat and during an extraintestinal cycle with passage to the tissues via the bloodstream (Fig. 73.7). The organisms from the intestinal cycle are passed in cat feces and mature into infective cysts within 3 to 4 days in the external environment. These oocysts are similar to those of *Cystoisospora belli,* which is the human intestinal protozoan parasite, and can be ingested by mice and other animals (including humans) and produce acute and chronic infection of various tissues, including brain. Infection in cats is established when the tissues of infected rodents are eaten.

Some infective forms **(trophozoites)** of the oocyst develop as slender, crescentic types called **tachyzoites.** These rapidly multiplying forms are responsible for the initial infection and tissue damage. Slow-growing, shorter forms, called **bradyzoites,** also develop and form cysts in chronic infections.

EPIDEMIOLOGY

Human infection with *T. gondii* is ubiquitous; however, it is increasingly apparent that certain immunocompromised individuals (patients with acquired immunodeficiency syndrome [AIDS]) are more likely to have severe manifestations. The wide variety of animals that harbor the organism, such as carnivores, herbivores, and birds, accounts for the widespread transmission.

Human infection may be acquired in several ways: (1) ingestion of undercooked contaminated meat containing *T. gondii* cysts; (2) ingestion of oocysts from hands, food, soil, or water contaminated with cat feces; (3) organ transplantation or blood transfusion; (4) transplacental transmission; and (5) accidental inoculation of tachyzoites. Serologic studies show an increased prevalence in human populations in which the consumption of uncooked meat or meat juices is popular. It is noteworthy that serologic tests of human and rodent populations are negative in the few geographic areas in which cats have not existed. Outbreaks of toxoplasmosis in the United States are usually traced to poorly cooked meat (e.g., hamburger) and contact with cat feces.

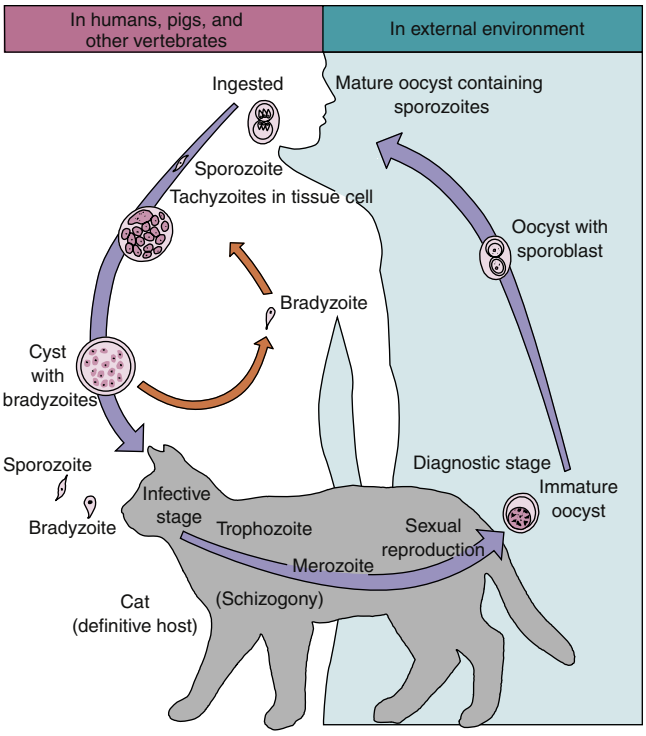

Fig. 73.7 Life cycle of *Toxoplasma gondii.*

Transplacental infection can occur in pregnancy, either from infection acquired from meat and meat juices or from contact with cat feces. Transplacental infection from an infected mother has a devastating effect on the fetus. Infection via contaminated blood or transplanted organs can occur but is not common. The sharing of needles between intravenous drug users may also facilitate the transmission of *Toxoplasma.*

Although the rate of seroconversion is similar for individuals within a geographic location, the rate of severe infection is dramatically affected by the immune status of the individual. Patients with defects in cell-mediated immunity, especially those who are infected with HIV or who have had an organ transplant or immunosuppressive therapy, are most likely to have disseminated or central nervous system (CNS) disease. Illness in this setting is generally believed to be caused by reactivation of previously latent infection rather than new exposure to the organism.

CLINICAL SYNDROMES

Most *T. gondii* infections are benign and asymptomatic, with symptoms occurring as the parasite moves from the blood to tissues, in which it becomes an intracellular parasite (Clinical Case 73.2). When symptomatic disease occurs, the infection is characterized by cell destruction, reproduction of more organisms, and eventual cyst formation. Many tissues may be affected; however, the organism has a particular predilection for cells of the lung, heart, lymphoid organs, and CNS, including the eye.

Symptoms of acute disease include chills, fever, headaches, myalgia, lymphadenitis, and fatigue; the symptoms occasionally resemble those of infectious mononucleosis. In chronic disease, the signs and symptoms include lymphadenitis, occasionally a rash, evidence of hepatitis,

Clinical Case 73.2 **Toxoplasmosis**

Vincent and colleagues (*Infect Med* 23:390, 2006) described a 67-year-old woman with a 3-year history of Hodgkin disease who received chemotherapy, followed by autologous stem cell transplantation. Shortly afterward, she became febrile and neutropenic, and treatment with broad-spectrum antibiotics was started. The results of blood and urine cultures were negative. After resolution of neutropenia (1 month posttransplantation), confusion and lethargy developed. Imaging studies of the brain revealed microinfarcts in both hemispheres and the midbrain. Findings from a lumbar puncture were unrevealing. Based on the suspicion of toxoplasmosis, pyrimethamine and sulfadiazine were added to the patient's regimen. When toxic epidermal necrolysis developed, the sulfadiazine was discontinued and clindamycin was begun. Multiorgan failure ensued, and the patient died 1 week later. At autopsy, cyst forms with bradyzoites were detected in the woman's brain and heart. Histopathologic findings and immunohistochemical staining confirmed a diagnosis of disseminated toxoplasmosis.

Disseminated toxoplasmosis is rare, especially after autologous stem cell transplantation. The likely cause of reactivation and dissemination of *Toxoplasma* in this patient was the cell-mediated immunosuppression associated with Hodgkin disease and its treatment. In addition to the brain, the heart, liver, and lungs are frequently involved in cases of disseminated toxoplasmosis.

encephalomyelitis, and myocarditis. In some of the cases, chorioretinitis appears and may lead to blindness.

Congenital infection with *T. gondii* also occurs in infants born to mothers infected during pregnancy. If infection occurs in the first trimester, the result is spontaneous abortion, stillbirth, or severe disease. Manifestations in the infant infected after the first trimester include epilepsy, encephalitis, microcephaly, intracranial calcifications, hydrocephalus, psychomotor or mental retardation, chorioretinitis, blindness, anemia, jaundice, rash, pneumonia, diarrhea, and hypothermia. Infants may be asymptomatic at birth only to develop disease months to years later. Most often these children develop **chorioretinitis** with or without blindness or other neurologic problems, including retardation, seizures, microcephaly, and hearing loss.

In immunocompromised older patients, a different spectrum of disease is seen. Reactivation of latent toxoplasmosis is a special problem for these people. The presenting symptoms of *Toxoplasma* infection in immunocompromised patients are usually neurologic, most frequently consistent with diffuse encephalopathy, meningoencephalitis, or cerebral mass lesions. Reactivation of cerebral toxoplasmosis has emerged as a major cause of encephalitis in patients with AIDS. The disease is usually multifocal, with more than one mass lesion appearing in the brain at the same time. Symptoms are related to the location of the lesions and may include hemiparesis, seizures, visual impairment, confusion, and lethargy. Other sites of infection that have been reported include the eye, lung, and testes. Although disease is seen predominantly in patients with AIDS, it also may occur with similar manifestations in other immunocompromised patients, in particular those undergoing solid organ transplantation.

LABORATORY DIAGNOSIS

Serologic testing is required for the diagnosis of acute active infection; the diagnosis is established by the finding of increasing antibody titers documented in serially collected blood specimens. Because contact with the organism is common, assays for different isotypes of antibodies and attention to increasing titers are essential to differentiate acute, active infection from previous asymptomatic or chronic infection. A panel of tests referred to as the *T. gondii* serologic profile (TSP) is used by specialized reference laboratories to determine whether the infection is consistent with acquisition recently or in the more distant past. The TSP consists of (1) the Sabin-Feldman dye test to measure IgG antibodies; (2) enzyme-linked immunosorbent assays (ELISAs) to measure IgM, IgA, and IgE antibodies; (3) the immunosorbent agglutination assay to measure levels of IgE antibodies; and (4) the differential agglutination test to measure levels of IgG antibodies.

The initial evaluation in the immunocompetent patient involves screening for IgG antibodies to *T. gondii.* Although many studies and guidelines suggest the usefulness of testing for IgM in parallel, IgM antibodies to *T. gondii* may persist for more than 12 months after an acute infection, leading to a false-positive result. If IgG titers are equivocal, serial specimens should be collected 3 weeks apart and tested in parallel. If the IgG titer is negative (less than 1:16), then *Toxoplasma* infection is ruled out. A twofold rise in antibody titer indicates an acute infection, as does conversion from a negative to a positive result. A single high titer is not a sufficient basis for diagnosing toxoplasmosis because IgG titers may remain elevated for many years after infection.

Toxoplasmosis in patients with malignancies, organ transplants, or AIDS is generally assumed to arise from reactivation of a chronic asymptomatic (latent) infection. The diagnosis of *Toxoplasma* encephalitis usually involves a CT or magnetic resonance imaging study of the brain. However, *Toxoplasma*-associated brain abnormalities may be indistinguishable from AIDS-related cerebral lymphoma or cerebral Chagas disease. Therefore microscopy, serologic, and molecular techniques must be used for a definitive diagnosis. Diagnosis can be very difficult for these patients; IgM antibody is usually undetectable, and the presence of IgG antibody only confirms past infection. In the absence of serologic evidence of acute infection, diagnosis can be confirmed only by histologic detection of the organism in tissues or detection of nucleic acids by PCR. Immunosuppressed patients who are negative for IgG antibodies are at risk for acute acquired infection, whereas seropositive patients are at risk of reactivation.

The methods used to diagnose acute toxoplasmosis in pregnant women are the same as those used for immunocompetent adults. The FDA has issued a warning to physicians against the use of *T. gondii* IgM commercial kits as the sole method of diagnosis during pregnancy because of frequent false-positive and false-negative results in these patients. Confirmatory testing at a *Toxoplasma* reference laboratory is highly recommended. If IgM and IgG antibodies are both absent, active infection can be excluded.

Prenatal diagnosis of congenital toxoplasmosis can be achieved by ultrasonography and amniocentesis. Amniotic fluid PCR analysis to detect *T. gondii* is the test of choice,

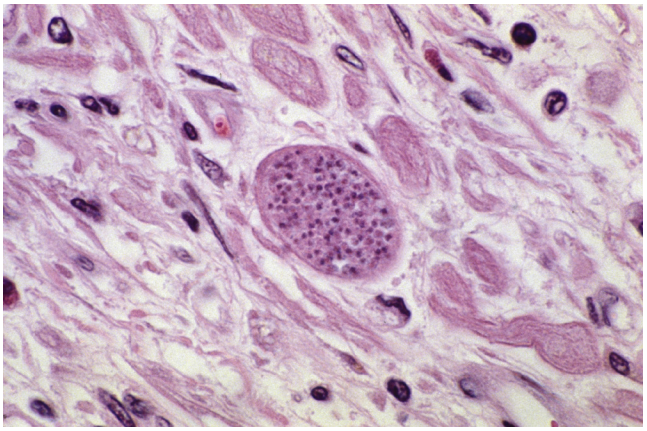

Fig. 73.8 Cyst of *Toxoplasma gondii* in tissue. Hundreds of organisms may be present in the cyst, which may become active and initiate disease with decreased host immunity (e.g., immunosuppression in transplant patients and in diseases such as AIDS).

offering excellent positive and negative predictive values. Because maternal IgG antibodies are present in newborns, detection of IgA and IgM antibodies is the foundation of serodiagnosis of toxoplasmosis in the newborn.

Demonstration of these organisms as trophozoites and cysts in tissue and body fluids is the definitive method of diagnosis (Fig. 73.8). Biopsy specimens from lymph nodes, brain, myocardium, or other suspected tissue, as well as body fluids, including cerebrospinal fluid (CSF), amniotic fluid, or bronchoalveolar lavage fluid, can be directly examined for the organisms. Newer monoclonal antibody–based fluorescent stains may facilitate direct detection of *T. gondii* in tissue. Culture methods for *T. gondii* are largely experimental and not usually available in clinical laboratories. The two methods available are to inoculate potentially infected material into either mouse peritoneum or tissue culture.

Advances in developing PCR-based detection methods are promising and may provide rapid and sensitive approaches for detecting the organism in blood, CSF, amniotic fluid, and other clinical specimens. The most important use of PCR is for prenatal diagnosis of congenital toxoplasmosis using amniotic fluid. When maternal serologic results indicate potential infection during pregnancy, PCR of amniotic fluid has been shown to be more sensitive for the confirmation of fetal infection than the conventional methods of inoculation of mice and tissue culture cells, and fetal blood testing for IgM. PCR technology for *Toxoplasma* is offered at the Toxoplasma Serology Laboratory, Palo Alto, California, and by a few commercial laboratories. Commercial systems are now available and compare favorably with reference laboratory systems.

TREATMENT, PREVENTION, AND CONTROL

The therapy for toxoplasmosis depends on the nature of the infectious process and the immunocompetence of the host. Most mononucleosis-like infections in normal hosts resolve spontaneously and do not require specific therapy. In contrast, disseminated or CNS infection in immunocompromised people must be treated. Before the association of *T. gondii* with HIV infection, immunocompromised patients with toxoplasmosis were treated for 4 to 6 weeks. In the setting of HIV infection, discontinuing therapy after 4 to 6 weeks is associated with a relapse rate of 25%. Such patients are currently treated with an initial high-dose regimen of pyrimethamine plus sulfadiazine and then continued on lower doses of both drugs indefinitely. Although this drug combination is the regimen of choice, toxicity (rash and bone marrow suppression) may necessitate changes to alternative agents. Clindamycin plus pyrimethamine is the best studied alternative. Atovaquone and azithromycin (each alone or with pyrimethamine) also have some activity, although their efficacy and safety compared with those of clindamycin-pyrimethamine need to be assessed. Trimethoprim-sulfamethoxazole is another alternative to pyrimethamine-sulfadiazine for treatment of disseminated or CNS toxoplasmosis. The use of corticosteroids is indicated as part of therapy of cerebral edema and ocular infections that involve or threaten the macula.

Infections in the first trimester of pregnancy are difficult to manage because of the teratogenicity of pyrimethamine in laboratory animals. Both clindamycin and spiramycin have been substituted with apparent success. Spiramycin does not appear to be effective for the treatment of toxoplasmosis in immunocompromised patients.

As more immunocompromised patients at risk for disseminated infection are identified, greater emphasis is placed on preventive measures and specific prophylaxis. Routine serologic screening of patients before organ transplantation and early in the course of HIV infection is now being performed. Individuals with positive serologic tests are at much higher risk for the development of disease and are now being considered for prophylaxis. Trimethoprim-sulfamethoxazole, which also is used as prophylaxis to prevent *Pneumocystis jirovecii* infections, also appears to be effective at preventing infections with *T. gondii.* Additional preventive measures for pregnant women and immunocompromised hosts should include avoiding the consumption and handling of raw or undercooked meat and avoiding exposure to cat feces. As is the case with other protozoa, the availability of antiretroviral therapy has led to a major reduction in AIDS-associated toxoplasmosis. In particular, cases of *Toxoplasma* encephalitis have been greatly reduced to the extent that they are now very uncommon in regions with access to antiretroviral therapy.

Sarcocystis lindemanni

S. lindemanni is a typical coccidian closely related to the intestinal forms *S. suihominis, S. bovihominis,* and *C. belli,* and the blood and tissue parasite *T. gondii. S. lindemanni* occurs worldwide in various animals, especially sheep, cattle, and pigs. Humans are accidentally infected only as the result of eating meat from these animals. Most infections are asymptomatic, but occasionally an infection may cause myositis, which is swelling of muscle, dyspnea, and eosinophilia. Infection of the myocardium has been observed but is extremely rare. There is no specific treatment for the muscle infection.

Free-Living Amebae

Naegleria species, *Acanthamoeba* species, *Balamuthia* species, *Sappinia pedata, Paravahlkampfia francinae,* and other

free-living amebae are found in soil and in contaminated lakes, streams, and other water environments. Most human infections with these amebae are acquired during the warm summer months by people exposed to the amebae while swimming in contaminated water. Inhalation of cysts present in dust may account for some infections, whereas ocular infections with *Acanthamoeba* species are associated with the contamination of contact lenses with nonsterile cleaning solutions.

CLINICAL SYNDROMES

Naegleria, Acanthamoeba, Balamuthia, Sappinia, and *Paravahlkampfia* organisms are opportunistic pathogens (Clinical Case 73.3). Although colonization of the nasal passages is usually asymptomatic, these amebae can invade the nasal mucosa and extend into the brain. Acute primary **amebic meningoencephalitis** (PAM) is most commonly caused by *N. fowleri.* Destruction of brain tissue is characterized by a fulminant, rapidly fatal meningoencephalitis. Symptoms include intense frontal headache, sore throat, fever, blocked nose with altered senses of taste and smell, stiff neck, and Kernig sign. The CSF is purulent and may contain many erythrocytes and motile amebae. Clinically, the course of the disease is rapid, with death usually occurring within 4 or 5 days. Postmortem findings show *Naegleria* trophozoites present in the brain but no evidence of cysts (Fig. 73.9). Although all cases were fatal before 1970, survival has now been reported in a few cases in which the disease was rapidly diagnosed and treated.

Other small free-living amebae may rarely cause encephalitis in humans. *S. diploidea* is a free-living ameba that is found in soil contaminated with the feces of elk and buffalo. *S. diploidea* was identified in an excised brain lesion from a 38-year-old immunocompetent man presenting with bifrontal headache, blurred vision, and loss of consciousness after a sinus infection. Recently a new species of the free-living ameba genus *Paravahlkampfia (P. francinae)* was isolated from the CSF of a patient with headache, sore throat, and vomiting symptoms typical of PAM. The patient recovered within a few days, suggesting that previous reports of nonfatal PAM may have been caused by this organism.

In contrast to *Naegleria, Acanthamoeba* and *Balamuthia* organisms produce granulomatous amebic encephalitis and single or multiple brain abscesses, primarily in immunocompromised individuals. The course of the disease is slower, with an incubation period of at least 10 days. The resulting disease is chronic granulomatous encephalitis with edema of the brain tissue.

Eye and skin infection caused by *Acanthamoeba* organisms also may occur. Keratitis is usually associated with eye trauma that occurred before contact with contaminated soil, dust, or water. The use of improperly cleaned contact lenses is also associated with this disease. Invasion by *Acanthamoeba* species produces corneal ulceration and severe ocular pain. Cases of apparent disseminated cutaneous and subcutaneous infection with *Acanthamoeba* and *Balamuthia* organisms have been described in patients with AIDS and in solid organ transplant recipients. These infections include multiple soft-tissue nodules, which on biopsy contain amebae. CNS or deep tissue involvement also may be present with this form of infection.

Clinical Case 73.3 **Amebic Encephalitis**

Rahimian and Kleinman (*Infect Med* 22:382–385, 2005) described a 43-year-old man, originally from the Dominican Republic, who presented after a seizure. The patient had a history of diabetes and hypertension but denied any previous history of seizures. Results of a CT scan without contrast were normal. Neurologic examination was unrevealing, and the patient was sent home. Approximately 2 weeks later, he was readmitted to the hospital because of a new, left facial droop. A CT scan without contrast showed the new appearance of thickening and hypodensity of the right frontal gray matter. Progressive generalized weakness developed, along with paralysis of the left upper extremity. A repeat CT scan without contrast revealed an increase in the size of the right frontal hypodense area, with vasogenic edema and a new left parietal hypodense lesion. At that time, dysarthria and a bilateral occipital headache also developed. The patient was a construction worker who denied injection drug use, recent dental work, and risk factors for HIV infection. His travel history was significant only for a trip to the Dominican Republic 2 years previously. Clinical examination was remarkable for dysarthria, a left facial droop, and left upper extremity paralysis. A lumbar puncture revealed an elevated white blood count, CSF protein level of 50 mg/dl, and glucose of 145 mg/dl (serum glucose was 327 mg/dl). Gram stain of the CSF was negative. A magnetic resonance imaging scan of the head showed two large ring-enhancing lesions with possible central necrosis. Results of an HIV test were negative. A brain biopsy showed lymphocytic infiltration, predominantly in the perivascular areas. A closer examination revealed trophozoites and amebic cysts consistent with a diagnosis of amebic encephalitis. Results of a PCR assay were consistent with *Balamuthia mandrillaris* infection. Therapy with pentamidine was initiated, but the patient died 3 days later.

Balamuthia encephalitis has been described in both immunosuppressed and immunocompetent individuals. Many infected patients do not have a history of swimming or exposure to contaminated water. The portal of entry is believed to be the respiratory tract or skin ulceration, with dissemination to the brain. Most cases of amebic encephalitis have been diagnosed postmortem. Recently, a PCR assay specific for *Balamuthia* has been used for diagnosis, as was done in this case. The majority of patients have died within weeks after the onset of neurologic symptoms, despite treatment with pentamidine.

CSF, Cerebrospinal fluid; *CT,* computed tomography; *PCR,* polymerase chain reaction.

LABORATORY DIAGNOSIS

For the diagnosis of infections caused by the free-living amebae, nasal discharge, CSF, and (in the case of eye infections) corneal scrapings should be collected. The specimens should be examined using a saline wet preparation and iodine-stained smears. Giemsa stain, Gram stain, or the fluorescent stain calcofluor white also can be used. *Naegleria* and *Acanthamoeba* species are difficult to differentiate except by experienced microscopists. However, the observation of an ameba in a normally sterile tissue

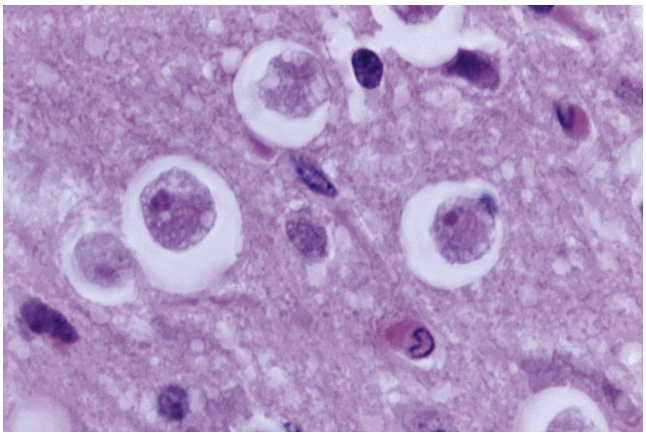

Fig. 73.9 Numerous *Naegleria* trophozoites in brain tissue from a patient with amebic meningoencephalitis. (From CDC Public Health Image Library.)

is diagnostic (see Fig. 73.9). In *Naegleria* infection, only the **ameboid trophozoites** are found within the tissue, whereas with *Acanthamoeba* and *Balamuthia* infection, both trophozoites and cysts are found in tissues. The clinical specimens can be cultured on agar plates seeded with live gram-negative enteric bacilli. Amebae present in the specimens use the bacteria as a nutritional source and can be detected within 1 or 2 days by the presence of the trails that form on the agar surface as the amebae move. *Balamuthia* do not grow on agar plates used for *Naegleria* and *Acanthamoeba* but have been recovered in tissue culture using mammalian cell lines. Most cases of *Balamuthia* infection are diagnosed by immunofluorescent antibody testing.

A real-time multiplex PCR test that simultaneously identifies *Acanthamoeba, Balamuthia,* and *N. fowleri* in CSF and biopsy tissue specimens has been developed at the Centers for Disease Control and Prevention (CDC). The real-time multiplex PCR assay is a fast, sensitive, and robust assay that has many advantages over conventional PCR. This test is used at the CDC to identify *Acanthamoeba, Balamuthia,* and *N. fowleri* in patient specimens with great success. Because of its high sensitivity and specificity, this assay can specifically identify a single ameba in a specimen. Unfortunately, these molecularly based tests are not routinely available in clinical laboratories because of the lack of commercially available reagents.

TREATMENT, PREVENTION, AND CONTROL

Treatment of free-living amebic infections is largely ineffective. Amebic meningoencephalitis caused by *Naegleria, Acanthamoeba,* or *Balamuthia* is unresponsive to most antimicrobial agents. The treatment of choice for *Naegleria* infections is amphotericin B combined with miconazole and rifampin. Some patients with *Acanthamoeba* CNS infections have been cured with a combination of pharmaceuticals that included amikacin, voriconazole, sulfa drugs, and miltefosine, whereas several patients with *Balamuthia* infections have survived after treatment initially with pentamidine isethionate and subsequently with a combination of sulfadiazine, clarithromycin, and fluconazole. The ability of miltefosine and voriconazole to penetrate brain tissue and CSF and their low toxicity makes them attractive possibilities in the treatment of the amebic CNS disease. In combination with other antimicrobials, these two drugs may form the basis of an optimal therapy for treatment of *Acanthamoeba, Balamuthia,* and *Naegleria* infections. For example, miltefosine in conjunction with other pharmaceuticals has been used in the successful treatment of CNS infections caused by *Acanthamoeba, Balamuthia,* and *N. fowleri.* Amebic keratitis and cutaneous infections may respond to topical miconazole, chlorhexidine gluconate, or propamidine isethionate. Treatment of amebic keratitis may require repeated corneal transplantation or, rarely, enucleation of the eye. The wide distribution of these organisms in fresh and brackish waters makes the prevention and control of infection difficult. It has been suggested that known sources of infection should be off limits to bathing, diving, and water sports, although this is generally difficult to enforce. Swimming pools with cracks in the walls, allowing soil seepage, should be repaired to avoid creation of a source of infection.

Leishmania

Leishmania are obligate intracellular parasites that are transmitted from animal to human or human to human by bites from an infected female sand fly. For *Leishmania* in the Old World, there is only one subgenus, *Leishmania;* however, in the New World, the genus has been split into subgenera (*Leishmania* and *Viannia*) according to the development of the organism in the digestive tract (peripylarian or suprapylarian) of the sand fly. Depending on the geographic area, many different species can infect humans, producing a variety of diseases that range from cutaneous, diffuse cutaneous, and mucocutaneous to visceral (Table 73.2). New species of *Leishmania* are being detected frequently. Whereas the older literature focused primarily on three species, *L. donovani* (visceral leishmaniasis), *L. tropica* (cutaneous leishmaniasis), and *L. braziliensis* (cutaneous leishmaniasis), the current taxonomy of leishmaniasis is in a state of flux. Species differentiation is currently based on molecular techniques, rather than geographic distribution and clinical presentation.

PHYSIOLOGY AND STRUCTURE

The life cycles of all leishmanial parasites are quite similar (Fig. 73.10), whereas the associated infections differ in epidemiology, tissues affected, and clinical manifestations. The **promastigote** stage (long, slender form with a free flagellum) is present in the saliva of infected sand flies. Human infection is initiated by the bite of an infected sand fly, which injects the promastigotes into the skin, in which they lose their flagella; enter the **amastigote** stage; and invade reticuloendothelial cells. The change from promastigote to amastigote helps avoid the host's immune response. Changes in the organism's surface molecules play an important role in macrophage attachment and evading the immune response, including manipulating the macrophage's signaling pathways. Reproduction occurs in the amastigote stage, and as cells rupture, destruction of specific tissues (e.g., cutaneous tissues, visceral organs such as the liver and spleen) develops. The amastigote stage (Fig. 73.11) is diagnostic for

TABLE 73.2 Leishmaniasis in Humans

Parasite	Disease	Geographic Distribution
L. donovani (subgenus *Leishmania*)	Visceral leishmaniasis Mucocutaneous leishmaniasis Cutaneous leishmaniasis Dermal leishmanoid	Africa, Asia, South America
L. infantum *L. chagasi* (subgenus *Leishmania*)	Visceral leishmaniasis	Africa, Europe, Mediterranean area, Southeast Asia, Central and South America

leishmaniasis and the infectious stage for sand flies. Ingested amastigotes transform in the sand fly into the promastigote stage, which multiplies by binary fission in the fly midgut. After development, this stage migrates to the fly proboscis, in which new human infection can be introduced during feeding. The life cycles of *Leishmania* organisms are similar for cutaneous, mucocutaneous, and visceral leishmaniasis, except that infected reticuloendothelial cells can be found throughout the body in visceral leishmaniasis.

EPIDEMIOLOGY

Leishmaniasis is a zoonosis transmitted by adult female sand flies belonging to the genera *Phlebotomus* and *Lutzomyia.* The natural reservoirs include rodents, opossums, anteaters, sloths, cats, and dogs. In areas of the world in which leishmaniasis is endemic, the infection may be transmitted by a human-vector-human cycle. The infection may also be transmitted by direct contact with an infected lesion or mechanically by stable flies or dog flies.

Mucocutaneous leishmaniasis most often occurs in Bolivia, Brazil, and Peru, whereas the cutaneous form is much more widespread throughout the Middle East (Afghanistan, Algeria, Iran, Iraq, Saudi Arabia, and Syria) and in focal areas in South America (Brazil, Peru). Cutaneous leishmaniasis has been diagnosed among U.S. military personnel deployed in Afghanistan, Iraq, and Kuwait.

Visceral leishmaniasis (kala-azar, dumdum fever) occurs at a rate of approximately 500,000 new cases per year, 90% of which are localized to Bangladesh, Brazil, India, Nepal, and the Sudan. This infection may exist as an endemic, epidemic, or sporadic disease and is a zoonosis except in India, in which **kala-azar** ("black fever" in Hindi) is an anthroponosis (human-vector-human). Individuals with post–kala-azar dermal leishmaniasis may be very important reservoirs for maintaining the infection in the population because of the high concentration of organisms in the skin. In contrast to cutaneous and mucocutaneous leishmaniasis, for which a large number of leishmanial species have been implicated, only *L. donovani, L. infantum,* and *L. chagasi* commonly cause visceral leishmaniasis. *L. infantum* is present in countries along the Mediterranean basin (European, Near Eastern, and African) and is found in parts of China, South Africa, and the former Soviet Union, whereas *L. chagasi* is found in Latin America. *L. donovani* is concentrated in Africa and Asia. Although *L. tropica* usually causes cutaneous leishmaniasis, rare viscerotropic strains have been reported in the Middle East, Africa, and India.

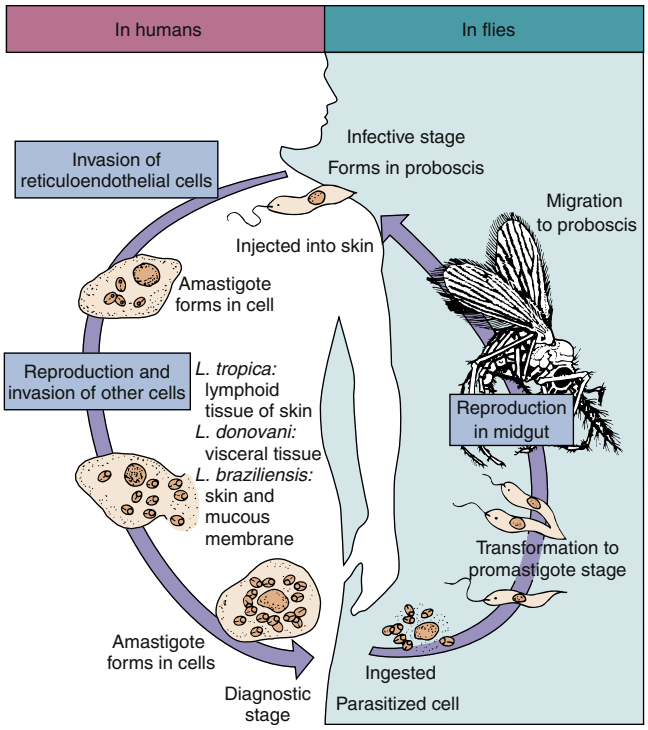

Fig. 73.10 Life cycle of *Leishmania* species.

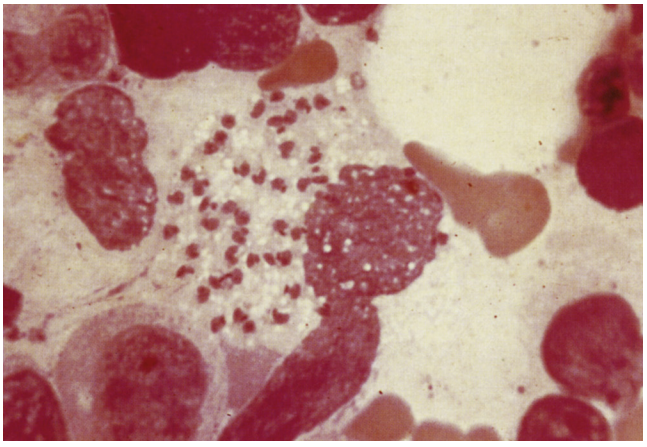

Fig. 73.11 Giemsa-stained amastigotes (Leishman-Donovan bodies) of *Leishmania donovani* present in a touch preparation of spleen. A small, dark-staining kinetoplast can be seen next to the spheric nucleus in some parasites. (From Connor, D.H., et al., 1997. Pathology of Infectious Diseases, vol 2, Appleton & Lange, Stamford, CT.)

CLINICAL SYNDROMES

Depending on the species of *Leishmania* involved, infection can result in a cutaneous, diffuse cutaneous, mucocutaneous, or visceral disease. With the spread of the HIV pandemic, there is increasing recognition of HIV-related visceral leishmaniasis caused by *L. donovani* in southern Asia and Africa and by *L. chagasi (L. infantum)* in South America. In these co-infected patients, leishmaniasis will manifest as an opportunistic infection, with parasites detected in atypical sites and a high associated mortality.

The first sign of **cutaneous leishmaniasis,** a red papule, appears at the site of the fly's bite between 2 weeks and 2 months after initial exposure. The lesion becomes irritated and intensely pruritic and begins to enlarge and ulcerate. Gradually the ulcer becomes hard and crusted and exudes a thin, serous material. At this stage, secondary bacterial infection may complicate the disease. The lesion may heal without treatment in a matter of months but usually leaves a disfiguring scar. The species that is commonly associated with cutaneous leishmaniasis, *L. tropica,* also may exist in a viscerotropic form. A disseminated nodular type of cutaneous leishmaniasis has been reported from Ethiopia, probably caused by an allergy to *L. aethiopica* antigens.

Mucocutaneous leishmaniasis is produced most often by the *L. braziliensis* complex. The incubation period and appearance of the primary cutaneous ulcers for *L. braziliensis* are similar to those found in other forms of cutaneous leishmaniasis. The essential difference in clinical disease is the involvement and destruction of mucous membranes and related tissue structures. Untreated primary lesions may develop into the mucocutaneous form in up to 80% of cases. Spread to the nasal and oral mucosa may become apparent concomitant with the primary lesion or many years after the primary lesion has healed. The mucosal lesions do not heal spontaneously, and secondary bacterial infections are common, producing severe and disfiguring facial mutilation and occasionally death.

The **visceral form of leishmaniasis** may present as a fulminating, rapidly fatal disease; as a more chronic debilitating process; or as an asymptomatic, self-limiting infection. The incubation period may be from several weeks to a year, with a gradual onset of fever, diarrhea, and anemia. Chills and sweating that may resemble malaria symptoms are common early in the infection. As organisms proliferate and invade the cells of the reticuloendothelial system, marked enlargement of the liver and spleen, weight loss, and emaciation occur. Kidney damage also may occur as the cells of the glomeruli are invaded. With persistence of the disease, deeply pigmented, granulomatous areas of skin, referred to as **post–kala-azar dermal leishmaniasis,** develop. In this condition, the macular or hypopigmented dermal lesions are associated with few parasites, whereas erythematous and nodular lesions are associated with abundant parasites.

LABORATORY DIAGNOSIS

Although the diagnosis of visceral, mucocutaneous, or cutaneous leishmaniasis may be made on clinical grounds in endemic areas, definitive diagnosis depends on detecting either the amastigotes in clinical specimens or the promastigotes in culture. Demonstration of the amastigotes in properly stained smears from touch preparations or ulcer biopsy specimens and cultures of ulcer tissue determines the diagnosis of cutaneous and mucocutaneous leishmaniasis. Specimens for the diagnosis of visceral leishmaniasis include splenic puncture, lymph node aspirates, liver biopsy, sternal aspirates, iliac crest bone marrow, and buffy coat preparations of venous blood. These specimens may be examined microscopically, cultured, and subjected to molecular detection methods. Molecular techniques for the detection of leishmanial DNA or RNA have been used for diagnosis, prognosis, and species identification and are more sensitive than microscopy or culture, especially for the detection of mucocutaneous leishmaniasis. Because

TABLE 73.3 Trypanosoma Species Responsible for Human Diseases

Parasite	Vector	Disease
Trypanosoma brucei gambiense and *T. b. rhodesiense*	Tsetse fly	African trypanosomiasis (sleeping sickness)
T. cruzi	Reduviids	American trypanosomiasis (Chagas disease)

infections caused by *Leishmania* subgenus *Viannia* are considered more aggressive and are more likely to result in treatment failure, molecular techniques to identify the organism to the species and strains can be very important for therapy. Serologic tests are available; however, they are not especially useful for the diagnosis of mucocutaneous or visceral leishmaniasis. The detection of urinary antigens has been used for the diagnosis of visceral leishmaniasis.

TREATMENT, PREVENTION, AND CONTROL

At present, the drug of choice for all forms of leishmaniasis is the pentavalent antimonial compound sodium stibogluconate (Pentostam). In the past several years, the ubiquitous use of this agent has been threatened by the development of drug resistance. Furthermore, drug treatment can be complicated by variation in the susceptibility of *Leishmania* species to drugs, variation in pharmacokinetics, and variation in drug–host immune response interaction. The toxicity of the antimonials also is considerable, and as a result, several alternative approaches to the treatment of leishmaniasis have been developed.

Standard therapy for cutaneous leishmaniasis consists of injections of antimonial compounds directly into the lesion or parenterally. Recently, both fluconazole and miltefosine have been shown to be efficacious. Other agents include amphotericin B, pentamidine, and various formulations of paromomycin. Alternatives to chemotherapy in the treatment of cutaneous leishmaniasis include cryotherapy, heat, and surgical excision.

Stibogluconate remains the drug of choice for mucocutaneous leishmaniasis, with amphotericin B as an alternative. Of note, patients clinically cured of *L. braziliensis,* which is noted for its chronicity, latency, and metastasis with mucous membrane involvement, have been found to be PCR positive up to 11 years posttherapy. Follow-up with smears, cultures, and/or PCR is necessary to ensure that treatment has been effective.

The role of stibogluconate in the treatment of visceral leishmaniasis has been challenged in recent years. Although in most parts of the world, more than 95% of previously untreated patients with visceral leishmaniasis respond to pentavalent antimonials, widespread primary failure of these agents has been reported in the North Bihar region of India. The incidence of primary response was only 54%, and 8% of those initially responding to treatment relapsed. Widespread misuse of the drug is blamed for this emerging resistance. Fortunately, in recent years, four new potential therapies have been introduced for visceral leishmaniasis: amphotericin B liposome formulation, oral miltefosine, a parenteral formulation of paromomycin, and oral sitamaquine (an 8-aminoquinolone). Miltefosine has shown remarkable efficacy (>95% cure rate) and tolerability. Unfortunately, preliminary data from India suggest an increasing relapse rate (as high as 30%) in patients treated with miltefosine, indicating that drug resistance could develop and that strategies must be developed to prevent it.

Prevention of the various forms of leishmaniasis involves prompt treatment of human infections and control of reservoir hosts, along with insect vector control. Protection from sand flies by screening and insect repellents is also essential. The protection of forest and construction workers in endemic areas is most difficult, and disease in those places may be effectively controlled only by vaccination. Work to develop a vaccine is ongoing.

Clinical Case 73.4 **Trypanosomiasis**

Herwaldt and colleagues (*J Infect Dis* 181:395–399, 2000) described a case in which the mother of an 18-month-old boy in Tennessee found a triatomine bug in his crib, which she saved because it resembled a bug shown on a television program about insects that prey on mammals. An entomologist identified the bug as *Triatoma sanguisuga,* which is a vector of Chagas disease. The bug was found to be engorged with blood and infected with *Trypanosoma cruzi.* The child had been intermittently febrile for the preceding 2 to 3 weeks but was otherwise healthy except for pharyngeal edema and multiple insect bites of unknown type on his legs. Whole-blood specimens obtained from the child were negative by buffy coat examination and hemoculture but positive for *T. cruzi* by polymerase chain reaction and DNA hybridization, suggesting that he had low-level parasitemia. Specimens obtained after treatment with benznidazole were negative. He did not develop anti-*T. cruzi* antibody; 19 relatives and neighbors were also negative. Two of three raccoons trapped in the vicinity had positive hemocultures for *T. cruzi.* The child's case of *T. cruzi* infection, the fifth reported U.S. autochthonous case, would have been missed without his mother's attentiveness and the availability of sensitive molecular techniques. Given that infected triatomine bugs and mammalian hosts exist in the southern United States, it is not surprising that humans could become infected with *T. cruzi.* Furthermore, given the nonspecific clinical manifestations of the infection, it is likely that other cases have been overlooked.

Trypanosomes

Trypanosoma, another hemoflagellate, causes two distinctly different forms of disease (Table 73.3). One infection is called **African trypanosomiasis, or sleeping sickness,** and is produced by *T. b. gambiense* and *T. b. rhodesiense*. It is transmitted by tsetse flies. The second infection is called **American trypanosomiasis, or Chagas disease,** produced by *T. cruzi.* It is transmitted by true bugs (triatomids and reduviids, also called *kissing bugs;* Clinical Case 73.4).

TRYPANOSOMA BRUCEI GAMBIENSE

Physiology and Structure

The life cycle of the African forms of trypanosomiasis is illustrated in Fig. 73.12. The infective stage of the organism

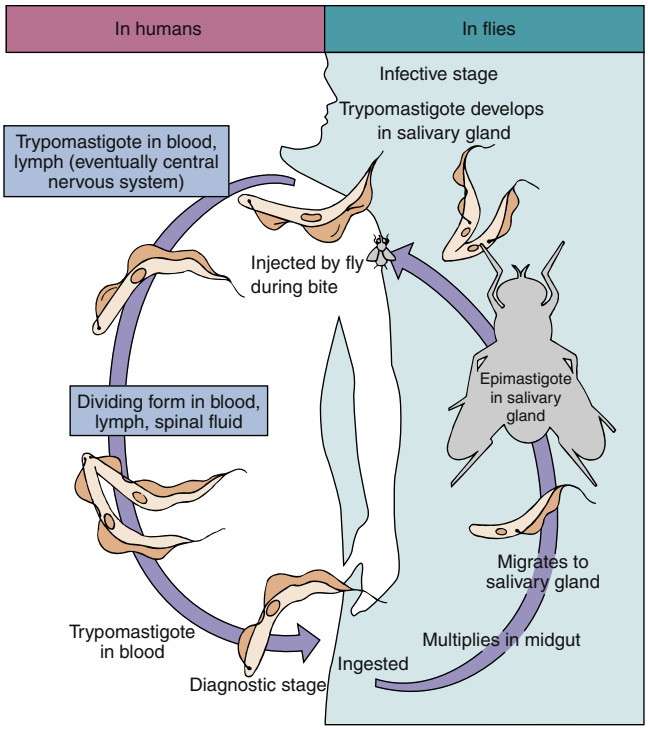

Fig. 73.12 Life cycle of *Trypanosoma brucei.*

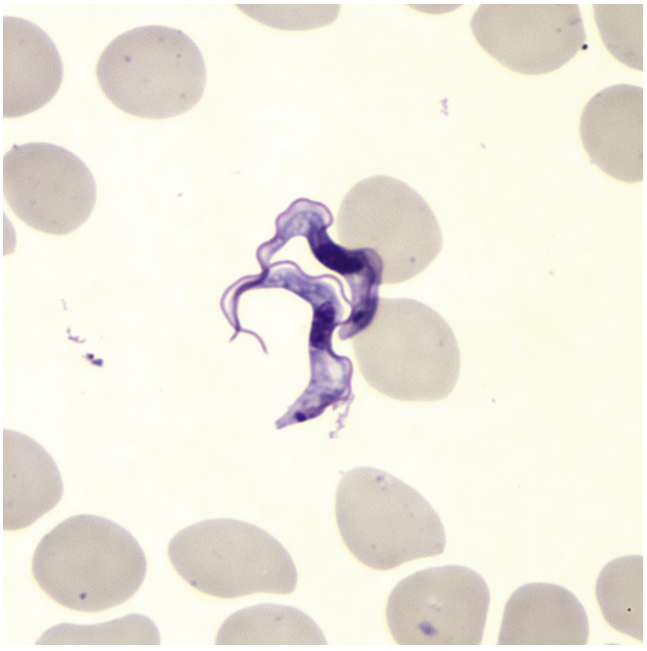

Fig. 73.13 Trypomastigote stage of *Trypanosoma brucei gambiense* in a blood smear. (From CDC Public Health Image Library.)

is the **trypomastigote** (Fig. 73.13), which is present in the salivary glands of transmitting tsetse flies. The organism in this stage has a **free flagellum** and an **undulating membrane** running the full length of the body. The trypomastigotes enter the wound created by the fly bite and find their way into blood and lymph, eventually invading the CNS. Reproduction of the trypomastigotes in blood, lymph, and spinal fluid is by binary or longitudinal fission. These trypomastigotes in blood are then infective for biting tsetse flies, in which further reproduction occurs in the midgut. The organisms then migrate to the salivary glands, in which an **epimastigote** form (with a free flagellum but only a partial undulating membrane) continues reproduction to the infective trypomastigote stage. Tsetse flies become infective 4 to 6 weeks after feeding on blood from a diseased patient.

Epidemiology

T. b. gambiense is limited to tropical West and Central Africa, correlating to the range of the tsetse fly vector. The tsetse flies transmitting *T. b. gambiense* prefer shaded stream banks for reproduction and proximity to human dwellings. Persons who work in such areas are at greatest risk of infection. An animal reservoir has not been proved, although several species of animals have been infected experimentally.

Clinical Syndromes

The incubation period of **Gambian sleeping sickness** varies from a few days to weeks. *T. b. gambiense* produces chronic disease, often ending fatally, with CNS involvement after several years' duration. One of the earliest signs of disease is an occasional **ulcer** at the site of the fly bite. As reproduction of organisms continues, the lymph nodes are invaded, and fever, myalgia, arthralgia, and lymph node enlargement result. Swelling of the posterior cervical lymph nodes is characteristic of Gambian disease and is called **Winterbottom sign.** Patients in this acute phase often exhibit hyperactivity.

Chronic disease progresses to CNS involvement, with lethargy, tremors, meningoencephalitis, mental retardation, and general deterioration. In the final stages of chronic disease, convulsions, hemiplegia, and incontinence occur, and the patient becomes difficult to arouse or evoke a response, eventually progressing to a comatose state. Death is the result of CNS damage and other infections such as malaria or pneumonia.

Laboratory Diagnosis

Organisms can be demonstrated in thick and thin blood films, in concentrated anticoagulated blood preparations, and in aspirations from lymph nodes and concentrated spinal fluid (see Fig. 73.13). Methods for concentrating parasites in blood may be helpful. Approaches include centrifugation of heparinized samples and anion-exchange chromatography. Levels of parasitemia vary widely and attempts to visualize the organism over several days may be necessary. Preparations should be fixed and stained immediately to avoid disintegration of the trypomastigotes. Serologic tests also are useful diagnostic techniques. Immunofluorescence, ELISA, precipitin, and agglutination methods have been used. ELISA has been used to detect antigen in serum and CSF. Biomarker tests (antigen detection) are not widely used because of the limited sensitivity of the test when there are limited numbers of trypomastigotes in the blood or CSF. Most reagents are not available commercially. Referral laboratories have used PCR to detect infections and to differentiate species (*T. b. gambiense* versus *T. b. rhodesiense*), but these methods are not routinely used in the field.

Treatment, Prevention, and Control

Suramin is the drug of choice for treating the acute blood and lymphatic stages of the disease, with pentamidine as

an alternative. Suramin and pentamidine do not cross the blood-brain barrier; therefore melarsoprol is the drug of choice when CNS involvement is suspected. Difluoromethylornithine (DFMO) is a cytostatic drug with activity against the acute and late (CNS) stages of the disease. The most effective control measures include an integrated approach to reduce the human reservoir of infection and the use of fly traps and insecticide; however, economic resources are limited, and effective programs have been difficult to sustain.

TRYPANOSOMA BRUCEI RHODESIENSE

Physiology and Structure

The life cycle of *T. b. rhodesiense* is similar to that of *T. b. gambiense* (see Fig. 73.12), with both trypomastigote and epimastigote stages and transmission by tsetse flies.

Epidemiology

The organism is found primarily in East Africa, especially the cattle-raising countries, in which tsetse flies breed in the brush rather than along stream banks. *T. b. rhodesiense* also differs from *T. b. gambiense* in that domestic animal hosts (cattle and sheep) and wild game animals act as reservoir hosts. This transmission and vector cycle make the organism more difficult to control than *T. b. gambiense.*

Clinical Syndromes

The incubation period for *T. b. rhodesiense* is shorter than that for *T. b. gambiense.* Acute disease (fever, rigors, and myalgia) occurs more rapidly and progresses to a fulminating, rapidly fatal illness. Infected persons are usually dead within 9 to 12 months if untreated.

This more virulent organism also develops in greater numbers in the blood. Lymphadenopathy is uncommon, and CNS invasion occurs early in the infection, with lethargy, anorexia, and mental disturbance. The chronic stages described for *T. b. gambiense* are not often seen because, in addition to rapid CNS disease, the organism produces kidney damage and myocarditis, leading to death.

Laboratory Diagnosis

Examination of blood and spinal fluid is carried out as for *T. b. gambiense.* Serologic tests are available; however, the marked variability of the surface antigens of trypanosomes limits the diagnostic usefulness of this approach.

Treatment, Prevention, and Control

The same treatment protocol applies as for *T. b. gambiense,* with early treatment for the more rapid neurologic manifestations. In contrast to *T. b. gambiense,* DFMO is not effective against late stage *T. b. rhodesiense* infections. Similar prevention and control measures are needed such as tsetse fly control and use of protective clothing, screens, netting, and insect repellent. In addition, early treatment is essential to control transmission, detect infection, and determine treatment in domestic animals. Control of infection in game animals is difficult, but infection can be reduced if measures to control the tsetse fly population, specifically eradication of brush and grassland breeding sites, are applied.

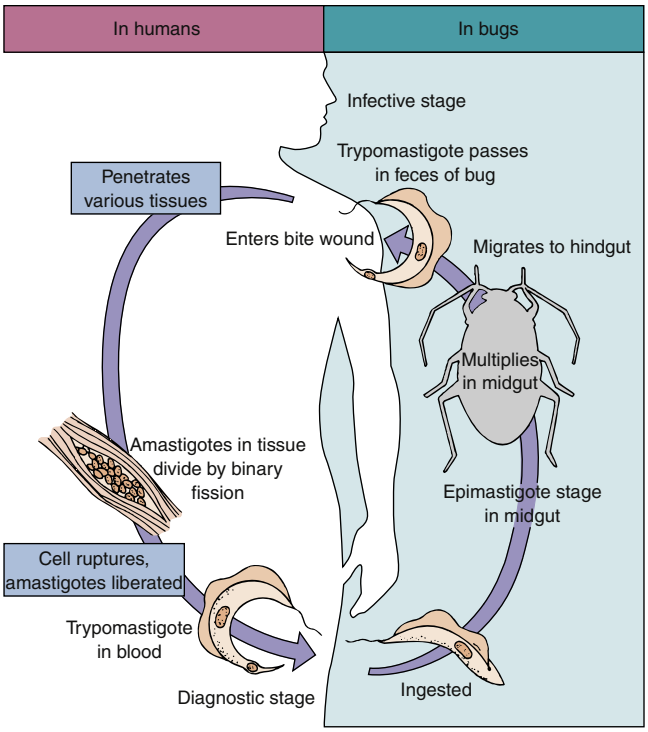

Fig. 73.14 Life cycle of *Trypanosoma cruzi.*

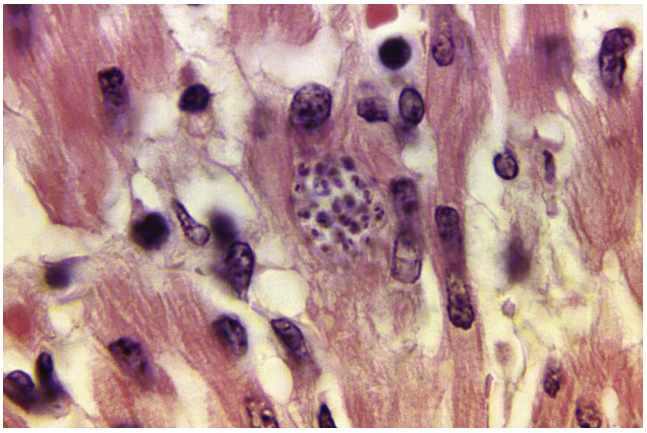

Fig. 73.15 Amastigote stage of *Trypanosoma cruzi* in heart muscle. (From CDC Public Health Image Library.)

TRYPANOSOMA CRUZI

Physiology and Structure

The life cycle of *T. cruzi* (Fig. 73.14) differs from *T. brucei* with the development of an additional form called an **amastigote** (Fig. 73.15). The amastigote is an intracellular form with no flagellum and no undulating membrane. It is smaller than the trypomastigote, is oval, and is found in tissues. The infective trypomastigote, which is present in the feces of a **reduviid bug ("kissing bug"),** enters the wound created by the biting, feeding bug. The bugs have been called **kissing bugs** because they frequently bite people around the mouth and in other facial sites. They are notorious for biting, feeding on blood and tissue juices, and then defecating into the wound. The organisms in the feces of the bug enter the wound; penetration is usually aided when

the patient rubs or scratches the irritated site. In addition to contracting *T. cruzi* infections through the insect's bite wound or exposed mucous membranes, one can be infected by blood transfusion, placental transfer, organ transplant, and accidental ingestion of parasitized reduviid bugs or their feces in food or drink.

The trypomastigotes then migrate to other tissues (e.g., cardiac muscle, liver, brain); lose the flagellum and undulating membrane; and become the smaller, oval, intracellular amastigote form. These intracellular amastigotes multiply by binary fission and eventually destroy the host cells. Then they are liberated to enter new host tissue as intracellular amastigotes or to become trypomastigotes infective for feeding reduviid bugs. Ingested trypomastigotes develop into epimastigotes in the midgut of the insect and reproduce by longitudinal binary fission. The organisms migrate to the hindgut of the bug; develop into metacyclic trypomastigotes; and then leave the bug in the feces after biting, feeding, and defecating, initiating a new human infection.

Epidemiology

T. cruzi occurs widely in both reduviid bugs and a broad spectrum of reservoir animals in North, Central, and South America. Human disease is found most often among children in South and Central America, in which 16 to 18 million people are infected. There is a direct correlation between infected wild animal reservoir hosts and the presence of infected bugs whose nests are found in human homes. Naturally acquired cases of Chagas disease are rare in the United States because the bugs prefer nesting in animal burrows and because homes are not as open to nesting as those in South and Central America. Chagas disease was considered a disease of rural areas; however, it is now ubiquitous because of social pattern changes of rural to urban migration and migration of infected persons to areas in which Chagas disease would never be suspected. Transmission was thought to be primarily through vector bites; but fecal contamination of the food supply by the vector also is a significant source of infection. Oral transmission of acute Chagas disease caused by fruit juices contaminated with the reduviid vector or feces containing the infective metacyclic trypomastigotes has been documented in South America and may be more common than previously thought. For example, in Brazil, oral infection now constitutes the most prominent mechanism of *T. cruzi* transmission. A very serious problem is disease acquisition through blood transfusion and organ transplantation. Infected patients with positive serology can remain asymptomatic yet transmit the infection. Screening of blood donors with a recommended enzyme immunoassay (EIA) has been implemented in the United States.

Clinical Syndromes

Chagas disease may be asymptomatic, acute, or chronic (see Clinical Case 73.4). One of the earliest signs is development of an erythematous and indurated area, called a **chagoma,** at the site of the bug bite. This is often followed by a rash and edema around the eyes and face **(Romaña sign).** The disease is most severe in children younger than 5 years and frequently is seen as an acute process with CNS involvement. Acute infection also is characterized by fever, chills, malaise, myalgia, and fatigue. Parasites may be present in the blood during the acute phase; however, they are sparse in patients older than 1 year. Death may ensue a few weeks after an acute attack, the patient may recover, or the patient may enter the chronic phase as organisms proliferate and enter the heart, liver, spleen, brain, and lymph nodes.

Chronic Chagas disease is characterized by hepatosplenomegaly, myocarditis, and enlargement of the esophagus and colon as a result of the destruction of nerve cells (e.g., Auerbach plexus) and other tissues that control the growth of these organs.

Megacardia and electrocardiographic changes are commonly seen in chronic disease. Involvement of the CNS may produce granulomas in the brain, with cyst formation and a meningoencephalitis. Death from chronic Chagas disease results from tissue destruction in the many areas invaded by the organisms, and sudden death results from complete heart block and brain damage.

Laboratory Diagnosis

T. cruzi can be demonstrated in thick and thin blood films or concentrated anticoagulated blood early in the acute stage. As the infection progresses, the organisms leave the bloodstream and become difficult to find. Biopsy of lymph nodes, liver, spleen, or bone marrow may demonstrate the organisms in the amastigote stage. Culture of blood or inoculation into laboratory animals may be useful when the parasitemia is low. In endemic areas, xenodiagnosis is widely used. Serologic tests also are also available. Several diagnostic EIA and immunochromatographic methods using parasite lysate and recombinant antigens have been approved by the FDA for screening blood donors and patients. The FDA and American Association of Blood Banks (AABB) require donated blood be screened for Chagas antibodies, and it is recommended that United Network Organ Sharing (UNOS) test tissue donors for the presence of Chagas antibodies. Gene amplification techniques, such as PCR, have been used to detect the organism in the bloodstream; however, these approaches are not widely available and have not been adapted for use in the field.

Treatment, Prevention, And Control

Treatment of Chagas disease is limited by the lack of reliable agents. The drugs of choice are benznidazole and nifurtimox. Although both drugs have proven activity against the acute phase of disease, they are less effective against chronic Chagas disease and have severe side effects. Alternative agents include allopurinol. Education regarding the disease, its insect transmission, and the wild animal reservoirs is critical. Bug control, eradication of nests, and construction of homes to prevent nesting of bugs are also essential. The use of dichlorodiphenyltrichloroethane (DDT) in bug-infested homes has demonstrated a drop in the transmission of malaria and Chagas disease. Screening of blood by serologic means or excluding blood donors from endemic areas prevents some infections that would otherwise be associated with transfusion therapy.

Development of a vaccine is possible because *T. cruzi* does not have the wide antigenic variation observed with the African trypanosomes.

For a case study and questions see StudentConsult.com.

Case Study and Questions

A tourist returned from a 4-week visit to peninsular Malaysia, where he stayed in a jungle area for 5 days. He did not take any malaria prophylaxis and presented to the emergency department with fever, chills, tachypnea, and tachycardia. He was thrombocytopenic and had mild liver function test abnormalities. Examination of Giemsa-stained blood films showed a hyperparasitemia of ≈10% with both ring forms and mature trophozoites.

1. What is the most likely cause of this infection?
   a. *Plasmodium falciparum*
   b. *Plasmodium knowlesi*
   c. *Plasmodium malariae*
   d. *Plasmodium vivax*
2. Why is this species of *Plasmodium* associated with such high levels of parasitemia?
3. How would you treat this patient?

74 Nematodes

A 10-year-old boy was brought in by his father for evaluation of crampy abdominal pain, nausea, and mild diarrhea that had persisted for approximately 2 weeks. On the day before evaluation, the boy reported to his parents that he passed a large worm into the toilet during a bowel movement. He flushed the worm before the parents could see it. Physical examination was completely unremarkable. The boy had no fever, cough, or rash and did not complain of anal pruritus. His travel history was unremarkable. Examination of a stool specimen revealed the diagnosis.

1. Which intestinal parasites of humans are nematodes?
2. Which nematode was likely in this case? Which organisms may be found in stool?
3. What was the most likely means of acquisition of this parasite?
4. Was this patient at risk of autoinfection?
5. Describe the life cycle of this parasite.
6. Can this parasite cause extraintestinal symptoms? Which other organs may be invaded and what might stimulate extraintestinal invasion?

Answers to these questions are available on www.StudentConsult.com.

Summaries Clinically Significant Organisms

ASCARIS LUMBRICOIDES

Trigger Words

Ascaris, roundworm, intestinal obstruction, pulmonary eosinophilia, decorticate, nematode

Biology, Virulence, and Disease

- Nematodes: most common helminths recognized in the United States; also called roundworms
- Large (20 to 35 cm long) pink worms with moderately complex life cycle but otherwise typical of intestinal roundworm (nematode)
- Infections caused by ingestion of only a few eggs may produce no symptoms
- Even a single adult *Ascaris* worm may be dangerous: migrate to liver, penetrate intestine, cause mechanical tissue damage
- Migration of a large number of larval worms to lung may produce pneumonitis
- A tangled bolus of mature worms in intestine may lead to obstruction and perforation
- A large worm burden may result in abdominal tenderness, fever, distention, nausea

Epidemiology

- *A. lumbricoides* prevalent in areas with poor sanitation and where human feces (night soil) are used as fertilizer
- ≈1 billion people infected worldwide
- No known animal reservoir
- *Ascaris* eggs very hardy; can survive extreme temperatures, persist for months in feces and sewage

Diagnosis

- Microscopic examination of sediment of concentrated stool
- Adult worms may be visualized on abdominal radiographs; cholangiograms may reveal worms in biliary tract
- Pulmonary phase of disease may be diagnosed by finding larvae and eosinophils in sputum

Treatment, Prevention, and Control

- Treatment of symptomatic infection highly effective
- Drugs of choice: albendazole or mebendazole
- Patients with mixed infections *(Ascaris* plus other helminths, *Giardia,* or *Entamoeba histolytica)* should be treated for ascariasis first to avoid provoking worm migration
- Prevention: education, improved sanitation, avoidance of human feces as fertilizer

ONCHOCERCA VOLVULUS

Trigger Words

Microfilaria, macrofilaria, nodules, hanging groin, blackfly, Africa, *Wolbachia* endosymbiont, skin snip, river blindness

Biology, Virulence, and Disease

- Filariae: long, slender roundworms; parasites of blood, lymph, subcutaneous and connective tissues; transmitted by mosquitoes or biting flies
- *O. volvulus:* filarial nematode transmitted by blackfly *(Simulium damnosum)*
- Onchocerciasis affects >18 million people worldwide; causes blindness in ≈5% of infected people
- All individual worms and all life cycle stages of *O. volvulus* contain *Wolbachia* bacterial endosymbiont
- Clinical onchocerciasis characterized by infection involving skin, subcutaneous tissue, lymph nodes, eyes
- Signs/symptoms: fever, eosinophilia, urticaria; migration of microfilariae to eyes causes severe tissue damage and blindness

Epidemiology

- *O. volvulus* endemic in many parts of Africa, especially the Congo and Volta river basins; common term is "river blindness"
- Prevalence: men > women; 50% of men in endemic areas are blind before they reach age 50

Diagnosis

- Diagnosis made by demonstration of microfilariae in skin snip preparations taken from infrascapular or gluteal regions
- In patients with ocular disease, organism may be seen in anterior chamber with aid of a slit lamp

Treatment, Prevention, and Control

- Surgical removal of nodules often used to eliminate adult worms and stop production of microfilariae
- Ivermectin: single dose reduces number of microfilariae in eyes and skin
- Protection from blackfly bites, prompt diagnosis and treatment of infections to prevent transmission

Fig. 74.1 **Adult Ascaris lumbricoides.** (Peters, W., Pasvol, G. 2007. Atlas of Tropical Medicine and Parasitology, 6th ed., Elsevier, Philadelphia, PA)

TABLE 74.1 Nematodes of Medical Importance

Parasite	Common Name	Disease
Enterobius vermicularis	Pinworm	Enterobiasis
Ascaris lumbricoides	Roundworm	Ascariasis
Toxocara canis	Dog ascaris	Visceral larva migrans
T. cati	Cat ascaris	Visceral larva migrans
Baylisascaris procyonis	Raccoon ascaris	Neural larva migrans
Trichuris trichiura	Whipworm	Trichuriasis
Ancylostoma duodenale	Old World hookworm	Hookworm infection
Necator americanus	New World hookworm	Hookworm infection
A. braziliense	Dog or cat hookworm	Cutaneous larva migrans
Strongyloides stercoralis	Threadworm	Strongyloidiasis
Trichinella spiralis	Pork worm	Trichinosis
Wuchereria bancrofti	Bancroft filaria	Filariasis
Brugia malayi	Malayan filaria	Filariasis
Loa loa	African eye worm	Loiasis
Mansonella species	—	Filariasis
Onchocerca volvulus	—	Onchocerciasis, river blindness
Dirofilaria immitis	Dog heartworm	Dirofilariasis
Dracunculus medinensis	Guinea worm	Dracunculosis

The most common helminths recognized in the United States are primarily intestinal nematodes, although in other countries, nematode infections of blood and tissues can cause devastating disease. The nematodes are the most easily recognized form of intestinal parasite because of their large size and cylindric, unsegmented bodies; hence the common name **roundworms** (Fig. 74.1). These parasites live primarily as adult worms in the intestinal tract, and nematode infections are most commonly confirmed by detecting the characteristic eggs in feces. The identification of eggs should be approached in a systematic manner, taking into account the size and shape of the egg, the thickness of the shell, and the presence or absence of specialized structures, such as polar plugs, knobs, spines, and opercula. The presence and characteristics of larvae within the eggs may also be useful. The most common nematodes of medical importance are listed in Table 74.1.

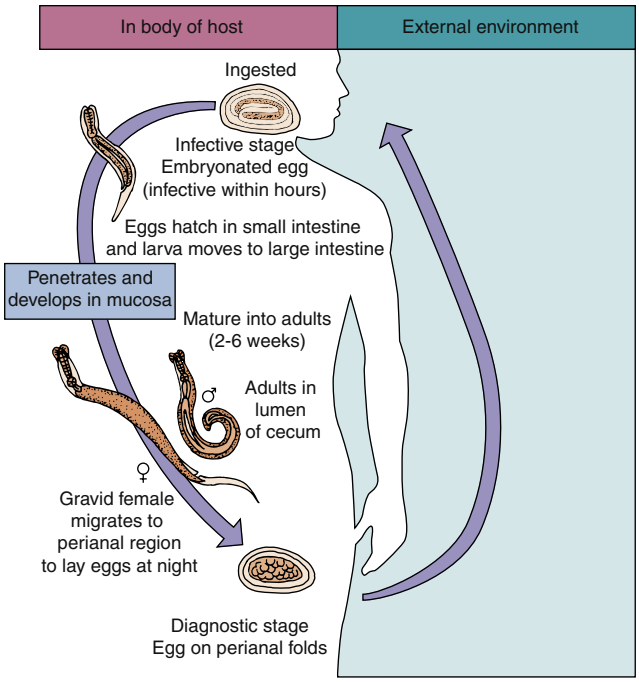

Fig. 74.2 Life cycle of *Enterobius vermicularis.*

The **filariae** are long, slender roundworms that are parasites of blood, lymph, subcutaneous, and connective tissues. All these nematodes are transmitted by mosquitoes or biting flies. Most produce larval worms called **microfilariae** that are demonstrated in blood specimens or in subcutaneous tissues and skin snips.

Enterobius vermicularis

PHYSIOLOGY AND STRUCTURE

E. vermicularis, the **pinworm,** is a small, white worm that is familiar to parents who find them in the perianal folds or vagina of an infected child. Infection is initiated by ingestion of embryonated eggs (Fig. 74.2). Larvae hatch in the small intestine and migrate to the large intestine, in which they mature into adults in 2 to 6 weeks. Fertilization of the female by the male produces the characteristic asymmetric eggs. These eggs are laid in the perianal folds by the migrating female. As many as 20,000 eggs are deposited on the perianal skin. The eggs rapidly mature and are infectious within hours.

EPIDEMIOLOGY

E. vermicularis occurs worldwide but is most common in the temperate regions, in which person-to-person spread is greatest in crowded conditions, such as in day-care centers, schools, and mental institutions. An estimated 500 million cases of pinworm infection are reported worldwide, and this is the most common helminthic infection in North America.

Infection occurs when the eggs are ingested and the larval worm is free to develop in the intestinal mucosa. These eggs may be transmitted from hand to mouth by children scratching the perianal folds in response to the irritation caused by the migrating, egg-laying female worms, or the eggs may find their way to clothing and play objects in day-care centers. They also can survive long periods in the dust that accumulates over doors, on windowsills, and under beds in the rooms inhabited by infected people. Egg-laden dust can be inhaled and swallowed to produce infestation. In addition, **autoinfection ("retrofection")** can occur, in which eggs hatch in the perianal folds and the larval worms migrate into the rectum and large intestine. Infected individuals who handle food also can be a source of infection. No animal reservoir for *Enterobius* is known. Physicians should be aware of the related epidemiology of *Dientamoeba fragilis*; this organism correlates well with the presence of *E. vermicularis*, with *D. fragilis* thought to be transported in the pinworm eggshell.

Fig. 74.3 *Enterobius vermicularis* egg. The thin-walled eggs are 50 to 60 × 20 to 30 μm, ovoid, and flattened on one side (not because children sit on them, but this is an easy way to correlate the egg morphology with the epidemiology of the disease).

CLINICAL SYNDROMES

Many children and adults show no symptoms and serve only as carriers. Patients who are allergic to the secretions of the migrating worms experience severe pruritus, loss of sleep, and fatigue. The pruritus may cause repeated scratching of the irritated area and lead to secondary bacterial infection. Worms that migrate into the vagina may produce genitourinary problems and granulomas.

Worms attached to the bowel wall may produce inflammation and granuloma formation around the eggs. Although the adult worms may occasionally invade the appendix, there remains no proven relationship between pinworm invasion and appendicitis. Penetration through the bowel wall into the peritoneal cavity, liver, and lungs has been infrequently recorded.

LABORATORY DIAGNOSIS

The diagnosis of **enterobiasis** is usually suggested by the clinical manifestations and confirmed by detection of the characteristic eggs on the anal mucosa. Occasionally, the adult worms are seen by laboratory personnel in stool specimens, but the method of choice for diagnosis involves use of an anal swab with a sticky surface that picks up the eggs (Fig. 74.3) for microscopic examination. Sampling can be done with clear tape or commercially available swabs. The sample should be collected when the child arises and before bathing or defecation, to pick up eggs laid by migrating worms during the night. Parents can collect the specimen and deliver it to the physician for immediate microscopic examination. Three swabs, one per day for 3 consecutive days, may be required to detect the diagnostic eggs. The eggs are rarely seen in fecal specimens. Systemic signs of infection, such as eosinophilia, are rare.

TREATMENT, PREVENTION, AND CONTROL

The drug of choice is albendazole or mebendazole. Pyrantel pamoate and piperazine are effective, but reinfection is common. To avoid reintroduction of the organism and reinfection in the family environment, it is customary to treat the entire family simultaneously. Although cure rates are high, reinfection is common. Repeat treatment after 2 weeks may be useful in preventing reinfection.

Personal hygiene, clipping of fingernails, thorough washing of bed clothes, and prompt treatment of infected individuals all contribute to control. When housecleaning is done in the home of an infected family, dusting under beds, on window sills, and over doors should be done with a damp mop to avoid inhalation of infectious eggs.

Ascaris lumbricoides

PHYSIOLOGY AND STRUCTURE

A. lumbricoides are large (20 to 35 cm in length), pink worms (see Fig. 74.1) that have a more complex life cycle than *E. vermicularis* but are otherwise typical of an intestinal roundworm (Fig. 74.4).

The ingested infective egg releases a larval worm that penetrates the duodenal wall, enters the bloodstream, is carried to the liver and heart, and then enters the pulmonary circulation. The larvae break free in the alveoli of the lungs, in which they grow and molt. In about 3 weeks, the larvae pass from the respiratory system to be coughed up, swallowed, and returned to the small intestine.

As the male and female worms mature in the small intestine (primarily jejunum), fertilization of the female by the male initiates egg production, which may amount to 200,000 eggs per day for as long as a year. Female worms can also produce unfertilized eggs in the absence of males. Eggs are found in the feces 60 to 75 days after the initial infection. Fertilized eggs become infectious after approximately 2 weeks in the soil.

EPIDEMIOLOGY

A. lumbricoides is prevalent in areas in which sanitation is poor and in which human feces are used as fertilizer. Because food and water are contaminated with *Ascaris* eggs, this parasite, more than any other, affects the world's population. Although no animal reservoir is known for *A.*

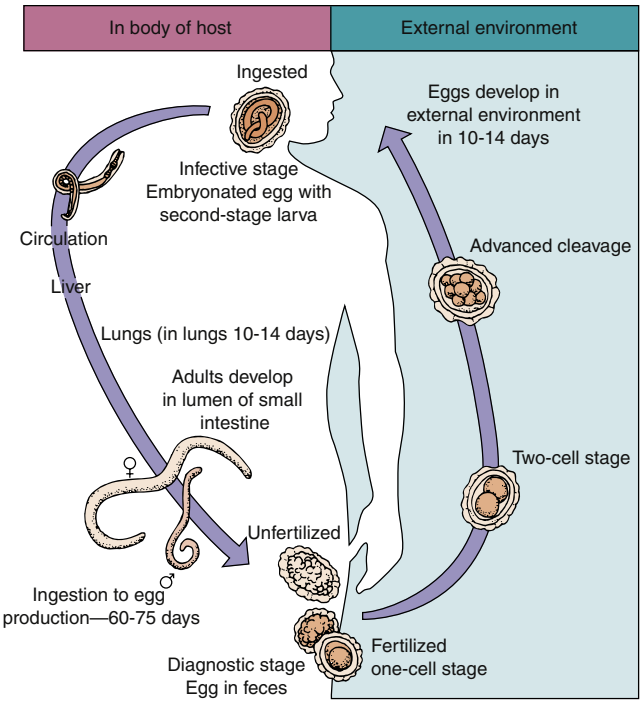

Fig. 74.4 Life cycle of *Ascaris lumbricoides*.

lumbricoides, an almost identical species from pigs, *A. suum*, can infect humans. This species is seen in swine farmers and is associated with the use of pig manure for gardening. *Ascaris* eggs are quite hardy and can survive extreme temperatures and persist for several months in feces and sewage. Ascariasis is the most common helminthic infection worldwide, with an estimated 1 billion people infected.

CLINICAL SYNDROMES

Infections caused by the ingestion of only a few eggs may produce no symptoms; however, even a single adult *Ascaris* worm may be dangerous because it can migrate into the bile duct, resulting in liver and damage tissue (Clinical Case 74.1). Furthermore, because the worm has a tough, flexible body, it can occasionally perforate the intestine, creating peritonitis with secondary bacterial infection. The adult worms do not attach to the intestinal mucosa but depend on constant motion to maintain their position within the bowel lumen.

After infection with many larvae, migration of worms to the lungs can produce pneumonitis resembling an asthmatic attack. Pulmonary involvement is related to the degree of hypersensitivity induced by previous infections and the intensity of the current exposure and may be accompanied by eosinophilia and oxygen desaturation. Also, a tangled bolus of mature worms in the intestine can result in obstruction, perforation, and occlusion of the appendix. As mentioned previously, migration into the bile duct, gallbladder, and liver can produce severe tissue damage. This migration can occur in response to fever, drugs other than those used to treat ascariasis, and some anesthetics. Patients with many larvae may also experience abdominal tenderness, fever, distention, and vomiting.

Clinical Case 74.1 **Hepatic Ascariasis**

Hurtado and colleagues (*N Engl J Med* 354:1295–1303, 2006) described a case of a 36-year-old woman who presented with recurrent RUQ abdominal pain. One year earlier, she also presented with RUQ abdominal pain, abnormal liver function tests, and positive serology for hepatitis C. An abdominal ultrasonographic examination showed biliary dilation, and ERCP showed multiple stones in the common bile duct, the left hepatic duct, and the left intrahepatic duct. The majority of the stones were removed. Examination of the bile duct aspirate was negative for ova and parasites. One month before the present admission, the patient experienced recurrent RUQ pain and jaundice. Repeat ERCP again showed multiple stones in the common and left main hepatic ducts; partial removal was accomplished.

One month later, the patient was admitted with severe epigastric pain and fever. The patient was born in Vietnam and had immigrated to the United States when she was in her early 20s. She had no history of recent travel. An abdominal computed tomography scan with contrast showed abnormal perfusion of the left hepatic lobe and dilation of the left biliary radicles with multiple filling defects. ERCP showed partial obstruction of the left main hepatic duct, a few small stones, and purulent bile. Magnetic resonance imaging showed diffuse enhancement of the left lobe and left portal vein suggestive of inflammation. Cultures of blood grew *Klebsiella pneumoniae*, and examination of a stool sample revealed a few *Strongyloides stercoralis* rhabditiform larvae. Biliary stents were placed, and the patient was treated with levofloxacin. Two weeks later, the patient was admitted to the hospital, in which a partial hepatectomy was performed for treatment of recurrent pyogenic cholangitis. Gross examination of the left hepatic lobe showed ectatic bile ducts containing bile-stained calculi. Microscopic examination of the calculous material revealed collections of parasite eggs and a degenerated and fragmented nematode. *Klebsiella* species were identified in cultures by the microbiology laboratory. The findings were consistent with recurrent pyogenic cholangiohepatitis with infection by *Ascaris lumbricoides* and *Klebsiella* species. In addition to antibiotics for the bacterial infection, the patient was treated with ivermectin for the *Strongyloides* infection and albendazole for the *Ascaris* organisms.

The aberrant migration of *A. lumbricoides* into the pancreatobiliary tree, with subsequent deposition of eggs, followed by death and degeneration of both worm and eggs, became a nidus for calculus formation and secondary bacterial infection. Although unusual in the United States, hepatic ascariasis is estimated to contribute to more than 35% of cases of biliary and pancreatic disease in the Indian subcontinent and parts of Southeast Asia.

ERCP, Endoscopic retrograde cholangiopancreatography; *RUQ*, right upper quadrant.

LABORATORY DIAGNOSIS

Examination of the sediment of concentrated stool reveals the knobby-coated, bile-stained, fertilized and unfertilized eggs. Eggs are oval, 55 to 75 µm long and 50 µm wide. The thick-walled outer shell can be partially removed **(decorticated egg).** Occasionally, adult worms pass with the

feces, which can be quite dramatic because of their large size (20 to 35 cm long) (see Fig. 74.1). Roentgenologists also may visualize the worms in the intestine, and cholangiograms often disclose their presence in the biliary tract of the liver. The pulmonary phase of the disease may be diagnosed by the finding of larvae and eosinophils in sputum.

TREATMENT, PREVENTION, AND CONTROL

Treatment of symptomatic infection is highly effective. The drug of choice is albendazole or mebendazole; pyrantel pamoate and piperazine are alternatives. Patients with mixed parasitic infections (*A. lumbricoides*, other helminths, *Giardia duodenalis*, and *Entamoeba histolytica*) in the stool should be treated for ascariasis first to avoid provoking worm migration and possible intestinal perforation. Education, improved sanitation, and avoidance of human feces as fertilizer are critical. A program of mass treatment in highly endemic areas has been suggested, but this may not be economically feasible. Furthermore, eggs can persist in contaminated soil for 3 years or more. Certainly, improved personal hygiene among people who handle food is an important aspect of control.

Toxocara and *Baylisascaris*

PHYSIOLOGY AND STRUCTURE

T. canis, *T. cati*, and *B. procyonis* are ascarid worms that are naturally parasitic in the intestines of dogs, cats, and raccoons, respectively. These organisms may accidentally infect humans, producing disease states known as **visceral larva migrans (VLM), neural larva migrans (NLM),** and **ocular larva migrans (OLM).** When ingested by humans, the eggs of these worms can hatch into larval forms that cannot follow the normal developmental cycle as in the natural host. They can penetrate the human gut and reach the bloodstream and then migrate as larvae to various human tissues. The *Toxocara* species are the most common causes of VLM and OLM, whereas *B. procyonis* is increasingly recognized as a cause of fatal NLM. Although the *Toxocara* species do not develop beyond the migrating larval form, *B. procyonis* larvae continue to grow to a large size within the human host.

EPIDEMIOLOGY

Wherever infected dogs and cats are present, the eggs are a threat to humans; likewise, contact with raccoons or their feces presents a significant risk of infection with *B. procyonis*. This is especially true for children who are exposed more readily to contaminated soil and who tend to put objects in their mouths.

CLINICAL SYNDROMES

The clinical manifestations of VLM, NLM, and OLM in humans are related to the migration of the larvae through tissues (Clinical Case 74.2). The larvae may invade any tissue of the body in which they can induce bleeding, the formation of eosinophilic granulomas, and necrosis. Patients may be asymptomatic and have only eosinophilia, but they also can have serious disease directly related to the number and location of the lesions caused by the migrating larvae, as well as the degree to which the host is sensitized to the larval antigens. The organs most frequently involved are the lungs, heart, kidneys, liver, skeletal muscles, eyes, and central nervous system (CNS). NLM is a common sequela of infection with *B. procyonis* and is attributed to the extensive somatic larval migration of this species. Continued

Clinical Case 74.2 **Baylisascariasis**

Gavin and colleagues (*Pediatr Infect Dis J* 21:971–975, 2002) described a case of a previously normal 2½-year-old boy who was admitted to the hospital with fever and recent onset of encephalopathy. Past medical history was significant for pica and geophagia, and he was receiving ferrous sulfate for iron-deficiency anemia. He was in good health until 8 days before admission, when a temperature of 38.5° C and a mild cough developed. Three days before admission, he developed increasing lethargy and marked somnolence. He was irritable, confused, and ataxic. The family lived in suburban Chicago, and there were no sick contacts or pets at home. There was no travel history. On admission, he was febrile and lethargic but irritable and agitated when disturbed. Neck stiffness with generalized hypertonicity, hyperreflexia, and bilateral extensor plantar responses were present. The WBC was elevated, and eosinophilia was present. CSF examination revealed an elevated protein and WBC with 32% eosinophils. Gram, acid-fast, and India ink stains and bacterial and cryptococcal antigen tests were all negative. Broad-spectrum antibacterial and antiviral therapy was begun empirically; however, the patient became comatose, with opisthotonos, decerebrate posturing, hypertonicity, and tremulousness. Cranial magnetic resonance imaging demonstrated areas of increased signal involving both cerebellar hemispheres. Bacterial, fungal, mycobacterial, and viral cultures of blood and CSF were negative. Viral serologies were negative, as were tests for antibodies against *Toxocara*, cysticercosis, coccidioidomycosis, blastomycosis, and histoplasmosis. A detailed epidemiologic history revealed that 18 days before hospitalization, the family attended a picnic in a nearby suburb. Numerous raccoons were observed regularly in the vicinity, and the patient was observed playing with and eating dirt beneath the trees. CSF and serum antibodies against third-stage *Baylisascaris procyonis* were demonstrated by indirect immunofluorescence assay, with titers increasing from 1/4 to 1/1024 during a 2-week period. The patient was treated with albendazole and corticosteroids for 4 weeks but has remained severely affected with marked generalized spasticity and cortical blindness. Subsequent examination of soil and debris from the child's play site revealed thousands of infective *Baylisascaris procyonis* eggs. This case underscores the devastating effects of neural larva migrans. In many regions of North America, large populations of raccoons with high rates of endemic *Baylisascaris procyonis* infection (e.g., 60% to 80%) live in proximity to humans, which suggests that the risk of human infection is probably substantial.

CSF, Cerebrospinal fluid; *WBC*, white blood cell count.

growth and migration within the CNS produce extensive mechanical tissue damage. Signs and symptoms caused by the migrating larvae include cough, wheezing, fever, rash, anorexia, seizures, fatigue, and abdominal discomfort. On examination, patients may have hepatosplenomegaly and nodular pruritic skin lesions. Death may result from respiratory failure, cardiac arrhythmia, or brain damage. Ocular disease can also occur with the movement of larvae through the eye and may be mistaken for malignant retinoblastoma. Prompt diagnosis is required to avoid unnecessary enucleation.

LABORATORY DIAGNOSIS

The diagnosis of VLM, NLM, and OLM is based on clinical findings; the presence of **eosinophilia;** known exposure to dogs, cats, or raccoons; and serologic confirmation. Enzyme-linked immunosorbent assays are available and appear to offer the best serologic marker for disease. The examination of feces from infected patients is not useful because egg-laying adults are not present. However, examination of fecal material from infected pets often supports the diagnosis. Tissue examination for larvae may provide a definitive diagnosis but may be negative because of sampling error.

TREATMENT, PREVENTION, AND CONTROL

Treatment is primarily symptomatic because antiparasitic agents are not of proven benefit. Anthelmintic therapy with albendazole, mebendazole, diethylcarbamazine (DEC), or thiabendazole is often used. Corticosteroid therapy may be lifesaving if the patient has serious pulmonary, myocardial, or CNS involvement because a major component of the infection is an inflammatory response to the organism. Despite anthelmintic treatment of cases of *B. procyonis* NLM, there are no neurologically intact survivors. These zoonoses can be greatly reduced if pet owners conscientiously eradicate worms from their animals and clean up pet fecal material from yards and school playgrounds. Children's play areas and sandboxes should be carefully monitored. Raccoons should not be encouraged to visit homes or yards for food, and the keeping of raccoons as pets should be strongly discouraged.

Trichuris trichiura

PHYSIOLOGY AND STRUCTURE

Commonly called **whipworm** because it resembles the handle and lash of a whip (Fig. 74.5), *T. trichiura* has a simple life cycle (Fig. 74.6). Ingested eggs hatch into a larval worm in the small intestine and then migrate to the cecum, in which they penetrate the mucosa and mature to adults. About 3 months after the initial infection, the fertilized female worm starts laying eggs and may produce 3000 to 10,000 eggs per day. Female worms can live for as long as 8 years. Eggs passed into the soil mature and become infectious in 3 weeks. *T. trichiura* eggs are distinctive, with dark bile staining, a barrel shape, and the presence of polar plugs in the egg shell (Fig. 74.7).

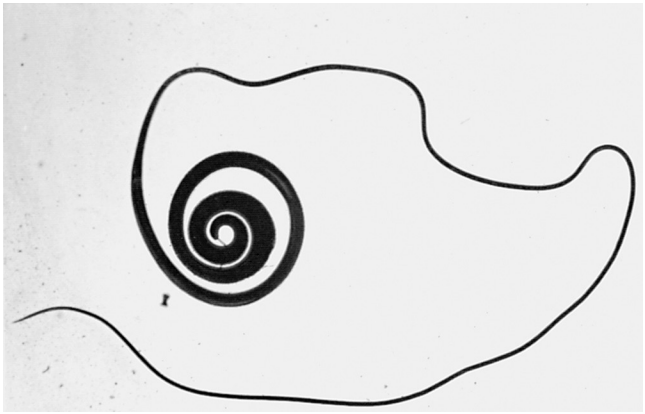

Fig. 74.5 **Trichuris trichiura, adult male.** (From John, D.T., Petri Jr., W.A., 2006. Markell and Voge's Medical Parasitology, ninth ed. Elsevier, Philadelphia, PA.)

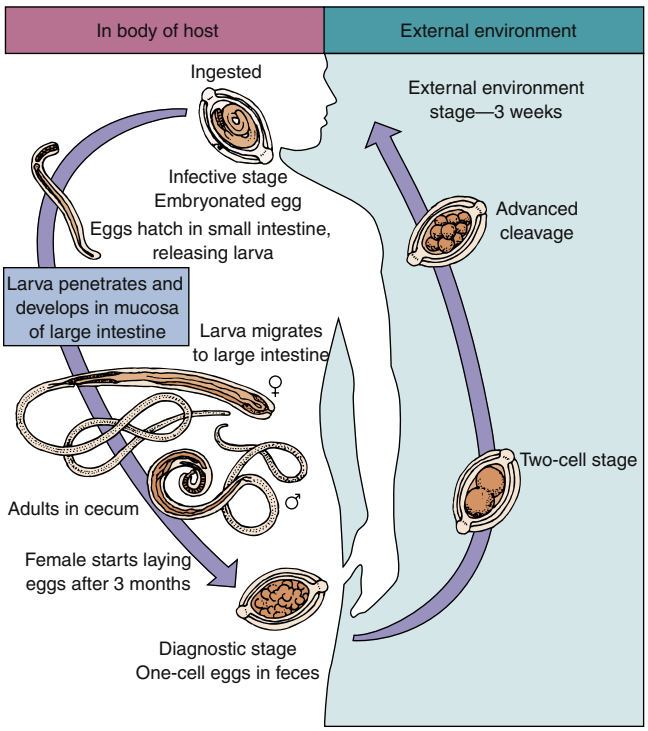

Fig. 74.6 Life cycle of *Trichuris trichiura.*

EPIDEMIOLOGY

Like *A. lumbricoides*, *T. trichiura* has worldwide distribution, and its prevalence is directly correlated with poor sanitation and the use of human feces as fertilizer. No animal reservoir is recognized.

CLINICAL SYNDROMES

The clinical manifestations of **trichuriasis** are generally related to the intensity of the worm burden. Most infections are with small numbers of *Trichuris* organisms and are usually asymptomatic, although secondary bacterial infection may occur because the heads of the worms penetrate deep into the intestinal mucosa. Infections with many larvae may produce abdominal pain and distention, bloody diarrhea, weakness, and weight loss. Appendicitis may occur

as worms fill the lumen, prolapse of the rectum is seen in children because of the irritation and straining during defecation. Anemia and eosinophilia also are seen in severe infections.

LABORATORY DIAGNOSIS

Stool examination reveals the characteristic bile-stained eggs with polar plugs (see Fig. 74.7). Light infestations may be difficult to detect because of the paucity of eggs in the stool specimens.

TREATMENT, PREVENTION, AND CONTROL

The drug of choice is albendazole or mebendazole. Combination chemotherapies have showed the highest efficacy, such as albendazole plus oxantel pamoate. As with *A. lumbricoides*, prevention of *T. trichiura* depends on education, good personal hygiene, adequate sanitation, and avoidance of the use of human feces as fertilizer.

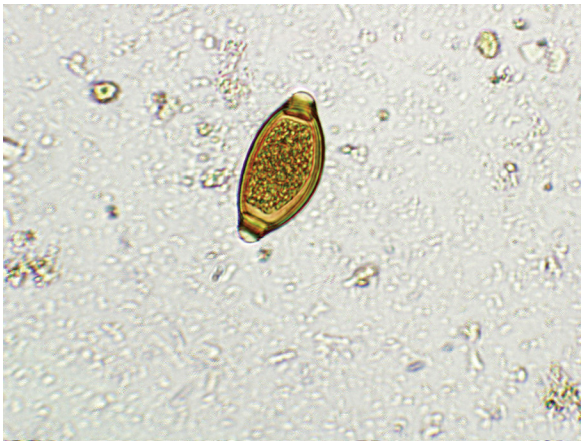

Fig. 74.7 *Trichuris trichiura* egg. The eggs are barrel shaped, measuring 50 × 24 μm, with a thick wall and two prominent plugs at the ends. Internally, an unsegmented ovum is present.

Hookworms

ANCYLOSTOMA DUODENALE AND *NECATOR AMERICANUS*

Physiology and Structure

The two human hookworms are *A. duodenale* **(Old World hookworm)** and *N. americanus* **(New World hookworm).** Differing only in geographic distribution, structure of mouthparts (Fig. 74.8), and relative size, these two species are discussed together as agents of hookworm infection. The human phase of the hookworm life cycle is initiated when a filariform (infective form) larva penetrates intact skin (Fig. 74.9). The larva then enters the circulation, is carried to the lungs, and similar to *A. lumbricoides*, is coughed up, swallowed, and develops to adulthood in the small intestine. Adult worms lay as many as 10,000 to 20,000 eggs per day, which are released into the feces. Egg laying is initiated 4 to 8 weeks after the initial exposure and can persist for as long as 5 years. On contact with soil, the **rhabditiform** (noninfective) larvae are released from the eggs and within 2 weeks develop into **filariform** larvae. The filariform larvae can then penetrate exposed skin (e.g., bare feet) and initiate a new cycle of human infection.

Both species have mouthparts designed for sucking blood from injured intestinal tissue. *A. duodenale* has chitinous teeth, and *N. americanus* has shearing chitinous plates (see Fig. 74.8).

Epidemiology

Transmission of hookworm infection requires the deposition of egg-containing feces on shady, well-drained soil and is favored by warm, humid (tropical) conditions. Hookworm infections are reported worldwide in places in which direct contact with contaminated soil can lead to human disease, but they occur primarily in warm subtropical and tropical regions and in

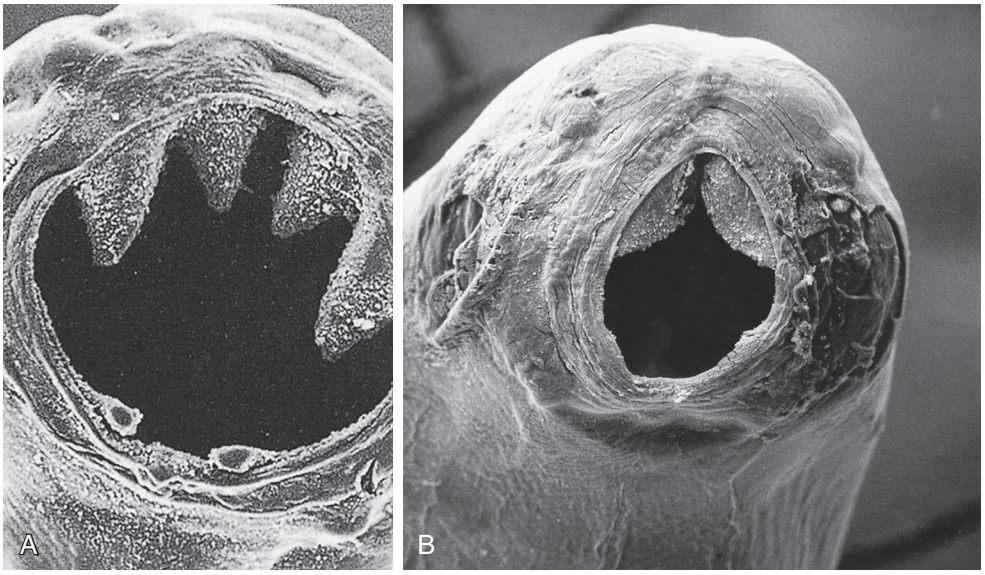

Fig. 74.8 Scanning electron micrographs of adult hookworm mouthparts. (A) *Ancylostoma duodenale* (×630). (B) *Necator americanus* (×470). (From Peters, W., Pasvol, G., 2007. Atlas of Tropical Medicine and Parasitology, sixth ed. Elsevier, Philadelphia, PA.)

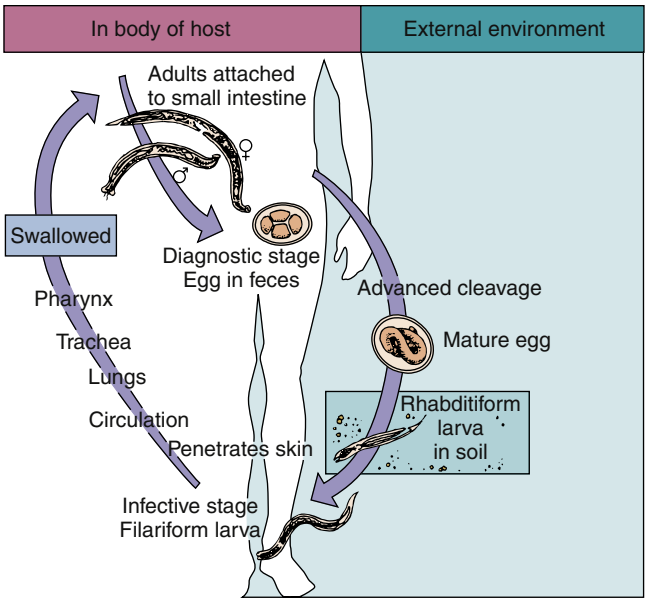

Fig. 74.9 Life cycle of human hookworms.

southern parts of the United States. It is estimated that more than 900 million individuals worldwide are infected with hookworms, including 700,000 in the United States.

Clinical Syndromes

Skin-penetrating larvae may produce an allergic reaction and rash at sites of entry, and larvae migrating in the lungs can cause pneumonitis and eosinophilia. Adult worms produce the gastrointestinal symptoms of nausea, vomiting, and diarrhea. As blood is lost from feeding worms, a microcytic hypochromic anemia develops. Daily blood loss is estimated at 0.15 to 0.25 ml for each adult *A. duodenale* and 0.03 ml for each adult *N. americanus*. In severe, chronic infections, emaciation and mental and physical retardation may occur related to anemia from blood loss and nutritional deficiencies. Also, intestinal sites may be secondarily infected by bacteria when the worms migrate along the intestinal mucosa.

Laboratory Diagnosis

Stool examination reveals the characteristic non–bile-stained segmented eggs shown in Fig. 74.10. Adult worms are rarely seen because they remain firmly attached to the intestinal mucosa. Larva are not found in stool specimens unless the specimen was left at ambient temperature for a day or more. The eggs of *A. duodenale* and *N. americanus* cannot be distinguished. The larvae must be examined to identify these hookworms specifically, although this is clinically unnecessary.

Treatment, Prevention, and Control

The drug of choice is albendazole or mebendazole; pyrantel pamoate is an alternative. In addition to eradication of the worms to stop blood loss, iron therapy is indicated to raise hemoglobin levels to normal. Blood transfusion may be necessary in severe cases of anemia. Education, improved sanitation, and controlled disposal of human feces are critical preventive measures. Wearing shoes in endemic areas helps reduce the prevalence of infection.

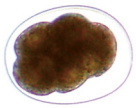

Fig. 74.10 Human hookworm egg. Eggs are 60 to 75 μm long and 35 to 40 μm wide, are thin shelled, and enclose a developing larva.

ANCYLOSTOMA BRAZILIENSE

Physiology and Structure

A. braziliense, a species of hookworm, is naturally parasitic in the intestines of dogs and cats and accidentally infects humans. It produces a disease properly called **cutaneous larva migrans** that also is called **ground itch** and **creeping eruption.** The filariform larvae of this hookworm penetrate intact skin but can develop no further in humans. The larvae remain trapped in the skin of the wrong host for weeks or months, wandering through subcutaneous tissue and creating serpentine tunnels.

Epidemiology

Similar to the situation with *Ascaris* worms, the threat of infection with *A. braziliense* is greatest among children coming into contact with soil or sandboxes contaminated with animal feces containing hookworm eggs. Infections are prevalent throughout the year on beaches in subtropical and tropical regions; in the summer, infection is reported as far north as the Canadian-U.S. border.

Clinical Syndromes

The migrating larvae may provoke a severe erythematous and vesicular reaction. Pruritus and scratching of the irritated skin may lead to secondary bacterial infection. About half of patients develop transient pulmonary infiltrates with peripheral eosinophilia **(Löffler syndrome),** presumably resulting from pulmonary migration of the larvae.

Laboratory Diagnosis

Occasionally, larvae are recovered in skin biopsy or after freezing of the skin, but most diagnoses are based on the clinical appearance of the tunnels and a history of contact with dog and cat feces. The larvae are rarely found in sputum.

Treatment, Prevention, and Control

The drug of choice is albendazole; ivermectin and thiabendazole are alternatives. Antihistamines may be helpful in controlling pruritus. This zoonosis, as with animal *Ascaris* infection, can be reduced by educating pet owners to treat their animals for worm infections and to pick up pet feces from yards, beaches, and sandboxes. In endemic areas, shoes or sandals should be worn to prevent infection.

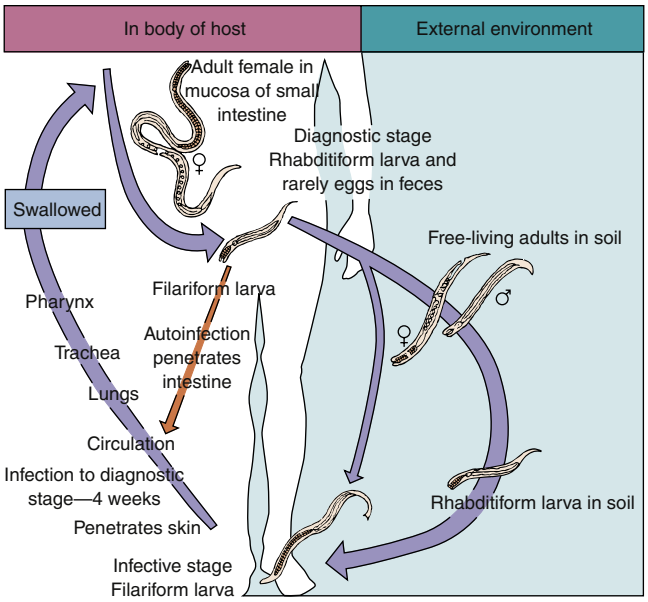

Fig. 74.11 Life cycle of *Strongyloides stercoralis*.

Strongyloides stercoralis

PHYSIOLOGY AND STRUCTURE

Although the morphology of these worms and the epidemiology of their infections are similar to the hookworm, the life cycle of *S. stercoralis* (Fig. 74.11) differs in three aspects: (1) eggs hatch into larvae in the intestine and before they are passed in feces; (2) larvae can mature into filariforms in the intestine and cause autoinfection; and (3) a free-living, nonparasitic cycle can be established outside the human host.

In direct development, such as the hookworm, a skin-penetrating *S. stercoralis* larva enters the circulation and follows the pulmonary course. It is coughed up and swallowed, and adults develop in the small intestine. Adult females burrow into the mucosa of the duodenum and reproduce parthenogenetically. Each female produces about a dozen eggs each day, which hatch within the mucosa and release **rhabditiform** larvae into the lumen of the bowel. The rhabditiform larvae are distinguished from the larvae of hookworms by their short buccal capsule and large genital primordium. The rhabditiform larvae are passed in the stool and may either continue the direct cycle by developing into infective **filariform** larvae or develop into free-living adult worms and initiate the indirect cycle.

In indirect development, the larvae in soil develop into free-living adults that produce eggs and larvae. Several generations of this nonparasitic existence may occur before new larvae become skin-penetrating parasites.

Finally, in **autoinfection,** rhabditiform larvae in the intestine do not pass with feces but become filariform larvae. These penetrate the intestinal mucosa or perianal skin and follow the course through the circulation and pulmonary structures, are coughed up, and then are swallowed; at this point, they become adults, producing more larvae in the intestine. This cycle can persist for years and can lead to **hyperinfection** and massive or disseminated, often fatal infection.

EPIDEMIOLOGY

Similar to hookworms in its requirements for warm temperatures and moisture, *S. stercoralis* demonstrates low prevalence but a somewhat broader geographic distribution, including parts of the northern United States and Canada. Sexual transmission also occurs. Animal reservoirs, such as domestic pets, are recognized.

CLINICAL SYNDROMES

Individuals with **strongyloidiasis** frequently are afflicted with pneumonitis from migrating larvae similar to that seen in ascariasis and hookworm infection. The intestinal infection is usually asymptomatic. However, heavy worm loads may involve the biliary and pancreatic ducts, the entire small bowel, and the colon, causing inflammation and ulceration leading to epigastric pain and tenderness, vomiting, diarrhea (occasionally bloody), and malabsorption. Symptoms mimicking peptic ulcer disease, coupled with peripheral eosinophilia, should strongly suggest the diagnosis of strongyloidiasis.

Autoinfection may lead to chronic strongyloidiasis that can last for years, even in nonendemic areas. Although many of these chronic infections may be asymptomatic, as many as two-thirds of patients have recurring episodic symptoms referable to the involved skin, lungs, and intestinal tract. Individuals with chronic strongyloidiasis are at risk of developing severe, life-threatening hyperinfection syndrome if the host-parasite balance is disturbed by any drug or illness that compromises the host's immune status (Clinical Case 74.3). **Hyperinfection syndrome** is seen most commonly in individuals immunocompromised by malignancies (especially hematologic malignancies), corticosteroid therapy, or both. Hyperinfection syndrome also has been observed in patients who have undergone solid organ transplantation and in malnourished people. Loss of cellular immune function may be associated with the conversion of rhabditiform larvae to filariform larvae, followed by dissemination of the larvae via the circulation to virtually any organ. Most commonly, extraintestinal infection involves the lung and includes bronchospasm, diffuse infiltrates, and occasionally cavitation. Widespread dissemination that involves the abdominal lymph nodes, liver, spleen, kidneys, pancreas, thyroid, heart, brain, and meninges is common. Intestinal symptoms of hyperinfection syndrome include profound diarrhea, malabsorption, and electrolyte abnormalities. Of note, hyperinfection syndrome is associated with a mortality rate of approximately 86%. Bacterial sepsis, meningitis, peritonitis, and endocarditis secondary to larval spread from the intestine are frequent and often fatal complications of hyperinfection syndrome.

LABORATORY DIAGNOSIS

The diagnosis of strongyloidiasis may be difficult because of the intermittent passage of low numbers of first-stage larvae in stool. Examination of concentrated stool sediment reveals the larval worms (Fig. 74.12), but in contrast with hookworm infections, in *S. stercoralis* infections, eggs are generally not seen. Collecting samples from three stools, one per day for 3 days (as for *G. duodenalis*), is recommended because *S.*

Clinical Case 74.3 **Strongyloides Hyperinfection**

Gorman and colleagues (*Infect Med* 23:480, 2006) described a case of necrotizing myositis complicated by diffuse alveolar hemorrhage and sepsis after corticosteroid therapy. The patient was a 46-year-old Cambodian man with a history of Raynaud phenomenon. He presented to the rheumatology clinic with worsening symptoms of Raynaud syndrome and diffuse muscle aches. He was employed as a truck driver and had emigrated from Cambodia 30 years earlier. Pertinent laboratory studies included markedly elevated creatine kinase and aldolase levels. Pulmonary function studies showed decreased forced vital capacity, forced expiratory volume, and carbon monoxide diffusing capacity. A high-resolution CT scan of the chest showed mild ground-glass changes in both lung bases and interlobular septate thickening. Muscle biopsy showed myocyte necrosis and random atrophy but no inflammatory cells. Bronchoscopy was unremarkable, and all cultures were negative. The patient was started on prednisone for presumed necrotizing myopathy secondary to undifferentiated connective tissue disease.

He was admitted to the hospital 1 month later with profound muscle weakness and dyspnea, which improved with the administration of methylprednisolone and intravenous immunoglobulin. Three weeks later, the patient was readmitted with fever, nausea, vomiting, abdominal pain, and diffuse joint pain. A CT scan of the abdomen suggested small bowel intussusception and colitis, but his symptoms improved without treatment. Another high-resolution CT scan of the chest showed early honeycombing and worsening interstitial infiltrates. The patient was scheduled for a lung biopsy; however, while awaiting the biopsy, he suffered an abrupt and fulminant deterioration, with hemoptysis and hypoxemic respiratory failure that required intubation and mechanical ventilation. A chest radiograph showed new, diffuse, bilateral infiltrates. The patient developed an acute abdomen accompanied by purpura on the lower trunk. An abdominal CT showed pancolitis. Refractory septic shock caused by *Escherichia coli* bacteremia and lactic acidosis ensued. Bronchoscopy showed diffuse alveolar hemorrhage, and numerous larvae of *Strongyloides stercoralis* were demonstrated on staining of an aspirate of endotracheal secretions. Serology was positive for anti-*Strongyloides* antibodies. Despite treatment with ivermectin, albendazole, cefepime, vancomycin, vasopressors, steroids, and dialysis, the patient died.

This case of *Strongyloides* hyperinfection syndrome emphasizes the importance of screening and treating persons at risk for latent *S. stercoralis* infection (endemic in tropical and subtropical areas) before the initiation of immunosuppressive therapy. Contact precautions should be taken in patients with hyperinfection syndrome because of the risk of infection to health care workers and visitors on exposure to infectious larvae in the patient's stool and secretions.

CT, Computed tomography.

stercoralis larvae may occur in "showers," with many present one day and few or none the next. Several authors favor the **Baermann funnel gauze method** of concentrating living *S. stercoralis* larvae from fecal specimens. This method uses a funnel with a stopcock and a gauze insert. The funnel is filled with lukewarm water to a level just covering the gauze, and a specimen of stool is placed on the gauze, partially in contact with the water. The larvae in the stool migrate through the gauze into the water and then sediment into the neck of the funnel, in which they may be detected by low-power microscopy. When absent from stool, larvae may be detected in duodenal aspirates or in sputum in the case of massive infection. Finally, culture of the larvae from stool using charcoal cultures or an agar plate method may be used, although these are not routine in most laboratories. Demonstration of anti-*Strongyloides* antibodies in blood may be useful as a screening test or as an adjunct for diagnosis. Diagnosis by nucleic acid amplification tests (NAATs) has been developed for testing stool and urine and is now available in many reference laboratories.

Fig. 74.12 *Strongyloides stercoralis* larvae. The larvae are 180 to 380 μm long and 14 to 24 μm wide. They are differentiated from hookworm larvae by the length of the buccal cavity and esophagus and by the structure of the genital primordium.

TREATMENT, PREVENTION, AND CONTROL

All infected patients should be treated to prevent autoinfection and potential dissemination (hyperinfection) of the parasite. The drug of choice is ivermectin, with albendazole or mebendazole as an alternative. *Strongyloides* serology and at least three stool examinations to rule out *S. stercoralis* infection should be performed for all patients in endemic areas (and other at-risk patients) who are preparing to undergo immunosuppressive therapy (e.g., before organ transplant or treatment for malignancies) to avoid the risks of hyperinfection syndrome. Strict infection-control measures should be enforced when clinicians care for patients with hyperinfection syndrome because stool, saliva, vomitus, and body fluids may contain infectious filariform larvae. As with hookworm, control of *Strongyloides* species requires education, proper sanitation, and prompt treatment of existing infections.

Trichinella spiralis

PHYSIOLOGY AND STRUCTURE

T. spiralis is the most important cause of human disease, but other species, such as *T. pseudospiralis* and *T. britovi,* may

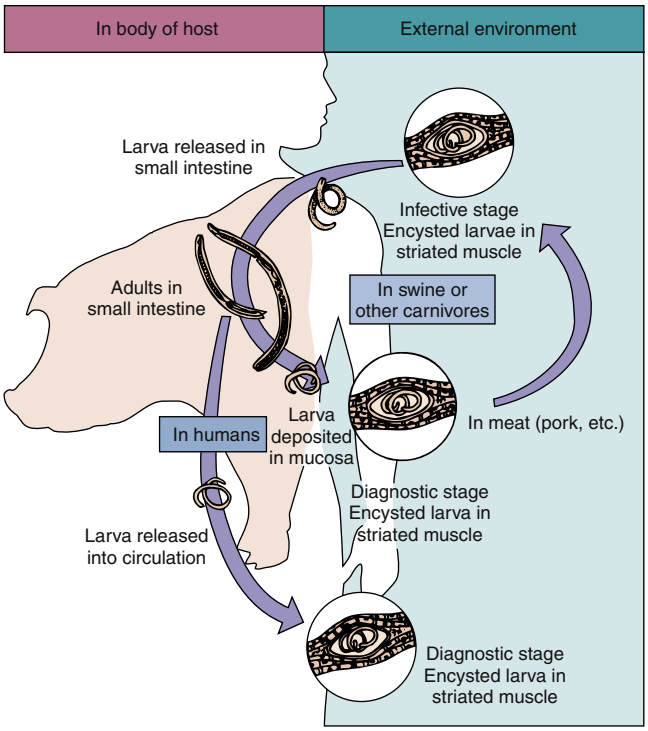

Fig. 74.13 Life cycle of *Trichinella spiralis.*

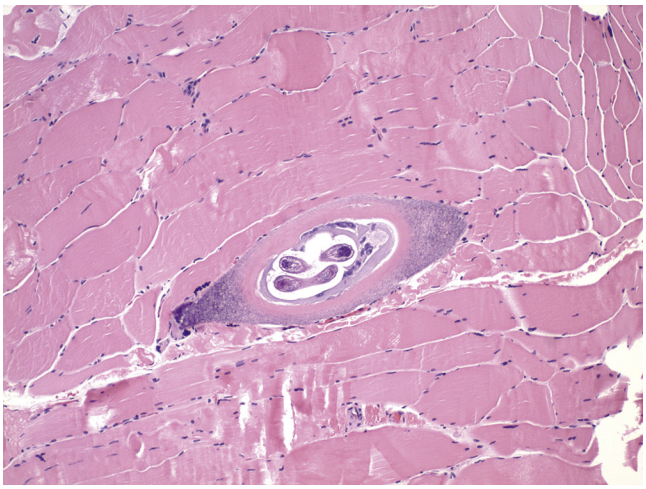

Fig. 74.14 Encysted larva of *Trichinella spiralis* in a muscle biopsy specimen. (From CDC Public Health Image Library.)

also cause **trichinosis.** The adult form of this organism lives in the duodenal and jejunal mucosa of flesh-eating mammals worldwide. The infectious larval form is present in the striated muscles of carnivorous and omnivorous mammals. Among domestic animals, swine are most frequently involved. Fig. 74.13 illustrates the simple, direct life cycle, which terminates in the musculature of humans, in which the larvae eventually die and calcify.

The infection begins when meat that contains encysted larvae is digested. The larvae leave the meat in the small intestine and within 2 days develop into adult worms. A single fertilized female produces more than 1500 larvae in 1 to 3 months. These larvae move from the intestinal mucosa into the bloodstream and are carried in the circulation to various muscle sites throughout the body, in which they coil in striated muscle fibers and become encysted (Fig. 74.14). The muscles invaded most frequently include the extraocular muscles of the eye; the tongue; the deltoid, pectoral, and intercostal muscles; the diaphragm; and the gastrocnemius muscle. The encysted larvae remain viable for many years and are infectious if ingested by a new animal host. The muscle larvae of *T. pseudospiralis* do not induce the formation of a cyst and generate less inflammation than that of *T. spiralis*.

EPIDEMIOLOGY

Trichinosis occurs worldwide in humans, and its greatest prevalence is associated with the consumption of pork products. In addition to its transmission from pigs, many carnivorous and omnivorous animals harbor the organism and are potential sources of human infection. Of note, polar bears and walruses in the Arctic account for outbreaks in human populations, especially with a strain of *T. spiralis (T. nativa)* that is more resistant to freezing than the *T. spiralis* strains found in the continental United States and other temperate regions. It is estimated that more than 1.5 million Americans carry live *Trichinella* cysts in their musculature and that 150,000 to 300,000 acquire new infection annually.

CLINICAL SYNDROMES

Trichinosis is one of the few tissue parasitic diseases still seen in the United States. As with other parasitic infections, most patients have minimal or no symptoms. The clinical presentation depends largely on the tissue burden of organisms and the location of the migrating larvae. Patients in whom no more than 10 larvae are deposited per gram of tissue are usually asymptomatic, those with at least 100 generally have significant disease, and those with 1000 to 5000 have a very serious course that occasionally ends in death. In mild infections with few migrating larvae, patients may experience only an influenza-like syndrome with slight fever and mild diarrhea. With more extensive larval migration, persistent fever, gastrointestinal distress, marked eosinophilia, muscle pain, and periorbital edema occur. "Splinter" hemorrhages beneath the nails, a common finding, are probably caused by vasculitis resulting from toxic secretions of the migrating larvae. In heavy infections, severe neurologic symptoms, including psychosis, meningoencephalitis, and cerebrovascular accident, may occur.

Patients who survive the migration, muscle destruction, and encystment of larvae in moderate infections experience a decline in clinical symptoms in 5 or 6 weeks. Lethal trichinosis results when myocarditis, encephalitis, and pneumonitis combine; the patient dies 4 to 6 weeks after infection. Respiratory arrest often follows heavy invasion and muscle destruction in the diaphragm.

LABORATORY DIAGNOSIS

The diagnosis is usually established with clinical observations, especially when an outbreak can be traced to consumption of improperly cooked pork or bear meat. The laboratory may confirm the diagnosis if the encysted larvae

are detected in the implicated meat or in a muscle biopsy specimen from the patient. Marked **eosinophilia** is characteristically present in patients with trichinosis. Serologic procedures also are available for confirmation of the diagnosis. Significant antibody titers are usually absent before the third week of illness but then may persist for years.

TREATMENT, PREVENTION, AND CONTROL

Treatment of trichinosis is primarily symptomatic because there are no good antiparasitic agents for tissue larvae. Treatment of the adult worms in the intestine with mebendazole may halt the production of new larvae. Steroids, along with thiabendazole or mebendazole, are recommended for severe symptoms. In infections caused by *T. pseudospiralis*, albendazole may be effective. Education regarding disease transmission from pork and bear meat is essential, especially the recommendation that pork and bear meat be cooked until the interior is gray. Microwave cooking and smoking or drying meat do not kill all larvae.

Laws regulating the feeding of garbage to pigs help control transmission, as may regulations controlling the foraging of bears in garbage pits and public parks. Freezing pork, as conducted in federally inspected meat packing plants, has reduced transmission. Quick freezing of pork at −40° C effectively destroys the organisms, as does low-temperature storage at −15° C for 20 days or more.

Wuchereria bancrofti and *Brugia malayi*

PHYSIOLOGY AND STRUCTURE

Because of their many similarities, *W. bancrofti* and *B. malayi* are discussed together. Human infection is initiated by the introduction of infective larvae, present in the saliva of a biting mosquito, into a bite wound (Fig. 74.15). Various species of *Anopheles*, *Aedes*, and *Culex* mosquitoes are vectors of **Bancroft and Malayan filariasis.** The larvae migrate from the location of the bite to the lymphatic system, primarily in the arms, legs, or groin, in which larval growth to adulthood occurs. From 3 to 12 months after the initial infection, the adult male worm fertilizes the female, which in turn produces the sheathed larval microfilariae that find their way into the circulation. The presence of **microfilariae** in blood is diagnostic for human disease and is infective for feeding mosquitoes. In the mosquito, the larvae move through the stomach and thoracic muscles in developmental stages and finally migrate to the proboscis. There they become infective third-stage larvae and are transmitted by the feeding mosquito. The adult form in humans can persist for as long as 10 years. These organisms harbor **bacterial endosymbionts** of the genus *Wolbachia* and depend on these endosymbionts for normal metabolic and reproductive activities.

EPIDEMIOLOGY

Infection with *W. bancrofti* occurs in tropical and subtropical areas and is endemic in central Africa, along the Mediterranean coast, and in many parts of Asia, including

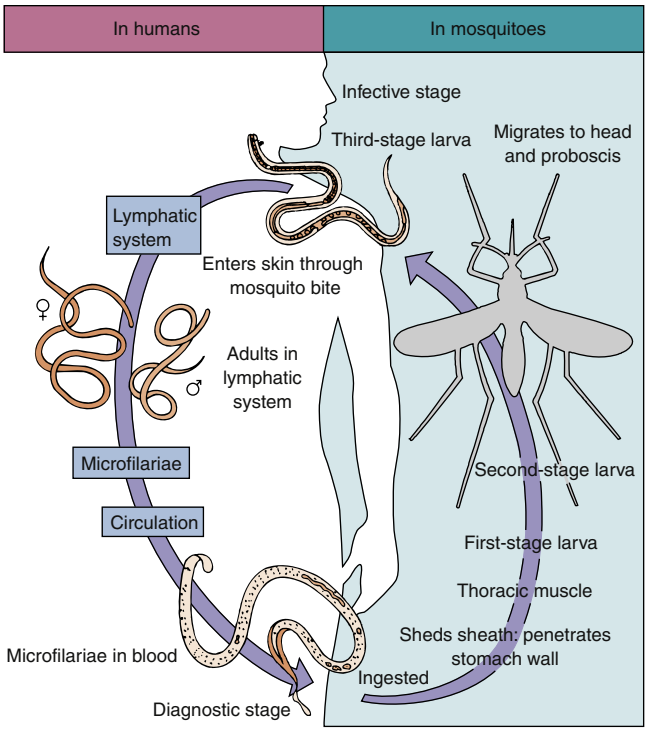

Fig. 74.15 Life cycle of *Wuchereria bancrofti.*

China, Korea, Japan, and the Philippines. It is also present in Haiti, Trinidad, Suriname, Panama, Costa Rica, and Brazil. No animal reservoir has been identified. *B. malayi* is found primarily in Malaysia, India, Thailand, Vietnam, and parts of China, Korea, Japan, and many Pacific islands. Animal reservoirs, such as cats and monkeys, are recognized.

CLINICAL SYNDROMES

In some patients, there is no sign of disease, even though blood specimens may show the presence of many microfilariae. In other patients, early acute symptoms are fever, lymphangitis and lymphadenitis with chills, and recurrent febrile attacks. The acute presentation is thought to result from the inflammatory response to the presence of molting adolescent worms and dead or dying adults within the lymphatic vessels. As the infection progresses, the lymph nodes enlarge, possibly involving many parts of the body, including the extremities, the scrotum, and the testes, with occasional abscess formation. This results from the physical obstruction of lymph in the vessels caused by the presence of adult worms and host reactivity in the lymphatic system. This process may be complicated by recurrent bacterial infections, which contribute to the tissue damage. The thickening and hypertrophy of tissues infected with the worms may lead to the enlargement of tissues, especially the extremities, progressing to filarial **elephantiasis.** Filariasis of this type is thus a chronic, debilitating, and disfiguring disease requiring prompt diagnosis and treatment. Occasionally, ascites and pleural effusions secondary to rupture of the enlarged lymphatic vessels into the peritoneal or pleural cavity may be observed.

Tropical pulmonary eosinophilia (TPE) is a syndrome caused by immune hyperresponsiveness to microfilariae trapped in the lungs. This syndrome affects males more often

than females, most commonly young adults, especially in the third decade of life. The main features include a history of residence in filaria-endemic regions, paroxysmal cough and wheezing that are usually nocturnal, weight loss, low-grade fever, and adenopathy and pronounced blood eosinophilia (≥3000 eosinophils/μl). Patients are rarely found to have microfilariae in the blood. Chest radiographs may be normal in 20% to 30% of cases, but generally show increased bronchoalveolar markings, diffuse interstitial lesions, and/or mottled opacities prominently in the lower lung fields. Although there is no single clinical or laboratory criterion that aids in distinguishing TPE from other pulmonary diseases, residence in the tropics, the presence of high levels of antifilarial antibodies, and a rapid clinical response to DEC favor the diagnosis of tropical eosinophilia.

LABORATORY DIAGNOSIS

Eosinophilia is usually present during acute inflammatory episodes; however, demonstration of microfilariae in the blood is required for definitive diagnosis. As with malaria, microfilariae can be demonstrated in Giemsa-stained blood films in infections with *W. bancrofti* and *B. malayi* (Figs. 74.16 and 74.17). *W. bancrofti* and *B. malayi* have both nocturnal and subperiodic periodicity in the production of microfilariae. Nocturnal periodicity results in greater numbers of microfilariae in blood at night, whereas with the subperiodic form, microfilariae are always present, with a peak in the afternoon. Buffy coat films concentrate the white blood cells and are useful for the detection of microfilariae. The presence of small numbers of microfilariae in blood can be detected by a membrane-filtration technique in which anticoagulated blood is mixed with saline and forced through a 5-μm membrane filter. After several washes with saline or distilled water, the filter is examined microscopically for living microfilariae, or it is dried, fixed, and stained as for a thin blood film.

W. bancrofti, as well as *B. malayi* and *Loa loa*, demonstrate a sheath on their microfilariae. The *B. malayi* sheath stains bright pink with Giemsa, whereas the *W. bancrofti* and *L. loa* sheaths tend not to stain. This feature can be the first step in identifying the specific types of filariasis. Further identification is based on study of head and tail structures (Fig. 74.18). Clinically, an exact species identification is not critical because treatment for all the filarial infections, except *Onchocerca volvulus*, is identical.

Serologic testing for antifilarial antibodies is also available through reference laboratories so that a diagnosis can be reached. Assays for circulating antigens of *W. bancrofti* permit the diagnosis of microfilaremic and cryptic (amicrofilaremic) infection. Tests for antigen detection are commercially available for use on whole blood, plasma, or serum (although not in the United States). These assays have sensitivities that range from 96% to100% and specificities that approach 98%. Circulating antigen may be detected in blood drawn any time of day or night, avoiding the need for specific bleeding times depending on the periodicity of microfilariae. None of the tests is approved by the U.S. Food and Drug Administration (FDA). There are currently no tests for circulating antigens in brugian filariasis. NAAT can detect parasite deoxyribonucleic acid (DNA) and is now the most sensitive technique for definitive diagnosis; however, there are no commercially available platforms.

TREATMENT, PREVENTION, AND CONTROL

Treatment is of little benefit in most cases of chronic lymphatic filariasis because of scarring and lymphedema. At present, treatment targets the microfilarial stage. The discovery of the **bacterial endosymbiont *Wolbachia*** raises the possibility of using antibiotics such as doxycycline to treat the adult worm. These *Wolbachia* are vital for parasite larval development and adult-worm fertility and viability. Use of antibiotics (e.g., the tetracyclines) that target the *Wolbachia* have been shown to reduce microfilarial levels and circulating filarial antigen. . The drug of choice for treatment of *W. bancrofti* and *B. malayi* microfilariae is DEC. Ivermectin and albendazole also may be used, often in combination with DEC. Supportive and surgical therapy for lymphatic obstruction may be of some cosmetic help. Education regarding filarial infections, mosquito control, use of protective clothing and insect repellents, and treatment of infections to prevent further transmission is essential. Control of *B. malayi* infections is more difficult because of the presence of disease in animal reservoirs.

Loa loa

PHYSIOLOGY AND STRUCTURE

The life cycle of *L. loa* is similar to that illustrated in Fig. 74.15, except the vector is a biting fly called *Chrysops* (the mango fly). Approximately 6 months after infection, the production of microfilariae starts and can persist for 17 years or more. The microfilariae are sheathed and, in contrast to the lymphatic filariae, the nuclei are somewhat irregularly arranged and extend to the end of the tail. The sheath does not stain with Giemsa. Adult worms can migrate through subcutaneous tissues, through muscle, and in front of the eyeball.

EPIDEMIOLOGY

L. loa is confined to the equatorial rain forests of Africa and is endemic in tropical West Africa, the Congo basin, and parts of Nigeria. Monkeys in these areas serve as reservoir hosts in the life cycle, with mango flies as vectors.

CLINICAL SYNDROMES

Symptoms usually do not appear until a year or so after the fly bite because the worms are slow in reaching adulthood. One of the first signs of infection is the so-called **fugitive** or **Calabar swellings.** These swellings are transient and usually appear on the extremities. They are produced as the worms migrate through subcutaneous tissues, creating large, nodular areas that are painful and pruritic. Because eosinophilia (50% to 70%) is observed, Calabar swellings are believed to result from allergic reactions to the worms or their metabolic products.

Adult *L. loa* worms also can migrate under the conjunctiva, producing irritation, painful congestion, edema of the eyelids, and impaired vision. The presence of a worm in the eye can obviously cause anxiety in the patient. The infection may be long-lived and in some cases asymptomatic.

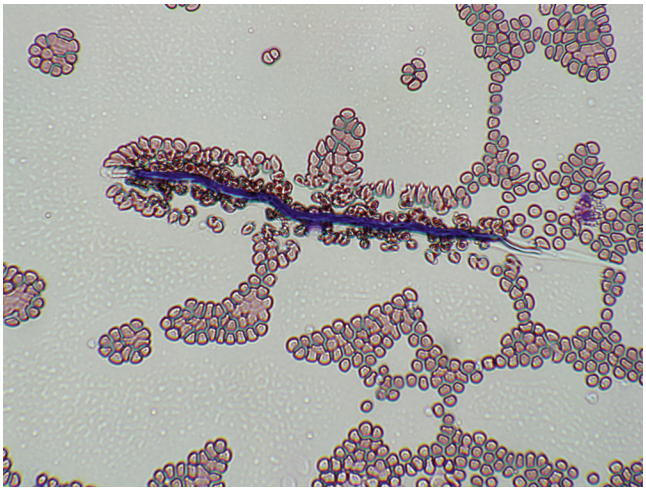

Fig. 74.19 Giemsa stain of sheathed *Loa loa* microfilaria in blood smear; 230 to 250 μm long × 6 to 9 μm wide.

LABORATORY DIAGNOSIS

The clinical observation of Calabar swellings or migration of adult worms in the eye, combined with eosinophilia, should alert the physician to consider infection with *L. loa*. The microfilariae can be found in the blood (Fig. 74.19). In contrast to the other filariae, *L. loa* is primarily present during the daytime. Antifilarial IgG and IgG4, although nonspecific, may be useful in confirming the diagnosis of loiasis in visitors to endemic areas with suggestive clinical symptoms or unexplained eosinophilia. NAAT-based assays for the detection and quantitation of *L. loa* DNA in blood are now available in research laboratories and are highly sensitive and specific.

TREATMENT, PREVENTION, AND CONTROL

DEC is effective against adults and microfilariae; however, destruction of the parasites may induce severe allergic reactions that require treatment with corticosteroids. Albendazole or ivermectin (not approved by the FDA) has been shown to be effective in reducing microfilarial loads. Surgical removal of worms migrating across the eye or bridge of the nose can be accomplished by immobilizing the worm with instillation of a few drops of 10% cocaine. Education regarding the infection and its vector, especially for people entering the known endemic areas, is essential. Protection from fly bites by using screening, appropriate clothing, and insect repellents, along with the treatment of cases, is critical in reducing the incidence of infection. However, the presence of disease in animal reservoirs (e.g., monkeys) limits the feasibility of controlling this disease.

Mansonella Species

Filarial infections caused by *Mansonella* species (*M. ozzardi, M. perstans,* and *M. streptocerca*) are less important than those previously discussed, but physicians should be aware of the names because they may encounter patients with these infections. Infections caused by these organisms are

generally asymptomatic but may cause dermatitis, lymphadenitis, hydrocele, and rarely, lymphatic obstruction resulting in elephantiasis.

All *Mansonella* species produce nonsheathed microfilariae in blood *(M. ozzardi, M. perstans)* and subcutaneous tissues *(M. streptocerca)*, and all are transmitted by biting midges (*Culicoides* species) or blackflies (*Simulium* species). Ivermectin is the treatment of choice for *M. ozzardi* and *M. streptocerca*, whereas DEC is used for *M. perstans*. Consistent with the identification of a *Wolbachia* species in *M. perstans,* a randomized trial in Mali has demonstrated the utility of doxycycline treatment for this infection. Species identification, if desired, can be accomplished with blood smears, noting the structure of the microfilariae (see Fig. 74.18). Serologic and NAAT tests are also available.

Prevention and control require measures involving insect repellents, screening, and other precautions as for all insect-transmitted diseases.

MANSONELLA PERSTANS

M. perstans occurs primarily in parts of tropical Africa and Central and South America. It may produce allergic skin reactions, edema, and Calabar swellings similar to those of *L. loa* infection. Reservoir hosts are chimpanzees and gorillas.

MANSONELLA OZZARDI

M. ozzardi is found primarily in Central and South America and the West Indies. It may produce swelling of the lymph nodes and occasional hydrocele. There are no known reservoir hosts.

MANSONELLA STREPTOCERCA

M. streptocerca occurs primarily in Africa, especially in the Congo basin. It may produce edema in the skin and rarely, a form of elephantiasis. Monkeys serve as reservoir hosts.

Onchocerca volvulus

PHYSIOLOGY AND STRUCTURE

Infection occurs after the introduction of *O. volvulus* larvae through the skin during the biting and feeding of the *Simulium,* or blackfly vector (Fig. 74.20). The larval worms migrate from the skin to subcutaneous tissue and develop into adult male and female worms. The adults become encased in fibrous subcutaneous nodules within which they may remain viable for as long as 15 years. The female worm, after fertilization by the male, begins producing as many as 2000 nonsheathed microfilariae each day. The microfilariae exit the capsule and migrate to the skin, the eyes, and other body tissues. These nonsheathed microfilariae appearing in skin tissue are infective for feeding blackflies. Of note, all individual worms and all life cycle stages contain the ***Wolbachia* bacterial endosymbionts.** It is now understood that clearance of the endosymbionts by antibiotic treatment causes inhibition of worm development, blocks embryogenesis and fertility, and reduces worm viability. It is suggested that various biochemical pathways that are intact in *Wolbachia* but absent or incomplete in the nematode, including heme, nucleotide, and enzyme cofactor biosynthesis, may be the bacteria's contribution to nematode biology.

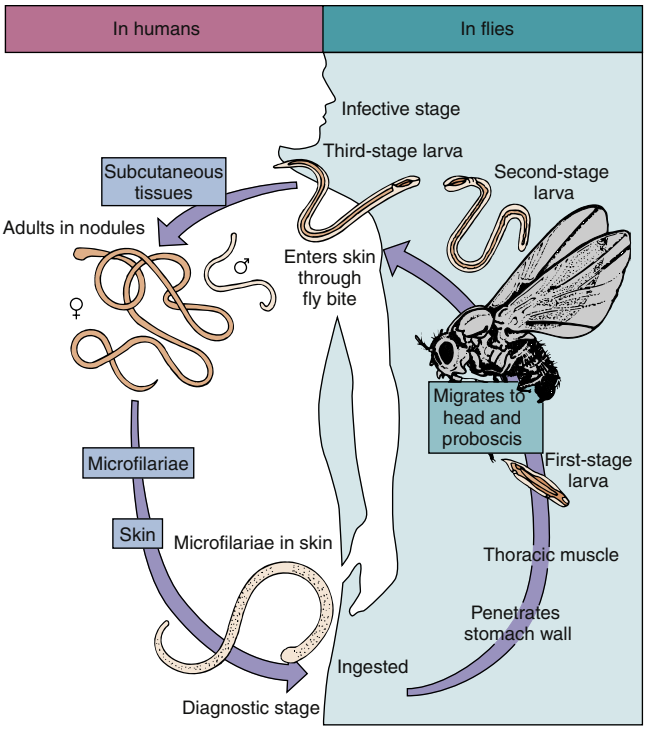

Fig. 74.20 Life cycle of *Onchocerca volvulus.*

EPIDEMIOLOGY

O. volvulus is endemic in many parts of Africa, especially in the Congo basin and the Volta River basin. In the Western Hemisphere, it occurs in many Central and South American countries. **Onchocerciasis** affects >18 million people worldwide and causes blindness in approximately 5% of infected people.

Several species of the blackfly genus *Simulium* serve as vectors but none so appropriately named as the principal vector, *Simulium damnosum* ("the damned blackfly"). These blackflies, or buffalo gnats, breed in fast-flowing streams, which makes control or eradication by insecticides almost impossible because the chemicals are rapidly washed away from the eggs and larvae.

There is a greater prevalence of infection in men than women in endemic areas because of their work in or near the streams in which the blackflies breed. Studies in endemic areas in Africa have shown that 50% of men are totally blind before they reach 50 years of age. This accounts for the common term **river blindness,** which is applied to the disease onchocerciasis. This fear of blindness has created an additional problem in many parts of Africa because entire villages leave the area near streams and farmland that could produce food. The migrating populations then find themselves in areas in which they face starvation.

Clinical Case 74.4 **Onchocerciasis**

Imtiaz and colleagues (*Infect Med* 22:187–189, 2005) described the case of a 21-year-old man who emigrated from the Sudan to the United States 1 year before presenting with a maculopapular rash that was associated with severe pruritus. The rash and pruritus had been present for the past 3 to 4 years. In the past, the patient had undergone multiple treatments for this condition, including corticosteroids, without relief. The patient denied any systemic symptoms but did complain of blurred vision. On physical examination, his skin was somewhat thickened over different parts of the body, and he had scattered maculopapular lesions with increased pigmentation; some lesions had keloid nodules, as well as wrinkling. There was no lymphadenopathy. The remainder of his evaluation was unremarkable.

Because of the presence of intense pruritus unresponsive to treatment, blurred vision, and the prevalence of onchocerciasis in his native country, skin snips were taken from the scapular area. Microfilariae of *Onchocerca volvulus* were revealed on microscopic examination. Ivermectin was prescribed, to which the patient's condition responded. Onchocerciasis, although not common in the United States, should be considered in immigrants and expatriates with suggestive symptoms if they came from areas in which the disease is endemic.

CLINICAL SYNDROMES

Clinical onchocerciasis is characterized by infection involving the skin, subcutaneous tissue, lymph nodes, and eyes (Clinical Case 74.4). The clinical manifestations of the infection are caused by the acute and chronic inflammatory reaction to antigens released by the microfilariae as they migrate through the tissues. The incubation period from infectious larvae to adult worms is several months to a year. The initial signs of disease are fever, eosinophilia, and urticaria. As the worms mature, copulate, and produce microfilariae, subcutaneous nodules begin to appear on any part of the body. These nodules are most dangerous when they are present on the head and neck because the microfilariae may migrate to the eyes and cause serious tissue damage, leading to blindness. The mechanisms for development of eye disease are thought to be a combination of both direct invasion by the microfilaria and antigen-antibody complex deposition within the ocular tissues. It is now apparent that the *Wolbachia* bacterial endosymbiont plays an important role in the inflammatory pathogenesis of onchocerciasis. *Wolbachia* release after microfilarial death in the cornea causes corneal edema and opacity by inducing neutrophil and macrophage infiltration and activation in the corneal stroma. Patients progress from conjunctivitis with photophobia to punctate and sclerosing keratitis. Internal eye disease with anterior uveitis, chorioretinitis, and optic neuritis may also occur.

Within the skin, the inflammatory process results in loss of elasticity and areas of depigmentation, thickening, and atrophy. A number of skin conditions, including pruritus, hyperkeratosis, and myxedematous thickening, are related to the presence of this parasite. A form of elephantiasis, called **hanging groin,** also occurs when the nodules are located near the genitalia.

Fig. 74.21 Giemsa stained unsheathed *Onchocerca volvulus* microfilaria; 300 to 315 μm long × 5 to 9 μm wide.

LABORATORY DIAGNOSIS

The diagnosis of onchocerciasis is made by the demonstration of microfilariae in skin snip preparations from the infrascapular or gluteal region. A sample is obtained by raising the skin with a needle and shaving the epidermal layer with a razor. The specimen is incubated in saline for several hours and is then inspected with a dissecting microscope for the presence of nonsheathed microfilariae (Fig. 74.21). In patients with ocular disease, the organism also may be seen in the anterior chamber with the aid of a slit lamp. Serologic methods using recombinant antigens have been useful along with assays using polymerase chain reaction to detect onchocercal DNA in skin snip specimens.

TREATMENT, PREVENTION, AND CONTROL

Surgical removal of the encapsulated nodule is often performed to eliminate the adult worms and stop production of microfilariae (Fig. 74.22). In addition, treatment with ivermectin is recommended. A single oral dose of ivermectin greatly reduces the number of microfilariae in the skin and eyes, diminishing the likelihood of developing a disabling onchocerciasis. In endemic areas, the dose of ivermectin can be repeated every 6 to 12 months to maintain suppression of dermal and ocular microfilariae. Suppression of dermal microfilariae reduces the transmission of this vector-borne disease; thus mass chemotherapy may prove to be a successful strategy for the prevention of onchocerciasis. At present, there is no firm evidence that *O. volvulus* is becoming resistant to ivermectin; however, whenever a single agent is used for disease control, with varying doses over a long period of time, it is prudent to be on guard for the possibility of resistance developing. Human field trials with antiwolbachial drugs, such as doxycycline, have demonstrated both sterilizing and macrofilaricidal activity. Based on these trials, doxycycline at 200 mg/day for 6 weeks is recommended for patients in whom the highest possible macrofilaricidal activity is desired and who have moved away from areas with ongoing transmission.

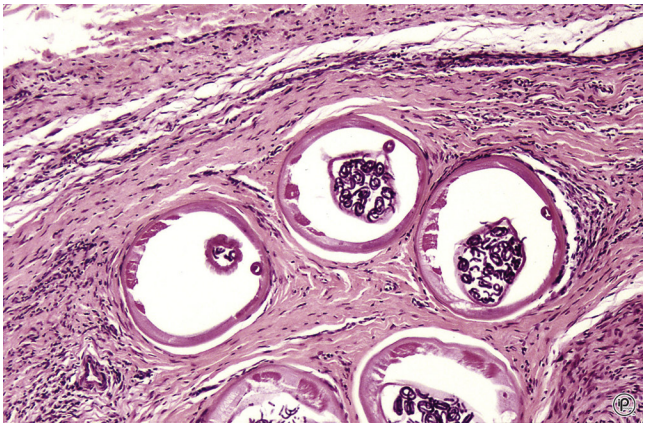

Fig. 74.22 Cross-section of an adult female *Onchocerca volvulus* in an excised nodule showing numerous microfilariae.

Education regarding the disease and its transmission is essential. Protection from blackfly bites through the use of protective clothing, screening, and insect repellents, as well as prompt diagnosis and treatment of infections to prevent further transmission, are critical.

Although control of blackfly breeding is difficult because insecticides wash away in the streams, some form of biologic control of this vector may reduce fly reproduction and disease transmission.

Dirofilaria immitis

Several mosquito-transmitted filariae infect dogs, cats, raccoons, and bobcats in nature and occasionally are found in humans. *D. immitis*, the **dog heartworm,** is notorious for forming a lethal worm bolus in the dog's heart. This nematode also may infect humans, producing a nodule, called a **coin lesion,** in the lung. Only very rarely have these worms been found in human hearts.

The coin lesion in the lung presents a problem for the radiologist and the surgeon because it resembles a malignancy requiring surgical removal. Unfortunately, no laboratory test can provide an accurate diagnosis of **dirofilariasis.** Peripheral eosinophilia is rare, and the radiographic features are insufficient to allow the clinician to distinguish pulmonary dirofilariasis from bronchogenic carcinoma. Serologic tests are not sufficiently sensitive or specific to preclude the surgical intervention. A definitive diagnosis is made when a thoracotomy specimen is examined microscopically, revealing the typical cross-sections of the parasite.

Transmission of the filarial infections can be controlled by mosquito control and the prophylactic use of the drug ivermectin in dogs.

Dracunculus medinensis

The name *Dracunculus medinensis* means "little dragon of Medina." This is a very ancient worm infection thought by some scholars to be the "fiery serpent" noted by Moses with the Israelites at the Red Sea.

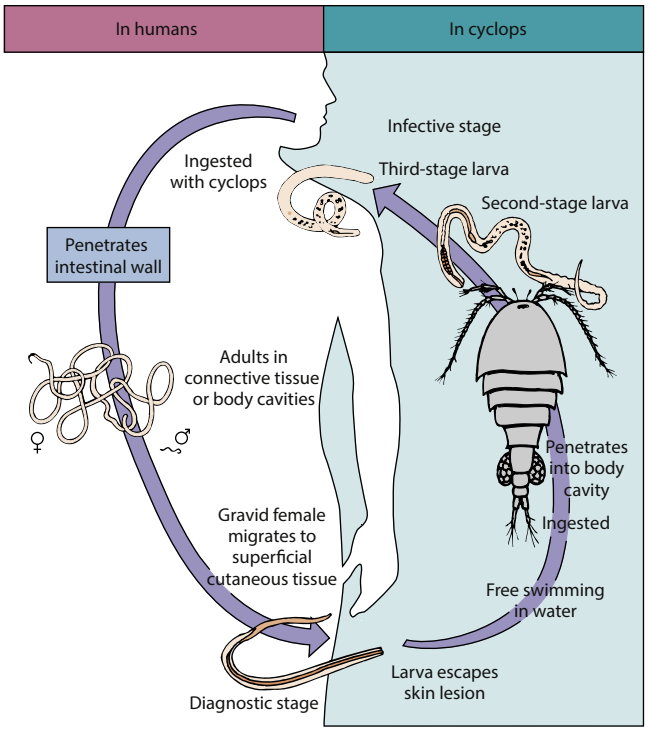

Fig. 74.23 Life cycle of *Dracunculus medinensis.*

PHYSIOLOGY AND STRUCTURE

D. medinensis is not a filarial worm, but it is a tissue-invading nematode of medical importance in many parts of the world. The worms have a very simple life cycle, depending on fresh water and a microcrustacean **(copepod)** of the genus *Cyclops* (Fig. 74.23). When *Cyclops* species harboring larval *D. medinensis* are ingested in drinking water, the infection is initiated with liberation of the larvae in the stomach. These larvae penetrate the wall of the digestive tract and migrate to the retroperitoneal space, in which they mature. These larvae are not microfilariae and do not appear in the blood or other tissues. Male and female worms mate in the retroperitoneum, and the fertilized female then migrates to the subcutaneous tissues, usually in the extremities. When the fertilized female worm becomes gravid, a vesicle is formed in the host tissue, which will ulcerate. When the ulcer is completely formed, the worm protrudes a loop of uterus through the ulcer. On contact with water, the larval worms are released. The larvae are then ingested by the *Cyclops* species in fresh water, in which they are then infective for humans or animals drinking the water containing the *Cyclops* species.

EPIDEMIOLOGY

D. medinensis occurs in many parts of Asia and equatorial Africa. Dracunculiasis is a crippling parasitic disease on the verge of eradication, with only 19 human cases reported in 2019. The disease is usually transmitted when people who have little or no access to improved drinking water sources swallow stagnant water contaminated with parasite-infected water fleas *(Cyclops)* that carry infective larvae.

An ongoing and intensive effort by the World Health Organization, local governments, and numerous other humanitarian organizations has significantly decreased the annual incidence of disease by more than 99% in recent years. Of the 20 countries that were endemic for the disease in the mid-1980s, only 2 reported cases in 2019: Chad (18 cases) and Angola (1 case).. Political unrest and war have hampered eradication efforts. Additionally, the recognition of canine infections and, more recently, transmission through the ingestion of meat from paratenic hosts (i.e., fish and frog) have significantly complicated eradication efforts.

Human infections usually result from ingestion of water from so-called **"step wells"** in which people stand or bathe in the water, at which time the gravid female worm discharges larvae from lesions on the arms, legs, feet, and ankles to infect *Cyclops* species in the water. Ponds and standing water are occasionally the source of infection when humans use them for drinking water.

CLINICAL SYNDROMES

Symptoms of infection usually do not appear until the gravid female creates the vesicle and the ulcer in the skin for the liberation of larval worms. This usually occurs 1 year after initial exposure. At the site of the ulcer, there are erythema and pain, as well as an allergic reaction to the worm. There is also the possibility of abscess formation and secondary bacterial infection, leading to further tissue destruction and inflammatory reaction with intense pain and sloughing of skin.

If the worm is broken in attempts to remove it, there may be toxic reactions, and if the worm dies and calcifies, there may be nodule formation and some allergic reaction. Once the gravid female worm has discharged all the larvae, it may retreat into deeper tissue, in which it is gradually absorbed, or it may simply be expelled from the site.

LABORATORY DIAGNOSIS

Diagnosis is established by observing the typical ulcer and by flooding the ulcer with water to recover the larval worms when they are discharged. Occasionally, radiographic examination reveals worms in various parts of the body.

TREATMENT, PREVENTION, AND CONTROL

The ancient method of slowly wrapping the worm on a twig is still used in many endemic areas (Fig. 74.24). Surgical removal is also a practical and reliable procedure for the patient. There is no evidence that any chemotherapeutic agent has a direct effect on *D. medinensis*, although various benzimidazoles may have an antiinflammatory effect and either eliminate the worm or make surgical removal easier. Treatment with mebendazole has been associated with aberrant migration of the worms, with the result that they were more likely to emerge at anatomic sites other than the lower limbs.

Education regarding the life cycle of the worm and avoidance of water contaminated with *Cyclops* species are critical. Protection of drinking water by prohibiting bathing and washing of clothing in wells is essential. Persons who live in or travel to endemic areas should boil water before drinking it. The treatment of water with chemicals and the use of fish that consume *Cyclops* species as food also help control transmission. Prompt diagnosis and treatment of cases also limit further transmission. These preventive measures have been incorporated into an ongoing global effort to eliminate dracunculiasis with dramatic success.

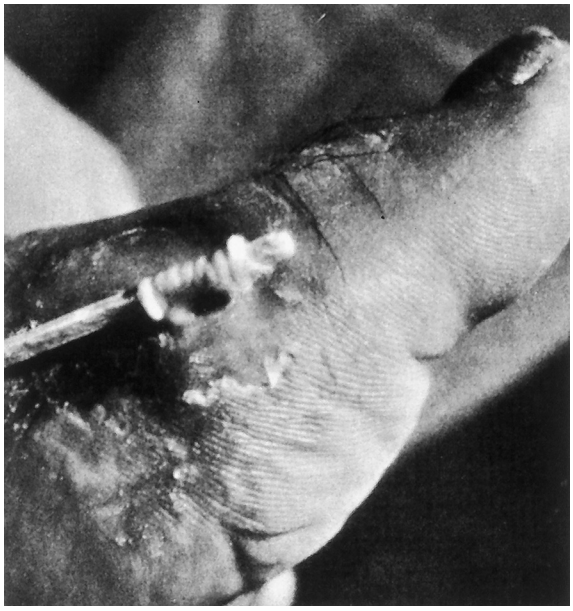

Fig. 74.24 Removal of a *Dracunculus medinensis* adult from an exposed ulcer by winding the worm slowly around a stick. (From Binford, C.H., Conner, D.H., 1976. Pathology of Tropical and Extraordinary Diseases. Armed Forces Institute of Pathology, Washington, DC.)

Case Study and Questions

A 50-year-old male trophy hunter recently returned from an expedition to the North Pole with complaints of facial swelling and myalgias in his arms, chest, and thighs. During his expedition, he killed a polar bear and, as part of the "ritual," ate a piece of raw heart muscle from the bear.

1. What is the likely cause of his symptoms?
   a. *Ascaris lumbricoides*
   b. *Strongyloides stercoralis*
   c. *Ancylostoma duodenale*
   d. *Trichinella spiralis*
2. How would you make the diagnosis?
3. How would you treat this patient?

75 Trematodes

A 45-year-old Egyptian man was referred for evaluation of hematuria and urinary frequency of 2 months' duration. This individual had lived in the Middle East for most of his life, but for the past year he has lived in the United States. He denied previous renal or urologic problems. His physical examination was unremarkable. A midstream urine specimen was grossly bloody.

1. What was the differential diagnosis of hematuria in this patient?
2. What was the etiologic agent of this patient's urologic process?
3. What exposures might put an individual at risk for this infection?
4. What are the major complications of this infection?
5. How is this disease treated?

Answers to these questions are available on www.StudentConsult.com.

Summaries Clinically Significant Organisms

FASCIOLOPSIS BUSKI

Trigger Words

Aquatic vegetation, intermediate host, snail, intestinal fluke, operculum, cercariae, metacercariae, reservoir hosts

Biology, Virulence, and Disease

- Trematodes (flukes): members of Platyhelminthes; generally flat, fleshy, leaf-shaped worms
- *F. buski:* largest, most prevalent, most important intestinal fluke; from 1.5 to 3.0 cm long (rarely found in feces or specimens collected during surgery)
- Life cycle typical for intestinal flukes
- Symptomatology of *F. buski* infection relates directly to worm burden in small intestine; includes mucosal inflammation, ulceration and hemorrhage, abdominal discomfort and diarrhea, intestinal obstruction, eosinophilia

Epidemiology

- Distribution depends on location of appropriate snail host; most prevalent in Southeast Asia and Indian subcontinent
- Pigs, dogs, and rabbits serve as reservoir hosts in endemic regions

Diagnosis

- Microscopic examination of stool reveals large, golden, bile-stained eggs with an operculum on top
- Adult worms can rarely be found in feces or specimens collected at surgery

Treatment, Prevention, and Control

- Drug of choice: praziquantel; alternative is niclosamide
- Education regarding safe consumption of infective aquatic vegetation, proper sanitation, and control of human feces reduces incidence of disease
- Snail population may be eliminated with molluscicides
- Control of reservoir hosts reduces worm transmission

SCHISTOSOMES AND SCHISTOSOMIASIS

Trigger Words

Snails, bladder cancer, cirrhosis, clay pipestem fibrosis, Katayama syndrome, swimmer's itch

Biology, Virulence, and Disease

- Schistosomiasis (bilharziasis, snail fever): major parasitic infection of tropical areas, ≈230 million infections worldwide
- Three schistosomes (blood flukes) account for majority of human disease: *Schistosoma mansoni, S. haematobium,* and *S. japonicum*
- Schistosomes differ from other flukes: male and female sexes (not hermaphroditic), oral and ventral suckers, incomplete digestive system
- Infective forms are skin-penetrating cercariae liberated from snails
- Disease results primarily from host immune response to eggs; clinical significance directly related to number and location of eggs
- Clinical manifestations of chronic infection: hepatosplenomegaly and cirrhosis, esophageal varices, bladder neck obstruction, squamous cell bladder carcinoma, transverse myelitis, and other forms of central nervous system involvement

Epidemiology

- *S. mansoni:* most widely distributed; endemic in Africa, Saudi Arabia, Madagascar; has also become established in Western Hemisphere
- *S. japonicum* (Oriental blood fluke): found only in China, Japan, the Philippines, and on the island of Sulawesi in Indonesia
- *S. haematobium:* occurs predominantly throughout the Nile Valley and many other parts of Africa
- Infection first acquired in early childhood; prevalence and intensity of infection peak at age 15 to 20 years; intensity declines with age
- Reservoir hosts include domestic animals, primates, rodents, marsupials
- Disease of economic progress: development of land irrigation projects in desert and tropical areas has resulted in dispersion of infected humans and snails to previously uninvolved areas

Diagnosis

- Demonstration of eggs in patient's stool or urine on microscopic examination
- Morphology of eggs specific for each species: *S. mansoni,* prominent lateral spine; *S. japonicum,* less prominent spine; *S. haematobium,* terminal spine
- Serologic tests have been developed to detect the presence of specific antischistosomal antibodies; positive serology does not distinguish between current and past infection
- Ultrasound imaging useful in determining extent of disease

Treatment, Prevention, and Control

- Treatment of choice: praziquantel
- Improved sanitation, control of human fecal deposits, control of reservoir hosts is critical

The trematodes **(flukes)** are members of the Platyhelminthes and are generally flat, fleshy, leaf-shaped worms (Fig. 75.1). In general, they are equipped with two muscular suckers: an oral type, which is the beginning of an incomplete digestive system, and a ventral sucker, which is simply an organ of attachment. The digestive system consists of lateral tubes that do not join to form an excretory opening. Most flukes are **hermaphroditic,** with both male and female reproductive organs in a single body. Schistosomes are the only exception; they have cylindric bodies (similar to the nematodes), and separate male and female worms exist.

All flukes require intermediate hosts for the completion of their life cycles, and without exception, the first intermediate hosts are mollusks (snails and clams). In these hosts, an asexual reproductive cycle is a type of germ cell propagation. Some flukes require various second intermediate hosts before reaching the final host and developing into adult worms. This variation is discussed in the sections on the individual species.

Fluke eggs are equipped with a "lid" at the top of the shell. Called an **operculum,** the lid opens to allow the larval worm to find its appropriate snail host. The schistosomes do not have an operculum; rather, the eggshell splits to liberate the larva. The medically significant trematodes are summarized in Table 75.1.

Fasciolopsis buski

A number of intestinal flukes are recognized, including *Fasciolopsis buski* (see Fig. 75.1), *Heterophyes heterophyes, Metagonimus yokogawai, Echinostoma ilocanum,* and *Gastrodiscoides hominis*. *F. buski* is the largest, most prevalent, and most important intestinal fluke. The other flukes are similar to *F. buski* in many respects (epidemiology, clinical syndromes, treatment) and are not discussed further. It is important only that physicians recognize the relationship among these different flukes.

Fig. 75.1 Adult *Fasciolopsis buski* (natural size). (From Peters, W., Pasvol, G., 2007. Atlas of Tropical Medicine and Parasitology, sixth ed. Elsevier, Philadelphia, PA.)

PHYSIOLOGY AND STRUCTURE

This large intestinal fluke has a typical life cycle (Fig. 75.2). Humans ingest the encysted larval stage **(metacercaria)** when they peel the husks from aquatic vegetation (e.g., water chestnuts) with their teeth. The metacercariae are scraped from the husk, swallowed, and develop into immature flukes in the duodenum. The fluke attaches to the mucosa of the small intestine with two muscular suckers, develops into an adult form, and undergoes self-fertilization. Egg production is initiated 3 months after the initial infection with the metacercariae. The operculated eggs pass in feces to water, in which the operculum at the top of the eggshell pops open, liberating a free-swimming larval stage **(miracidium).** Glands at the pointed anterior end of the miracidium produce lytic substances that allow the penetration of the soft tissues of snails. In the snail tissue, the miracidium develops through a series of stages by asexual germ cell propagation. The final stage **(cercaria)** in the snail is a free-swimming form that, after release from the snail, encysts on the aquatic vegetation, becoming the metacercariae, or infective stage.

EPIDEMIOLOGY

Because it depends on the distribution of its appropriate snail host, *F. buski* is found only in China, Vietnam, Thailand, parts of Indonesia, Malaysia, and India. Pigs, dogs, and rabbits serve as reservoir hosts in these endemic areas.

CLINICAL SYNDROMES

The symptomatology of *F. buski* infection relates directly to the worm burden in the small intestine. Attachment of the flukes in the small intestine can produce inflammation, ulceration, and hemorrhage. Severe infections produce abdominal discomfort similar to that of a duodenal ulcer, as well as diarrhea. Stools may be profuse, a malabsorption syndrome similar to giardiasis is common, and intestinal obstruction can occur. Marked eosinophilia is also present. Although death can occur, it is rare.

TABLE 75.1 Medically Important Trematodes

Trematode	Common Name	Intermediate Host	Biologic Vector	Reservoir Host
Fasciolopsis buski	Giant intestinal fluke	Snail	Water plants (e.g., water chestnuts)	Pigs, dogs, rabbits, humans
Fasciola hepatica	Sheep liver fluke	Snail	Water plants (e.g., watercress)	Sheep, cattle, humans
Clonorchis (Opisthorchis) sinensis	Chinese liver fluke	Snail, freshwater fish	Uncooked fish	Dogs, cats, humans
Paragonimus westermani	Lung fluke	Snail, freshwater crabs, crayfish	Uncooked crabs, crayfish	Pigs, monkeys, humans
Schistosoma species	Blood fluke	Snail	None	Primates, rodents, domestic pets, livestock, humans

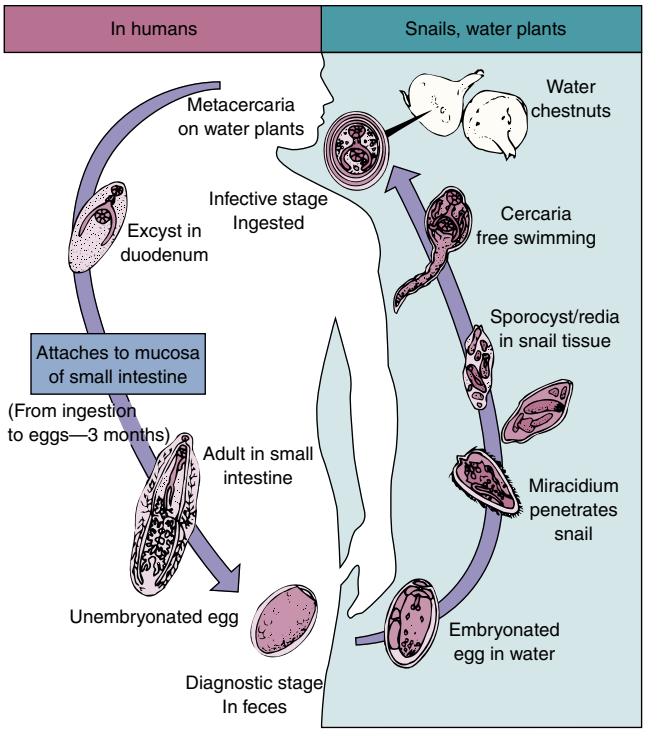

Fig. 75.2 Life cycle of *Fasciolopsis buski* (giant intestinal fluke).

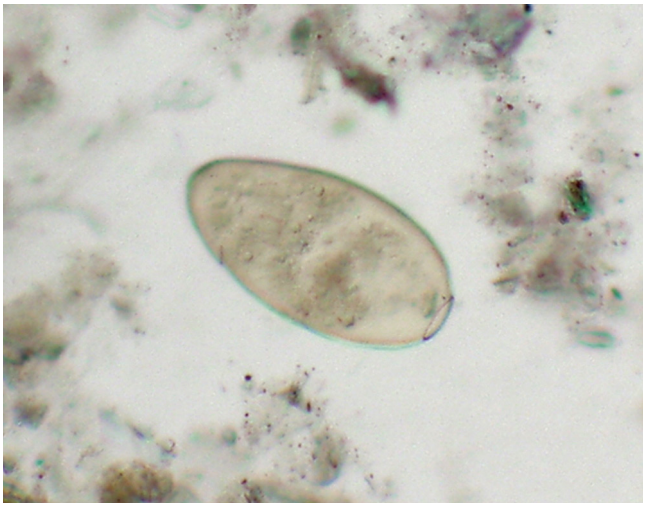

Fig. 75.3 *Fasciolopsis buski* egg, 130 to 150 µm long and 65 to 90 µm wide, with a thin operculum at one end.

LABORATORY DIAGNOSIS

Stool examination reveals the large, golden, bile-stained eggs with an operculum on the top (Fig. 75.3). The measurements and appearance of *F. buski* eggs are similar to those of the liver fluke *Fasciola hepatica*, and differentiation of the eggs of these species usually is not possible. Large (approximately 1.5 to 3.0 cm) adult flukes (see Fig. 75.1) can rarely be found in feces or specimens collected at surgery. Attempts have been made toward development of a molecular diagnostic tool for discrimination of *F. buski* from other fasciolids using ribosomal sequences.

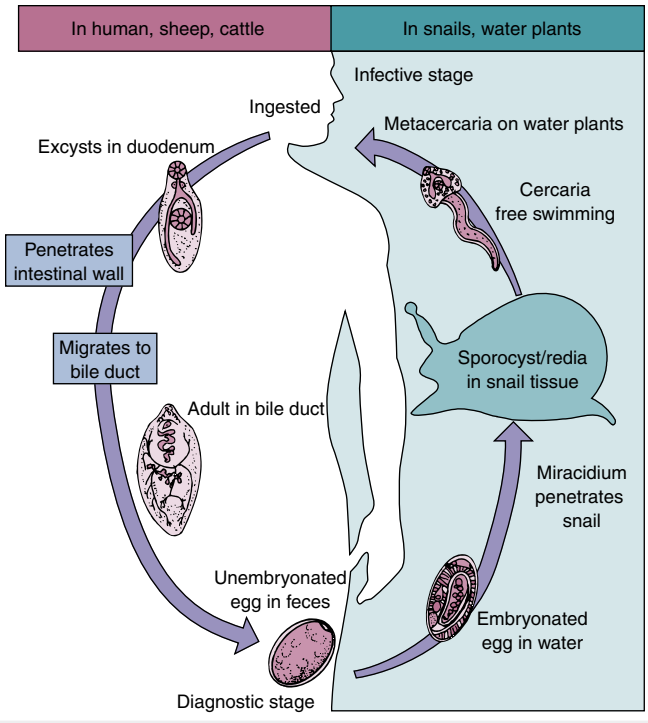

Fig. 75.4 Life cycle of *Fasciola hepatica* (sheep liver fluke).

TREATMENT, PREVENTION, AND CONTROL

The drug of choice is praziquantel, and the alternative is mebendazole. Education regarding the safe consumption of infective aquatic vegetation (particularly water chestnuts), proper sanitation, and control of human feces reduces the incidence of disease. In addition, the snail population may be eliminated with molluscicides. When infection occurs, treatment should be initiated promptly to minimize its spread. Control of the reservoir hosts also reduces transmission of the worm.

Fasciola hepatica

A number of liver flukes are recognized, including *Fasciola hepatica, Clonorchis sinensis*, *Opisthorchis felineus*, and *Dicrocoelium dendriticum*. Only *F. hepatica* and *C. sinensis* are discussed in this chapter, although the eggs of other flukes are occasionally detected in the feces of patients in other geographic areas.

PHYSIOLOGY AND STRUCTURE

Commonly called the **sheep liver fluke**, *F. hepatica* is a parasite of herbivores (particularly sheep and cattle) and humans. Its life cycle (Fig. 75.4) is similar to that of *F. buski*, with human infection resulting from the ingestion of watercress that harbors the encysted metacercariae. The larval flukes then migrate through the duodenal wall and across the peritoneal cavity, penetrate the liver capsule, pass through the liver parenchyma, and enter the bile ducts to become adult worms. Approximately 3 to 4 months after the initial infection, the adult flukes start producing operculated eggs that are identical to those of *F. buski*, as seen in stool examination.

Clinical Case 75.1 **Fascioliasis**

Echenique-Elizondo and colleagues (*JOP* 6:36–39, 2005) described a case of acute pancreatitis caused by the liver fluke *Fasciola hepatica*. The patient was a 31-year-old female who was admitted to the hospital because of a sudden onset of nausea and upper abdominal pain. She was otherwise healthy and gave a negative history of drug abuse, alcohol ingestion, gallstone disease, abdominal trauma, or surgery. On physical examination, she was markedly tender in the epigastric region and had hypoactive bowel sounds. Serum chemistries showed elevated pancreatic enzymes (amylase, lipase, pancreatic phospholipase A2, and elastase). Her white blood count was elevated, as were tests for alkaline phosphatase and bilirubin. Serum blood urea nitrogen, creatinine, lactate dehydrogenase, and calcium were normal. Abdominal ultrasonography and computed tomographic scan showed diffuse enlargement of the pancreas, and a cholangiogram demonstrated dilation and numerous filling defects in the common bile duct. An endoscopic sphincterotomy was performed, with extraction of numerous large flukes that were identified as *F. hepatica*. The patient was treated with a single oral dose of triclabendazole (10 mg/kg). Follow-up demonstrated normal blood chemistries and no evidence of disease 2 years postprocedure.

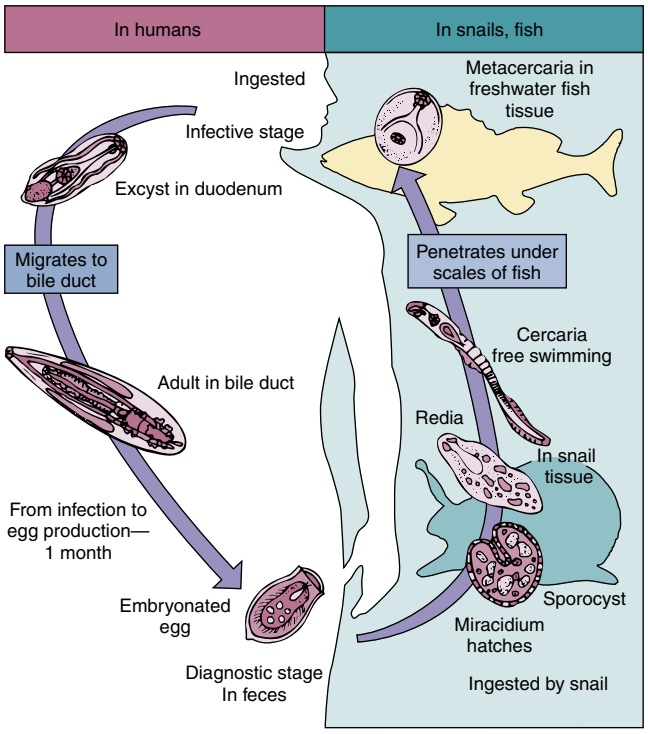

Fig. 75.5 Life cycle of *Clonorchis sinensis* (Chinese liver fluke).

EPIDEMIOLOGY

Infections have been reported worldwide in sheep-raising areas, with the appropriate snail as an intermediate host. These areas include Australia, China, Egypt, Bolivia, Peru, and many other Latin American countries. Outbreaks are directly related to human consumption of contaminated watercress in areas in which infected herbivores are present. Human infection is rare in the United States, but several well-documented cases have been reported in travelers from endemic areas.

CLINICAL SYNDROMES

Migration of the larval worm through the liver produces irritation of this tissue, tenderness, and hepatomegaly (Clinical Case 75.1). Pain in the right upper quadrant, chills, fever, and marked eosinophilia are commonly observed. As the worms take up residence in the bile ducts, their mechanical irritation and toxic secretions produce hepatitis, hyperplasia of the epithelium, and biliary obstruction. Some worms penetrate eroded areas in the ducts and invade the liver to produce necrotic foci referred to as **liver rot.** In severe infections, secondary bacterial infection can occur, and portal cirrhosis is common.

LABORATORY DIAGNOSIS

Stool examination reveals operculated eggs indistinguishable from the eggs of *F. buski* (see Fig. 75.3). Exact identification is a therapeutic problem because treatment is not the same for both infections. Whereas *F. buski* responds favorably to praziquantel, *F. hepatica* does not. When exact identification is desired, examination of a sample of the patient's bile differentiates the species; if the eggs are present in bile, they are *F. hepatica*, not *F. buski*, which is limited to the small intestine. Eggs may appear in stool samples from people who have eaten infected sheep or cattle liver. The spurious nature of this finding can be confirmed by having the patient refrain from eating liver and then rechecking the stool. Because of the very long prepatent period, fascioliasis is one disease in which serologic diagnosis is valuable. Immunologic tests, particularly enzyme-linked immunosorbent assay (ELISA), based on parasite excretory/secretory antigens, cysteine protease or saposin-like antigens, display high sensitivity and specificity. Detection of parasite antigen in stools is useful to distinguish between present and past infections. Molecular diagnosis, notably tests based on loop-mediated amplification (LAMP), for detection of parasite nucleic acid in feces, are promising alternatives.

TREATMENT, PREVENTION, AND CONTROL

In contrast to *F. buski*, *F. hepatica* responds poorly to praziquantel. Treatment with the benzimidazole compound triclabendazole has been effective. Preventive measures are similar to those for *F. buski* control; people who live in areas frequented by sheep and cattle should especially avoid ingestion of watercress and other uncooked aquatic vegetation.

Clonorchis sinensis

PHYSIOLOGY AND STRUCTURE

C. sinensis, also referred to as *Opisthorchis sinensis*, in the older literature, is commonly called the **Chinese liver fluke.** Fig. 75.5 illustrates its life cycle, which involves two intermediate hosts. This trematode differs from other fluke cycles in that the eggs are eaten by the snail, and then reproduction begins in the soft tissues of the snail. *C. sinensis* also requires a second intermediate host, such as a freshwater

Clinical Case 75.2 **Cholangitis Caused by Clonorchis (Opisthorchis) sinensis**

Stunell and colleagues (*Eur Radiol* 16:2612–2614, 2006) described a 34-year-old Asian woman who presented to a local emergency department with a 2-day history of right upper quadrant abdominal pain, fever, and rigors. She had emigrated from Asia to Ireland 18 months earlier and gave a history of intermittent upper abdominal pain occurring over a 3-year period. On examination, she appeared acutely ill and was clammy to the touch. She was febrile, tachycardic, and had mild scleral icterus. Her abdomen was tender, with guarding in the right upper quadrant. Routine hematologic and biochemical studies revealed a marked leukocytosis and obstructive liver function tests. Contrast-enhanced computed tomography of the abdomen demonstrated evidence of multiple ovoid opacities within dilatated intrahepatic bile ducts in the right lobe of the liver. The remainder of the liver parenchyma appeared normal. On stabilization of the patient, an ERCP was performed for biliary decompression. ERCP demonstrated intrahepatic and extrahepatic bile duct dilation, with multiple filling defects and strictures. A stool sample sent for analysis confirmed the presence of ova and adult flukes of *Clonorchis (Opisthorchis) sinensis*. The patient recovered with medical management (praziquantel) and had negative stool samples 30 days after treatment. This case and Clinical Case 75.1 demonstrate the various complications of liver fluke infestation. Of note, praziquantel is the drug of choice for treating the Oriental liver fluke *(C. sinensis)*, whereas triclabendazole is used to treat fascioliasis, emphasizing the importance of an epidemiologic history and identification of the fluke.

ERCP, Endoscopic retrograde cholangiopancreatography.

fish, in which the cercariae encyst and develop into infective metacercariae. When uncooked freshwater fish harboring metacercariae are eaten, flukes develop first in the duodenum and then migrate to the bile ducts, in which they become adults. The adult fluke undergoes self-fertilization and begins producing eggs. *C. sinensis* may survive in the biliary tract for as long as 50 years, producing approximately 2000 eggs per day. These eggs pass with feces and are once again eaten by snails, reinitiating the cycle.

EPIDEMIOLOGY

C. sinensis is found in China, Japan, Korea, and Vietnam, in which it is estimated to infect approximately 15 million people. It is one of the most frequent infections seen among Asian refugees, and it can be traced to the consumption of raw, pickled, smoked, or dried freshwater fish that harbor the viable metacercariae. Dogs, cats, and fish-eating mammals can also serve as reservoir hosts.

CLINICAL SYNDROMES

Infection in humans is usually mild and asymptomatic (Clinical Case 75.2). Severe infections with many flukes in the bile ducts produces fever, diarrhea, epigastric pain, hepatomegaly, anorexia, and occasionally jaundice. Biliary

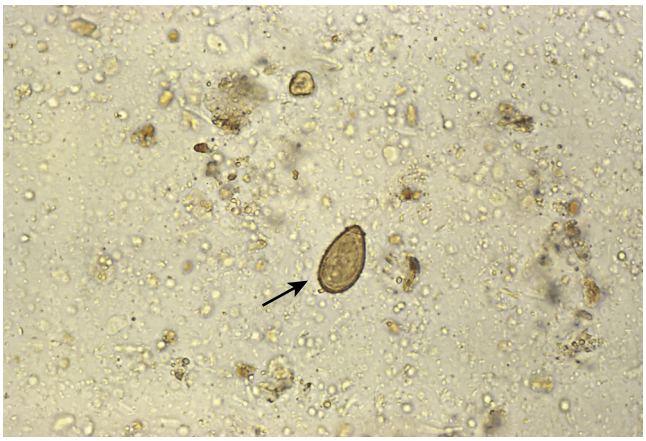

Fig. 75.6 *Clonorchis sinensis* egg *(arrow)*. These ovoid eggs are small (27 to 35 μm long and 12 to 19 μm wide) and have a yellowish brown, thick shell with a prominent operculum at one end and a small knob at the other. (From CDC Public Health Image Library.)

obstruction may occur, and chronic infection can result in adenocarcinoma of the bile ducts. Invasion of the gallbladder may produce cholecystitis, cholelithiasis, and impaired liver function, as well as liver abscesses.

LABORATORY DIAGNOSIS

The diagnosis is made by recovering the distinctive eggs from stool. The eggs measure 27 to 35 μm × 12 to 19 μm and are characterized by a distinct operculum with prominent shoulders and a tiny knob at the posterior **(abopercular)** pole (Fig. 75.6). In mild infections, repeated examinations of stool or duodenal aspirates may be necessary. In acute symptomatic infection, there are usually eosinophilia and an elevation of serum alkaline phosphatase levels. Radiographic imaging procedures may detect abnormalities of the biliary tract. A coproantigen ELISA has been developed and has displayed high specificity and sensitivity, whereas ELISA assays for circulating antibodies show high sensitivity but low specificity. Nucleic acid amplification test (NAAT) platforms have been developed that detect and discriminate between fish-borne zoonoses caused by opisthorchids and members of the related family Heterophyidae, based on mitochondrial and ribosomal sequences.

TREATMENT, PREVENTION, AND CONTROL

The drug of choice is praziquantel. Prevention of infection is accomplished by not eating uncooked fish and by implementing proper sanitation policies, including the disposal of human, dog, and cat feces in adequately protected sites so that they cannot contaminate water supplies with the intermediate snail and fish hosts.

Paragonimus westermani

PHYSIOLOGY AND STRUCTURE

P. westermani, commonly called the **lung fluke,** is one of several species of *Paragonimus* that infect humans and many other animals. Fig. 75.7 shows a familiar fluke life

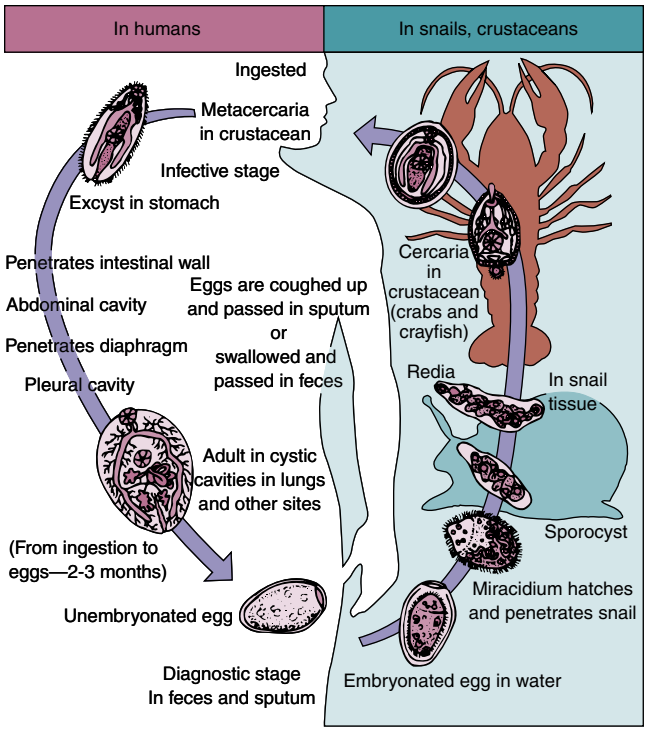

Fig. 75.7 Life cycle of *Paragonimus westermani* (Oriental lung fluke).

cycle from egg to snail to infective metacercaria. The infective stage occurs in a second intermediate host: the muscles and gills of freshwater crabs and crayfish. In humans who ingest infected meat, the larval worm hatches in the stomach and follows an extensive migration through the intestinal wall to the abdominal cavity, then through the diaphragm, and finally to the pleural cavity. Adult worms reside in the lungs and produce eggs that are liberated from ruptured bronchioles and appear in sputum or, when swallowed, in feces.

EPIDEMIOLOGY

Paragonimiasis occurs in many countries in Asia, Africa, and Latin America. It can be seen in refugees from Southeast Asia. Its prevalence is directly related to the consumption of uncooked freshwater crabs and crayfish. It is estimated that approximately 3 million people are infected with this lung fluke. As many as 1% of all Indochinese immigrants to the United States are infected with *P. westermani*. A wide variety of shore-feeding animals (e.g., wild boars, pigs, and monkeys) serve as reservoir hosts, and some human infections result from ingestion of meat containing migrating larval worms from these reservoir hosts. Human infections endemic to the United States are usually caused by a related species, *P. kellicotti*, which is found in crabs and crayfish in eastern and midwestern waters.

CLINICAL SYNDROMES

The clinical manifestations of paragonimiasis may result from larvae migrating through tissues or from adults established in the lungs or other ectopic sites (Clinical Case 75.3). The onset of disease coincides with larval migration and is associated with fever, chills, and high eosinophilia. The adult flukes in the lungs first produce an inflammatory reaction that results in fever, cough, and increased sputum. As the destruction of lung tissue progresses, cavitation occurs around the worms, sputum becomes blood tinged and dark with eggs (so-called rusty sputum), and patients experience severe chest pain. The resulting cavity may become secondarily infected with bacteria. Dyspnea, chronic bronchitis, bronchiectasis, and pleural effusion may be seen. Chronic infections lead to fibrosis in the lung tissue. The location of larvae, adults, and eggs in ectopic sites may produce severe clinical symptoms depending on the site involved. The migration of larval worms may result in invasion of the spinal cord and brain, producing severe neurologic disease (visual problems, motor weakness, and convulsive seizures) referred to as **cerebral paragonimiasis.** Migration and infection also may occur in subcutaneous sites, the abdominal cavity, and the liver.

Clinical Case 75.3 **Paragonimiasis**

Singh and colleagues (*Indian J Med Microbiol* 23:131–134, 2005) described a case of pleuropulmonary paragonimiasis mimicking pulmonary tuberculosis. The patient was a 21-year-old man who was admitted to the hospital for progressive dyspnea, with a 1-month history of headache, fever, cough with scant hemoptysis, fatigue, pleuritic pain, anorexia, and weight loss. He had a history of antituberculous therapy for 6 months without improvement clinically. Two months before admission, after ingesting three raw crabs, he had a 3-day episode of watery diarrhea. On hospital admission, the patient was cachectic and afebrile. There was bilateral dullness to percussion and absent breath sounds in the lower two-thirds of the chest. He was found to be anemic and had clubbing without lymphadenopathy, cyanosis, or jaundice. A chest radiograph showed bilateral pleural effusions that also were confirmed by computed tomography. Ultrasound-guided thoracentesis of the right lung yielded about 200 ml of yellowish fluid. The fluid was exudative and contained 2700 white blood cells/ml, 91% of which were eosinophils. Gram stain of the fluid was negative, as was culture for bacteria and fungi. Sputum smears revealed operculated yellowish eggs consistent with *Paragonimus westermani* infection. The patient was treated with a 3-day course of praziquantel and responded well. Of note, the right-sided pleural effusion did not recur after the thoracentesis and praziquantel treatment. This case emphasizes the importance of making an etiologic diagnosis of a pleuropulmonary process to differentiate paragonimiasis from tuberculosis in regions in which both are endemic infectious diseases.

LABORATORY DIAGNOSIS

Examination of sputum and feces reveals golden brown, operculated eggs (Fig. 75.8). Pleural effusions, when present, should be examined for eggs. Chest radiographs often show infiltrates, nodular cysts, and pleural effusion. Marked eosinophilia is common. Serologic procedures are available through reference laboratories and can be helpful, particularly in cases with extrapulmonary (e.g., central nervous system) involvement. A range of NAATs for diagnosis of *Paragonimus* species, including conventional polymerase chain reaction (PCR), real-time PCR, and LAMP, have been evaluated.

Fig. 75.8 *Paragonimus westermani* egg. These large, ovoid eggs (80 to 120 μm long and 45 to 70 μm wide) have a thick, yellowish brown shell and a distinct operculum. (From CDC Public Health Image Library.)

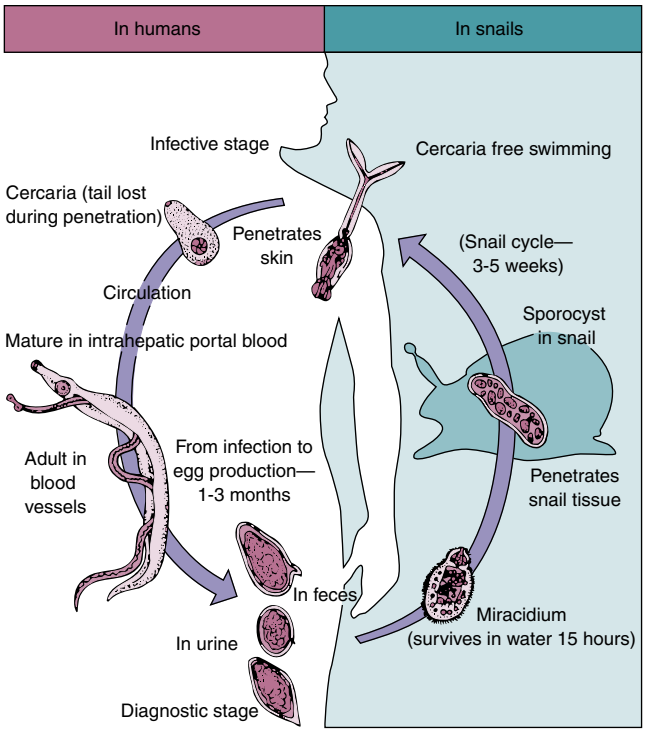

Fig. 75.9 Life cycle of schistosomes.

TREATMENT, PREVENTION, AND CONTROL

The drug of choice is praziquantel; triclabendazole is an alternative. Education regarding the consumption of uncooked freshwater crabs and crayfish, as well as the flesh of animals found in endemic areas, is critical. Pickling and wine soaking of crabs and crayfish do not kill the infective metacercarial stage. Proper sanitation and control of the disposal of human feces are essential.

Schistosomes

Schistosomiasis is a major parasitic infection of tropical areas, with some 230 million infections worldwide. The three schistosomes most frequently associated with human disease are *Schistosoma mansoni*, *S. japonicum*, and *S. haematobium*. They collectively produce the disease called **schistosomiasis,** also known as **bilharziasis** or **snail fever.** As discussed earlier, the schistosomes differ from other flukes: they are male and female rather than hermaphroditic, and their eggs do not have an operculum. They also are obligate intravascular parasites and are not found in cavities, ducts, and other tissues. The infective forms are skin-penetrating **cercariae** liberated from snails, and these differ from other flukes in that they are not eaten on vegetation, in fish, or in crustaceans.

Fig. 75.9 illustrates the life cycle of the different schistosomes. Infection is initiated by ciliated, free-swimming, freshwater cercariae that penetrate intact skin, enter the circulation, and develop in the intrahepatic portal circulation (*S. mansoni* and *S. japonicum*) or in the vesical, prostatic, rectal, and uterine plexuses and veins (*S. haematobium*). The female has a long, slender, cylindric body, whereas the shorter male, which appears cylindric, is actually flat (Fig. 75.10). The cylindric appearance derives from folding the sides of the body to produce a groove, the gynecophoral canal, in which the female resides for fertilization. Both sexes have oral and ventral suckers and an incomplete digestive system, which is typical of a fluke.

As the worms develop in the portal circulation, they elaborate a remarkable defense against host resistance. They coat themselves with substances that the host recognizes as itself; consequently, there is little host response directed against their presence in blood vessels. This protective mechanism accounts for chronic infections that may last 20 to 30 years or longer.

Fig. 75.10 Living male and female *Schistosoma mansoni*. The slender female *(right)* is normally seen within the gynecophoral groove of the male *(left)* (×14). (From Peters, W., Pasvol, G., 2007. Atlas of Tropical Medicine and Parasitology, sixth ed. Elsevier, Philadelphia, PA; courtesy Professor R.E. Howells.)

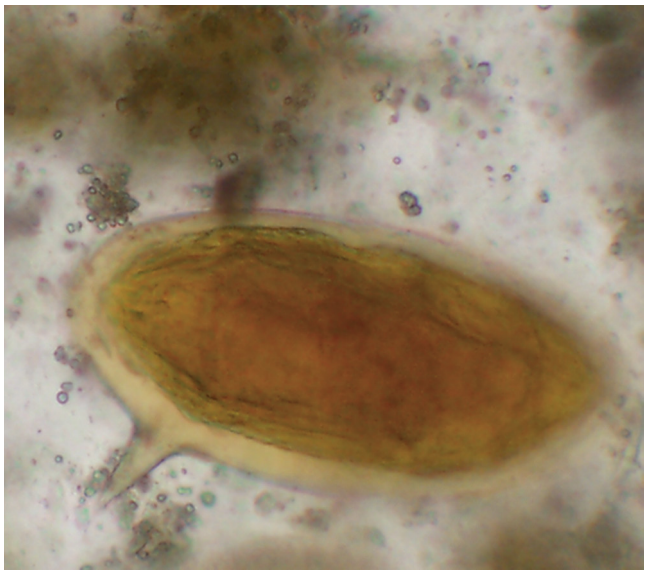

Fig. 75.11 *Schistosoma mansoni* egg. These eggs are 115 to 175 μm long and 45 to 70 μm wide, contain a miracidium, and are enclosed in a thin shell with a prominent lateral spine.

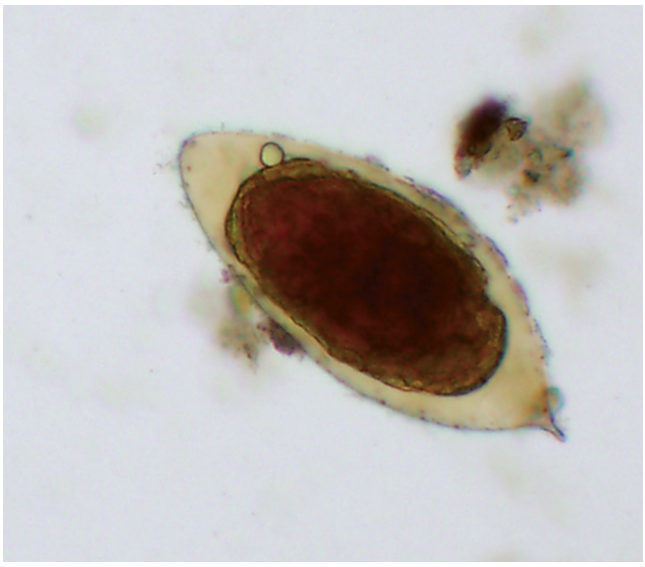

Fig. 75.13 *Schistosoma haematobium* egg. These eggs are similar in size to those of *Schistosoma mansoni* but can be differentiated by the presence of a terminal, rather than lateral, spine.

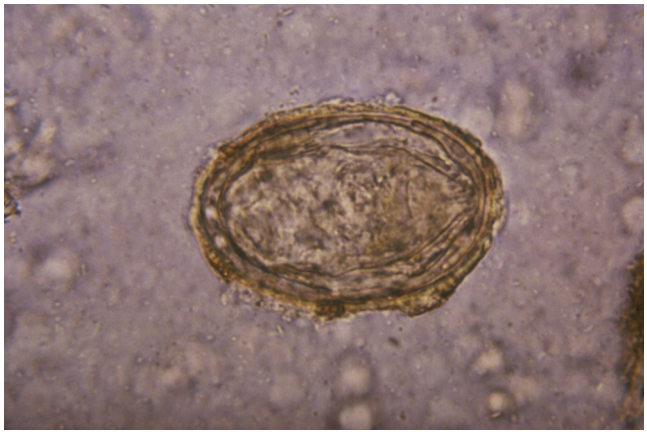

Fig. 75.12 *Schistosoma japonicum* egg. These eggs are smaller than those of *Schistosoma mansoni* (70 to 100 μm long and 55 to 65 μm wide) and have a spine that is inconspicuous. (From CDC Public Health Image Library.)

After developing in the portal vein, the male and female adult worms pair up and migrate to their final locations, where fertilization and egg production begin. *S. mansoni* and *S. japonicum* are found in mesenteric veins and produce intestinal schistosomiasis; *S. haematobium* occurs in veins around the urinary bladder and causes vesicular schistosomiasis. On reaching the submucosal venules of their respective locations, the worms initiate oviposition, which may continue at the rate of 300 to 3000 eggs daily for 4 to 35 years. Although the host inflammatory response to the adult worms is minimal, the eggs elicit an intense inflammatory reaction, with mononuclear and polymorphonuclear cellular infiltrates and the formation of microabscesses. In addition, the larvae inside the eggs produce enzymes that aid in tissue destruction and allow the eggs to pass through the mucosa and into the lumen of the bowel and bladder, where they are passed to the external environment in the feces and urine, respectively.

The eggs hatch quickly on reaching fresh water to release motile **miracidia.** The miracidia then invade the appropriate snail host, where they develop into thousands of infectious cercariae. The free-swimming cercariae are released into the water, where they are immediately infectious for humans and other mammals.

The infection is similar in all three species of human schistosomes in that disease results primarily from the host's immune response to the eggs. The very earliest signs and symptoms are caused by the penetration of the cercariae through the skin. Immediate and delayed hypersensitivity to parasite antigens result in an intensely pruritic papular skin rash.

The onset of oviposition results in a symptom complex known as **Katayama syndrome,** which is marked by fever, chills, cough, urticaria, arthralgias, lymphadenopathy, splenomegaly, and abdominal pain. This syndrome is typically seen 1 to 2 months after primary exposure and may persist for 3 months or more. It is thought to result from the massive release of parasite antigens, with subsequent immune complex formation. Associated laboratory abnormalities include leukocytosis, eosinophilia, and polyclonal gammopathy.

The more chronic and significant phase of schistosomiasis is caused by the presence of eggs in various tissues and the resulting formation of granulomas and fibrosis. The retained eggs induce extensive inflammation and scarring, the clinical significance of which is directly related to the location and number of eggs.

Because of differences in some aspects of disease and epidemiology, these worms are discussed as separate species.

SCHISTOSOMA MANSONI

Physiology and Structure

S. mansoni usually resides in the small branches of the inferior mesenteric vein near the lower colon. The species of *Schistosoma* can be differentiated by their characteristic egg morphology (Figs. 75.11 to 75.13). The eggs of *S. mansoni* are oval, possess a **sharp lateral spine,** and measure 115 to 175 μm × 45 to 70 μm (see Fig. 75.11).

Clinical Case 75.4 **Schistosomiasis**

Ferrari (*Medicine [Baltimore]* 78:176–190, 1999) described a case of neuroschistosomiasis caused by *Schistosoma mansoni* in an 18-year-old Brazilian man. The patient was admitted to the hospital because of the recent onset of paraplegia. He was in good health until 33 days before admission, when he noted the onset of progressive low back pain with radiation to the lower limbs. During this period, he was evaluated three times in another institution, in which radiographic films of the lower thoracic, lumbar, and sacral spine were normal. He received antiinflammatory agents, with only transient relief in his symptoms. Four weeks after the pain began, the disease progressed acutely with sexual impotence, fecal and urinary retention, and paraparesis progressing to paraplegia. At this time, the pain disappeared, replaced by a marked impairment of sensation in the lower limbs. On admission to the hospital, he gave a history of exposure to schistosomal infection. Neurologic examination revealed flaccid paraplegia, marked sensory loss, and absence of superficial and deep reflexes at and below the level T11. The CSF contained 84 white blood cells/ml (98% lymphocytes, 2% eosinophils) and 1 red blood cell, 82 mg/dl total protein, and 61 mg/dl glucose. Myelography, computed tomography–myelography, and magnetic resonance imaging showed a slight widening of the conus. The diagnosis of neuroschistosomiasis was confirmed by the demonstration of viable and dead eggs of *S. mansoni* on rectal mucosal biopsy. The concentration of CSF IgG against soluble egg antigen of *S. mansoni* quantitated by enzyme-linked immunosorbent assay was 1.53 µg/ml. He was treated with prednisone and praziquantel. Despite therapy, his condition remained unaltered at follow-up 7 months later. *S. mansoni* is the most frequently reported cause of SMR worldwide. SMR is among the most severe forms of schistosomiasis, and prognosis depends largely on early diagnosis and treatment.

CSF, Cerebrospinal fluid; *SMR,* schistosomal myeloradiculopathy.

Epidemiology

The geographic distribution of the various species of *Schistosoma* depends on the availability of a suitable snail host. *S. mansoni* is the most widespread of the schistosomes and is endemic in Africa, Saudi Arabia, and Madagascar. It also has become well established in the Western Hemisphere, particularly in Brazil, Suriname, Venezuela, parts of the West Indies, and Puerto Rico. Cases originating in these areas may present in the United States. In all of these areas, there also are reservoir hosts, specifically primates, marsupials, and rodents. Schistosomiasis may be considered a disease of economic progress; the development of massive land irrigation projects in desert and tropical areas has resulted in the dispersion of infected humans and snails to previously uninvolved areas.

Clinical Syndromes

As noted previously, cercarial penetration of intact skin may be seen as dermatitis with allergic reactions, pruritus, and edema (Clinical Case 75.4). Migrating worms in the lungs may produce cough; as they reach the liver, hepatitis may appear.

Infections with *S. mansoni* may produce hepatic and intestinal abnormalities. As the flukes take up residence in the mesenteric vessels and egg laying begins, fever, malaise, abdominal pain, and tenderness of the liver may be observed. Deposition of eggs in the bowel mucosa results in inflammation and thickening of the bowel wall with associated abdominal pain, diarrhea, and blood in the stool. Eggs may be carried by the portal vein to the liver, where inflammation can lead to periportal fibrosis and eventually to portal hypertension and its associated manifestations.

Chronic infection with *S. mansoni* produces a dramatic hepatosplenomegaly with large accumulations of ascitic fluid in the peritoneal cavity. On gross examination, the liver is studded with white granulomas (pseudotubercles). Although *S. mansoni* eggs are primarily deposited in the intestine, eggs may appear in the spinal cord, lungs, and other sites. A similar fibrotic process occurs at each site. Severe neurologic problems may follow when eggs are deposited in the spinal cord and brain. In fatal schistosomiasis caused by *S. mansoni*, fibrous tissue, reacting to the eggs in the liver, surrounds the portal vein in a thick, grossly visible layer **("clay pipestem fibrosis").**

Laboratory Diagnosis

The diagnosis of schistosomiasis is usually established by the demonstration of characteristic eggs in feces. Stool examination reveals the large golden eggs with a sharp lateral spine (see Fig. 75.11). Concentration techniques may be necessary in light infections. Using rectal biopsy, the clinician can see the egg tracks laid by the worms in rectal vessels. Quantitation of egg output in stool is useful in estimating the severity of infection and in following the response to therapy. Serologic tests are also available but are largely of epidemiologic interest only. The development of newer tests using stage-specific antigens may allow the distinction of active from inactive disease and thus have greater clinical application. Two antigens detected in urine of patients with schistosomiasis, the circulating anodic and cathodic antigens (CAA and CCA), have been targeted for point-of-care diagnosis of schistosomiasis, notably for detection of *S. mansoni* infection. A lateral flow kit for detection of CCA is available commercially and has been widely used in studies in Africa and Brazil, but it does not have U.S. Food and Drug Administration (FDA) approval. There has been interest in the use of NAAT for detection of cell-free schistosome deoxyribonucleic acid (DNA) from plasma, blood, saliva, and urine samples. The molecular tests have proven highly sensitive and are suited for epidemiologic surveys in low-intensity settings, but relative costs of instrumentation and reagents remain an issue for point-of-care diagnosis with molecular tools.

Treatment, Prevention, and Control

The drug of choice is praziquantel, and the alternative is oxamniquine. Anthelmintic therapy may terminate oviposition but does not affect lesions caused by eggs already deposited in tissues. **Schistosomal dermatitis** and Katayama syndrome may be treated with the administration of antihistamines and corticosteroids. Education regarding the life cycles of these worms and molluscicide control of snails are essential. Improved sanitation and control of human fecal deposits are critical. Unfortunately, treatment

with praziquantel provides low cure rates in some areas, raising the specter of emerging resistance to this important therapeutic agent. The addition of artemether, an antimalarial, in combination with praziquantel has shown improved activity against *S. mansoni* and *S. haematobium*. In contrast to praziquantel, artemether acts against juvenile schistosomes in the host and may be used as a chemoprophylactic agent. Vaccine trials are in progress, but the ideal target antigen has not been identified.

SCHISTOSOMA JAPONICUM

Physiology and Structure

S. japonicum resides in branches of the superior mesenteric vein around the small intestine and in the inferior mesenteric vessels. *S. japonicum* eggs (see Fig. 75.12) are smaller, are almost spheric, and possess a **tiny spine**. These eggs are produced in greater numbers than those of *S. mansoni* and *S. haematobium*. Because of the size, shape, and numbers of these eggs, they are carried to more sites in the body (liver, lungs, brain), and infection with a few *S. japonicum* adults can be more severe than infections involving similar numbers of *S. mansoni* or *S. haematobium*.

Epidemiology

This **Oriental blood fluke** is found only in China, the Philippines, and on the island of Sulawesi, Indonesia. Epidemiologic problems correlate directly with a broad range of reservoir hosts, many of which are domestic (cats, dogs, cattle, horses, and pigs).

Clinical Syndromes

The initial stages of infection with *S. japonicum* are similar to those of *S. mansoni*, with dermatitis, allergic reactions, fever, and malaise, followed by abdominal discomfort and diarrhea. Katayama syndrome associated with the onset of oviposition is observed more commonly with *S. japonicum* than with *S. mansoni*. In chronic *S. japonicum* infection, hepatosplenic disease, portal hypertension, bleeding esophageal varices, and accumulation of ascitic fluid are commonly seen. Granulomas that appear as pseudotubercles in and on the liver are common, along with the clay pipestem fibrosis as described for *S. mansoni*.

S. japonicum frequently involves cerebral structures when eggs reach the brain and granulomas develop around them. The neurologic manifestations include lethargy, speech impairment, visual defects, and seizures.

Laboratory Diagnosis

Stool examination demonstrates the small, golden eggs with tiny spines, and usually, rectal biopsy is similarly revealing. Serologic tests are available. A lateral flow immunoassay targeting the CAA remains under development and has been tested successfully for sensitive diagnosis of *S. japonicum* and *S. haematobium* in low-intensity and near eradication settings. NAATs have been used in epidemiologic surveys.

Treatment, Prevention, and Control

The drug of choice is praziquantel. Prevention and control may be achieved by measures similar to those for *S. mansoni*, especially education of populations in endemic areas regarding proper water purification, sanitation, and control of human fecal deposits. Control of *S. japonicum* also must involve the broad range of reservoir hosts and consider the fact that people work in rice paddies and on irrigation projects in which infected snails are present. Mass treatment may offer help, and a vaccine may be developed someday.

SCHISTOSOMA HAEMATOBIUM

Physiology and Structure

After development in the liver, these blood flukes migrate to the vesical, prostatic, and uterine plexuses of the venous circulation, occasionally the portal bloodstream, and only rarely in other venules.

Large eggs with a **sharp terminal spine** (see Fig. 75.13) are deposited in the wall of the bladder and occasionally in the uterine and prostatic tissues. Those deposited in the bladder wall can break free and are found in urine.

Epidemiology

S. haematobium occurs throughout the Nile Valley and in many other parts of Africa, including islands off the eastern coast. It also appears in Asia Minor, Cyprus, southern Portugal, and India. Reservoir hosts include monkeys, baboons, and chimpanzees.

Clinical Syndromes

Early stages of infection with *S. haematobium* are similar to those of infections involving *S. mansoni* and *S. japonicum*, with dermatitis, allergic reactions, fever, and malaise. Unlike the other two schistosomes, *S. haematobium* produces hematuria, dysuria, and urinary frequency as early symptoms. Associated with hematuria, bacteriuria is frequently a chronic condition. Egg deposition in the walls of the bladder may eventually result in scarring, with loss of bladder capacity and the development of obstructive uropathy.

Patients with *S. haematobium* infections involving many flukes frequently demonstrate squamous cell carcinoma of the bladder. It is commonly stated that the leading cause of cancer of the bladder in Egypt and other parts of Africa is *S. haematobium*. The granulomas and pseudotubercles seen in the bladder may also be present in the lungs. Fibrosis of the pulmonary bed caused by egg deposition leads to dyspnea, cough, and hemoptysis.

Laboratory Diagnosis

Examination of urine specimens reveals the large, **terminally spined** eggs. Occasionally, bladder biopsy is helpful in establishing the diagnosis. *S. haematobium* eggs may appear in stool if worms have migrated to mesenteric vessels. Serologic tests (antigen and antibody) and NAATs are also available.

Treatment, Prevention, and Control

The drug of choice is praziquantel. At present, education, possible mass treatment, and development of a vaccine are the best approaches to the control of *S. haematobium* disease. The basic problems of irrigation projects (e.g., dam building), migratory human populations, and multiple reservoir hosts make prevention and control extremely difficult. A recent report of the safety and efficacy of mefloquine-artesunate in the treatment of schistosomiasis caused by *S. haematobium* is of great interest given the potential for the development of resistance to praziquantel among the schistosomes.

CERCARIAL DERMATITIS

Several nonhuman schistosomes have cercariae that penetrate human skin, producing a severe dermatitis **("swimmer's itch"),** but these schistosomes cannot develop into adult worms. The natural hosts are birds and other shore-feeding animals from freshwater lakes throughout the world and a few marine beaches. The intense pruritus and urticaria from this skin penetration may lead to secondary bacterial infection from scratching the sites of infection.

Treatment consists of oral trimeprazine and topical applications of palliative agents. When indicated, sedatives may be given. Control is difficult because of bird migration and the transfer of live snails from lake to lake. Molluscicides, such as copper sulfate, have produced some reduction in the snail populations. Immediate drying of the skin when people leave such waters offers some protection.

Case Study and Questions

A businessman who has traveled frequently to Northern Africa for many years has ascites, hepatosplenomegaly, and other signs of portal hypertension.

1. Which of the following parasites is most likely to be the cause of his illness?
   a. *Schistosoma mansoni*
   b. *Fasciolopsis buski*
   c. *Paragonimus westermani*
   d. *Schistosoma haematobium*

2. What is the pathogenesis of his disease?

3. How would you make the diagnosis?

76 Cestodes

A 30-year-old Hispanic man entered the emergency department after a focal neurologic seizure. The patient had recently emigrated from Mexico and was in his usual state of good health before the seizure. Neurologic examination revealed no persistent focal findings. A computed tomography (CT) scan of the head revealed multiple small cystic lesions in both cerebral hemispheres. Punctate calcification was noted in several of the lesions. A lumbar puncture revealed a glucose level of 65 mg/dl (normal) and a protein level of 38 mg/dl (normal) in cerebrospinal fluid. The white blood cell count was 20/cells/mm3 (abnormal) with a differential of 5% neutrophils, 90% lymphocytes, and 5% monocytes. A purified protein derivative skin test was negative with positive controls. Serologic test for human immunodeficiency virus (HIV) was negative.

1. What was the differential diagnosis of this patient's neurologic process?
2. Which parasite or parasites may have caused this condition?
3. What diagnostic tests were available for this infection?
4. What were the therapeutic options for this patient?
5. How do people become infected with this parasite?
6. What tissue sites (along with the central nervous system) may be involved? How would these additional foci of infection be documented?

 **Answers to these questions are available on www.StudentConsult.com.**

Summaries Clinically Significant Organisms

TAENIA SOLIUM

Trigger Words

Tapeworm, cysticercosis, proglottid, pig tapeworm, scolex, oncosphere

Biology, Virulence, and Disease

- *Taenia solium* (pork tapeworm): cestode; flat, segmented, ribbon-like body (strobila); head (scolex) equipped with four muscular cup-shaped suckers and a crown of hooklets that serve as organs of attachment
- Complex life cycle involving intermediate hosts; humans may serve as a form of intermediate host (cysticercosis) that harbors larval stages at extraintestinal sites
- Adult *T. solium* in intestine seldom causes abdominal discomfort, chronic indigestion, diarrhea
- Cysticercosis: infection of humans with larval stage of *T. solium* (cysticercus or bladder worm), which normally infects pigs

Epidemiology

- *T. solium* infection directly correlated with eating insufficiently cooked pork
- Cysticercosis found in areas where *T. solium* is prevalent; directly correlated with human fecal contamination
- *T. solium* infection and cysticercosis prevalent in Latin American countries, Africa, Asia, and Slavic countries; seen infrequently in the United States

Diagnosis

- Stool examination may reveal eggs and proglottids
- Cysticercosis usually diagnosed by detection of calcified cysticerci in soft tissue roentgenograms, surgical removal of subcutaneous nodules, and visualization of cysts in the eye
- Central nervous system lesions may be detected by imaging studies
- Serologic studies may be useful in diagnosis of cysticercosis

Treatment, Prevention, and Control

- Drug of choice for *T. solium* infection: niclosamide; praziquantel, paromomycin, and quinacrine are effective alternatives
- Prevention of pork tapeworm infection: cook until interior of meat is gray; freeze at −20° C for at least 12 hours
- Drug of choice for cysticercosis: praziquantel or albendazole
- Surgical removal of cerebral and ocular cysts may be necessary
- Prevention and control: treatment of human cases harboring adult *T. solium,* controlled disposal of human feces

DIPHYLLOBOTHRIUM LATUM

Trigger Words

Fish tapeworm, vitamin B_{12} deficiency, gefilte fish, copepod

Biology, Virulence, and Disease

- *D. latum* (fish tapeworm): one of largest tapeworms infecting humans (20 to 30 feet long)
- Life cycle of *D. latum* is complex; two intermediate hosts: freshwater crustaceans, freshwater fish
- Humans infected when they eat raw or undercooked fish containing larval forms
- *D. latum* establishes infection in small bowel; may reach a length of 20 to 30 feet and produce more than 1 million eggs per day
- Most *D. latum* infections asymptomatic; symptoms include epigastric pain, abdominal cramping, nausea, weight loss

Epidemiology

- *D. latum* infection occurs worldwide, most prevalently in cool lake regions where raw or pickled fish is popular
- Insufficient cooking over campfires and tasting and seasoning "gefilte fish" account for many infections
- Dumping raw sewage into freshwater lakes contributes to propagation of this tapeworm

Diagnosis

- Microscopic examination of stool reveals bile-stained operculated egg with knob at bottom of shell
- Typical proglottids may also be detected

Treatment, Prevention, and Control

- Drug of choice is niclosamide; praziquantel and paromomycin acceptable alternatives
- Vitamin B_{12} supplementation may be necessary in people with evidence of clinical B_{12} deficiency
- Prevalence of this infection reduced by avoiding ingestion of raw or undercooked fish, controlling disposal of human waste, promptly treating infections

The bodies of cestodes, or **tapeworms,** are flat and ribbon-like (Fig. 76.1), and the heads are equipped with organs of attachment. The head, or **scolex,** of the worm usually has four muscular, cup-shaped suckers and a crown of hooklets (Fig. 76.2). An exception is *Diphyllobothrium latum*, the fish tapeworm, whose scolex is equipped with a pair of long, lateral, muscular grooves and lacks hooklets.

Fig. 76.1 Intact adult *Diphyllobothrium latum*. The chain of proglottids (strobila) may reach a length of 10 m. (From Peters, W., Pasvol, G., 2007. Atlas of Tropical Medicine and Parasitology, sixth ed. Elsevier, Philadelphia, PA.)

The individual segments of tapeworms are called **proglottids** (see Fig. 76.2), and the chain of proglottids is called a **strobila** (see Fig. 76.1). As new proglottids develop, existing ones mature as they become more distal. The more distal proglottids are gravid, almost completely occupied by a uterus full of eggs, which are passed with the stools of the carrier, either inside completed proglottids or free after proglottid breakage. Differentiation of the various adult cestodes may be accomplished by examination of the structure of shed proglottids (length, width, number of uterine branches) or (more rarely) of the scolex (number and placement of suckers, presence or absence of hooklets).

All tapeworms are hermaphroditic, with male and female reproductive organs present in each mature proglottid. The eggs of most tapeworms are nonoperculated and contain a six-hooked **hexacanth embryo;** the one exception, *D. latum*, has an unembryonated, operculated egg resembling fluke eggs. Tapeworms have no digestive system, and food is absorbed from the host intestine through the soft body wall of the worm. Most tapeworms found in the human intestine have complex life cycles involving intermediate hosts, and in some instances (cysticercosis, echinococcosis, sparganosis), humans serve as a form of intermediate host that harbors larval stages. The presence of extraintestinal larvae is at times more serious than that of adult worms in the intestine. The most common cestodes of medical importance are listed in Table 76.1.

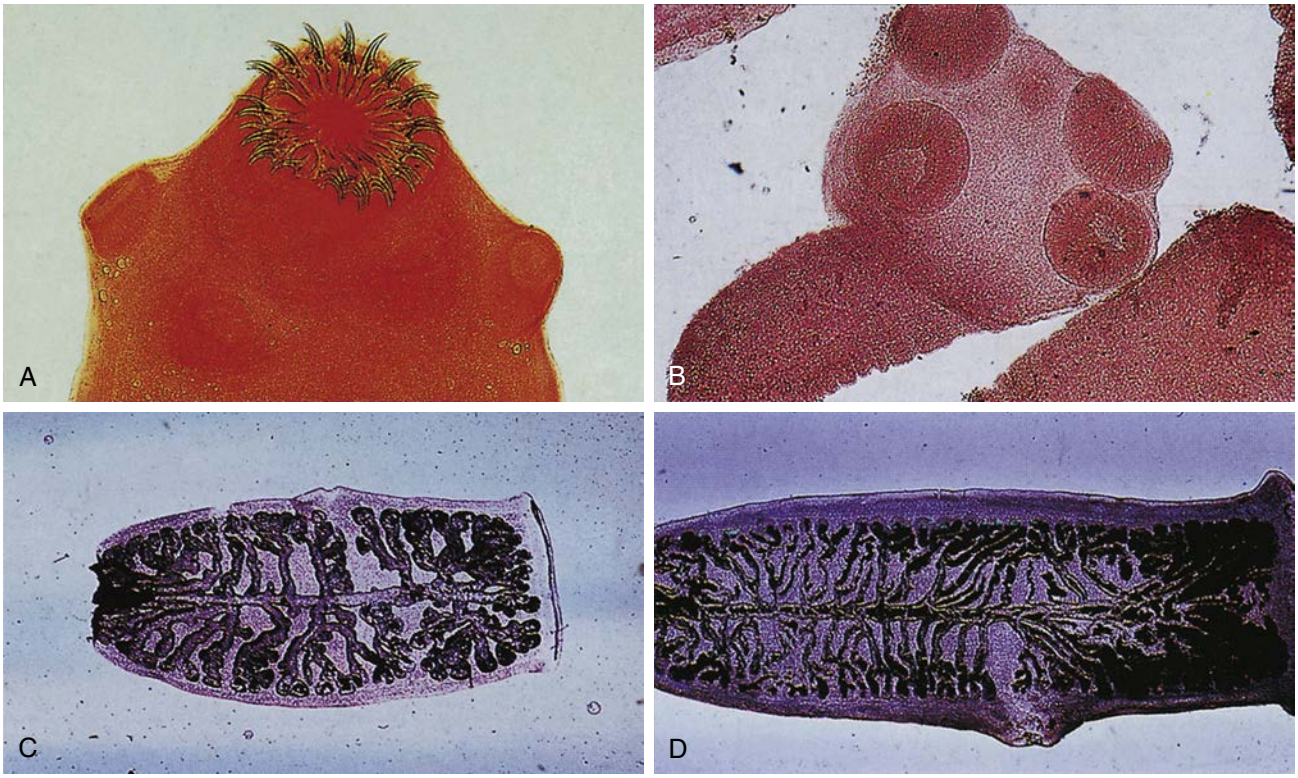

Fig. 76.2 Scolices and proglottids of (A and C) *Taenia solium* and (B and D) *T. saginata*. The scolex of *T. solium* (A) is armored with hooks in addition to four suckers. *T. saginata* has no hooks (B). The gravid proglottids of *T. solium* (C) contain a central uterus with fewer than a dozen lateral branches. The gravid segments of *T. saginata* (D) contain a central uterus with 15 to 20 lateral branches. (From Peters, W., Pasvol, G., 2007. Atlas of Tropical Medicine and Parasitology, sixth ed. Elsevier, Philadelphia, PA. C and D, Courtesy Professor D. Greenwood.)

TABLE 76.1 Medically Important Cestodes

Cestode	Common Name	Reservoir for Larvae	Reservoir for Adults
Taenia solium	Pork tapeworm	Hogs	Humans
	Cysticercosis	Humans	—
Taenia saginata	Beef tapeworm	Cattle	Humans
Diphyllobothrium latum	Fish tapeworm	Freshwater crustaceans and fish	Humans, dogs, cats, bears
Echinococcus granulosus	Unilocular hydatid cyst	Herbivores, humans	Canines
E. multilocularis	Alveolar hydatid cyst	Herbivores, humans	Foxes, wolves, dogs, cats
Hymenolepis nana	Dwarf tapeworm	Rodents, humans	Rodents, humans
H. diminuta	Dwarf tapeworm	Insects	Rodents, humans
Dipylidium caninum	Pumpkin seed tapeworm	Fleas	Dogs, cats

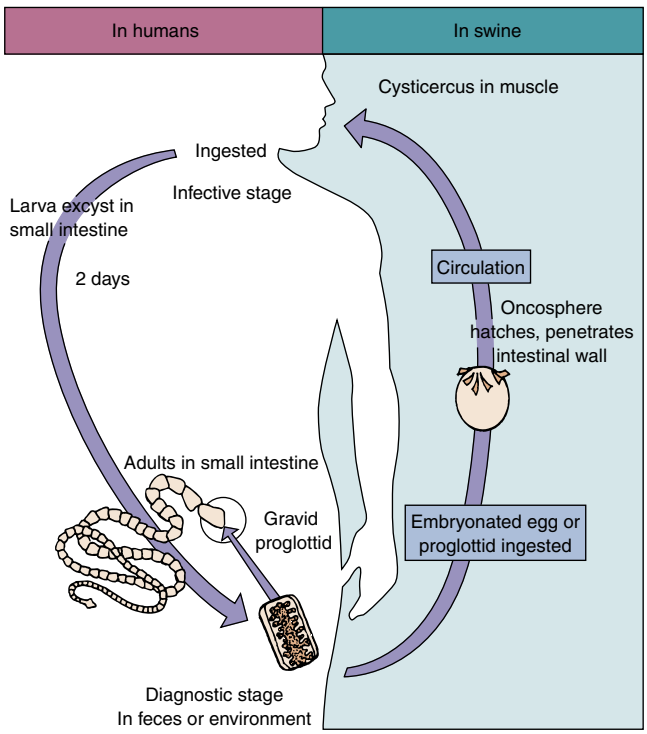

Fig. 76.3 Life cycle of *Taenia solium* (pork tapeworm).

Fig. 76.4 *Taenia* egg. The eggs are spheric, 30 to 40 µm in diameter, and contain three pairs of hooklets internally. The eggs of the different *Taenia* species cannot be differentiated.

Taenia solium

PHYSIOLOGY AND STRUCTURE

The larval stage, or **cysticercus** ("bladder worm"), of *Taenia* species consists of a scolex, which is invaginated into a fluid-filled bladder. Larval cysts develop in the tissues of the intermediate host, are 4 to 6 mm long × 7 to 11 mm wide, and have a pearl-like appearance in the tissues. After a person ingests pork muscle containing a larval worm, attachment of the scolex with its four muscular suckers and crown of hooklets (see Fig. 76.2) initiates infection in the small intestine (Fig. 76.3). The worm then produces proglottids until a strobila of proglottids is developed, which may be several meters in length. The sexually mature proglottids contain eggs, and as these proglottids leave the host in feces, they can contaminate water and vegetation ingested by swine. The gravid proglottids have a similar length and width (1 × 1 cm) and contain few (<12) lateral uterine branches (see Fig. 76.2). The eggs in swine become a six-hooked larval form, called an *oncosphere,* which penetrates the pig's intestinal wall, migrates in the circulation to the tissues, and becomes a cysticercus to complete the cycle.

EPIDEMIOLOGY

T. solium infection is directly correlated with eating insufficiently cooked pork and is prevalent in Africa, India, Southeast Asia, China, Mexico, Latin American countries, and Slavic countries. It is seen infrequently in the United States.

CLINICAL SYNDROMES

Adult *T. solium* in the intestine seldom causes appreciable symptoms. The intestine may be irritated at sites of attachment, and abdominal discomfort, chronic indigestion, and diarrhea may occur. Most patients become aware of the infection only when they see proglottids or a strobila of proglottids in their feces.

LABORATORY DIAGNOSIS

Stool examination may reveal proglottids and eggs, and treatment may produce the entire worm for identification. The eggs are spheric, are 30 to 40 µm in diameter, and possess a thick, radially striated shell containing a six-hooked hexacanth embryo (Fig. 76.4). The eggs are identical to those of *T. saginata* **(beef tapeworm),** so eggs alone are not sufficient for species identification.

Critical examination of the proglottids reveals their internal structure, which is important for the differentiation of *T. solium* and *T. saginata*. Gravid proglottids of *T. solium* are smaller than those of *T. saginata* and contain only 7 to 12 lateral uterine branches, compared with 15 to 30 for the beef tapeworm (see Fig. 76.2). Recently, stage-specific serologic assays directed to the adult tapeworm have been developed, with high sensitivity and specificity. Antibody detection by enzyme-linked immunoelectrotransfer blot assay is the method of choice, with a sensitivity of 98% and a specificity of 100%. Coproantigen detection by enzyme-linked immunosorbent assay (ELISA) is much more sensitive than microscopy and thus highly recommended for the diagnosis of human taeniasis (specifically in the case of *T. solium* because of the risks of cysticercosis transmission), as well as to monitor the effectiveness of treatment, but its availability is still limited. Species-specific PCR techniques that differentiate *T. saginata* from *T. solium* have been described. Most of these assays require actual parasite material, although some are apparently able to establish the difference with deoxyribonucleic acid (DNA) from eggs in feces.

TREATMENT, PREVENTION, AND CONTROL

The drug of choice is niclosamide. Praziquantel, paromomycin, or quinacrine is an effective alternative. Prevention of **pork tapeworm** infections requires that pork be either cooked until the interior of the meat is gray or frozen at −20° C for at least 12 hours. Sanitation is critical; every effort must be made to keep human feces containing *T. solium* eggs out of water and vegetation ingested by pigs.

Cysticercosis

PHYSIOLOGY AND STRUCTURE

Cysticercosis involves infection of people with the larval stage of *T. solium* (the cysticercus), which normally infects pigs (Fig. 76.5). Human ingestion of water or vegetation contaminated with *T. solium* eggs from human feces initiates the infection. Autoinfection may occur when eggs from a person infected with the adult worm are transferred from the perianal area to the mouth on contaminated fingers. Once ingested, the eggs hatch in the stomach of the intermediate host, releasing the hexacanth embryo or **oncosphere.** The oncosphere penetrates the intestinal wall and migrates in the circulation to the tissues, where it develops into a cysticercus in 3 to 4 months. The cysticerci may develop in muscle, connective tissue, brain, lungs, and eyes and remain viable for as long as 5 years.

EPIDEMIOLOGY

Cysticercosis is found in the areas in which *T. solium* is prevalent and is directly correlated with human fecal contamination. In addition to fecal-oral transmission, autoinfection may occur when a proglottid containing eggs is regurgitated from the small intestine into the stomach, allowing the eggs to hatch and release the infectious oncosphere.

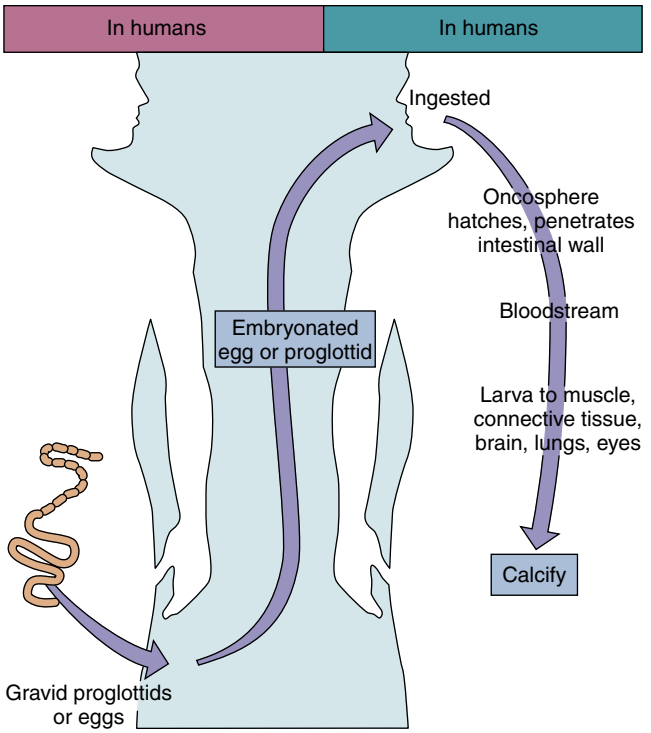

Fig. 76.5 Development of human cysticercosis.

CLINICAL SYNDROMES

A few cysticerci in nonvital areas (e.g., subcutaneous tissues) may not provoke symptoms, but serious disease may follow as the cysticerci lodge in vital areas, such as the brain and eyes (Clinical Case 76.1). In the brain, they may produce hydrocephalus, meningitis, cranial nerve damage, seizures, hyperactive reflexes, and visual defects. In the eye, loss of visual acuity may occur, and if the larvae lodge along the optic tract, visual field defects result. Tissue reaction to viable larvae may be only moderate, thus minimizing symptoms. However, death of the larvae results in the release of antigenic material that stimulates a marked inflammatory reaction; exacerbation of symptoms can result in fever, muscle pains, and eosinophilia.

LABORATORY DIAGNOSIS

The presence of cysticerci is usually established by the appearance of calcified cysticerci in soft-tissue roentgenograms, surgical removal of subcutaneous nodules, and visualization of cysts in the eye. Central nervous system lesions may be detected by CT, radioisotope scanning, or ultrasonography. Serology is directed to the detection of *T. solium* antibodies in relation to the diagnosis of neurocysticercosis; false-positive results may occur in people with other helminthic infections. *T. solium* antigen detection in serum or cerebrospinal fluid has been performed in cases of human cysticercosis. Although these assays can detect parasite burdens of <50 cysts in infected animals, they have not yet been routinely applied except in research settings. *T. solium* antigen detection is likely to be a helpful tool to monitor the evolution of patients with severe, subarachnoid neurocysticercosis, in which high antigen levels occur. Species-specific polymerase chain reaction (PCR) techniques that differentiate *T. saginata* from *T. solium* have been described.

Clinical Case 76.1 **Neurocysticercosis**

Chatel and colleagues (*Am J Trop Med Hyg* 60:255–256, 1999) described a case of neurocysticercosis in an Italian traveler to Latin America. The patient was a 49-year-old man with a history of a 30-day stay in Latin America (El Salvador, Colombia, and Guatemala) 3 months before presentation with fever and myalgia. The clinical examination and routine laboratory test results were normal except for elevated creatine phosphokinase levels and mild eosinophilia. He received symptomatic antiinflammatory therapy, rapidly improved, and was discharged with a diagnosis of polymyositis. Two years later, he was admitted to the hospital with retroocular headache and recurrent right hemianopsia. A neurologic examination revealed a left Babinski reflex with no motor or sensory dysfunctions. Laboratory tests were unremarkable, including a negative stool examination for ova and parasites. Cerebral MRI showed the presence of several intraparenchymal, subarachnoidal, and intraventricular cysts (4 to 15 mm in diameter) with perilesional focal edema and ringlike enhancement. A specific antibody response to cysticercosis was demonstrated by enzyme-linked immunosorbent assay and immunoblotting techniques. The patient was treated with albendazole for two cycles of 8 days each. One year later, he was in good health, and cerebral MRI revealed significant reduction in the diameter of the lesions. This case provides an interesting reminder of the minimal but real risks to travelers for acquiring *Taenia solium* infections during foreign travel.

MRI, Magnetic resonance imaging.

TREATMENT, PREVENTION, AND CONTROL

The drug of choice for cysticercosis is either praziquantel or albendazole. Concomitant steroid administration may be necessary to minimize the inflammatory response to dying larvae. Surgical removal of cerebral and ocular cysts may be necessary. Critical to the prevention and control of human infection are the treatment of human cases harboring adult *T. solium* (to reduce egg transmission) and the controlled disposal of human feces. These measures also reduce the likelihood of infection in pigs.

Taenia saginata

PHYSIOLOGY AND STRUCTURE

The life cycle of *T. saginata* (the beef tapeworm) is similar to that of *T. solium* (Fig. 76.6), with infection resulting after cysticerci are ingested in insufficiently cooked beef. After excystment, the larvae develop into adults in the small intestine and initiate egg production in maturing proglottids. The adult worm may parasitize the jejunum and small intestine of humans for as long as 25 years, attaining a length of 10 m. In contrast with *T. solium* infections, cysticercosis produced by *T. saginata* does not occur in humans. The adult *T. saginata* worm also differs from *T. solium* in that it lacks a crown of hooklets on the scolex and has a different proglottid uterine branch structure (see Fig. 76.2). The gravid proglottids are longer than they are wide (18 to 20 mm × 5 to 7 mm) and contain 15 to 30 lateral uterine branches. These facts are important in differentiating between the two tapeworms but do not affect therapy.

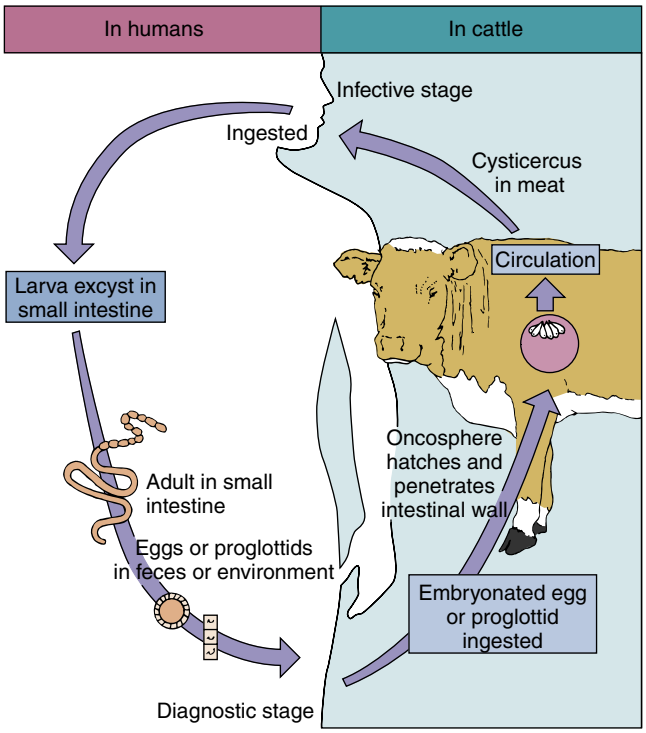

Fig. 76.6 Life cycle of *Taenia saginata* (beef tapeworm).

EPIDEMIOLOGY

T. saginata occurs worldwide and is one of the most frequent causes of cestode infections in the United States. Humans and cattle perpetuate the life cycle: human feces contaminate water and vegetation with eggs, which are then ingested by cattle. The cysticerci in cattle produce adult tapeworms in humans when rare or insufficiently cooked beef is eaten.

CLINICAL SYNDROMES

The syndrome that results from *T. saginata* infection is similar to intestinal infection with *T. solium*. Patients are generally asymptomatic or may complain of vague abdominal pains, chronic indigestion, and hunger pains. Proglottids may pass out of the anus directly.

LABORATORY DIAGNOSIS

The diagnosis of *T. saginata* infection is similar to that of *T. solium*, with recovery of proglottids and eggs or recovery of an entire worm whose scolex lacks hooklets. Study of the uterine branches in the proglottids differentiates *T. saginata* from *T. solium*. Antigens in stools (coproantigen) have been detected by ELISA since 1990, but this assay is used mainly in research settings because of its limited availability. Species-specific PCR techniques have been described to detect parasite DNA and differentiate *T. saginata* from *T. solium*.

TREATMENT, PREVENTION, AND CONTROL

Treatment is identical to that for the intestinal phase of *T. solium*. Both praziquantel and niclosamide are highly effective in eliminating the adult worm. Education

regarding cooking beef and controlling of the disposal of human feces is a critical measure.

Diphyllobothrium latum

PHYSIOLOGY AND STRUCTURE

One of the largest tapeworms (20 to 30 feet long) (see Fig. 76.1), *D. latum* **(fish tapeworm)** has a complex life cycle involving two intermediate hosts: freshwater crustaceans and freshwater fish (Fig. 76.7). The ribbon-like larval worm in the flesh of freshwater fish is called a **sparganum.** Ingestion of this sparganum in raw or insufficiently cooked fish initiates infection. The scolex of *D. latum* is shaped like a lance and has long, lateral grooves **(bothria),** which serve as organs of attachment. The proglottids (Fig. 76.8) of *D. latum* are much wider than they are long (≈8 by 4 mm), have a central uterine structure resembling a rosette, and produce eggs with an operculum (like fluke eggs) and a knob on the shell at the bottom of the egg. The adult worms may produce eggs for months or years. More than 1 million eggs per day are released into the fecal stream. On reaching fresh water, the unembryonated, operculate eggs require a period of 2 to 4 weeks to develop a ciliated, free-swimming larval form called a **coracidium.** The fully developed coracidium leaves the egg via the operculum and is ingested by tiny crustaceans that are called **copepods** (e.g., *Cyclops* and *Diaptomus* species); then the coracidium develops into a **procercoid** larval form. The crustacean harboring the larval stage is then eaten by a fish, and the infectious **plerocercoid,** or sparganum larvae, develop in the musculature of the fish. If the fish is in turn eaten by another fish, the sparganum simply migrates into the muscles of the second fish. Humans are infected when they eat raw or undercooked fish containing the larval forms.

EPIDEMIOLOGY

D. latum infection occurs worldwide and is most prevalent in cool lake regions where raw or pickled fish is popular. Insufficient cooking over campfires and tasting and seasoning "gefilte fish" account for many infections. A reservoir of infected wild animals, such as bears, minks, walruses, and members of the canine and feline families that eat fish, is also a source for human infections. The practice of dumping raw sewage into freshwater lakes contributes to the propagation of this tapeworm.

CLINICAL SYNDROMES

Clinically, as is the case with most adult tapeworm infections, most *D. latum* infections are asymptomatic (Clinical Case 76.2). Occasionally, people complain of epigastric pain, abdominal cramping, nausea, vomiting, and weight loss. As many as 40% of *D. latum* carriers may have low serum levels of vitamin B_{12}, presumably because of the competition between the host and the worm for dietary vitamin B_{12}. A small percentage (0.1% to 2%) of people infected with *D. latum* develop clinical signs of vitamin B_{12} deficiency, including megaloblastic anemia and neurologic manifestations, such as numbness, paresthesia, and loss of vibration sense.

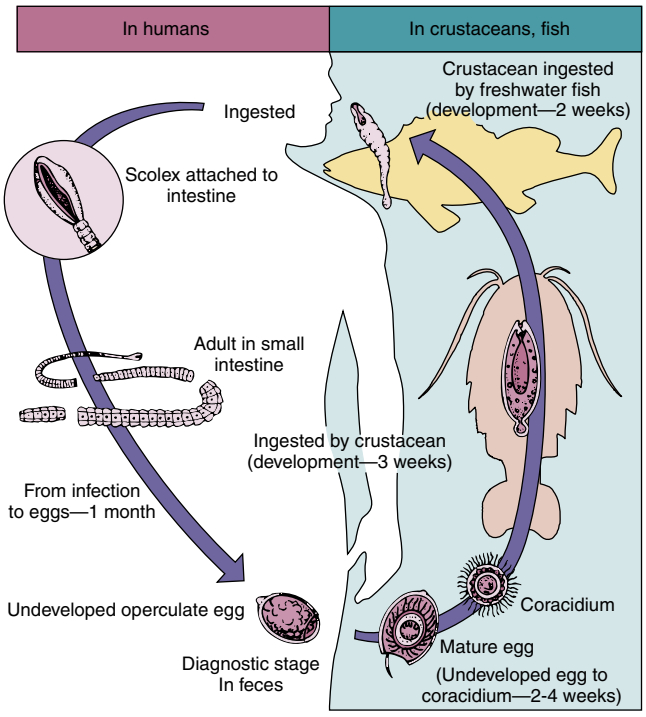

Fig. 76.7 Life cycle of *Diphyllobothrium latum* (fish tapeworm).

Fig. 76.8 Proglottids of *Diphyllobothrium latum*. In contrast to those of the *Taenia,* the proglottids of *D. latum* are wider than they are long. (From Peters, W., Pasvol, G., 2007. Atlas of Tropical Medicine and Parasitology, sixth ed. Elsevier, Philadelphia, PA.)

LABORATORY DIAGNOSIS

Stool examination reveals the bile-stained, operculated egg with its knob at the bottom of the shell (Fig. 76.9). Typical proglottids with the rosette uterine structure may also be

Clinical Case 76.2 **Diphyllobothriasis**

Lee and colleagues (*Korean J Parasitol* 39:319–321, 2001) reported a case of diphyllobothriasis in a young girl. A 7-year-old girl was seen in an outpatient clinic after the discharge of a chain of tapeworm proglottids measuring 42 cm in length. She had no history of eating raw fish, except once when she ate raw salmon flesh along with the rest of her family approximately 7 months earlier. The salmon was caught in a local river. She did not complain of any gastrointestinal discomfort, and all blood chemistry and hematologic studies were normal. The coprologic studies were positive for *Diphyllobothrium latum* eggs. The worm was identified as *D. latum*, based on the biologic characteristics of the proglottids: broad narrow external morphology, coiling of uterus, number of uterine loops, and position of the genital opening. A single dose of praziquantel 400 mg was given, but stool examination remained positive a week later. Another dose of 600 mg was given, and repeat stool examination 1 month later was negative. Among four family members who ate the raw fish, just two, the girl and her mother, were identified as infected. Consumption of raw salmon, especially those produced by aquaculture, is a risk for human diphyllobothriasis.

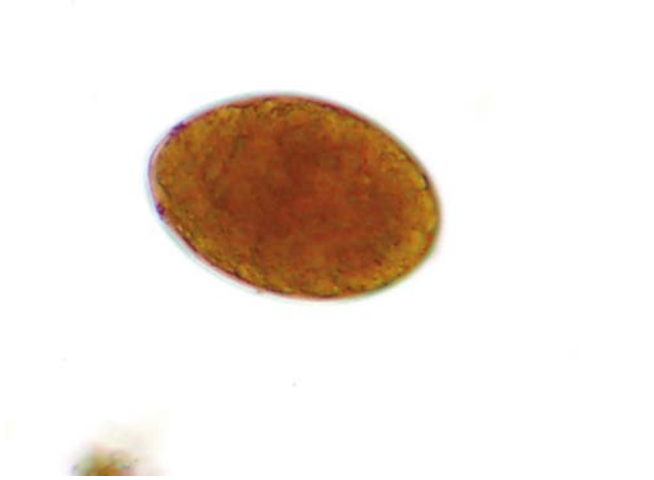

Fig. 76.9 *Diphyllobothrium latum* egg. Unlike other tapeworm eggs, *D. latum* eggs are operculated. They are 45 × 90 μm in size.

found in stool specimens. Concentration techniques are usually not necessary because the worms produce large numbers of ova. Neither serologic nor molecular-based detection is relevant for the diagnosis of infection caused by *D. latum*.

TREATMENT, PREVENTION, AND CONTROL

The drug of choice is niclosamide; praziquantel and paromomycin are acceptable alternatives. Vitamin B_{12} supplementation may be necessary in people with evidence of clinical vitamin B_{12} deficiency. The prevalence of this infection is reduced by avoiding the ingestion of insufficiently cooked fish, controlling the disposal of human feces (especially the proper treatment of sewage before disposal in lakes), and promptly treating infections.

Sparganosis

PHYSIOLOGY AND STRUCTURE

The larval forms of several tapeworms closely related to *D. latum* (most often *Spirometra* species) can produce human disease in subcutaneous sites and in the eye. In these cases, humans act as the end-stage host for the larval stage, or **sparganum.** Infections are acquired primarily by drinking pond or ditch water that contains crustaceans (copepods) that carry a larval tapeworm. This larval form penetrates the intestinal wall and migrates to various sites in the body, in which it develops into a sparganum. Infections may also occur if tadpoles, frogs, and snakes are ingested raw or if the flesh of these animals is applied to wounds as a poultice. The larval worm leaves the relatively cold flesh of the dead animal and migrates into the warm human flesh.

EPIDEMIOLOGY

Cases have been reported from various parts of the world, including the United States, but the infection is most prevalent in Asia. Regardless of location, drinking contaminated water and eating raw tadpole, frog, and snake flesh lead to infection.

CLINICAL SYNDROMES

In subcutaneous sites, **sparganosis** can produce painful inflammatory tissue reactions and nodules. In the eye, the tissue reaction is intensely painful, and periorbital edema is common. Corneal ulcers may develop with ocular involvement. Ocular disease is frequently associated with the use of frog or snake flesh as a poultice over a wound near the eye.

LABORATORY DIAGNOSIS

Sections of tissue removed surgically show characteristic tapeworm features, including highly convoluted parenchyma and dark-staining calcareous corpuscles.

TREATMENT, PREVENTION, AND CONTROL

Surgical removal is the customary approach. The drug praziquantel may be used; however, no clinical data support its efficacy. Education regarding possible contamination of drinking water with crustaceans that harbor larval worms is essential, and contamination most likely occurs in pond and ditch water. Ingestion of raw frog and snake flesh or their use as poultices over wounds should also be avoided.

Echinococcus granulosus

PHYSIOLOGY AND STRUCTURE

Infection with *E. granulosus* is another example of accidental human infection, with humans serving as dead-end intermediate hosts in a life cycle that occurs naturally in

other animals. *E. granulosus* adult tapeworms are found in nature in the intestines of canines (dog, fox, wolf, coyote, jackal, dingo); the larval cyst stage is present in the viscera of herbivores (sheep, cattle, swine, deer, moose, elk) (Fig. 76.10). The worm consists of a *Taenia*-like scolex with four sucking disks and a double row of hooklets, as well as a strobila containing three proglottids: one immature, one mature, and one gravid. Adult tapeworms in the canine intestine produce infective eggs that pass in feces. The eggs are identical in appearance to those of the *Taenia* species. When these eggs are ingested by humans, a six-hooked larval stage called an **oncosphere** hatches. The oncosphere penetrates the human intestinal wall and enters the circulation to be carried to various tissue sites, primarily the liver and lungs but also the central nervous system and bone. This same cycle occurs in the viscera of herbivores. When the herbivore is killed by a canine predator or viscera is fed to canines, the ingestion of cysts produces adult tapeworms in the canine intestine to complete the cycle and initiate new egg production. Adult tapeworms do not develop in the intestines of herbivores or humans.

In humans, the larvae form a unilocular **hydatid cyst,** which is a slow-growing, tumor-like, and space-occupying structure enclosed by a laminated germinative membrane. This membrane produces structures on its wall called **brood capsules,** where tapeworm heads **(protoscolices)** develop. Daughter cysts may develop in the original mother cyst and also produce brood capsules and protoscolices. The cysts and daughter cysts accumulate fluid as they grow. This fluid is potentially toxic; if spilled into body cavities, anaphylactic shock and death can result. Spillage and the escape of protoscolices can lead to the development of cysts in other sites because the protoscolices have

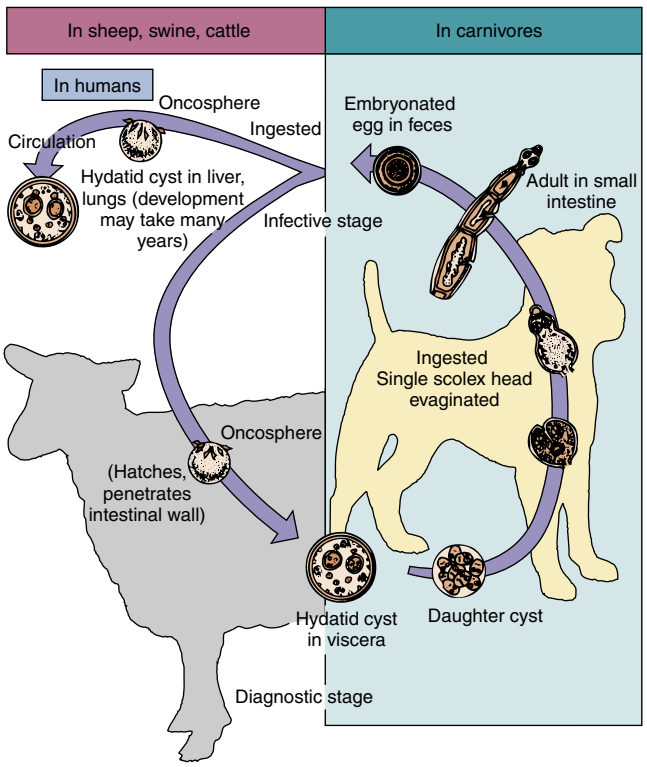

Fig. 76.10 Life cycle of *Echinococcus granulosus.*

the germinative potential to form new cysts. Eventually, the brood capsules and daughter cysts disintegrate within the mother cyst, liberating the accumulated protoscolices. These become known as **hydatid sand.** This type of echinococcus cyst is called a **unilocular cyst** to differentiate it from related cysts that grow differently. The unilocular cyst is generally about 5 cm in diameter, but some are as large as 20 cm, containing almost 2 liters of cyst fluid, have been reported. The cyst may die and become calcified over long periods.

EPIDEMIOLOGY

Human infection with *E. granulosus* unilocular cyst is directly correlated with raising sheep in many countries in Europe, South America, Africa, Asia, Australia, and New Zealand. It occurs in Canada and in the United States, with cases reported in Alaska, Utah, New Mexico, Arizona, California, and the lower Mississippi Valley. Human infection follows ingestion of contaminated water or vegetation, as well as hand-to-mouth transmission of canine feces carrying the infective eggs.

CLINICAL SYNDROMES

Because the unilocular cyst grows slowly, 5 to 20 years may pass before any symptoms appear (Clinical Case 76.3). In many instances, it appears that the cyst is as old as its host. The pressure of the expanding cyst in an organ is usually the first sign of infection. In the majority of cases, the cysts are located in the liver or lung. In the liver, the cyst may exert pressure on both bile ducts and blood vessels and create pain and biliary rupture. In the lungs, cysts may produce cough, dyspnea, and chest pains. Rupture of the cysts may occur in 20% of cases, producing fever, urticaria, and occasionally anaphylactic shock and death, which are caused by the release of antigenic cyst contents. Cyst rupture may also lead to dissemination of infection resulting from the release of thousands of protoscolices. In bone, the cyst is responsible for erosion of the marrow cavity and the bone itself. In the brain, severe damage may occur as a result of the cyst's tumor-like growth into brain tissue.

LABORATORY DIAGNOSIS

The diagnosis of **hydatid disease** is difficult and depends primarily on clinical, radiographic, and serologic findings. Radiologic examination, scanning procedures, CT, and ultrasound techniques are all valuable and may provide the first evidence of the cyst's presence. Aspiration of cyst contents may demonstrate the presence of the protoscolices (hydatid sand); however, it is contraindicated because of the risk of anaphylaxis and dissemination of the infection. Serologic testing may be useful, but results are negative in 10% to 40% of infections. It is more sensitive for hepatic cases than for pulmonary cases.

TREATMENT, PREVENTION, AND CONTROL

Surgical resection of the cyst is the treatment of choice. In some instances, the cyst is first aspirated to remove the fluid and hydatid sand, and then it is instilled with

formalin to kill and detoxify remaining fluid; finally, it is rolled into a marsupial pouch and sewn shut. If the condition is inoperable because of the cyst's location, medical therapy with high-dose albendazole, mebendazole, or praziquantel may be considered. The most important factor in preventing and controlling **echinococcosis** is education regarding the transmission of infection and the role of canines in the life cycle. Proper personal hygiene and the washing of hands and cooking utensils in environments inhabited by dogs are critical. Dogs should not be allowed in the vicinity of animal slaughter and should never be fed the viscera of slain animals. In some areas, the killing of stray dogs has reduced the incidence of infection.

Clinical Case 76.3 **Echinococcosis**

Yeh and colleagues (*N Engl J Med* 357:489–494, 2007) described a 36-year-old pregnant woman at 21 weeks of gestation who presented with a 4-week history of a dry, nonproductive cough. The patient denied any constitutional symptoms and had no new pets, environmental exposures, or sick contacts. It was her first pregnancy, and there were no complications. She had no medical conditions and did not smoke or drink alcohol. She was a financial consultant and enjoyed running and hiking. She had traveled to Australia, Central Asia, and sub-Saharan Africa in the past. The patient appeared well, with appropriate weight gain for the second trimester of her pregnancy. Her physical examination, including auscultation of her lungs, was normal. Her cough did not improve with use of an inhaled bronchodilator. Imaging studies were not performed because of her pregnancy. She had a normal, uncomplicated vaginal delivery 4 months later. She continued to have a dry cough and presented to her physician months after delivery for a reevaluation of her cough. At that time, her physical examination and laboratory studies were unremarkable. A chest radiograph revealed a soft-tissue mass, 7 cm in diameter, adjacent to the right heart border. High-resolution CT scans of the chest confirmed the presence of a homogeneous and fluid-filled structure without septa, which was thought to be in the mediastinum. Subsequent echocardiography also confirmed a simple cystic structure with thin walls surrounding echo-free fluid that was indenting the right atrium. On the basis of the radiographic and echocardiography findings, the clinicians caring for the patient thought that the mass was most likely a benign pericardial cyst. Because she was not experiencing dyspnea, the patient declined surgical resection. However, because of worsening cough over the next few months, she consulted a thoracic surgeon for elective resection. Intraoperative findings revealed an intraparenchymal pulmonary cyst in the right lung that was not attached to the pericardium or bronchus. The cyst was removed intact without gross spillage of the contents. Staining of the cyst wall with hematoxylin and eosin after cross-sectioning showed an acellular laminated layer. Microscopic examination of the cyst contents showed protoscolices with hooklets and suckers in a background of histiocytes and eosinophilic debris, consistent with *Echinococcus granulosus*. CT of the abdomen after removal of the thoracic cyst revealed no hepatobiliary disease. Postoperative screening for serum antibody against *Echinococcus* was positive. Praziquantel was administered for 10 days after surgery and albendazole for 1 month after surgery with no complications. After this course of therapy, the patient had resolution of her cough and returned to her normal level of activity. There was no evidence of recurrent disease on CT follow-up 6 months after surgery.

CT, Computed tomography.

Echinococcus multilocularis

PHYSIOLOGY AND STRUCTURE

Similar to infection with *E. granulosus*, human infection with *E. multilocularis* is accidental (Fig. 76.11). Adult *E. multilocularis* tapeworms are primarily found in foxes and wolves, although farm dogs and cats harbor them in some rural environments. The intermediate hosts that harbor the cyst stage are rodents (mice, voles, shrews, and lemmings). Humans become infected with the cyst stage as a result of contact with fox, dog, or cat feces contaminated with eggs. Trappers and workers who handle fur pelts may become infected by inhaling fecal dust that carries eggs.

Infective eggs hatch in and penetrate the intestinal tract to become oncospheres. These forms enter the circulation and take up residence primarily in the liver and lungs but also possibly in the brain.

The **alveolar hydatid cyst** develops as an alveolar or honeycombed structure that is not covered by a unilocular-limiting mother cyst–laminated membrane. The cyst grows via exogenous budding, eventually resembling a carcinoma.

EPIDEMIOLOGY

E. multilocularis is found primarily in northern areas, such as Canada, the former Soviet Union, northern Japan, Central Europe, and Alaska, Montana, North and South

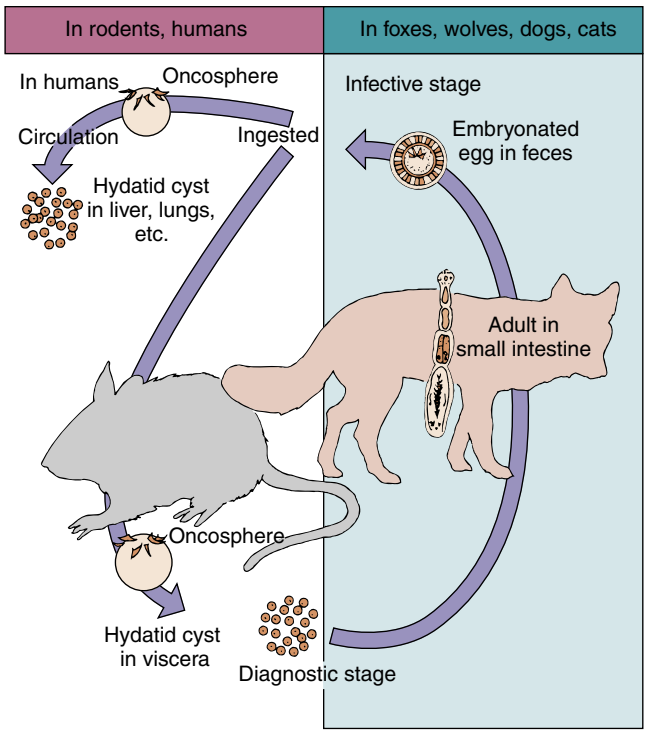

Fig. 76.11 Life cycle of *Echinococcus multilocularis*.

Dakota, Minnesota, and Iowa in the United States. There is evidence that the life cycle may be extending to other midwestern states, where foxes and mice transmit the organism to dogs and cats and eventually to humans.

CLINICAL SYNDROMES

E. multilocularis, because of its slow growth, may be present in human tissues for many years before symptoms appear. In the liver, cysts eventually mimic a carcinoma, with liver enlargement and obstruction of biliary and portal pathways. Often the growth metastasizes to the lungs and brain. Malnutrition, ascites, and portal hypertension produced by *E. multilocularis* create the appearance of hepatic cirrhosis. Among all the worm infections of humans, *E. multilocularis* is one of the most lethal. If the infection is left untreated, the mortality rate is approximately 70%.

LABORATORY DIAGNOSIS

Unlike *E. granulosus*, the tissue form of *E. multilocularis* presents no protoscolices, and the material so resembles a neoplasm that even pathologists mistake it for carcinoma. Radiologic procedures and scanning techniques are helpful, and serologic methods are available.

TREATMENT, PREVENTION, AND CONTROL

Surgical removal of the cyst is indicated, especially if an entire hepatic area can be resected. The same surgical approach applies to lesions in the lung, in which a lobe can be resected. Mebendazole and albendazole, as used for the treatment of *E. granulosus*, have produced clinical cures. As with *E. granulosus*, education, proper personal hygiene, and deworming of farm dogs and cats are critical. It is extremely important to treat animals that have contact with children.

Hymenolepis nana

PHYSIOLOGY AND STRUCTURE

H. nana, the **dwarf tapeworm,** is only 2 to 4 cm in length, unlike *Taenia* organisms, which measure several meters. The life cycle also is simple and does not require an intermediate host (Fig. 76.12), although mice and beetles may be infected and enter the cycle.

Infection begins when the embryonated eggs are ingested and develop in the intestinal villi into a larval cysticercoid stage. This cysticercoid larva attaches its four muscular suckers and crown of hooklets to the small intestine, and on maturation, the adult worm produces a strobila of egg-laden proglottids. Eggs passing in the feces are then immediately and directly infective, initiating another cycle. Infection also may be acquired by ingesting infected insect intermediate hosts.

H. nana also can cause autoinfection, with a subsequent increased worm burden. Eggs are able to hatch in the intestine, develop into a cysticercoid larva, and then grow into adult worms without leaving the host. This can lead to hyperinfection with very heavy worm burdens and severe clinical symptoms.

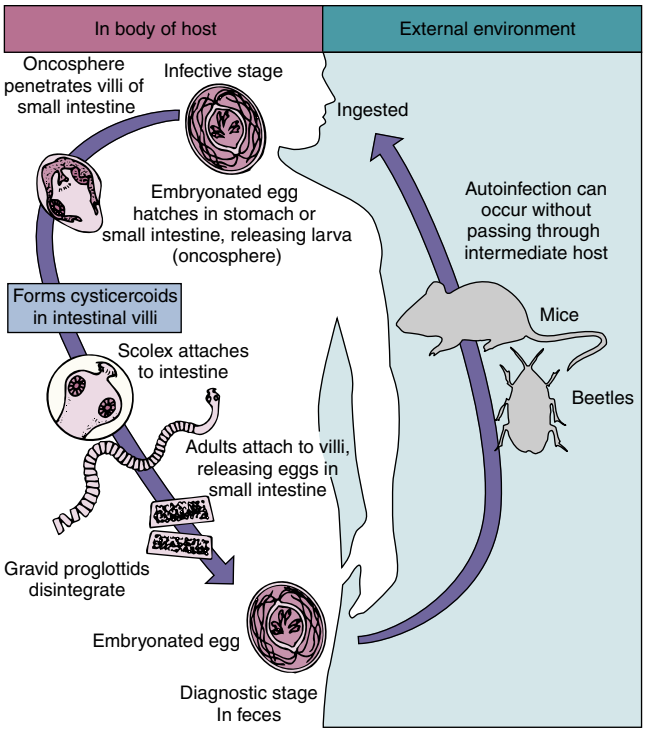

Fig. 76.12 Life cycle of *Hymenolepis nana* (dwarf tapeworm).

EPIDEMIOLOGY

H. nana occurs worldwide in humans and is a common parasite of mice. The most common tapeworm infection in North America, it occasionally develops its cysticercoid stage in beetles; humans and mice may ingest these beetles in contaminated grain and flour. Children are especially at risk of infection, and because of the simple life cycle of the parasite, families with children in day-care centers experience problems in controlling the transmission of this organism.

CLINICAL SYNDROMES

With only a few worms in the intestine, there are no symptoms. In heavy infections, especially if autoinfection and hyperinfection occur, patients experience diarrhea, abdominal pain, headache, anorexia, and other vague complaints.

LABORATORY DIAGNOSIS

Stool examination reveals the characteristic *H. nana* egg with its six-hooked embryo and polar filaments (Fig. 76.13). Neither culture, serology, antigen detection, nor nucleic acid detection techniques are relevant for the detection and identification of *H. nana*.

TREATMENT, PREVENTION, AND CONTROL

The drug of choice is praziquantel; an alternative is niclosamide. Treatment of cases, improved sanitation, and proper personal hygiene, especially in the family and institutional environments, are essential for controlling the transmission of *H. nana*.

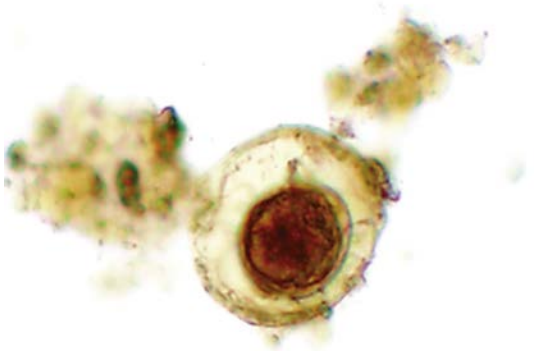

Fig. 76.13 *Hymenolepis nana* egg. The eggs are 30 to 45 μm in diameter and have a thin shell containing a six-hooked embryo.

Fig. 76.14 *Hymenolepis diminuta* egg. The eggs are large (70 to 85 μm × 60 to 80 μm) and have a six-hooked embryo surrounded by a membrane that is widely separated from the outer shell.

Hymenolepis diminuta

PHYSIOLOGY AND STRUCTURE

H. diminuta, closely related to *H. nana*, is primarily a tapeworm of rats and mice, but it is also found in humans. It differs from *H. nana* in length, measuring 20 to 60 cm. The scolex lacks hooklets, and the egg is larger and bile stained and has no polar filaments (Fig. 76.14). The life cycle of *H. diminuta* is more complex than that of *H. nana*, and it requires larval insects ("mealworms") to reach the infective cysticercoid stage.

EPIDEMIOLOGY

Infections have been found all over the world, including in the United States. Larval beetles and other larval insects become infected when they feed on rat feces that carry *H. diminuta* eggs. Humans are infected by ingesting the larval insects (mealworms) in contaminated grain products (e.g., flour, cereals).

CLINICAL SYNDROMES

Mild infections produce no symptoms, but heavier worm burdens produce nausea, abdominal discomfort, anorexia, and diarrhea.

LABORATORY DIAGNOSIS

Stool examination demonstrates the characteristic bile-stained egg that lacks polar filaments.

TREATMENT, PREVENTION, AND CONTROL

The drug of choice is niclosamide, with praziquantel an alternative. Rodent control in areas in which grain products are produced or stored is essential. Thorough inspection of uncooked grain products to detect mealworms is also important.

Dipylidium caninum

PHYSIOLOGY AND STRUCTURE

D. caninum, a small tapeworm averaging about 15 cm in length, is primarily a parasite of dogs and cats, but it can infect humans, especially children whose mouths are licked by infected pets. The life cycle involves the development of larval worms in dog and cat fleas. These fleas, when crushed by the teeth of the infected pet, are carried on the tongue to the child's mouth when the child kisses the pet or the pet licks the child. Swallowing the infected flea leads to intestinal infection.

Because of the size and shape of the mature and terminal proglottids, *D. caninum* is often called the **pumpkin seed tapeworm.** The eggs are distinctive because they occur in packets covered with a tough, clear membrane. There may be as many as 25 eggs in a packet, and a single egg free of the packet is seldom seen.

EPIDEMIOLOGY

D. caninum occurs worldwide, especially in children. Its distribution and transmission are directly correlated with dogs and cats infected with fleas.

CLINICAL SYNDROMES

Light infections are asymptomatic; heavier worm burdens produce abdominal discomfort, anal pruritus, and diarrhea. Anal pruritus results from the active migration of the motile proglottid.

LABORATORY DIAGNOSIS

Stool examination reveals the colorless egg packets (Fig. 76.15), and proglottids may be in feces brought to physicians by patients.

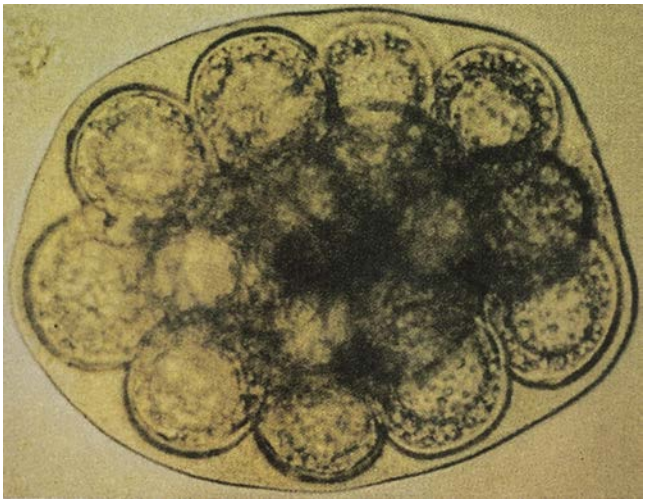

Fig. 76.15 *Dipylidium caninum* eggs. Free eggs are rarely seen. Instead, egg packets that contain 8 to 15 six-hooked oncospheres enclosed in a thin membrane are most commonly found in fecal specimens. (From Murray, P.R., et al., 1999. Manual of Clinical Microbiology, seventh ed. American Society for Microbiology Press, Washington, DC.)

TREATMENT, PREVENTION, AND CONTROL

The drug of choice is niclosamide; praziquantel and paromomycin are alternatives. Dogs and cats should be dewormed and not be allowed to lick the mouths of children. Pets should be treated to eradicate the fleas.

Case Study and Questions

A woman from Minnesota complains of abdominal pain and weight loss. Laboratory studies indicate that she has megaloblastic anemia. She is known in her community for her homemade gefilte fish and usually tastes the seasoned minced fish before cooking it.

1. Which of the following parasites is the most likely cause of her illness?
   a. *Echinococcus granulosus*
   b. *Diphyllobothrium latum*
   c. *Dipylidium caninum*
   d. *Taenia saginata*

2. How would you make the diagnosis?

3. How would you treat this patient?

77 Arthropods

A 4-year-old child with a complaint of itchy hands was brought in by her mother. The child stayed at a day-care center during the day while her mother worked. The girl had intense itching and a rash on her hands and arms for about 2 weeks. The itching became more severe and interfered with the child's sleep. On physical examination, the child appeared well nourished and cared for. The skin on her hands, wrists, and forearms appeared red and excoriated. Raised, serpiginous "tracks" were noted on the sides of her fingers, on the ventral aspects of her wrists, and in the popliteal folds. Several of the tracks were inflamed and were beginning to form pustules. The mother stated that several other children at the day-care center were experiencing a similar problem.

1. What was the likely diagnosis?
2. How would this diagnosis have been confirmed?
3. How would this child have been treated, and what advice would have been given to the mother regarding prevention?
4. Did this child require antibiotic therapy? If so, why?
5. What should have been done regarding the other children at the day-care center?

Answers to these questions are available on www.StudentConsult.com.

Summaries Clinically Significant Organisms

MYRIAPODA

Trigger Words

- Centipedes, maxillipeds, *Scolopendra,* Epsom salts, rubbish

Biology, Virulence, and Disease

- Myriapoda (formerly Chilopoda) consist of terrestrial forms such as centipedes
- Centipedes are elongated, multisegmented (15 to >181 segments), many-legged, tracheate arthropods
- Medically significant because of venomous claws that may produce a painful bite with localized swelling
- Bite of most centipedes is harmless to humans

Epidemiology

- Most centipedes are predaceous insectivores
- Found in dark, damp environments
- Human contact almost always caused by accidental exposure during outdoor activities

Diagnosis

- Gross observation of typical organism

Treatment, Prevention, and Control

- Treatment of centipede bite includes local measures (e.g., compress, Epsom salts)
- Control consists of removing rubbish near dwellings

CRUSTACEA

Trigger Words

- Crab, copepod, decapod, crayfish, intermediate host, intestinal helminth

Biology, Virulence, and Disease

- Crustaceans include familiar aquatic forms: decapods (crabs, crayfish, shrimp); copepods (water fleas)
- Several involved as intermediate hosts in life cycles of various intestinal or blood and tissue helminths

Epidemiology

- Worldwide distribution
- Helminthic diseases acquired by consuming contaminated water, ingesting uncooked flesh of intermediate host

Diagnosis

- Identification of specific helminthic parasite

Treatment, Prevention, and Control

- Depends on infecting parasite

CHELICERATA (ARACHNIDA)

Trigger Words

- Spider, scorpion, mite, tick, venom, vector

Biology, Virulence, and Disease

- Chelicerata (formerly Arachnida) include familiar terrestrial forms such as mites, ticks, spiders, scorpions
- Chelicerata have no wings or antennae; adults have four pairs of legs
- Mites and ticks serve as vectors for microbial diseases; scorpions and some spiders medically significant for venomous bites

Epidemiology

- Spiders: wood and brush piles, basements
- Scorpions: southwestern United States, Mexico, Venezuela
- Mites: worldwide
- Ticks: worldwide in wooded and rural areas

Diagnosis

- Gross morphology
- Clinical and laboratory diagnosis of specific infection
- Recognition of envenomation event

Treatment, Prevention, and Control

- Symptomatic for bites
- Specific treatment for infectious disease
- Protective clothing, insect repellent, remove brush and clutter from dwellings (inside and out)

HEXAPODA (INSECTS)

Trigger Words

Insect, mosquito, fly, flea, wasp, local reaction, vector

Biology, Virulence, and Disease

- Largest and most important of all classes of arthropods
- Accounts for ≈70% of all known species of animals; includes mosquitoes, flies, fleas, lice, roaches, bees, wasps, beetles, moths
- Body consists of head, thorax, and abdomen; one pair of antennae, three pairs of appendages, one or two pairs of wings or no wings
- Medical significance varies, related to mouthparts and feeding habits, vectors, and mechanical injury

Epidemiology

- Worldwide and extremely variable

Diagnosis

- Gross morphology
- Clinical and laboratory diagnosis of specific infection

Treatment, Prevention, and Control

- Protective clothing, insect repellent
- Insecticides, removal of habitat
- Supportive care for local reaction to bite
- Prompt removal of ticks
- Specific therapy for infection

The arthropods are the largest of the animal phyla, with more than 1 million species. The phylum Arthropoda comprises invertebrate animals with a segmented body, several pairs of jointed appendages, bilateral symmetry, and a rigid, chitinous exoskeleton that is molted periodically as the animal grows. Characteristically, arthropods develop from egg to adult by a process known as **metamorphosis.** As they mature, the organisms pass through several distinct morphologic stages, including egg, larva or nymph, pupa (certain insects), and adult. Four subphyla of arthropods are of medical importance on the basis of the number or the severity of the illnesses they cause: the Myriapoda, Crustacea, Chelicerata (Arachnida), and Hexapoda (Insecta) (Table 77.1).

The arthropods or their larvae may affect human health in many ways. Most arthropods function indirectly in human disease; they transmit but do not produce disease. Arthropods may transmit disease mechanically, as when flies carry enteric bacterial pathogens from feces to human food. Of outstanding importance is the ability of many arthropods to act as biologic **vectors and intermediate hosts** in the transmission and developmental cycle of viruses, bacteria, protozoa, and metazoa (Table 77.2). Certain arthropods may inflict direct injury by their bites or stings. Other species, such as lice, scabies mites, and tissue-invading maggots, may act as true parasites. Still other species may function as both parasites and vectors of disease.

It is not the purpose of this chapter to consider medical entomology in detail. Rather, our purpose is to provide a brief overview of several of the more important aspects of arthropods and their relationship to human disease. More detailed information on arthropods of medical importance and the therapy and control of arthropod infestations may be found in the references listed in the Bibliography.

TABLE 77.1 Medically Important Classes of Arthropods

Phylum	Subphylum	Organisms
Arthropoda	Myriapoda	Centipedes (Chilopoda), millipedes (Diplopoda)
	Crustacea	Copepods, decapods (crabs, crayfish), Pentastomes (tongue worms)
	Chelicerata (Arachnida)	Spiders, scorpions, mites, ticks
	Hexapoda (Insecta)	Flies, mosquitoes, lice, fleas, bugs, stinging insects

Myriapoda

CENTIPEDES (CHILOPODA)

Physiology and Structure

The centipedes are elongated, multisegmented (15 to more than 181 segments), many-legged, tracheate arthropods. They possess a distinct head and trunk. The body is dorsoventrally flattened, and each trunk segment bears a single pair of legs. **Maxillipeds**, or poison claws, are situated on the first segment and are used for capturing prey. The millipedes are sometimes classified with the centipedes; however, millipedes (Diplopoda) lack the poison claws of centipedes and have two pairs of legs per segment.

Epidemiology

Most centipedes are predaceous insectivores and are commonly found in dark, damp environments, such as the areas beneath logs, among trash, and inside old buildings. Human bites are almost invariably the result of accidental exposure to the organism during outdoor activities.

Clinical Syndromes

Centipede bites may be extremely painful and cause swelling at the site of the bite. Reports of the effects of centipede bites on humans are conflicting. One species, *Scolopendra gigantea,* which is found in Central and South America and the Galapagos Islands, has reportedly caused several deaths. With the exception of *Scolopendra* and related tropical genera, the bite of most centipedes is harmless to humans.

Treatment, Prevention, and Control

Treatment of a centipede bite includes local measures, such as the application of compresses of sodium bicarbonate or solutions of Epsom salts. Control consists of removing trash near dwellings.

Crustacea

The crustaceans are primarily gill-breathing arthropods of fresh and salt water. Those of medical importance are found in fresh water and serve as intermediate hosts of various worms or as endoparasites (Pentastomids or tongue worms) of reptiles, birds, and mammals, including humans (see Table 77.2).

The copepods, or water fleas, are represented by the genera *Cyclops* and *Diaptomus.* The larger crustaceans, called **decapods,** include crabs and crayfish. These crustaceans also serve as the second intermediate hosts of the lung fluke *Paragonimus westermani* (see Table 77.2).

COPEPODS

Physiology and Structure

Copepods are small, simple aquatic organisms. They lack a carapace, have one pair of maxillae, and have five pairs of biramous swimming legs. Free and parasitic forms exist. The genera *Diaptomus* and *Cyclops* are medically important.

Copepods are an intermediate host in the life cycle of several human parasites, including *Dracunculus medinensis* (dracunculiasis), *Diphyllobothrium latum* (diphyllobothriasis), *Gnathostoma spinigerum* (gnathostomiasis), and *Spirometra* species (sparganosis). Copepods have been associated with a single case of a perirectal abscess but generally are not considered a primary cause of human infection.

Epidemiology

Copepods have a worldwide distribution and serve as intermediate hosts for helminthic diseases in the United States and Canada, as well as in Europe and the tropics. Human infection with these helminthic parasites results from ingesting water contaminated with copepods or from eating the

TABLE 77.2 Select Human Illnesses Transmitted by Arthropods

Primary Vector or Intermediate Host	Disease	Etiologic Agent
CHELICERATA		
Mite: *Leptotrombidium* species	Scrub typhus (tsutsugamushi disease)	*Orientia tsutsugamushi*
Mite: *Liponyssoides sanguineus*	Rickettsial pox	*Rickettsia akari*

Mosquito: various species	Dirofilariasis	*Dirofilaria immitis*

raw or insufficiently cooked flesh of infected fish. Pseudooutbreaks of copepods present in human stool specimens submitted for ova and parasite examination have been reported from New York. As many as 40% of concentrated stools submitted for ova and parasite examination were found to contain copepods, presumably caused by contamination of a hospital water supply. The single reported case of apparent human infection with copepods occurred in this hospital.

Clinical Syndromes

The clinical signs and symptoms associated with helminthic infections in which copepods serve as intermediate hosts are described in Chapters 74 and 76. The single case of apparent human infection with copepods occurred in a 22-year-old man with Crohn disease who had a perirectal abscess. Drainage of the abscess revealed purulent material that, on microscopic examination, contained numerous copepods surrounded by leukocytes. It was hypothesized that the copepods were introduced into preexisting perirectal lesions during sitz baths that were prepared with unfiltered tap water and may have contained copepods. Although the copepods contained within the abscess material were viable and may have been successfully feeding on body tissue, it was believed that the copepods were unlikely to have been the primary cause of the abscess.

Laboratory Diagnosis

The laboratory diagnosis of helminthic infections in which copepods serve as intermediate hosts are described in Chapters 74 and 76. In general, infection is demonstrated by detection of the infecting organism by microscopic examination of clinical material.

Treatment, Prevention, and Control

Specific treatment of copepod-associated helminthic infection is covered in Chapters 74 and 76. Prevention of these infections requires attention to standard public health measures, such as the chlorination and filtration of water and thorough cooking of all fish. Infected people must not be allowed to bathe in water used for drinking, and suspect water should be avoided.

DECAPODS

The decapods include the prawns, shrimps, lobsters, crayfish, and crabs. The cephalothorax of these animals is always covered by a carapace. They have three anterior pairs of thoracic appendages that are modified into biramous maxillipeds and five posterior pairs that are developed into uniramous legs. Crabs and crayfish are medically important as the second intermediate hosts of the lung fluke *P. westermani.* The parasitic, epidemiologic, and clinical aspects of infection with *P. westermani* are described in Chapter 75. Thorough cooking of crabs and crayfish is the most effective means of preventing infection with *P. westermani.*

Pentastomida

TONGUE WORMS

The pentastomids, or **tongue worms,** are bloodsucking endoparasites of reptiles, birds, and mammals. Their taxonomic status is uncertain. Some scientists include pentastomids among the arthropods because their larvae superficially resemble those of mites. Others consider them annelids, and still others place them in an entirely separate phylum. For purposes of this discussion, they are considered with the arthropods. Based on molecular studies the Pentastomida are now considered by some experts to be a subclass within the Crustacea.

Physiology and Structure

Tongue worms are degenerate, wormlike arthropods that live primarily in the nasal and respiratory passages of reptiles, birds, and mammals. Adult pentastomids are white, cylindric, or flattened parasites that possess two distinct body regions: an anterior head, or cephalothorax, and an abdomen. The adults are elongated and may attain a length of 1 to 10 cm. The head has a mouth and two pairs of hooks. Although the abdomen may appear annulated, it is not segmented (Fig. 77.1). The pentastomids possess digestive and reproductive organs; however, they lack circulatory and respiratory systems.

The adult pentastomids are found in the lungs of reptiles (*Armillifer armillatus* and *Porocephalus crotali*) and the nasal passages of mammals *(Lingulata serrata).* Many vertebrates, including humans, may serve as intermediate hosts. The embryonated eggs are discharged in the feces or respiratory secretions of the infected definitive host and contaminate vegetation or water, which is in turn ingested by one of several possible intermediate hosts (fish, rodents, goats, sheep, or humans). The eggs hatch in the intestine, and the primary larvae penetrate the intestinal wall and attach to the peritoneum. The larvae mature in the peritoneum and develop into infective larvae, encyst in viscera, or die and become calcified. In tissue sections, encysted larvae can be identified by acidophilic glands, a chitinous cuticle, and prominent hooks, which are present in the anterior end of the organism. Subcuticular glands and striated muscle fibers may also be observed beneath the cuticle.

Humans also may become infected by ingesting the inadequately cooked flesh of infected intermediate hosts (e.g., goats, sheep) containing infective larvae. In the latter instance, the infective larvae migrate from the stomach to the nasopharyngeal tissues, where they develop into adult pentastomids and produce the symptoms of **halzoun syndrome** (see the following section Clinical Syndromes). In this case, the human host is considered a temporary definitive host.

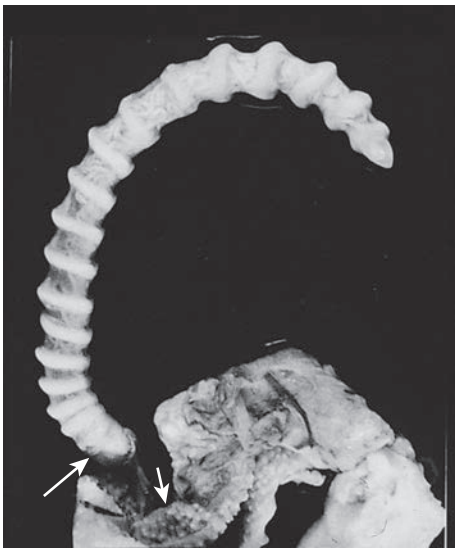

Fig. 77.1 Adult female pentastome *(Armillifer armillatus)* attached to the respiratory surface of the lung *(short arrow)* of a rock python. Note the short cephalothorax *(long arrow)* and a long, annulated abdomen. (From Binford, C.H., Connor, D.H., 1976. Pathology of Tropical and Extraordinary Diseases, vol 2. Armed Forces Institute of Pathology, Washington, DC.)

Epidemiology

Most tongue worm infections are reported in Europe, Africa, and South and Central America. The infection is common in Malaysia, in which autopsy studies reveal **pentastomiasis** in up to 45% of people. As previously described, the infection is acquired by ingesting raw vegetables or water contaminated with pentastome eggs or by consuming the raw or undercooked flesh of infected animals.

Clinical Syndromes

In most cases, infection is asymptomatic and is discovered accidentally during roentgenographic examination (calcified larvae), at surgery, or at autopsy. Pneumonitis, pneumothorax, peritonitis, meningitis, nephritis, and obstructive jaundice have all been ascribed to pentastomid infections; however, definitive proof of a causal relationship between disease and the presence of the parasite is frequently lacking. Localized infection of the eye has been reported, presumably secondary to direct inoculation.

Halzoun syndrome, caused by the attachment of adult pentastomes to the nasopharyngeal tissues, is characterized by pharyngeal discomfort, paroxysmal coughing, sneezing, dysphagia, and vomiting. Asphyxiation has been rarely reported.

Laboratory Diagnosis

The diagnosis is made by identifying a pentastomid in a biopsy specimen obtained at surgery or at autopsy. Occasionally, calcified larvae may be observed on radiographic

films of the abdomen or chest, providing a presumptive diagnosis. There are no useful serologic tests.

Treatment, Prevention, and Control

Treatment is not usually warranted. In symptomatic patients, surgical removal of free or encysted parasites should be attempted. Preventive measures include thorough cooking of meat and vegetables and avoidance of contaminated water.

Chelicerata (Arachnida)

SPIDERS

Spiders have many characteristic features that permit easy identification. Specifically, they possess eight legs, no antennae, a body divided into two regions (cephalothorax and abdomen), and an unsegmented abdomen with spinnerets posteriorly. All true spiders produce venom and kill their prey by biting; however, few have fangs **(chelicerae)** powerful enough to pierce human skin or venom potent enough to produce more than a transitory local skin irritation. Venomous spiders may be classified as those that cause **systemic arachnidism** and those that cause **necrotic arachnidism.** This classification is based on the type of tissue damage produced.

Systemic arachnidism is primarily caused by tarantulas and black widow spiders. Tarantulas (family Theraphosidae) are large, hairy spiders of the tropics and subtropics. The tarantulas are of little importance because they are not very aggressive and avoid human habitations. Their bite causes intense pain and a phase of agitation, followed by stupor and somnolence. The black widow spider, *Latrodectus mactans,* is widespread through the southern and western United States. Related species of *Latrodectus* are found throughout temperate and tropical regions of all continents, but none is primarily domestic; thus their contact with humans is limited.

Necrotic arachnidism is produced by spiders that belong to the genus *Loxosceles.* The bites of these spiders may produce severe tissue reaction. *Loxosceles reclusa,* the brown recluse spider, is a medically important spider of this genus.

Black Widow Spiders

Physiology and Structure

The female black widow spider *(L. mactans)* is easily recognized by the presence of a globose, shiny, black abdomen bearing the characteristic orange or reddish hourglass marking on the ventral surface (Fig. 77.2). Females vary from 5 to 13.5 mm in body length, but the males are much smaller.

The venom of the black widow spider is a potent peripheral neurotoxin, which is delivered by a pair of jawlike structures, or chelicerae. Only the female *Latrodectus* spider is dangerous to humans; the small, feeble male delivers an ineffective bite.

Epidemiology

These spiders frequent wood and brush piles, old wooden buildings, cellars, hollow logs, and privies. Given these locations, the bite is often located on the genitalia, buttocks, or extremities. Black widow spiders are common in the southern United States but are found throughout the temperate and tropical regions of both the New and Old World.

Fig. 77.2 Female black widow spider *(Latrodectus mactans).* (From Peters, W., 1992. A Colour Atlas of Arthropods In Clinical Medicine. Wolfe, London.)

Clinical Syndromes

As is true with most cases of envenomation, the clinical picture depends on factors such as the amount of venom injected; the location of the bite; and the age, weight, and sensitivity of the patient. Shortly after the bite, there is a sharp pain but little or no immediate swelling. This is followed by local redness, swelling, and burning. Systemic signs and symptoms generally occur within an hour of the bite and include muscular cramps, chest pains, nausea, vomiting, diaphoresis, intestinal spasms, and visual difficulties. Abdominal tetanic cramps producing a "boardlike" abdomen are highly characteristic and may mimic an acute surgical abdomen. The acute symptoms usually subside within 48 hours; however, in severe cases, paralysis and coma may precede cardiac or respiratory failure. Mortality from the bite of the black widow spider is estimated at 4% to 5%.

Treatment, Prevention, and Control

Healthy adults usually recover, but small children or weakened people suffer considerably from these bites and may die without treatment. Muscle spasms may be severe and may require the intravenous administration of calcium gluconate or other muscle relaxant agents. A specific antivenin is available and remains the treatment of choice. It is valuable if given shortly after the bite. Because it is prepared from the serum of hyperimmunized horses, patients must be tested for sensitivity to horse serum before administration. Hospitalization is advisable for the care of people with known or suspected bites.

Good housekeeping can be the simplest and most effective control for spiders in homes. This includes dusting webs and carefully removing debris from around homes and adjacent sheds. Children should be discouraged from playing on woodpiles and in woodsheds.

Brown Recluse Spiders

Physiology and Structure

Spiders producing necrotic arachnidism belong to the genus *Loxosceles.* These spiders are yellow to brown and

Fig. 77.3 Female brown recluse spider *(Loxosceles laeta).* (From Peters, W., 1992. A Colour Atlas of Arthropods in Clinical Medicine. Wolfe, London; courtesy Professor H. Schenone.)

of medium size (5 to 10 mm long) with relatively long legs (Fig. 77.3). They commonly display two distinguishing characteristics: a dark fiddle- or violin-shaped marking on the dorsal side of the cephalothorax, and six eyes arranged in three pairs forming a semicircle. The venom injected by the female or male spider is a necrotoxin (that may also have hemolytic properties) and causes necrotic lesions with deep tissue damage.

Epidemiology

Four species of the genus *Loxosceles* are found in the Americas. *L. reclusa* is found in the southern and central United States, *L. arizonica* is in the western states, and *L. laeta* is in South America. *L. reclusa* is found outdoors in woodpiles and debris in warmer climates and in basements or storage areas in cooler regions. *L. laeta* is found in closets and corners of rooms. Humans are bitten only when the spider is threatened or disturbed.

Clinical Syndromes

Initially, the bite of *Loxosceles* species tends to be painless; however, several hours later, itching, swelling, and soreness may develop in the area of the bite. Frequently a vesicle or bleb may form at the site. General systemic symptoms are unusual but when present may include chills, headache, and nausea. Within 3 to 4 days, the bleb sloughs and may be followed by ulceration and radiating necrosis, which does not heal but continues to spread for weeks or months.

Intravascular coagulation and hemolysis may occur and be accompanied by hemoglobinuria and cardiac and renal failure. This hemolytic syndrome may be life-threatening and occurs more commonly after the bite of *L. laeta.* In South America, this syndrome is known as **visceral loxoscelism.**

Diagnosis

The discrimination of a species of spider is not possible from the appearance of the lesion alone; however, a working diagnosis is commonly based on the appearance of bleb formation around puncture marks and the nature of the developing lesion. It should be noted that necrotic dermal lesions are frequently classified as loxoscelism, even if the appropriate species are not known to be present in the area. The spider may be identified easily by the characteristic features previously described. An enzyme-linked immunosorbent assay has been developed to confirm the diagnosis of brown recluse spider bite but is not widely available.

Fig. 77.4 Scorpion (*Centruroides* species). (From Peters, W., 1992. A Colour Atlas of Arthropods in Clinical Medicine. Wolfe, London; courtesy Dr. J.C. Cokendolpher.)

Treatment, Prevention, and Control

The treatment of brown recluse spider bites is variable and based on the severity of the necrotic reaction. Most bites in the United States are inconsequential and require no specific therapy. Cleansing the bite wound and providing tetanus prophylaxis and antibiotics to prevent secondary infection may all be indicated. Healing is generally uncomplicated, and debridement or excision should not be performed for 3 to 6 weeks to allow natural healing to commence. Excision and skin grafting may be necessary for bites that have not healed in 6 to 8 weeks. Systemic therapy with corticosteroids may be useful in treating the hemolytic syndrome but are of little proven value in preventing or treating cutaneous necrosis. Although not available in the United States, an antivenin is used in South America for the treatment of visceral loxoscelism.

Preventive measures are similar to those recommended for black widow spiders. *Loxosceles* (and other) spiders may be controlled in dwellings with insecticide compounds.

SCORPIONS

Physiology and Structure

The typical scorpion is elongated with conspicuous, pincer-like claws (or **pedipalps**) at the anterior end of the body, four pairs of walking legs, and a distinctly regimented abdomen that tapers to a curved, hollow, needle-like stinger (aculeus) (Fig. 77.4). When the scorpion is disturbed, it uses the stinger for defense. Both male and female scorpions can sting. Venom is injected through the stinger from two venom glands in the abdomen. Most scorpions are unable to penetrate human skin or inject enough venom to cause real damage; however, a few species are capable of inflicting painful wounds that may cause death.

Epidemiology

Scorpions considered dangerous may be found in the southwestern United States, Mexico, and Venezuela. This includes several species of the genus *Centruroides,* which accounts for as many as 1000 deaths annually. Also important are several species of *Tityus,* found in Trinidad, Argentina, Brazil, Guyana, and Venezuela. Children younger than 5 years are most likely to be fatally stung by scorpions.

Scorpions are nocturnal, and during the day, they remain concealed under logs or rocks and in other dark, moist places. At night they may invade human habitations, where they may hide in shoes, towels, clothing, and closets.

Clinical Syndromes

The effect of a scorpion sting in a patient is highly variable and depends on factors such as the species and age of the scorpion; the kind and amount of venom injected; and the age, size, and sensitivity of the person who was stung. Although the sting of many scorpions is relatively nontoxic and produces only local symptoms, other stings may be quite serious. Scorpions produce two types of venom: a neurotoxin and a hemorrhagic or hemolytic toxin. The hemolytic toxin is responsible for local reactions at the site of the sting, including radiating, burning pain; swelling; discoloration; and necrosis. The neurotoxin produces minimal local reaction but rather severe systemic effects, including chills, diaphoresis, excessive salivation, difficulty speaking and swallowing, muscle spasm, tachycardia, and generalized seizures. In severe cases death may result from pulmonary edema and respiratory paralysis.

Diagnosis

Local or systemic signs and symptoms coupled with physical evidence of a single point of skin penetration are usually sufficient to establish the diagnosis. The patient may have observed the scorpion or brought it in for identification. Although scorpions are relatively easy to identify, it is important to realize that other nonvenomous arachnids strongly resemble scorpions. An entomologist or parasitologist should be consulted if there is a taxonomic question.

Treatment, Prevention, and Control

The management of scorpion stings varies. In the absence of systemic symptoms, palliative treatment may be all that is necessary. Pain may be relieved by analgesics or local injection of Xylocaine; however, opiates appear to increase toxicity. Local cryotherapy (cold packs) may reduce swelling and retard the systemic absorption of the toxin. Hot packs produce vasodilation and may accelerate toxin distribution systemically and are therefore contraindicated. Antivenin is available and is effective if administered soon after the sting. Antivenin is usually species-specific and without the identification of the offending agent would be administered on a presumptive basis according to the most common species in the area. Very young children with systemic symptoms should be treated as medical emergencies. Systemic symptoms and shock should be treated supportively.

Preventive measures include the use of chemical pesticides to reduce scorpion populations. Removal of debris around dwellings can reduce hiding and breeding places.

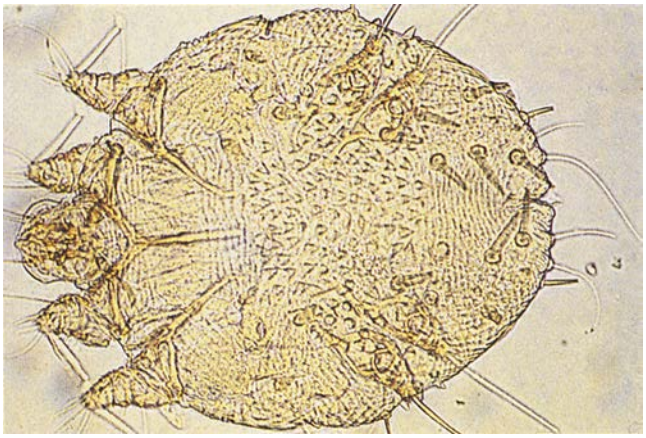

Fig. 77.5 Scabies mite (*Sarcoptes* species). (From Peters, W., 1992. A Colour Atlas of Arthropods in Clinical Medicine. Wolfe, London.)

MITES

Mites are small, eight-legged arthropods characterized by a saclike body and no antennae. A large number of mite species are free-living or are normally associated with other vertebrates (e.g., birds, rodents) and may cause dermatitis in humans on rare occasions. The number of mites that are considered true human parasites or present real medical problems is quite small and include the house mouse mite *(Liponyssoides sanguineus)* human itch mite *(Sarcoptes scabiei),* the human follicle mite *(Demodex folliculorum),* and the chigger mite (*Leptotrombidium deliense* or *L. akamushi*). Mites affect humans in three ways: by causing dermatitis, by serving as vectors of infectious diseases, and by acting as a source of allergens.

Itch Mites

Physiology and Structure

The itch mite *(S. scabiei)* causes an infectious skin disease variably known as **scabies, mange, or the itch.** The adult mites average 300 to 400 μm in length with an oval, saclike body in which the first and second pairs of legs are widely separated from the third and fourth pairs (Fig. 77.5). The body has dorsal transverse parallel ridges, spines, and hairs. The ova measure 100 to 150 μm.

Adult mites enter the skin, creating serpiginous burrows in the upper layers of the epidermis. The female mite lays her eggs in the skin burrows, and the larval and nymph stages that develop also burrow in the skin. The female mites live and deposit eggs and feces in epidermal burrows for up to 2 months. Characteristically, the preferred sites of infestation are the interdigital and popliteal folds, the wrist and inguinal regions, and the inframammary folds. The presence of the mites and their secretions cause intense itching of the involved areas. The mite is an obligate parasite and can perpetuate itself in a single host indefinitely.

Epidemiology

Scabies is cosmopolitan in distribution, with an estimated global prevalence of about 300 million cases. The mite is an obligate parasite of domestic animals and humans; however, it may survive for hours to days away from the host, facilitating its spread. Transmission is accomplished by direct contact or by contact with contaminated objects

such as clothing. Sexual transmission has been well documented. Spread of the infection to other areas of the body is accomplished by scratching and manual transfer of the mite by the affected person. Scabies may occur in epidemic fashion among people in crowded conditions, such as day-care centers, nursing homes, military camps, and prisons.

Clinical Syndromes

The outstanding clinical diagnostic symptom is intense itching, usually in the interdigital folds and sides of the fingers, buttocks, external genitalia, wrists, and elbows. The uncomplicated lesions appear as short, slightly raised cutaneous burrows. At the end of the burrow, there is frequently a vesicle containing the female mite. The intense pruritus usually leads to excoriation of the skin secondary to scratching, which in turn produces crusts and secondary bacterial infection. Patients experience their first symptoms within weeks to months after exposure; however, the incubation period may be as little as 1 to 4 days in persons sensitized by prior exposure. Host hypersensitivity (delayed or type IV) probably plays an important role in determining the variable clinical manifestations of scabies.

Some immunodeficient people may develop a variant of scabies, so-called **Norwegian scabies,** characterized by generalized dermatitis with extensive scaling and crusting and the presence of thousands of mites in the epidermis. This disease is highly contagious and suggests that host immunity also plays a role in suppressing *S. scabiei.*

Diagnosis

The clinical diagnosis of scabies is based on the characteristic lesions and their distribution. The definitive diagnosis of scabies depends on the demonstration of the mite in skin scrapings. Because the adult mite is most frequently found in the terminal portions of a fresh burrow, it is best to make scrapings in these areas. The scrapings are placed on a clean microscope slide, cleared by the addition of one or two drops of a 20% solution of potassium hydroxide, covered with a coverslip, and examined under a low-power microscope. With experience, the mite and ova may be recognized. Skin biopsy also may reveal the mites and ova in tissue sections.

Treatment, Prevention, and Control

The standard, and very effective, treatment for scabies is 1% gamma benzene hexachloride (lindane) in a lotion base. One or two applications (head to toe) at weekly intervals is effective against scabies. Lindane is absorbed through the skin, and repeated applications may be toxic. For this reason its use is not advisable in treating infants, small children, or pregnant or lactating women.

Recently, A 5% permethrin cream (Elmite) has replaced lindane lotions as the treatment of choice for scabies. Clinical trials have shown permethrin to be more effective and less toxic than lindane. Other preparations used to treat scabies include oral ivermectin, crotamiton sulfur (6%) preparations, benzyl benzoate, and tetraethylthiuram monosulfide. The last two preparations are not available in the United States.

Primary prevention of scabies is best achieved with good hygiene habits, personal cleanliness, and routine washing of clothing and bed linens. Secondary prevention includes the identification and treatment of infected people and possibly their household and sexual contacts. In an epidemic situation, simultaneous treatment of all affected people and their contacts may be necessary. This is followed by thorough cleansing of the environment (e.g., boiling clothing and linens) and ongoing surveillance to prevent recurrence.

Human Follicle Mites

Physiology and Structure

The human follicle mites include two species of the genus *Demodex, D. folliculorum,* and *D. brevis.* These mites are minute (0.1 to 0.4 mm) organisms with a wormlike body, four pairs of stubby legs, and an annulate abdomen. *D. folliculorum* parasitizes the hair follicles of the face of most adult humans, whereas *D. brevis* is found in the sebaceous glands of the head and trunk.

Epidemiology

Organisms of the *Demodex* genus are obligate parasites of the human integument and are cosmopolitan in their distribution. Infestations are uncommon in young children and increase at the time of puberty. It is estimated that 50% to 100% of adults are infested with these mites.

Clinical Syndromes

The role of *Demodex* species in human disease is uncertain (Clinical Case 77.1). They have been associated with acne, blackheads, blepharitis, abnormalities of the scalp, and truncal rashes. More recently, extensive papular folliculitis resulting from *Demodex* infestation has been described in people with acquired immunodeficiency syndrome (AIDS). Factors such as poor personal hygiene, increased sebum production, mite hypersensitivity, and immunosuppression may increase host susceptibility and enhance the clinical presentation of *Demodex* infestation. Most people infested with these mites remain asymptomatic.

Clinical Case 77.1 **Demodex Folliculitis**

Antille and colleagues (*Arch Dermatol* 140:457–460, 2004) reported a case of *Demodex* folliculitis in a 49-year-old man. The patient had rosacea for 12 years and presented with telangiectatic and papular rosacea on the cheeks and forehead. His condition had progressively deteriorated in spite of intermittent systemic treatments with ciprofloxacin. Six months previously, the patient had stopped all treatments except antihypertensive and antiuricemic therapies. An alternating treatment with clindamycin solution and 0.03% tacrolimus ointment once daily was initially effective and well tolerated. Three weeks later, however, he experienced an acute flare with intense erythema and extensive pustulation. A pustular smear revealed an abundance of *Demodex* mites, which were also seen in a biopsy specimen that confirmed the diagnosis of rosacea. Tacrolimus treatment was discontinued, and the flare resolved rapidly with systemic ciprofloxacin therapy. Ciprofloxacin therapy was stopped 1 month later, and there was no relapse during an 11-month follow-up. This case is an example of a situation in which the immunosuppressive properties of tacrolimus facilitated the overgrowth of follicular *Demodex* mites, resulting in a pustular dermatitis.

Diagnosis
Mites may be demonstrated microscopically in material expressed from an infested follicle. They may be seen as incidental findings in histologic sections of facial skin.

Treatment
Effective treatment consists of a single application of 1% gamma benzene hexachloride.

Chigger Mites

Physiology and Structure
Chiggers are the larvae of mites of the family Trombiculidae. The adult trombiculid mites infest grass and bushes, and their larvae (i.e., chiggers) attack humans and other vertebrates, producing severe dermatitis. The larvae have three pairs of legs and are covered with characteristic branched, feather-like hairs.

The larvae appear as minute, barely visible, reddish dots attached to the skin, on which they use their hooked mouth parts to ingest tissue fluids. Chiggers typically attach to the skin areas on which clothing is tight or restricted, such as the wrists, ankles, armpits, groin, and waistline. After feeding, the engorged larvae fall to the ground where they molt and undergo development into nymphs and adults.

Epidemiology
Chiggers that are important in North America include the larvae of *Eutrombicula alfreddugesi* and *E. splendens.* In Europe, the important species is the harvest mite, *Trombicula autumnalis.* Chiggers are a particular problem for outdoor enthusiasts, such as campers and picnickers. In Europe and the Americas, they are associated with intensely pruritic lesions; however, in Asia, Australia, and the western Pacific rim, they serve as vectors of the rickettsial disease scrub typhus or tsutsugamushi fever *(Orientia tsutsugamushi)* (see Table 77.2 and Chapter 34).

Clinical Syndromes
Saliva injected into the skin at the time of mite attachment produces an intense pruritus and dermatitis. The skin lesions appear as small erythematous marks that progress to papules and may persist for weeks. Mite larvae may be visible in the center of the reddened, swollen area. The irritation may be so severe that it causes fever and sleep disruption. Secondary bacterial infection of the excoriated lesions may occur.

Treatment, Prevention, and Control
Treatment for dermatitis caused by chiggers is largely symptomatic and consists of antipruritics, antihistamines, and steroids. The use of insect repellents such as *N,N*-9-diethyl-*m*-toluamide (DEET) may be of some help in prevention for persons going into chigger-infested areas.

TICKS

Physiology and Structure
Ticks are bloodsucking ectoparasites of a number of vertebrates, including humans. Ticks are opportunistic rather than host specific and tend to suck blood from a number of large and small animals. Ticks have a four-stage life cycle that includes the egg, larva, nymph, and adult. Although the larva, nymph, and adult are all bloodsuckers, it is the adult tick that usually bites humans.

Ticks comprise two large families, the Ixodidae, or hard ticks, and the Argasidae, or soft ticks. Soft ticks have a leathery body that lacks a hard dorsal scutum, and the mouthparts are located ventrally and are not visible from above (Fig. 77.6). Hard ticks have a hard dorsal plate or scutum, and the mouthparts are clearly visible from above (Fig. 77.7). Both hard and soft ticks serve as ectoparasites of humans. Soft ticks differ from hard ticks primarily in their feeding behavior. Soft ticks complete engorgement in a matter of minutes or at most a few hours; hard ticks feed slowly, taking 7 to 9 days to become engorged.

Epidemiology
Ticks are found in wooded and rural areas worldwide. In North America, the important species of hard ticks include

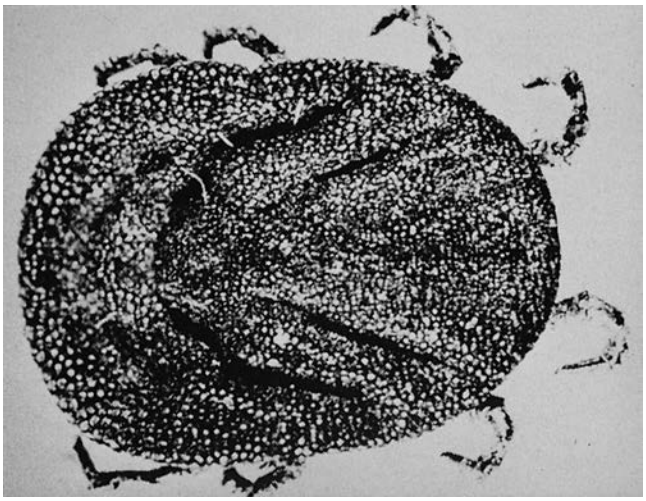

Fig. 77.6 Soft tick (*Ornithodoros* species). (From Strickland, G.T., 1991. Hunter's Tropical Medicine, seventh ed. WB Saunders, Philadelphia, PA.)

Fig. 77.7 Hard tick (Ixodes dammini). (From Peters, W., 1992. A Colour Atlas of Arthropods in Clinical Medicine. Wolfe, London; courtesy Professor A. Spielman.)

Dermacentor variabilis (the American dog tick), *D. andersoni* (the Rocky Mountain wood tick), *Amblyomma americanum* (the lone star tick), *Rhipicephalus sanguineus* (the brown dog tick), and *Ixodes dammini* (the deer tick). These ticks are found variably throughout the United States and are important vectors of several infectious diseases, including Rocky Mountain spotted fever (*Dermacentor* species), tularemia (*Dermacentor* species), Q fever (*Dermacentor* species), Lyme disease (*Ixodes* species), babesiosis (*Ixodes* species), and ehrlichiosis (*D. variabilis* and *A. americanum*) (see Table 77.2). Soft ticks of the genus *Ornithodoros* transmit relapsing fever spirochetes *(Borrelia* species*)* in limited areas in the West (see Table 77.2). In general, people at risk for tick exposure are involved in outdoor activities in wooded areas. Tick exposure may also occur during stays in rural cabins inhabited by small rodents, which commonly serve as hosts for ticks and other ectoparasites.

Clinical Syndromes

Tick bites are generally of minor consequence and are limited to small erythematous papules (Clinical Case 77.2). More serious consequences of tick bite include the development of a type of paralysis (tick paralysis) or a hypersensitivity (red meat allergy) reaction resulting from substances released by ticks during feeding and transmission of a number of rickettsial, bacterial, viral, spirochetal, and protozoan diseases of humans and other animals.

Ticks may attach at any point on the body but typically favor the scalp, hairline, ears, axillae, and groin. The initial bite is usually painless, and the presence of the tick may not be detected for several hours after contact. After the tick has dropped off or has been removed manually, the area may become reddened, painful, and pruritic. The wound may become secondarily infected and necrotic requiring antibiotic therapy. It should be noted that on removal of the tick the mouthparts often remain imbedded in the skin. Removal of the mouthparts is not critical as they will either be walled off as a foreign body or be worked out in the process of scratching.

Clinical Case 77.2 **African Tick Bite Fever**

Owen and colleagues (*Arch Dermatol* 142:1312–1314, 2006) described a middle-aged woman who returned from a mission trip to Zimbabwe with an influenza-like illness and an inoculation eschar; she also had a history of travel to a game farm. Biopsy of the cutaneous lesion revealed a histopathologic pattern consistent with an infectious pathogenesis. Immunohistochemical staining confirmed the presence of rickettsial organisms. In light of the patient's history and the clinical constellation of signs and symptoms, a diagnosis of African tick bite fever was made. The patient was treated with doxycycline and had an uncomplicated course.

African tick bite fever is an illness caused by *Rickettsia africae* that has recently emerged as a significant disease among international travelers. The vector is the *Amblyomma* tick, which is endemic to sub-Saharan Africa. This is an example of just one of many rickettsial diseases transmitted by ticks.

Three species of tick, *D. andersoni, D. variabilis,* and *A. americanum,* have been reported to cause **tick paralysis.** This is characterized by an ascending flaccid paralysis, fever, and general intoxication, which may lead to respiratory compromise and death. The paralysis is caused by toxic substances released in the saliva of the tick and may be reversed by tick removal. Tick paralysis is observed more commonly in young children and when tick attachment is in opposition to the central nervous system (e.g., scalp, head, neck).

An enigmatic **red meat allergy** has been associated with the bites of Lone Star ticks in the eastern United States. Similar associations have also been reported for Europe and Australia, with sheep ticks *(I. ricinus)* and paralysis tick *(I. holocyclus),* respectively, suspected to be the culprits. A severe hypersensitivity reaction to treatment with cetuximab was found to be geographically limited and caused by IgE reactivity with **galactose-alpha-1,3-galactose (alpha-gal).** Such IgE reactivity also was associated with a newly recognized red meat allergy, which manifested as urticaria or anaphylaxis 3 to 6 hours after ingesting beef, pork, or lamb. The delayed onset of symptoms distinguishes this red meat allergy from other food allergies. Patients recalled recent multiple tick bites and subsequently detailed studies of individual cases, epidemiologic association between anti–alpha-gal IgE and Lone Star tick bites, and correlation of IgE to tick proteins and alpha-gal together have provided evidence for causality. The majority of patients have a blood type other than B, which is biologically consistent with the structural similarity of alpha-gal and the B blood group determinants. Alpha-gal is a major component of internal tick tissues, hence the demonstrated associations are biologically plausible. Specific treatment has not been described other than avoidance of red meat and tick bites; apparently the allergy will resolve in the absence of additional tick bites. This unusual example of direct, delayed injury caused by arthropod remains to be fully understood.

Ticks also are involved in the transmission of infections such as Lyme disease, Rocky Mountain spotted fever, ehrlichiosis, Colorado tick fever, relapsing fever, tularemia, Q fever, and babesiosis (see Table 77.2). The reader is referred to the appropriate sections of this book for discussion of the clinical and microbiologic aspects of these infections (see Chapters 29, 32,34, and 73).

Diagnosis

The diagnosis of tick bites and tick-borne diseases usually rests on the finding of a tick or a history of exposure to tick-infested areas. The identification of an organism as an adult tick is usually straightforward and based on the observations of an organism that is dorsoventrally flattened and possesses four pairs of legs and no visible segmentation (see Figs. 77.6 and 77.7). An entomologist or parasitologist should be consulted if further identification is desired. The diagnosis of specific tick-borne infectious diseases is covered in the respective sections of this book (see Chapters 29, 32,34, and 73).

Treatment, Prevention, and Control

Early removal of attached ticks is of primary importance and may be accomplished by steady traction on the tick body, grasped with forceps as close to the skin as possible. Care

should be taken to avoid twisting or crushing the tick, which may leave the mouthparts attached to the skin or inject potentially infectious material into the wound. Steady traction is superior to noxious stimuli or occlusive techniques for the removal of ticks. After removal, the wound should be cleansed and observed for secondary infection. Because ticks may harbor highly infectious agents, the clinician should use appropriate infection-control precautions (e.g., use of gloves, handwashing, proper disposal of ticks and contaminated material) during tick removal. Tick removal is imperative in cases of tick paralysis. Unless the tick is removed quadriplegia and respiratory paralysis may ensue; the case fatality rate without tick removal approaches 10%. Complete recovery generally is seen within 48 hours of removal.

Preventive measures used in tick-infested areas include the wearing of protective clothing that fits snugly about the ankles, wrists, waist, and neck so that ticks cannot gain access to the skin. Insect repellents, such as DEET, are generally effective. People and pets should be inspected for ticks after visits to tick-infested areas.

Hexapoda (Insecta)

The insects, or **hexapods,** constitute the largest and most important of all the classes of arthropods, accounting for approximately 70% of all known species of animals. Insects include animals such as mosquitoes, flies, fleas, lice, roaches, bees, wasps, beetles, and moths, to name just a few. The insect body is divided into three parts (head, thorax, and abdomen) and is equipped with one pair of antennae, three pairs of appendages, and one or two pairs of wings or no wings at all. The medical significance of any insect is related to its way of life, particularly its mouthparts and feeding habits. Insects may serve as vectors for a number of bacterial, viral, protozoan, and metazoan pathogens. Certain insects may serve merely as mechanical vectors for the transmission of pathogens, whereas in other insects, the pathogens undergo multiplication or cyclic development within the insect host. The methods by which the insects transmit pathogens vary and are discussed here. Insects can also be pathogens themselves by causing mechanical injury through bites, chemical injury through the injection of toxins, and allergic reactions to materials transmitted by bites or stings. There are more than 30 orders of insects, but only those of major medical importance are discussed in this section.

BLOODSUCKING DIPTERA

Diptera is the large order of flying insects. All dipterans have a single pair of functional membranous wings and various modifications of the mouthparts, which have been adapted for piercing the skin and sucking blood or tissue juices. Their most important feature is their role as mechanical or biologic vectors of a number of infectious diseases, including leishmaniasis, trypanosomiasis, malaria, filariasis, onchocerciasis, tularemia, bartonellosis, and the viral encephalitides (see Table 77.2). The bloodsucking flies include mosquitoes, sandflies, and blackflies, all of which are capable of transmitting diseases to humans. Other dipterans, such as horseflies and stable flies, are capable of inflicting painful bites but are not known to transmit human pathogens. Although the common housefly does not bite, it certainly is capable of mechanical transmission of a number of viral, bacterial, and protozoan infections to human hosts. The infectious diseases transmitted by bloodsucking flies are well covered in other chapters of this book (see Chapters 29, 73, and 74). The following section deals only with injury resulting from the bite of these insects and the effects of salivary substances introduced into the human skin and tissues.

Mosquitoes

Physiology and Structure

Adult mosquitoes are small and have delicate legs, one pair of wings, long antennae, and greatly elongated mouthparts adapted for piercing and sucking. The two major subfamilies of mosquitoes (Culicidae family), the Anophelinae and the Culicidae, share a number of similarities in their life cycles and development. They lay eggs on or near water, are good fliers, and feed on nectar and sugars. The females of most species also feed on blood, which they require for each clutch of 100 to 200 eggs. Females may take a blood meal every 2 to 4 days. In the act of feeding, the female mosquito injects saliva, which produces mechanical damage to the host but also may transmit disease and produce immediate and delayed immune reactions.

Epidemiology

Within the subfamily Anophelinae, the genus *Anopheles* contains the species responsible for the transmission of human malaria. In the tropics, these mosquitoes breed continually in relation to rainfall. These species vary in their capacity for the transmission of malaria, and within each geographic area, the number of species that serve as malaria vectors is small. *A. gambiae* is an important vector of malaria in sub-Saharan Africa.

Mosquitoes from *Aedes,* the largest genus of the subfamily Culicidae, are found in all habitats, ranging from the tropics to the Arctic. This species may develop overwhelming populations in marshes, tundra, pasture, or floodwater and have a severe impact on wildlife, livestock, and humans. *A. aegypti,* the yellow fever mosquito, usually breeds in synthetic containers (flowerpots, gutters, cans) and is the primary vector of yellow fever and dengue in urban environments throughout the world.

Clinical Syndromes

Mechanical damage induced by the feeding mosquito is usually minor but may be accompanied by mild pain and irritation. The bite is usually followed within a few minutes by a small, flat weal surrounded by a red flare. The delayed reaction consists of itching, swelling, and reddening of the wound region. Secondary infection may follow as a result of scratching.

Treatment, Prevention, and Control

Medical attention is usually not sought for a bite unless secondary infection occurs. Local anesthetics or antihistamines may be useful in treating reactions to mosquito bites.

Preventive measures in mosquito-infested areas include the use of window screens, netting, and protective clothing.

Insect repellents, such as DEET, are generally effective. Mosquito-control measures that involve the use of insecticides have been effective in some areas.

Gnats and Biting Midges

Physiology and Structure

Ceratopogonids represent an assortment of tiny flies such as **gnats, midges,** and **punkies.** The majority of the flies that attack humans belong to the genus *Culicoides;* they are minute (0.5 to 4 mm long) and slender enough to pass through the fine mesh of ordinary window screens. The females suck blood and typically feed at dusk, when they may attack in large numbers.

Epidemiology

Biting midges may be important pests in beach and resort areas near salt marshes. Those of the genus *Culicoides* are the main vectors of filariasis in Africa and the New World tropics.

Clinical Syndromes

The mouthparts of biting midges are lancet like and produce a painful bite. Bites may produce local lesions lasting hours or days.

Treatment, Prevention, and Control

Local treatment is palliative, with lotions, anesthetics, and antiseptic measures. The treatment of breeding sites with pesticides and repellents may be useful against some of the common species of these pests.

Sandflies

Physiology and Structure

Sandflies, or moth flies, belong to a single subfamily of the Psychodidae, the Phlebotominae. They are small (1 to 3 mm), delicate, hairy, weak-flying insects that suck the blood of humans, dogs, and rodents. They transmit a number of infections, including leishmaniasis (see Table 77.2). Female flies become infected when they feed on infected people.

Epidemiology

Phlebotomine larvae develop in nonaquatic habitats, such as moist soil, stone walls, and rubbish heaps. In many areas, sandflies cause problems as pests. They also serve as vectors of infectious diseases, such as leishmaniasis in the Mediterranean, the Middle East, Asia, and Latin America.

Clinical Syndromes

The bite may be painful and pruritic around the local lesion. Sensitized people may have allergic reactions. **Sandfly fever** is characterized by severe frontal headaches, malaise, retroorbital pain, anorexia, and nausea.

Treatment, Prevention, and Control

Sandflies are very sensitive to insecticides, which should be applied to breeding sites and window screens. Various insect repellents also may be useful.

Blackflies

Physiology and Structure

Members of the family Simuliidae are commonly called **blackflies** or **buffalo gnats**. They are 1 to 5 mm long, are humpbacked, and have mouthparts consisting of six "blades" that are capable of tearing skin (Fig. 77.8). Blackflies are bloodsucking insects and breed in fast-flowing streams and rivers. They are of major importance as vectors of onchocerciasis (see Table 77.2).

Fig. 77.8 Blackfly (*Simulium* species), the vector of onchocerciasis. (From Peters, W., 1992. A Colour Atlas of Arthropods in Clinical Medicine. Wolfe, London; courtesy Dr. S. Meredith.)

Epidemiology

Blackflies are common in Africa and South America, where they serve as vectors of onchocerciasis. In North America, they are common around the lake regions of Canada and the northern United States. They are pests to hunters and fisherman in these areas. In large numbers, they may cause significant blood loss and pose a major threat to wild and domestic animals.

Clinical Syndromes

A variety of responses have been observed in humans after the bite of blackflies. The bite of the female can tear the skin surface and induce bleeding that continues for some time after the fly has departed. There is usually a distinct hemorrhagic spot at the site of the bite. Multiple bites may result in considerable blood loss. The bite is painful and accompanied by local inflammation, itching, and swelling.

The local reaction may also be accompanied by a systemic response that varies according to the number of bites and the sensitivity of the person. This syndrome is known as **blackfly fever** and is marked by headache, fever, and adenitis. It usually subsides within 48 hours and is considered a hypersensitivity reaction to the salivary secretions of the fly.

In addition to local and systemic responses to blackfly bites, a **hemorrhagic syndrome** has been described after bites of blackflies in certain areas of Brazil. This syndrome resembles thrombocytopenic purpura and is characterized by local and disseminated cutaneous hemorrhages associated with mucosal bleeding. It is thought that this hemorrhagic syndrome may be produced by a hypersensitivity phenomenon or response to a toxin caused by multiple blackfly bites.

Diagnosis

The blackfly bite is characteristically marked by a point of dried blood and subcutaneous hemorrhage at the wound site. In people with the hemorrhagic syndrome, platelet counts are reduced; there is a prolonged bleeding time and poor clot retraction in about half of patients.

Treatment, Prevention, and Control

Treatment includes the usual palliative measures (e.g., anesthetics, antihistamines, lotions) to relieve local pruritus and swelling. Patients with the hemorrhagic syndrome have shown marked improvement with corticosteroid therapy.

Preventive measures include protective clothing. In general, insect repellents are ineffective against blackflies. Some control is achieved by pouring insecticides into rivers and streams.

HORSEFLIES AND DEERFLIES

The family Tabanidae consists of species including horseflies, deerflies, gadflies, and mango flies that attack mainly animals. They are large, ranging in length from 7 to 30 mm. The males feed on plant juices, and the females feed on blood. In the act of biting, the female fly leaves a deep wound, causing blood to flow, which the fly laps up. The fly may serve as a mechanical vector of infectious diseases when the fly's mouthparts become contaminated on one host and transfer organisms to the next. These flies are not considered important vectors of infectious disease in humans.

MUSCOID FLIES

Physiology and Structure

The muscoid flies include three medically important insects: the housefly, *Musca domestica;* the stable fly, *Stomoxys calcitrans;* and the **tsetse flies** of the genus *Glossina.* The stable fly, often mistaken for the housefly, is a true bloodsucker capable of serving as a short-term mechanical vector of a number of bacterial, viral, and protozoal infections. The tsetse fly (Fig. 77.9) is also a biting fly and serves as the biologic vector and intermediate host for the agents of African trypanosomiasis, *Trypanosoma brucei rhodesiense* and *T. b. gambiense.* The common housefly represents a host of genera that are nonpiercing or contaminating flies. Because of their living and feeding habits, they mechanically transmit diverse agents to humans.

Epidemiology

The tsetse fly is found in the eastern and central regions of Africa, where it is of major medical and veterinary importance as the intermediate host and biologic vector of a number of trypanosomes that infect humans and animals. The housefly and stable fly are cosmopolitan in distribution and serve as indicators of poor sanitation. The housefly, *M. domestica,* lays eggs on any matter (feces, garbage, decaying plant matter) that will serve as food for developing fly larvae, or maggots. Stable flies commonly lay eggs in moist, decaying vegetable matter, such as grass clippings or compost heaps found in suburban communities.

Fig. 77.9 Tsetse fly, the vector of African trypanosomiasis. (From Peters, W., 1992. A Colour Atlas of Arthropods in Clinical Medicine. Wolfe, London; courtesy Wellcome Foundation, Berkhamsted, England.)

Prevention and Control

Control of tsetse fly populations has been problematic because of their widespread distribution in primarily rural and undeveloped areas. Insect repellents and insecticides may be effective against adult flies. Improved sanitation is important in controlling houseflies. Plant refuse should be protected from rain or should be destroyed.

MYIASIS-CAUSING FLIES

Myiasis is the term applied to the disease produced by maggots that live parasitically in human tissues (Clinical Case 77.3). Clinically, myiasis may be classified according to the body part involved (e.g., nasal, intestinal, or urinary myiasis). The number of myiasis-producing flies and the diversity in lifestyle requirements are enormous. Only the host relations and sites of predilection of some of the more important species are covered in this section.

Specific myiasis refers to myiasis caused by flies that require a host for larval development. One important example is the human botfly, *Dermatobia hominis,* which is found in the humid regions of Mexico and Central and South America. The adult botfly attaches her eggs to the abdomen of bloodsucking flies or mosquitoes, which in turn distribute the eggs while obtaining a blood meal from an animal or human. The larvae enter the skin through the wound created by the biting insect. The larvae develop over 40 to 50 days, during which time a painful lesion known as a **warble** appears. When the larvae reach maturity, they leave the host to pupate. The resulting lesion may take weeks to months to heal and may become secondarily infected. If the larva dies before leaving the skin, an abscess forms.

Semispecific myiasis is caused by flies that normally lay their eggs on decaying animal or plant matter; it develops in a host if entry is facilitated by the presence of wounds or sores. Representatives of this group include the greenbottle

Clinical Case 77.3 **Furuncular Myiasis**

Bakos and colleagues (*Arch Dermatol* 143:123–124, 2007) described a 54-year-old woman who was seen with a 2-week history of a painful inflammatory nodule on the inner aspect of her right leg. She vaguely remembered having been bitten in that area by a "bug." After 1 week of oral antibiotic treatment prescribed to relieve the surrounding inflammatory reaction, a poorly delimited nodule was observed, with a small pore on top from which a serosanguineous fluid exuded. Dermoscopy revealed a central opening surrounded by dilated blood vessels from which a yellowish structure with black barblike spines on the extremity extruded intermittently. This corresponded to the posterior extremity of *Dermatobia hominis* (human botfly) larva. The lesion was occluded with a double layer of plaster for 24 hours, and the immobile dead larva was removed with forceps and gentle squeezing. Furuncular myiasis caused by *D. hominis* is a common disease in tropical American countries. The diagnosis of furuncular myiasis should always be considered in every boil-like lesion not responding to ordinary treatment, especially in travelers returning from tropical countries.

fly, *Phaenicia;* bluebottle flies, *Cochliomyia;* and black bottle flies, *Phormia.* These flies are worldwide in distribution, and their presence is encouraged by poor sanitation. They occasionally lay their eggs on the open sores or wounds of animals and humans. Another group that causes myiasis in humans is the flesh flies, or sarcophagids. These flies have a worldwide distribution and normally breed in decomposing matter. They may deposit their larvae on foods that, if ingested, may serve as a source of infection.

Flies that produce **accidental myiasis** have no requirement for development in a host. Accidental infection may occur when eggs are deposited on oral or genitourinary openings and the resulting larvae gain entry into the intestinal or genitourinary tract. Flies that may produce accidental myiasis include *M. domestica,* which is the common housefly.

SUCKING LICE

Physiology and Structure

Although several species of lice *(Anoplura)* infest humans as blood-feeding parasites, only the body louse is important in medicine as the vector of the rickettsia of typhus and trench fevers and the vector of the spirochetes of relapsing fever (see Table 77.2). The **body louse,** *Pediculus humanus,* and the **head louse,** *P. humanus capitis,* are elongated, wingless, flattened insects with three pairs of legs and mouthpieces adapted for piercing flesh and sucking blood (Fig. 77.10). The pubic or **crab louse,** *Phthirus pubis,* has a short, crablike abdomen with clawed second and third legs (Fig. 77.11).

Epidemiology

Epidemics of head lice are reported frequently in the United States, particularly among schoolchildren. The head lice inhabit the hairs of the head and are transmitted by physical contact or sharing of hair brushes or hats. Crab lice survive on blood meals around the hairs of the pubic and perianal areas of the body. They are transmitted frequently from one person to another by sexual contact and contaminated toilet seats or clothing. Body lice are usually found on clothing. Unlike head or crab lice, they move to the body for feeding and return to the clothing after obtaining a blood meal. All of the lice inject salivary fluids into the body during the ingestion of blood, which causes varying degrees of sensitization in the human host.

Fig. 77.10 Body louse *(Pediculus humanus).* (From Peters, W., 1992. A Colour Atlas of Arthropods in Clinical Medicine. Wolfe, London; courtesy Oxford Scientific Films [Dr. R.J. Warren].)

Fig. 77.11 Crab louse *(Phthirus pubis).* (Peters, W., 1992. A Colour Atlas of Arthropods in Clinical Medicine. Wolfe, London; courtesy Dr. R.V. Southcott.)

Clinical Syndromes

Intense itching is the usual characteristic of infestation by lice **(pediculosis).** The patient may have pruritic, red

papules around the ears, face, neck, or shoulders. Secondary infection and regional adenopathy may be present.

Diagnosis

The diagnosis is made by demonstration of the lice or eggs from a patient complaining of pruritus. Frequently, the patient has noticed the insects, and the diagnosis may be made over the telephone. The eggs, or **nits,** are white, round objects that may be found attached to the hair shafts (head and crab lice) or on clothing (body lice).

Treatment, Prevention, and Control

Gamma benzene hexachloride (lindane) lotion applied to the entire body and left on for 24 hours is an effective treatment for lice. Shaving the hair of affected areas is a desirable adjunct. Adult lice in clothing must be destroyed by the application of lindane or dichlorodiphenyltrichloroethane (DDT) powder or by boiling. Lice may survive in the environment for up to 2 weeks; thus items such as brushes, combs, and bedding must be treated with a pediculicide or by boiling.

The best strategy for primary prevention is education and practice of good hygiene habits. Secondary prevention may be practiced by a policy of routine surveillance (e.g., scalp inspections) in schools, day-care centers, military camps, and other institutions. Repellents may be necessary for people who run a high risk of exposure in crowded conditions.

FLEAS

Physiology and Structure

Fleas *(Siphonaptera)* are small, wingless insects with laterally compressed bodies and long legs adapted for jumping (Fig. 77.12). Their mouthparts are adapted for sucking or "siphoning" blood from the host.

Epidemiology

Fleas are cosmopolitan in distribution. Most species are adapted to a particular host; however, they can readily feed on humans, particularly when deprived of their preferred host. Fleas are important as vectors of plague and murine typhus and as intermediate hosts for dog (*Dipylidium caninum*) and rodent (*Hymenolepis* species) tapeworms that occasionally infect humans.

In contrast to the majority of fleas that do not invade the human integument, the **chigoe flea,** *Tunga penetrans,* may cause considerable damage by actively invading the skin. The female chigoe flea burrows into the skin, often under the toenails or between the toes, where she sucks blood and lays her eggs. The chigoe flea is found in tropical and subtropical regions of America, as well as in Africa and the Far East. It is not known to transmit human pathogens.

Clinical Syndromes

As with the bites of other bloodsucking arthropods, flea bites result in pruritic, erythematous lesions of varying severity, which depends on the intensity of the infestation and the sensitivity of the bitten person. The irritation caused by the flea's saliva may produce physical findings that vary from small red welts to a diffuse red rash. Secondary infection may be a complication.

Fig. 77.12 Flea. (From Peters, W., 1992. A Colour Atlas of Arthropods in Clinical Medicine. Wolfe, London.)

Cutaneous invasion by the chigoe flea produces an erythematous papule that is painful and pruritic. Infested tissue can become severely inflamed and ulcerated. Secondary infection is common. In severe cases, the infestation may be complicated by tetanus or by gas gangrene, resulting in amputation.

Diagnosis

The diagnosis of flea infestation is inferred in a patient with annoying bites who is also a pet (dog or cat) owner. Examination of the patient and pet usually reveals the characteristic insect. Diagnosis of tungiasis is made by detecting the dark portion of the chigoe flea's abdomen as it protrudes from the skin surface in the center of an inflamed lesion.

Treatment, Prevention, and Control

Palliative treatment with antipruritics and antihistamines is indicated for most flea bites. Surgical removal of the chigoe flea is indicated.

Commercially available insecticides may control fleas at the source. Topically applied repellents can protect people against flea bites. Flea collars or powders on pets are also effective preventive measures.

BUGS

Physiology and Structure

Bugs refer specifically to two bloodsucking insects, the **bedbug** and the **triatomid bug** (Figs. 77.13 and 77.14). Both bugs are characterized by a long proboscis that is folded ventrally under the body when not in use. The bedbug *(Cimex lectularius)* is a reddish brown insect approximately 4 to 5 mm long. It has short wing pads but cannot fly. The triatomid, or **"kissing" bug,** has yellow or orange markings on the body and an elongated head. Triatomid bugs have wings and are aerial.

Epidemiology

Both bedbugs and triatomid bugs are nocturnal and feed indiscriminately on most mammals. Bedbugs are cosmopolitan in distribution, whereas triatomid bugs are limited

Fig. 77.13 Bedbug *(Cimex lectularius)*. (From Peters, W., 1992. A Colour Atlas of Arthropods in Clinical Medicine. Wolfe, London.)

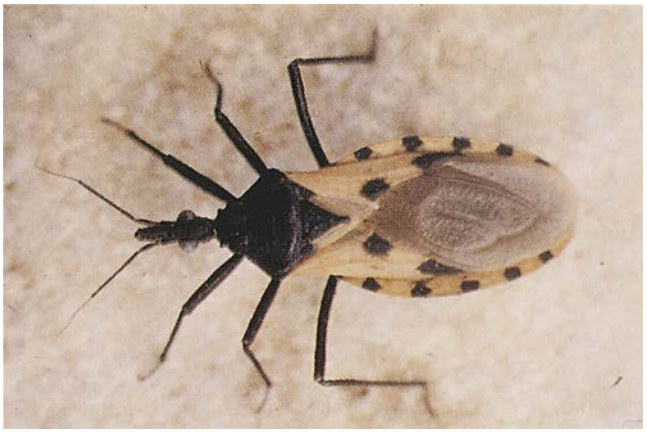

Fig. 77.14 Triatomid bug. (From Peters, W., 1992. A Colour Atlas of Arthropods in Clinical Medicine. Wolfe, London; courtesy Dr. D. Minter.)

to the Americas. Bedbugs hide during the day in cracks and crevices of wooden furniture, under loose wallpaper, in the tufts of mattresses, and in box springs. Triatomid bugs live in the cracks and crevices of walls and in thatched roofs. Bedbugs do not play a role in the transmission of human disease; however, triatomid bugs are important vectors of Chagas disease (see Table 77.2 and Chapter 73).

Clinical Syndromes

The bites of bedbugs and triatomid bugs produce lesions that range from small red marks to hemorrhagic bullae. Bedbugs tend to bite in linear fashion on the trunk and arms, whereas triatomid bugs bite with higher frequency on the face. The classic periorbital edema secondary to a triatomid bite is known as the **Romaña sign.** The intensity of reaction to a bite depends on the degree of sensitization of the patient. In addition to causing local lesions, repeated exposure to bedbug bites may (rarely) lead to anaphylactic reactions or more often be associated with nervous disorders and sleeplessness in children and adults.

Diagnosis

The pattern and location of bites suggest bedbugs or triatomid bugs. The detection of tiny spots of blood on bedding or the dead insects themselves is frequently the first sign of bedbug infestation.

Treatment, Prevention, and Control

Topical palliatives are appropriate for the relief of pruritus. Antihistamines may be indicated if dermatitis is severe. Control consists of proper hygiene and the environmental applications of insecticides. Control of bedbug infestations has become more challenging because of the development of resistance to commonly used insecticides.

STINGING INSECTS

Physiology and Structure

The order Hymenoptera comprises the bees, wasps, hornets, and ants. The modified ovipositor of the female, the apparatus for egg laying, serves as a stinging organ and is used for defense or to capture prey for food. Members of Hymenoptera are known for their complex social systems, castes, and elaborate hive or nest structures.

Epidemiology

Of the hymenopterans, the bees, or Apidae, live in complex social organizations, such as hives or in less structured underground nests. Only honeybees and bumblebees are of concern to humans because of their ability to sting. The Vespidae include wasps, hornets, and yellow jackets; all are aggressive insects and a major cause of stings in humans. In the act of stinging, the aroused insect inserts the sheath to open the wound. The thrust of the stylets and injection of venom immediately follow.

One group of ants of concern in the United States is the **fire ant**, *Solenopsis invicta.* Fire ants are particularly common in the southeastern states. They are well camouflaged in large, hard-crusted mounds and attack when disturbed. They bite their victim with strong mandibles and then sting repeatedly.

Clinical Syndromes

An estimated 50 to 100 people die each year in the United States from reactions to stings of the hymenopterans. Severe toxic reactions, such as fever and muscle cramps, can be caused by as few as 10 stings. Allergic reactions are the most serious consequence, but others include pain, edema, pruritus, and a heat sensation at the site of the sting. Anaphylactic shock from bee stings has resulted in death in some instances.

Treatment, Prevention, and Control

No satisfactory treatment has been discovered for stings. If left in the wound, the sting apparatus should be removed immediately. The injection of epinephrine is sometimes necessary to counteract anaphylaxis (emergency kits are available by prescription for sensitive people). For the relief of local discomfort, calamine lotion or a topical corticosteroid cream for more severe local lesions is helpful.

Although there are no effective repellents against these insects, their nests can be destroyed with any of several commercially available insecticidal compounds. General avoidance of areas inhabited by hymenopterans is advised for sensitive people.

Case Study and Questions

A 12-year-old boy presented with a 48-hour history of sleepiness, fatigue, and nausea. During the day before admission, he was unsteady while walking. On the day of admission, he developed diplopia and could neither stand nor walk without assistance. On physical examination, he was found to be drowsy but arousable. He was ataxic and had mild weakness of his arms and legs, but the deep tendon reflexes were brisk. Ocular convergence was poor, and there was coarse horizontal and slight vertical nystagmus. He had bilateral ptosis and bifacial weakness. An engorged tick, subsequently identified as *Dermacentor variabilis,* was found on his scalp.

1. What is the most likely diagnosis?
   a. Lyme disease
   b. Colorado tick fever
   c. Tick paralysis
   d. Guillain-Barré syndrome

2. What is the cause of this patient's signs and symptoms?

3. How would you treat this patient?

Chapter 2 Human Microbiome in Health and Disease

ANSWERS

1. The human genome consists of all the genes present in human chromosomes. These genes encode approximately 23,000 unique proteins. The microbiome genetic material includes all the genetic material present in the bacteria that live on and in us. This bacterial population contributes at least 100-fold more unique genes than the human genome.

2. Taxonomic diversity refers to the diverse population of bacterial species that compose the microbiome. The genetic diversity of this population refers to the number of unique protein-encoding genes in the microbiome. Whereas taxonomic diversity can be great (i.e., large number of different bacterial species in a community and highly variable from individual to individual), the genetic diversity is generally low in healthy individuals. This functional redundancy is necessary because the bacterial species perform a large number of critical functions to maintain health.

3. The core microbiome is the individual species of bacteria present in most individuals at a specific body site. The core microbiome typically consists of a small number of species but represents a large portion of the population. A large number of other bacterial species are less common in individuals and represent the minority population in the microbial community.

4. Diseases associated with microbiome dysbiosis include *Clostridium difficile* enterocolitis, inflammatory bowel disease, chronic wound infections, atopic dermatitis, vaginitis, and obesity.

Chapter 3 Sterilization, Disinfection, and Antisepsis

ANSWERS

1. There is not a uniform definition of *sterilization* or *disinfection.* In general, *sterilization* represents the total destruction of all microbes, including the more resilient forms such as bacterial spores, mycobacteria, nonenveloped viruses, and fungi. Examples of agents used for sterilization are ethylene oxide, hydrogen peroxide, peracetic acid, and glutaraldehyde. *Disinfection* results in the destruction of most organisms, although the more resilient microbes can survive some disinfection procedures. Examples of disinfectants include moist heat, hydrogen peroxide, and phenolic compounds. *Antisepsis* is used to reduce the number of microbes on skin surfaces. Examples of antiseptic agents include alcohols, iodophors, chlorhexidine, parachlorometaxylenol, and triclosan.

2. Disinfection is subdivided into high level, intermediate level, and low level. High-level disinfectants include moist heat, glutaraldehyde, hydrogen peroxide, peracetic acid, and chlorine compounds. Intermediate-level disinfectants include alcohols, iodophor compounds, and phenolic compounds. Low-level disinfectants include quaternary ammonium compounds. Although some agents are used for both sterilization and disinfection, the difference is the concentration of the agent and duration of treatment. The types of disinfectants used are determined by the nature of the material to be disinfected and how it will be used. If the material will be used for an invasive procedure but cannot withstand sterilization procedures (e.g., endoscopes, surgical instruments that cannot be autoclaved), then a high-level disinfectant would be used. Intermediate-level disinfectants are used to clean surfaces and instruments on which contamination with highly resilient organisms is unlikely. Low-level disinfectants are used to clean noncritical instruments and devices (e.g., blood pressure cuffs, electrodes, stethoscopes).

3. The effectiveness of moist heat is greatest when applied under pressure. This allows the temperature to be elevated. Other factors that determine the effectiveness of moist heat are the duration of exposure and penetration of the steam into the contaminated material (determined by load size and flow rate of steam). Dry heat is effective if applied at a high temperature for a long duration. Ethylene oxide sterilization is a slow process that is influenced by the concentration of the gas, relative humidity, exposure time, and temperature. The effectiveness improves with a higher concentration of ethylene oxide, elevated temperatures, and a relative humidity of 30%.

4. Iodine compounds precipitate proteins and oxidize essential enzymes. Examples include tincture of iodine and povidone-iodine (iodine complexed with polyvinylpyrrolidone). Chlorine compounds are strong oxidizing agents, although the precise mechanism of action is not well defined. Examples include elemental chlorine, hypochlorous acid, and hypochlorite ion. The most common commercial chlorine compound is bleach. Phenolic compounds act by disrupting lipid-containing membranes, resulting in a leakage of cellular contents. Examples include phenol (carbolic acid), *o*-phenylphenol, *o*-benzyl-*p*-chlorophenol, and *p-tert*-amyl-phenol. Quaternary ammonium compounds also denature cell membranes and include benzalkonium chloride and cetylpyridinium chloride.

Chapter 4 Microscopy and In Vitro Culture

ANSWERS

1. In **brightfield microscopy**, visible light passes through a condenser, then through the object under observation, and finally through a series of lenses to magnify the image. This method is the most commonly used microscopic technique to examine specimens placed on glass slides. **Darkfield microscopy** uses the same series of lenses as brightfield microscopy; however, a special condenser is used to illuminate the subject material from an oblique angle, thus the subject is brightly illuminated against a black background. This method is used to detect organisms that are too thin to be observed by brightfield microscopy (e.g., *Treponema,* the etiologic agent of syphilis). **Phase-contrast microscopy** illuminates objects with parallel beams of light that move out of phase relative to each other. This allows objects to appear as three-dimensional structures and is useful for observing internal structures. **Fluorescent microscopy** uses high-pressure mercury, halogen, or xenon vapor lamps that emit a short wavelength of light to illuminate the object. A series of filters block heat and infrared light and select a specific wavelength of light emitted by the object. This "fluorescence" is observed as a brightly illuminated object against a dark background. This technique is very useful for organisms with natural fluorescence (e.g., *Legionella*) and organisms stained with specific fluorescent dyes (e.g., *Mycobacterium*).

2. Methods of direct microscopic examination include suspending the sample in water (e.g., wet mount for fungi) or a contrasting dye (e.g., lactophenol cotton blue for fungi or iodine for parasites). Differential stains are used commonly to detect bacteria (e.g., Gram stain, acid-fast stain), parasites (e.g., iron hematoxylin and trichrome stains), and blood-borne pathogens (e.g., Giemsa stain for *Borrelia* and *Plasmodium*). A variety of acid-fast stain methods have been developed (e.g., Ziehl-Neelsen, Kinyoun, fluorochrome) that detect bacteria (*Mycobacterium, Nocardia*, and *Rhodococcus*) and parasites (*Cryptosporidium, Cyclospora*, and *Isospora*). Common fluorescent stains have been used to detect fungi (calcofluor white stain) or acid-fast organisms (auramine-rhodamine stain).

3. Biology of the organism (Does the organism have special growth requirements or require supplementation of the medium with growth factors?), site of the infection (Is the submitted specimen from the area of infection?), patient's immune response to the infection (Is the organism inactivated or killed by the patient's immune response?), and quality of the culture medium.

4. Blood agar, chocolate agar, and thioglycolate broth.

5. MacConkey agar, mannitol salt agar, xylose lysine deoxycholate agar.

Chapter 5 Molecular Diagnosis

ANSWERS

1. The gene for 16S ribosomal RNA is amplified by PCR using universal primers that recognize large groups of bacteria, and then specific sequences within the gene are amplified and sequenced to determine individual bacteria and strains.

2. The gene for 16S ribosomal RNA is amplified by PCR using universal primers that recognize large groups of bacteria, and then specific sequences within the gene are amplified and sequenced to determine individual bacteria and strains.

3. RNA can be isolated from the samples, converted to DNA with reverse transcriptase, and then amplified with a mixture of defined DNA primers by PCR (RT-PCR). The presence of specific viral sequences can then be detected by PCR using virus-specific primers.

4. Quantitative RT-PCR can be used to determine the number of genome copies.

5. In situ hybridization can be used to demonstrate the presence of HPV DNA sequences within the cells of the Pap smear. PCR assays also are available that detect, quantitate, and genotype HPV in cervical swab specimens.

6. In situ hybridization can be used to demonstrate the presence of CMV DNA sequences within the cells in the urine. PCR also can be used to detect viral sequences in the urine or the baby's blood.

7. Viral genome sequences can be detected by RT-PCR analysis of RNA isolated from blood. Specific target genes can subsequently be amplified and then sequenced to determine the basis for the resistance.

Chapter 6 Serologic Diagnosis

ANSWERS

1. Sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS-PAGE) to separate the proteins and Western blot to identify the HIV proteins are appropriate.

2. Genome detection methods, such as in situ hybridization on the Pap smear or a polymerase chain reaction (PCR) of extracts from the cells obtained during the procedure, can be used because virus proteins would be undetectable.

3. Cytopathologic effects, such as syncytia or Cowdry type A inclusion bodies, can be seen in Pap smears. Genome detection methods, such as in situ hybridization on the Pap smear or a PCR of DNA obtained from the cells or immunologic methods to detect virus antigen, can be used to detect evidence of the virus.

4. An Ouchterlony antibody diffusion or ELISA method can be used to detect fungal antigens.

5. Flow cytometry using immunofluorescence is probably the best method for identifying and quantitating CD4 and CD8 T cells.

6. ELISA is used to detect the presence and titer of anti-HIV antibody as a screening procedure for the blood supply. Western blot analysis with patient serum can be used as a qualitative means to confirm ELISA results.

7. PCR or genome sequencing can be used to detect genetic differences between strains or types of HSV.

8. Reverse transcriptase PCR and sequencing can be used to distinguish two parainfluenza viruses.

9. Rotavirus in stool can be quantitated by ELISA. During infection, there is a large enough amount of virus to be visualized by immune electron microscopy which is a qualitative method.

10. Group A *Streptococcus* can be detected by ELISA techniques, including rapid methods (similar to the over-the-counter pregnancy tests) for detecting streptolysin A and S. Fancier techniques, such as pulsed-field gel electrophoresis of restriction fragments of the chromosome and PCR, can be used to distinguish different strains. Technology is also available to sequence portions of the genome of the different strains for comparison.

Chapter 7 Elements of Host Protective Responses

ANSWERS

1. The macrophage is a phagocyte that is activated by IFN-γ and then becomes efficient at killing phagocytized (ingested) microbes and producing cytokines.

2. The lymph node is a repository for B and T cells. Evidence of infection is brought by the lymphatics or DCs and other APCs to the lymph node to activate the T cells to communicate with other cells through cytokines (like a radio) to be dispatched to take care of the problem.

3. The CD4 *T* cell is presented with the microbial problem by APCs, and it *tells* other cells to take care of the problems by producing cytokines.

4. The CD8 T cell gets activated in the lymph node and then moves to the periphery to patrol for virus-infected or tumor cells; it then grabs the perpetrator and inactivates it with an apoptotic hug.

5. Pre–B cells and B cells alter the DNA of their immunoglobulin genes to produce the genetic plans for a specific immunoglobulin, which is produced by that cell with slight modifications (somatic mutation) and a model change (class switch) when the market (T-cell–derived cytokines) tells them it is necessary, without changing the general theme of the product (variable region).

6. The plasma cell is an immunoglobulin-producing factory with a small office (nucleus) and many assembly lines (ribosomes) for making antibody.

7. The mast cell has Fc receptors for IgE that will trigger the release of histamines and other agents on binding to an allergen signal.

8. The neutrophil is very effective at phagocytosis and killing bacteria.

9. The *d*endritic cell phagocytoses antigen, processes the antigen into peptides, and brings it to the lymph node to *display*, initiate and *direct the nature of the* CD4 and CD8 T-cell responses.

Chapter 8 Innate Host Responses

ANSWERS

1. See the following table:

Factor	Action
Antimicrobial peptides	Killing of microbe
Complement: MAC	Kills gram-negative bacteria
Complement: C3b	Opsonization
Complement: C3d	Activates B cells
Complement: "a" fragments C3a, C4a, C5a	Attraction, activation and anaphylaxis
Lectins	Opsonization
C-reactive protein	Opsonization
Cytokines	Activation of responses
Chemokines	Attraction of leukocytes

MAC, Membrane attack complex.

2. Neutrophils leave the bone marrow ready to attack. Neutrophils are phagocytic and the major antibacterial response. Their granules are filled with antimicrobial substances and enzymes that are released into endosomes and leak from the cell on phagocytosis of a microbe. Neutrophils kill bacteria with antimicrobial substances from their granules and reactive oxygen species. They also release NETs of DNA to ensnare bacteria. Neutrophils are the first to be attracted to an infection and have a very short half-life. Monocytes enter later than neutrophils and mature into macrophages. Resident macrophages will also respond. Activation of macrophages with IFN-γ and TNF-α produced by ILC1 cells or T cells become M1 macrophages and maintain inflammatory antimicrobial activity. Macrophages have a long life span. M1 macrophages produce acute-phase cytokines, IL-12, and antibacterial substances such as reactive oxygen molecules, NO, and enzymes. Macrophages are also antigen-presenting cells and use the peptides presented on MHC II molecules to recruit and activate T-cell help. The M1 macrophages may progress to M2 to facilitate healing and resolution of the infection and its damage. M2 macrophages develop in the presence of IL-4, are also phagocytic, and promote wound healing and angiogenesis. DCs are the only cells that can initiate an immune response by activating naive T cells. The iDCs are also an early warning system that releases cytokines and chemokines appropriate to the microbial trigger, which will facilitate other host protections. Langerhans cells are a skin-resident DC that can also move to the lymph node to activate naive T cells. DCs are a bridge between the innate and the immune response.

3. The lipid A (endotoxin) of the LPS from the outer membrane of the enteric (probably *Escherichia coli*) bacteria in the blood binds to TLR4 on macrophages and other cells to activate the production of acute-phase cytokines (TNF-α, IL-1, and IL-6). TNF-α and IL-1 are endogenous pyrogens that promote fever production. These cytokines also induce other systemic effects. These bacteria will also activate the alternate and lectin pathways of complement, and the "a" components (C3a, C4a, and C5a) will also trigger systemic inflammatory responses.

4. The *S. aureus* infection triggers release of bactericidal peptides from epithelial and other cells, complement activation, and release of C3a and C5a to act as chemotactic and anaphylactic substances to attract neutrophils and, later, macrophages to the site. LTA will activate TLR2 to promote TNF-α and IL-1 production by macrophages, which will further promote the inflammation. Dead neutrophils produce pus.

Chapter 9 Antigen-Specific Immune Responses

ANSWERS

1. IgM molecules cannot cross the placenta. IgG binds to the FcRn (the neonatal Fc receptor for IgG), which promotes bidirectional passage across epithelial membranes.

2. Native immunoglobulin and $F(ab')_2$ molecules are divalent or multivalent and can bind to more than one cell-surface molecule, which will cross-link the cell surface.

3. IgG is produced at least 8 days after a first-time infection, and its production requires T-cell help. IgG could be present from a previous infection but not for a new strain. IgM is produced early in an infection as part of a primary response and is a good indication of a first-time infection, but 2 days after symptoms may be too early to even detect IgM.

4. Although IgG production requires T-cell help and will not be present, IgM will be present. IgM fixes complement very well and the patient is not at extensive risk for serious extracellular bacterial infections, but the patient will be at higher risk for intracellular, viral, and fungal infections. A deficiency in T cells will not affect the function or amount of complement.

5. Differentiation to a B cell requires successful recombination of the VDJ segments of the variable region, but this occurs without T-cell help. The inability to promote recombination of immunoglobulin and TCR sequences would cause severe combined immunodeficiency syndrome.

6. IgD and IgE are in very small quantities in serum; both are predominately cell associated, IgD as a membrane protein and IgE bound to its receptor on mast cells. If the person can make IgM and IgG, then he or she can make IgD because the immunoglobulin gene sequence is producing the Fc portions in the order of IgM, IgD, IgG, IgE, and IgA. It would be unlikely that a lack of expression of IgD would occur without a lack in all the rest of the genes.

Chapter 10 Immune Responses to Infectious Agents

ANSWERS

1. a. A TH2 response, which is predominantly an antibody response, will be generated to the bolus of tetanus toxoid protein presented in an "unnatural" manner. Lymph will bring the antigen to lymph nodes, in which DCs will present the protein to CD4 T cells in the absence of an inflammatory response. CD4 T cells will initiate a TH2 response and make IL-4, IL-5, IL-10, and IL-13 and present antigen to B cells to promote class switching, somatic mutation, and plasma cell production. Initial IgM production with transition to IgG production. Memory will not be efficient and regular boosters are required. The antibody that is produced will neutralize the toxin to prevent disease and facilitate phagocytosis and removal of the protein.

   b. The capsular polysaccharide will interact with surface IgM on B-1 B cells. B-1 B cells are natural B cells that originate from the fetal liver, make IgM to polysaccharides and other molecules, and proliferate on binding antigen. As a polysaccharide antigen, the response will be limited to IgM and IgM-producing plasma cells with poor memory because there is no protein in the immunogen to elicit T-cell help and a germinal center reaction. The response is transient. The antibody opsonizes the bacteria and promotes its clearance by phagocytes, especially macrophages in the spleen.

   c. The attenuated measles virus in the vaccine will activate IFN-α responses in the infected cell that will activate ILC1, NK, and NKT-cell responses, which will make small amounts of IFN-γ. DCs will become activated, process the measles viral proteins, move to the lymph node, and present antigen to CD4 and CD8 T cells while producing IL-12 to promote the generation of more IFN-γ by these TH1 cells. Production of IL-2 by CD4 T cells will promote the growth of T and B cells, including CD8 T cells. IFN-γ will also promote a class switch for B cells from IgM to IgG production. Later, the response will include a TH2 response with the maturation of the IgG response. Long-term memory cells will also be elicited. The immune response will block infection, disease, and spread of the virus. The vaccine is given after 1 year of age, and a booster immunization is necessary before high school years.

2. Characteristics of immunodeficiency diseases

Immunodeficiency Disease	Immune Defect	Susceptibility to Specific Infections
Chédiak-Higashi syndrome	Impaired release of lysosome contents into phagosome, delayed killing of phagocytized bacteria	Pyogenic infections (*Staphylococcus* and *Streptococcus*)
Chronic granulomatous disease	Inability to generate hydrogen peroxide for killing phagocytized bacteria	Recurrent infections with gram-negative and gram-positive bacteria, especially *Staphylococcus aureus* and *Pseudomonas aeruginosa*
Complement C5 deficiency	Decreased chemotaxis and bacterial killing	Bacterial infections
Complement C3 deficiency	Inhibition of complement cascade; C3 is the central actor for all the complement pathways	*Staphylococcus, Streptococcus,* and other gram-positive infections
Complement C1 deficiency	Inhibition of classical pathway	Bacterial infections
Complement C6, C7, C8, or C9 deficiency	Inability to form membrane attack complex	*Neisseria* infections
IgA deficiency	Genetic defect; insufficient cytokine production; mutation in J or secretory chains	Respiratory and gastrointestinal infections
X-linked agammaglobulinemia	CD40 deficiency (T-cell help disorder); defective pre–B-cell maturation	Bacterial and other infections; cannot undergo immunoglobulin class switch
X-linked T-cell deficiency	Defective receptor shared by IL-2, IL-7, IL-4, IL-9, or IL-15 cytokines or signaling from the receptor	Intracellular bacteria, viruses (especially herpes, JC), and fungi; inability to undergo immunoglobulin class switch
AIDS	CD4 T-cell infection by HIV, leading to their death	Intracellular bacteria, viruses (especially herpes, JC), fungi, and some parasites
DiGeorge syndrome	Lack of thymus and therefore lack of T cells	Intracellular bacteria, viruses (especially herpes, JC), and fungi; cannot undergo immunoglobulin class switch

Chapter 11 Antimicrobial Vaccines

ANSWERS

1. Inactivated vaccines are used when attenuated vaccines cannot be generated safely or when an antibody response is sufficient for protection. For rabies, influenza, and polio, antibody is sufficient to neutralize the virus and prevent spread. For HiB, antibody promotes opsonization and clearance of the bacteria; and for diphtheria, tetanus and pertussis, antibody neutralizes the toxin to prevent disease.

2. Treatment by passive immunization with antibody is like treating the infection with a drug that blocks the action of the tetanus toxin; it is immediate but lasts only approximately 2 months, until the antibody is cleared from the system. Active immunization establishes plasma cells that produce an antibody response that lasts longer and is stronger but takes time to establish.

3. The inactivated polio vaccine elicits a predominantly IgG antibody (TH2) response. This antibody does not prevent infection but it is sufficient to block progression of a poliovirus in the bloodstream from reaching its target tissue (muscle and brain), preventing the disease.

   The oral vaccine infects the individual with attenuated mutants of the three types (current vaccines only contain two types) of poliovirus to initiate a natural response to each virus, including a secretory IgA response. The IgA neutralizes any virus produced in the gastrointestinal tract, preventing it from entering the body and infecting other cells or other people. The development of memory cells is stronger and more permanent with the oral vaccine. Both vaccines prevent spread of the virus to its target tissues,

4. Vaccines to these microbes have not been developed for the following reasons:
   Rhinovirus: too many serotypes, other viruses cause similar diseases, and the disease is not life-threatening.
   Herpes simplex virus: protection requires antibody- and cell-mediated immunity but must block the initial infection to prevent spread to the neuron and establishment of latency. The virus hides from antibody by passing to other cells through the cell–cell junctions and by cell fusion (other vaccines need only block viremic spread). Attenuated viruses have not yet been developed that are sufficiently safe.
   Respiratory syncytial virus: antibody- and cell-mediated immunity must be elicited; the virus can spread from cell to cell and escape antibody control; and although there are limited strains, multiple viruses can cause similar disease.

5. These agents cause significant morbidity and mortality in the infected individual. There are limited serotypes for these agents, and stabile, safe, and relatively inexpensive vaccines can be developed.

Measles and smallpox are major killers for which there is only one serotype of virus. In addition, smallpox always causes visible disease, which allows quarantine to facilitate the success of its vaccine program and the elimination of the virus.

Mumps is problematic but usually not life-threatening; there is only one serotype, and an effective live vaccine was developed and can be administered with the measles and rubella vaccines.

The rubella vaccine was developed to establish herd immunity to reduce transmission to pregnant women and their fetus to prevent congenital disease. Again, there is only one serotype.

Tetanus vaccine is a toxoid that elicits antibody that prevents the action of the toxin. Booster immunizations are required. Tetanus is a prevalent life-threatening disease.

The acellular pertussis vaccine prevents whooping cough, which a deadly infection in young children. Increased onset of this disease in teens and adults has prompted development of a booster shot.

6. Immunization with the capsular polysaccharide for *S. pneumoniae* elicits T-cell–independent responses, IgM but not IgG antibody, and limited or no memory responses. The IgM is limited to the bloodstream. IgM opsonizes the bacteria facilitating clearance of the bacteria from the blood by spleen macrophages to prevent disease. The lung of the individual is **not** protected, and infection and spread of bacteria can occur. However, more *S. pneumoniae* types are represented in the polysaccharide vaccine to elicit broader protections for those at risk (elderly and asplenic individuals). Immunization with the conjugated polysaccharide vaccine for *S. pneumoniae* elicits T-cell–dependent immune responses that promote IgM and IgG (but not secretory IgA) and memory cell production. IgG can leak or be transported into the lung to limit the infection and spread of the bacteria. Immunity lasts much longer and does not require frequent booster immunizations.

Chapter 12 Bacterial Classification, Structure, and Replication

ANSWERS

1. *Size:* The smaller size of prokaryotes allows them to enter smaller spaces, which also means that the cells have a smaller chromosome.

   Nuclear structures: Lack of a nuclear membrane allows chromosome replication, transcription, and translation to be tied together. Inhibition of any one of them affects the others to a greater degree than for eukaryotes.

   Chromosomes: Most bacterial chromosomes are single, circular genomes. As a circular chromosome, topoisomerases are very important to relieve stress on the structure and maintain its function. As a result, these enzymes are excellent targets for antibacterial drugs (e.g., fluoroquinolones). Having only one copy of each gene (haploid genome) instead of a diploid genome means that a single mutation will inactivate a function because there is no "backup copy."

   Cytoplasmic structures: Prokaryotes lack organelles, but this does not have a big effect on bacterial infection and treatment.

   Ribosomes: The 70S (50S + 30S) provides an excellent target for antibacterial drugs because it differs so significantly from the 80S eukaryotic ribosome.

   Cytoplasmic membrane: The prokaryotic membrane contains different phospholipids. The bacterial membrane also provides the energy-generating functions of the mitochondria by maintaining a membrane potential to drive adenosine triphosphate (ATP) synthesis and provide energy for transport, motility and other functions.

   Cell wall: The bacterial cell wall is a complex structure containing protein, lipids, and peptidoglycan, which is unique to bacteria. The cell wall provides sufficient strength against osmotic shock to allow bacteria to exist in distilled water. It contains structures that promote interactions with tissues and target cells to promote and define the types of infections and diseases caused by bacteria; the enzymes that synthesize these structures are sufficiently unique to be excellent targets for antibacterial drugs (e.g., β-lactams, vancomycin, bacitracin).

2. The thickness of the gram-positive membrane facilitates its identification by the Gram stain by trapping the stain, whereas the gram-negative peptidoglycan is only a single layer thick, and the stain washes away during the procedure, requiring use of a counterstain. The LPS present in the outer membrane is the most potent activator of innate and immune host cell functions of any cell wall component and can induce fever and sepsis. As such, gram-negative bacteria are more likely to induce fever and sepsis than gram-positive bacteria. The presence of the outer membrane of gram-negative bacteria provides a unique barrier to complement and to the permeability of large and hydrophobic molecules, and it protects the peptidoglycan and other internal bacterial structures from degradative enzymes and antibacterial drugs.

3. Protection from immune responses:
   - The thick peptidoglycan of gram-positive bacteria prevents, and the O antigen of LPS of gram-negative bacteria limits, access of the complement membrane attack complex from the membrane surface.
   - The capsule protects against antibody, complement, and phagocytosis.
   - Proteins may inhibit specific functions (e.g., *Staphylococcus* protein A binds the Fc portion of immunoglobulin (Ig)G; M protein of *Streptococcus* is antiphagocytic).

Toxic responses:
- The lipid A portion of LPS provides the endotoxin activity and is a potent activator of Toll-like receptor 4 and other receptors to activate innate, immune, and inflammatory responses.
- Teichoic acid, peptidoglycan, and other cell wall components are weaker activators of pathogen pattern receptors.
- Flagellin also is an activator of a pathogen pattern receptor (Toll-like receptor 5).

4. Inhibition of peptidoglycan synthesis inhibits cell wall production and bacterial growth. Peptidoglycan is constantly being degraded, rebuilt, and reshaped. Inhibition of peptidoglycan synthesis does not prevent these autolytic processes; therefore the peptidoglycan IN A GROWING CELL will continue to degrade, become weakened, and promote the lysis of the cell.

   On inhibition of peptidoglycan synthesis by β-lactams, vancomycin, or bacitracin, the UDP-NAG-NAM-pentapeptide (the precursor with a terminal D-ala-D-ala) will build up in the cytoplasm because the chain is not extended (β-lactams, vancomycin) or because the bactoprenol translocation system is inhibited.

5. Spores are more resistant because they are not growing; they are desiccated, and they are covered with multilayers of a peptidoglycan-like material and a keratin-like protein coat.

6. EDTA will disrupt gram-negative outer membranes by removing the Mg and Ca divalent cations that bridge the phosphates of LPS units and hold them together, but it will have a minimal effect on gram-positive bacteria.

   Mild detergent will affect gram-positive bacteria to a greater extent than it affects gram-negative bacteria because the outer membrane of the latter provides some protection.

   Lysozyme will degrade the peptidoglycan of gram-positive bacteria, causing them to lyse in water, whereas the outer membrane of gram-negative bacteria poses a barrier and is a protection from lysozyme.

   Transpeptidase will have no effect on either bacterium.

   Ampicillin will inhibit peptidoglycan synthesis of both gram-positive and gram-negative bacteria because it can pass through the porin channels of the gram-negative outer membrane.

Chapter 13 Bacterial Metabolism and Genetics

ANSWERS

1. *Glycolysis:* During fermentation, each mole of glucose yields two moles of ATP and two moles of NADH. Conversion of pyruvate to acetyl-CoA produces two more NADH.

   TCA cycle: two moles GTP (equivalent to ATP) are produced plus two moles $FADH_2$ and six moles NADH, which are fed into the electron transport system.

   Electron transport: The two $FADH_2$ (four ATP) and six NADH (18 ATP) plus the two GTP (equivalent to two ATP) from the TCA cycle plus the two NADH (6 ATP) from glycolysis and the two NADH (six ATP) from conversion of pyruvate to acetyl-CoA and the two ATP from glycolysis add up to 38 ATP.

   Anaerobic conditions: Glycolysis occurs in a process called fermentation without respiration. This is not an efficient process. Anaerobic respiration can occur with electron acceptors other than oxygen, but the yield of ATP for each electron inserted into the electron transport chain is less for these electron acceptors.*Aerobic conditions:* Glycolysis, TCA cycle, and electron transport occur under aerobic conditions. This is the most efficient process for conversion of glucose to energy.

2. Anaerobic fermentation produces lactic, acetic, and SCFAs; CO_2; and hydrogen. The detrimental effect of these actions is seen in gas gangrene.

3. $N_t = 1000 \times 2^{480\ \text{min}/20\ \text{min}}$
   $N_t = 1000 \times 2^{24}$
   $N_t = 1000 \times 16{,}777{,}216$

4. A plasmid is extrachromosomal circular DNA with an origin of replication (allows replication) and often contains genes for antibiotic resistance, metabolism of unusual molecules (e.g., *Pseudomonas*), or virulence.

5. *Repression:* A repressor protein binds to the promoter sequence and prevents the polymerase from binding. For the *lac* operon, the repressor prevents expression of the gene unless lactose is present. Binding of lactose to the repressor causes it to dissociate from the DNA.

   Induction: The CAP protein binds cAMP to form a complex that enhances gene expression. cAMP is produced when levels of glucose are depleted to indicate a metabolic problem. This would enhance the expression of the *lac* operon in the presence of galactose.

   Attenuation: Translation of a protein can regulate the transcription of the gene because there is no nuclear membrane to separate these processes. The amount of tryptophan in a cell will determine the rate of synthesis of a test mRNA and peptide, which will determine whether the mRNA forms a hairpin loop. The loop will stop transcription.

6. Types of mutations:
   - Transition: purine to purine
   - Transversion: pyrimidine purine to purine
   - Missense: change in amino acid in protein
   - Nonsense: change codon to insert a stop codon into the protein
   - Frameshift: inserts or deletes one or two nucleotides to disrupt the reading of nucleotide codons
   - Null: destroys protein function (e.g., nonsense, frameshift)

   Agents:
   - DNA-reactive chemicals: alter chemical structure of nucleotide base, which may alter nucleotide pairing and cause misreading of the gene

- Frameshift mutagens: molecules (ethidium bromide) intercalate into the DNA to change the way the bases stack and interact within the double helix
- Nucleotide base analogs: cause misreading of the gene
- Radiation: produces free radicals, which alters the chemical structure of the nucleotide base
- Ultraviolet light: causes thymidine dimers, which require excision and repair

7. *Transformation:* acquisition of DNA from the extracellular space, which becomes part of the chromatin
   Transduction: infection by a bacteriophage that has acquired DNA sequences from another bacteria
   Conjugation: transfer of DNA via a sex pilus
   Transposition: acquisition of a transposon that inserts into the chromosome

8. Genetic engineering has been used to isolate genes for hormones (e.g., growth hormone, insulin), viral genes for vaccines (e.g., hepatitis B virus), and cytokine genes (e.g., interferon [IFN]-α, IFN-γ). These genes have been cloned into plasmids and expressed in large quantities to produce these proteins as drugs. In addition, DNA vaccines have been prepared in which viral or other genes are inserted into plasmids that can be expressed in mammalian cells. Expression of the gene and its protein in the vaccinated person will lead to the development of an immune response.

Chapter 14 Mechanisms of Bacterial Pathogenesis

ANSWERS

1. (1) Ingestion. Examples: *Salmonella, Shigella, Bacillus cereus, E. coli, Vibrio* species
   (2) Inhalation. Examples: *Mycobacterium* species, *Mycoplasma pneumoniae, Legionella* species, *Bordetella, Streptococcus, Chlamydia pneumoniae*
   (3) Arthropod bite. Examples: *Rickettsia, Ehrlichia, Coxiella, Francisella, Borrelia burgdorferi*

See Table 14.1 for more examples.

2. Encapsulation. Example: antiphagocytic: *S. pneumoniae*
   Intracellular growth. Example: *Francisella tularensis*
   Antiimmunoglobulin proteases. Example: *N. gonorrhoeae*
   IgG binding proteins. Example: *Staphylococcus* protein A
   Inhibition of phagolysosome fusion. Example: *Legionella, M. tuberculosis*
   Resistance to lysosomal enzymes. Example: *S. typhimurium*

3. (1) Degradative enzymes. Example: α-toxin (phospholipase C from *C. perfringens*)
   (2) A-B toxins. Example: tetanus toxoid
   (3) Superantigens: toxic shock syndrome toxin from *S. aureus*

4. As of yet, there are no successful vaccines for *S. aureus.* A recent attempt is quadrivalent and elicits antibody against the coagulase, a manganese-binding protein, and two polysaccharide antigens of the capsule. The coagulase distinguishes the more virulent *S. aureus* from *S. epidermidis.* The manganese-binding protein sequesters the ion to protect the bacteria from oxidative killing in phagocytes. Antibody to the capsule facilitates phagocytosis. There are many other potential components that could be included in such a vaccine.

Chapter 16 Laboratory Diagnosis of Bacterial Diseases

ANSWERS

1. The success of obtaining a positive blood culture from a bacteremic or fungemic patient is directly related to the volume of blood cultured. Most clinically septic patients have less than one organism per milliliter of blood. The recommendation for optimum recovery of organisms is to collect 20 ml of blood from an adult patient for each blood culture and proportionally smaller volumes from children and neonates. Two to three blood cultures should be collected during a 24-hour period.

2. *S. pyogenes* (group A *Streptococcus*) is the most common cause of bacterial pharyngitis. Other bacteria that can cause pharyngitis include *S. dysgalactiae* (group C or G *Streptococcus*), *Arcanobacterium haemolyticum, N. gonorrhoeae, C. pneumoniae,* and *M. pneumoniae. C. diphtheriae* and *B. pertussis* can also cause pharyngitis but are uncommonly isolated in the United States.

3. Organisms that cause lower respiratory tract infections (e.g., pneumonia, bronchitis, lung abscess) frequently originate from the upper respiratory tract. The appropriate specimen for the diagnosis of a lower respiratory tract infection must be free of upper respiratory tract contamination. This is assessed in the clinical laboratory by examining the specimen for the presence of squamous epithelial cells. Specimens containing many squamous epithelial cells and no predominant bacteria in association with leukocytes should not be processed for culture.

4. Currently, NAATs are used to detect *N. gonorrhoeae* and *C. trachomatis* in clinical specimens. A variety of commercial systems have been developed for this purpose. These methods are more sensitive than conventional culture techniques. Syphilis, caused by *T. pallidum,* is most commonly diagnosed by serologic methods. Darkfield microscopy can also be performed, but few laboratories have sufficient experience using this technique. The organism is too thin to be observed by Gram stain.

Chapter 17 Antibacterial Agents

ANSWERS

1. Penicillin interferes with cell wall synthesis by binding to specific PBPs, which are the regulatory enzymes (e.g., transpeptidases, transglycosylases, carboxypeptidases) responsible for construction of the peptidoglycan layer of the cell wall. Vancomycin also disrupts cell wall peptidoglycan synthesis, which in this case is gram-positive bacteria. This is accomplished by vancomycin interacting with the D-alanine-D-alanine termini of the pentapeptide side chains that form bridges between the peptidoglycan chains. Isoniazid disrupts the synthesis of mycolic acid, which is an important component of the cell wall in mycobacteria. Gentamicin, tetracycline, and erythromycin inhibit protein synthesis in bacteria. Gentamicin binds irreversibly to the 30S ribosomal proteins, leading to misreading of mRNA and premature release of the ribosome from mRNA. The tetracyclines bind reversibly to the 30S ribosomal subunits and block the binding of tRNA to the 30S ribosome–mRNA complex. Erythromycin, a macrolide antibiotic, binds reversibly to the 23S rRNA of the 50S ribosomal subunit and blocks polypeptide elongation. Polymyxin inserts into bacterial membranes, similar to detergents, by interacting with the lipopolysaccharides and phospholipids in the outer membrane, producing increased cell permeability. Ciprofloxacin, a fluoroquinolone, inhibits bacterial DNA topoisomerase type II (gyrase), which is required for DNA replication, recombination, and repair. Sulfamethoxazole is an antimetabolite that prevents synthesis of folic acid.

2. Bacteria can become resistant to β-lactam antibiotics by (1) degrading the antibiotic with β-lactamases; (2) modifying the target (i.e., PBP) so that either a new PBP is acquired by the organism or an existing PBP is altered, producing an enzymatically active PBP that is not recognized by the antibiotic; or (3) preventing access to the target by creating a permeability barrier (e.g., a change in porins in the gram-negative cell wall). ***S. aureus*** organisms become resistant to oxacillin and related β-lactams by acquiring a new PBP that is enzymatically active (e.g., can be used to build the peptidoglycan layer in the cell wall) but is not bound and inactivated by the antibiotic. ***S. pneumoniae*** organisms become resistant to penicillin when they acquire an altered PBP (through recombination). ***P aeruginosa*** can become resistant to imipenem by one of two mechanisms: (1) acquisition of a β-lactamase that degrades the carbapenem antibiotic or (2) alteration in the outer membrane of the cell wall (i.e., porin mutation) that prevents entry of the antibiotic into the cell.

3. Organisms can become resistant to aminoglycosides by (1) enzymatic modification of the antibiotic (the most common method), (2) decreased uptake of the antibiotic into the bacterial cell, (3) increased expulsion of the antibiotic from the cell, and (4) mutation of the ribosomal binding site.

4. Bacteria become resistant to quinolones by chromosomal mutations in the structural genes of the targets: DNA gyrase and topoisomerase IV. Other less common methods include decreased drug uptake caused by mutations in the membrane permeability regulatory genes and overexpression of efflux pumps that actively eliminate the drug.

5. Trimethoprim interferes with folic acid metabolism by inhibiting dihydrofolate reductase, preventing conversion of dihydrofolate to tetrahydrofolate. Sulfonamides inhibit dihydropteroic acid synthase, which functionally also inhibits folic acid synthesis but at a different step.

Chapter 18 *Staphylococcus* and Related Gram-Positive Cocci

1. Coagulase, protein A, species-specific teichoic acid; the first two are commonly used for identification of *S. aureus.*

2. *S. aureus* can produce a number of cytotoxins, including alpha toxin, beta toxin (also called sphingomyelinase C), delta toxin, gamma toxin, and Panton-Valentine (P-V) leukocidin. The latter two are bicomponent toxins (composed of two protein chains). These toxins are able to destroy many host cells, including leukocytes, erythrocytes, fibroblasts, macrophages, and platelets.

3. Exfoliative toxins (staphylococcal scalded skin syndrome [SSSS]); enterotoxin (food poisoning; toxic shock syndrome toxin-1 [TSST-1]) toxic shock syndrome (TSS).

4. Penicillinase-resistant penicillins including methicillin, oxacillin, nafcillin, and dicloxacillin. Staphylococci resistant to these penicillins (frequently called methicillin-resistant *S. aureus* [MRSA]) are resistant to all β-lactam antibiotics (penicillins, cephalosporins, β-lactams/β-lactamase inhibitors, and carbapenems).

CASE STUDY ANSWERS

1. This patient has septic arthritis caused by *S. aureus.* The organism could have been introduced into the joint either by direct extension from the skin surface, by hematogenous spread, or when the synovial fluid was originally aspirated. Although transient bacteremia with *S. aureus* can occur, this is very uncommon. Therefore without evidence of a *S. aureus* infection at another site (e.g., endocarditis), the most likely source of this organism is direct extension from the skin surface. Even though the skin surface appeared to be unbroken, localized trauma of this nature can introduce organisms into the deeper skin tissues. Alternatively, bacteria on the skin surface could have been introduced into the joint when the accumulated fluid was originally aspirated.

2. Staphylococcal diseases can be subdivided into two categories: localized pyogenic infections and disseminated toxin-mediated infections. Cutaneous infections

(e.g., impetigo, folliculitis, furuncles, carbuncles), wound infections, endocarditis, pneumonia, empyema, osteomyelitis, and septic arthritis are examples of localized pyogenic infections. Each is characterized by localized tissue destruction and abscess formation. SSSS, TSS, and staphylococcal food poisoning are examples of toxin-mediated infections. Each is characterized by disseminated symptoms and an absence of purulence.

3. *S. aureus* produces a variety of potent toxins. The disseminated toxin-mediated diseases are characterized by production of a specific toxin or group of toxins that spread systemically in the blood and are responsible for the clinical symptoms: SSSS, exfoliative toxins (ETA, ETB); TSS, TSST-1; and food poisoning, enterotoxins (A-R). Five groups of cytolytic toxins are responsible for the tissue destruction characteristic of pyogenic staphylococcal infections: alpha toxin, beta toxin (sphingomyelinase C), delta toxin, gamma toxins (five different bicomponent toxins), and P-V leukocidin toxin. P-V leukocidin is associated with fulminant wound and pulmonary infections. A variety of staphylococcal enzymes have also been implicated in disease, including coagulases (bound and free), catalase, hyaluronidase, fibrinolysin (staphylokinase), lipases, nuclease, and β-lactamases.

4. Staphylococci are protected from phagocytosis by their capsule; a loosely bound slime layer consisting of monosaccharides, proteins, and small peptides, as well as protein A.

5. Effective treatment of staphylococcal infections requires drainage of purulent collections and effective antibiotics. Because resistance to antibiotics is common, antimicrobial susceptibility tests must be performed. Almost 90% of staphylococci produce β-lactamases, so penicillin G is ineffective. β-Lactamase–resistant penicillins (e.g., methicillin, oxacillin, nafcillin, dicloxacillin) are effective and considered the drugs of choice if the antibiotics are active against the bacteria. If resistance is determined (commonplace in many hospitals), vancomycin should be used to treat serious staphylococcal infections.

Chapter 19 *Streptococcus* and *Enterococcus*

1. *S. pyogenes* colonizes the oropharynx and skin surface and causes pharyngitis, skin and soft-tissue infections, and nonsuppurative infections (rheumatic fever, glomerulonephritis); *S. agalactiae* colonizes the female genital tract and causes neonatal infections, as well as infections in pregnant women and older adults; *S. pneumoniae* colonizes the oropharynx and causes pneumonia, sinusitis, otitis media, and meningitis.

2. *Anginosus* group, abscess formation; *mitis* group, septicemia in neutropenic patients and endocarditis; *salivarius* group, endocarditis; *mutans* group, dental caries; and *bovis* group, bacteremia associated with gastrointestinal cancer and meningitis.

3. The bacteria are resistant to many commonly used antibiotics (oxacillin, cephalosporins, aminoglycosides, and vancomycin), so infections are most commonly seen in patients hospitalized for prolonged periods and receiving broad-spectrum antibiotics.

4. Staphylococci are catalase positive in contrast with streptococci and enterococci; enterococci are L-pyrrolidonyl arylamidase (PYR) positive, whereas most streptococci (except *S. pyogenes*) are PYR negative. The microscopic morphology of enterococci (gram-positive cocci in pairs) is also a distinguishing feature (staphylococci are in clusters, and most streptococci are in long chains).

CASE STUDY ANSWERS

1. Disease caused by *S. pneumoniae* is most common in young children and the elderly, which are populations that are unable to mount protective antibodies against the pneumococcal capsules. Additionally, patients with underlying pulmonary disease, such as COPD in this patient, or an antecedent viral respiratory infection that compromises the protective clearance of the ciliated respiratory epithelium, are susceptible to pneumonia caused by this organism. Other infections caused by *S. pneumoniae* include otitis media (primarily in young children), sinusitis (all age groups), meningitis (all age groups but primarily in the young and elderly), and bacteremia (usually secondary to pneumonia or meningitis). Patients with conditions that interfere with bacterial clearance, such as alcoholism, asplenia, congestive heart disease, diabetes mellitus, and chronic renal disease, are at increased risk for disseminated disease.

2. *S. pneumoniae* is able to acquire, by transformation (exchange of DNA between bacteria), DNA-encoded altered penicillin-binding proteins (e.g., PBP2x, PBP2b, PBP1a). These new penicillin-binding proteins make the bacteria less susceptible to penicillins and some cephalosporins.

3. *S. pyogenes* (group A *Streptococcus*) causes both suppurative and nonsuppurative diseases. It is the most common cause of bacterial pharyngitis and the systemic complication of scarlet fever. Other suppurative diseases include pyoderma, erysipelas, cellulites, necrotizing fasciitis, lymphangitis, and pneumonia. Nonsuppurative diseases include rheumatic fever and acute glomerulonephritis. *S. agalactiae* (group B *Streptococcus*) is an important pathogen in neonates, causing early-onset disease (bacteremia, pneumonia, meningitis) and late-onset disease (bacteremia, meningitis). *S. agalactiae* also causes disease in pregnant women, most commonly urinary tract infections, but it also causes endocarditis, meningitis, and osteomyelitis. Elderly men and women are also susceptible to disease presenting as pneumonia, bone and joint infections, and skin and soft-tissue infections. *S. dysgalactiae* is most commonly associated with pharyngitis, which is occasionally complicated by acute glomerulonephritis (but not rheumatic fever as in the case of *S. pyogenes*). *S. anginosus* causes abscesses in deep

tissues, and the viridans streptococci cause a variety of diseases, most commonly subacute bacterial endocarditis, dental caries, and abscess formation.

4. The major virulence factor of *S. pneumoniae* is the capsule, which provides antiphagocytic protection. Protein adhesins on the surface of the bacteria facilitate colonization of the oropharynx by binding to epithelial cells. Phosphorylcholine, present in the bacterial cell wall, binds to the surface of a variety of cells (endothelial, leukocytes, platelets) and allows entry into these cells, in which the bacteria are protected from opsonization and phagocytosis. Teichoic acid, peptidoglycan fragments, and pneumolysin stimulate the inflammatory response, leading to abscess formation. *S. pyogenes* has a large array of virulence factors. Bacterial antigens (e.g., lipoteichoic acid, M proteins, F protein) mediate adherence to host cells. M proteins also function to avoid opsonization and phagocytosis of the bacteria. The bacteria also produce a variety of toxins and cytolytic enzymes, including pyogenic exotoxins, streptolysins (S and O), streptokinases (A and B), deoxyribonucleases (A to D), C5a peptidase, and hyaluronidase. *S. agalactiae* primarily produces disease in hosts that are unable to mount an anticapsular antibody response (neonates, elderly). The role of hydrolytic enzymes (e.g., deoxyribonucleases, hyaluronidase, neuraminidase, proteases, hemolysins) is unknown.

5. Streptococcal toxic shock is defined as any *S. pyogenes* infection associated with sudden onset of shock and organ failure (including renal impairment, coagulopathies, liver involvement, pulmonary disease, soft-tissue necrosis, generalized erythematous rash). In contrast to staphylococcal toxic shock, which is mediated by toxic shock syndrome toxin-1 (TSST-1), streptococcal disease is characterized by the presence of bacteria in the blood and involved tissues.

6. Rheumatic fever and acute glomerulonephritis are complications of *S. pyogenes* disease. Rheumatic fever is associated with streptococcal pharyngitis but not cutaneous infections. Acute glomerulonephritis is associated with both pharyngeal and pyodermal infections, but the specific strains responsible for the complication are different.

Chapter 20 *Bacillus*

1. The emetic form of food poisoning is associated with consumption of rice contaminated with *B. cereus.* Heat-stable enterotoxin is produced when the bacteria are able to grow in the rice. Because it is an intoxication, the incubation period and duration of illness are short. The diarrheal form of disease is associated with contaminated meat and vegetables. This disease form, characterized by diarrhea, nausea, and abdominal cramps, has a longer incubation and duration of illness because the bacteria replicate in the patient's intestine.

2. *B. cereus* eye infections are typically associated with traumatic injury to the eye, in which a soil-contaminated foreign body strikes the eye, introducing the bacteria into the eye. Disease progresses rapidly because of the tissue destruction caused by the necrotic toxin, cereolysin, and phospholipase C.

CASE STUDY ANSWERS

1. Because patients with inhalation anthrax have overwhelming sepsis, cultures of the blood are the most sensitive method for detecting the organism. Although relatively few bacteria produce disease with large numbers of organisms in the blood, *B. anthracis* is an exception. This is one of the few diseases in which a Gram stain of blood may reveal the organism. Patients with inhalation anthrax also may have meningeal symptoms. For this reason, cerebrospinal fluid should also be collected for Gram stain and culture. Although respiratory secretions are frequently collected, the yield from these specimens is relatively low.

2. *B. anthracis* has genes that encode three proteins: PA, EF, and LF. When PA combines with EF, edema toxin is formed, which causes an increase in intracellular cAMP levels and subsequent edema. When PA combines with LF, lethal toxin is formed, which causes cell death by an incompletely understood mechanism(s). The other virulence factor produced by *B. anthracis* is a polypeptide capsule consisting of poly-D-glutamic acid, which interferes with phagocytosis.

3. PA binds to specific host receptors that are present on many cells and tissues (e.g., brain, heart, intestine, lung, skeletal muscle, pancreas, macrophages). After binding to the receptors, a host protease cleaves PA, with a 63-kDa fragment retained on the cell surface. These fragments self-associate, forming a pore of seven fragments. This pore can then bind three molecules of either LF or EF. LF or EF is transported into the cell when they exert their effects. LF is a metalloprotease that cleaves MAP kinase kinases, leading to cell death by undefined mechanisms. EF is an adenylate cyclase that increases the intracellular cAMP levels, resulting in edema.

4. *B. cereus* produces two enterotoxins. The heat-stable, protease-resistant enterotoxin causes the emetic, or vomiting, form of disease by an unknown mechanism. The heat-labile enterotoxin is similar to enterotoxins produced by *V. cholerae* and *E. coli* and causes a diarrheal form of disease by stimulating the adenylate cyclase–cAMP system to hypersecrete fluids.

5. Conditions associated with *B. cereus* eye infections are (1) traumatic penetrating injuries of the eye with a soil-contaminated object and (2) contamination of intravenous drugs with *B. cereus.*

Chapter 21 *Listeria* and Related Gram-Positive Bacteria

1. *Listeria* infections are associated with ingestion of contaminated foods (e.g., cheese, milk, turkey, raw vegetables) or transplacental spread from mother to infant. The most common diseases are neonatal disease, bacteremia in pregnant women, and disseminated disease,

including meningitis in these populations and immunocompromised patients. *Erysipelothrix* infections are transmitted from colonized animals (e.g., swine, turkeys) to humans. Individuals working with animals are at greatest risk (e.g., butchers, meat processors, farmers, poultry workers, fish handlers, veterinarians). Most infections are localized cutaneous infections, although endocarditis can also occur.

2. The antimicrobial susceptibility pattern for *Listeria* is similar to that of enterococci (e.g., resistant to cephalosporins and oxacillin).

3. *Erysipelothrix* morphologically resembles gram-negative rods, so an accurate diagnosis can be delayed.

4. Diphtheria is prevented by actively immunizing people with diphtheria toxoid. In the United States, children are given five injections of the toxoid combined with pertussis and tetanus antigens (DPT vaccine), followed by booster vaccination with tetanus every 10 years. The disease is seen in countries in which a vaccination program is not established.

5. Observation of gram-positive rods in a throat exudate is not specific for *C. diphtheriae* because other *Corynebacterium* species are commonly observed in throat swabs. Although experienced microbiologists may have a high index of suspicion when the bacteria are observed in a stained specimen, the accuracy of this test would be low except in an outbreak situation. Likewise, infections typically remain localized to the throat lesions, so blood cultures are usually negative. Culture is the usual laboratory method for diagnosis of diphtheria. Demonstration of toxin production is important because nontoxigenic strains have been described. Alternatively, the gene that encodes the exotoxin can be detected by polymerase chain reaction (PCR)–based nucleic acid amplification.

6. The diphtheria exotoxin is responsible for clinical disease. This is an A-B toxin (two components) that binds to the surface of heart and nerve cells, producing cardiac and neurologic symptoms.

CASE STUDY ANSWERS

1. The most common gram-positive coccobacillus that causes meningitis in immunosuppressed patients is *L. monocytogenes. S. pneumoniae,* the most common cause of bacterial meningitis in the United States, should also be considered. Although *S. pneumoniae* is a gram-positive diplococcus, the elongated cells may be mistaken for short gram-positive rods (coccobacilli) by inexperienced microscopists. However, *Listeria* are motile and produce weak β-hemolysis on blood agar media, properties not shared with *S. pneumoniae.*

2. The most common sources of this organism are soft cheeses and cold cuts. *Listeria* can multiply in these food products to high concentrations, even when stored in a refrigerator. Other sources of this organism include contaminated milk and raw vegetables, such as cabbage.

3. *Listeria* is an intracellular pathogen, which allows it to avoid phagocytosis. Virulent strains also produce cell attachment factors and hemolysins. The ability of the organism to grow at cold temperatures enables small numbers of organisms to multiply to concentrations that can cause disease.

4. Treatment of *Listeria* infections is complicated because the organism is naturally resistant to many commonly used antibiotics, including the cephalosporins. The treatment of choice for serious infections is a combination of ampicillin or penicillin with an aminoglycoside. Antimicrobial susceptibility tests must be performed because increased resistance has been noted.

Chapter 22 *Mycobacterium* and Related Acid-Fast Bacteria

1. The two most common genera that stain with the modified acid-fast stain are *Mycobacterium* and *Nocardia.* Other modified acid-fast genera include *Rhodococcus, Gordonia,* and *Tsukamurella.*

2. *Mycobacterium tuberculosis* is the best known pathogen in the genus but is uncommon in the United States. Without a travel history outside the United States, this pathogen is not the likely cause of this patient's illness. More likely, the patient has an infection with another *Mycobacterium* species or *Nocardia.*

3. *M. tuberculosis* is most commonly associated with pulmonary disease. Disease can develop after exposure to the organism, or more commonly *M. tuberculosis* establishes a chronic infection that persists in the infected individual for life. The organism can become active as immunity wanes in old age or through disease, initiate replication, and produce disease. Other mycobacteria species are opportunistic pathogens, most commonly infecting immunocompromised patients but also individuals with chronic pulmonary disease, such as bronchiectasis. *M. fortuitum* and the other "rapidly growing" mycobacteria are opportunistic pathogens introduced into wounds or contaminating intravenous catheters. The most common diseases associated with *Nocardia* are pulmonary infections and primary or secondary cutaneous infections. *Rhodococcus* is most commonly responsible for pulmonary abscesses in immunocompromised patients (particularly HIV-infected patients), and *Gordonia* and *Tsukamurella* are opportunistic pathogens most commonly responsible for catheter-associated bacteremia.

4. All acid-fast organisms are relatively slow-growing bacteria, requiring incubation for 2 to 7 days *(Nocardia, Rhodococcus, Gordonia,* and *Tsukamurella)* to as long as 1 month *(Mycobacteria).* This is particularly problematic with sputum specimens in which more rapidly growing bacteria from the oropharynx may obscure the colonies of these organisms, so preprocessing of the specimen to eliminate rapidly growing bacteria and use of selective media are required for optimum recovery. Only slow-growing mycobacteria stain uniformly with strong

acid-fast stains, but all genera will stain with weak or modified acid-fast stains. The most common mycobacterial species will appear as short, "beaded" rods, whereas *Nocardia* species form long filamentous rods. The appearance of weakly acid-fast–staining filamentous rods is sufficient for a preliminary identification of *Nocardia. Rhodococcus* initially appears as short rods and then evolves into cocci. Colonies can appear red, but this typically develops after incubation for a few days. *Gordonia* and *Tsukamurella* appear as short, weakly staining acid-fast rods.

CASE STUDY ANSWERS

1. Mycobacteria are unique in that their cell wall has long-chain (i.e., 70 to 90 carbons) mycolic acids. The unique lipid-rich cell wall renders the organisms acid-fast and resistant to detergents, common antibacterial antibiotics, and many disinfection procedures.

2. In a normal host, replication of mycobacteria stimulates helper ($CD4^+$) and cytotoxic ($CD8^+$) T cells. T cells release IFN-γ and other cytokines that activate macrophage, which can engulf and destroy the mycobacteria. Because HIV-positive patients have a depression of $CD4^+$ cells, immune clearance of mycobacteria is impeded; thus these patients have a more rapid progression of disease compared with immunocompetent patients.

3. The spectrum of clinical disease caused by *M. leprae* ranges from tuberculoid leprosy to lepromatous leprosy. Tuberculoid leprosy is a milder form characterized by hypopigmented skin macules, relatively few bacilli observed in the tissue, and a strong cellular immune reaction (positive skin test). The lepromatous form of leprosy is associated with disfiguring skin lesions, nodules, plaques, thickened dermis, and involvement of the nasal mucosa. Patients with the lepromatous form have a strong antibody response to the bacilli but a defect in cellular immunity. Because cellular immunity is responsible for the clearance of the bacilli, this defect is associated with an abundance of bacilli observed in the infected tissues.

4. Mycobacteria are relatively slow-multiplying organisms; thus prolonged therapy is required to eliminate the bacteria. Approximately 1 in every 100,000 to 1,000,000 bacteria will develop resistance to an antibiotic used for treatment. Large numbers of bacilli are typically present in an infection, so if a single antibiotic is used for treatment, resistant bacilli will be selected rapidly. Therefore multiple antibiotics prescribed over many months are commonly used to treat an infected patient.

Chapter 23 *Neisseria* and Related Genera

1. No other genera of bacteria resemble neisseriae, which appear as small, gram-negative diplococci. Members of the genus are also oxidase-positive. This property, combined with the microscopic morphology, permits a rapid preliminary diagnosis. Nonpathogenic species of *Neisseria* grow on nutrient agar; in contrast, *N. meningitidis* has variable growth on nutrient agar, and *N. gonorrhoeae* cannot grow on this medium. Biochemical properties, specifically the ability to use specific carbohydrates such as glucose and maltose, are used to differentiate these two species.

2. Pili, PorB, and Opa proteins mediate attachment and penetration of *N. gonorrhoeae* into host cells. The gonococcal lipooligosaccharide (LOS) stimulates release of tumor necrosis factor (TNF), which causes most of the symptoms associated with disease. The capsule of *N. meningitidis* protects the bacteria from phagocytosis and allows the bacteria to penetrate into host cells, in which replication occurs. Expression of LOS endotoxin is responsible for the clinical manifestations of disease.

3. Capsular proteins are used for the *N. meningitidis* vaccine, but *N. gonorrhoeae* does not have a true capsule. The surface proteins of *N. gonorrhoeae* have not been useful for production of a vaccine. Although the meningococcal vaccine provides effective protection against serotypes A, C, Y, and W135, serotype B is not a good immunogen and is not included in the vaccine. This is problematic because serotype B is one of the common serotypes responsible for meningitis or meningococcemia in the Americas and Europe.

CASE STUDY ANSWERS

1. The abundance of leukocytes in the CSF, high protein concentration, and low glucose level are consistent with bacterial meningitis. The most common causes of meningitis in a previously healthy young adult are *Streptococcus pneumoniae* (gram-positive diplococci) and *N. meningitidis* (gram-negative diplococci). The Gram stain morphology is consistent with *N. meningitidis.*

2. Exposure of healthy individuals to patients infected with *N. meningitidis* is a frightening medical event because of the rapid progression of disease. Chemoprophylaxis is recommended for individuals in close contact with the infected patient. This should be restricted to household contacts and persons sharing the same living quarters, particularly young children; daycare center or child-care contacts and frequent playmates of young children; close social contacts who were exposed to oral secretions in the week before onset (e.g., kissing, sharing eating utensils or toothbrushes); and medical staff who have an intimate exposure to patients (e.g., mouth-to-mouth resuscitation or exposure to secretions aerosolized during endotracheal intubation). The antibiotics currently recommended for chemoprophylaxis are rifampin, ciprofloxacin (adult), or ceftriaxone.

3. Other diseases caused by *N. meningitidis* include primary septicemia (meningococcemia), pneumonia, arthritis, and urethritis. Meningococcemia can progress to overwhelming DIC with shock and bilateral destruction of the adrenal glands (Waterhouse-Friderichsen syndrome).

4. The genus *Neisseria* contains two well-recognized pathogens, *N. meningitidis* and *N. gonorrhoeae,* and a variety of less pathogenic species. Both pathogenic species are able to attach and penetrate into host cells, in which they can avoid intracellular killing, replicate, and then migrate into subepithelial spaces, where an inflammatory response and subsequent tissue destruction are initiated by bacterial endotoxin.

Chapter 24 *Haemophilus* and Related Bacteria

1. *H. influenzae* type b, meningitis (in nonimmune patients); *Aggregatibacter,* endocarditis; *Pasteurella,* bite wounds.

2. Vaccination with conjugated PRP vaccines is protective.

3. Most *H. influenzae* infections are now caused by nonencapsulated strains, so detection of the capsular antigen is not useful.

4. Penicillin, an antibiotic traditionally used only for gram-positive bacteria.

CASE STUDY ANSWERS

1. Meningitis caused by *H. influenzae* is relatively uncommon, since the introduction of the conjugated *H. influenzae* type b vaccine. Disease is still seen in unvaccinated children and less commonly in elderly adults whose immunity has waned. More commonly, *H. influenzae* disease is now caused by nontypeable strains that commonly colonize the oropharynx and are able to invade the central nervous system after trauma (e.g., head injury after an automobile accident). Meningitis caused by *S. pneumoniae* and *Neisseria meningitidis* is seen most commonly in the very young and the elderly, although disease is reported for all age groups. In contrast with *H. influenzae,* vaccination has been less successful in controlling these infections.

2. This strain of *H. influenzae* is most likely a nontypeable strain, in contrast with the *H. influenzae* type b strains that caused pediatric disease before introduction of the *H. influenzae* type b vaccine.

3. Nontypeable strains of *H. influenzae* are commonly associated with sinusitis, otitis, and bronchopulmonary disease. The former two diseases are observed in previously healthy individuals, whereas the latter disease is seen most commonly in patients with underlying chronic pulmonary disease. Other species of *Haemophilus* that have been associated with clinical disease include *H. aegyptius* (conjunctivitis, Brazilian purpuric fever), *H. ducreyi* (chancroid), and *H. aphrophilus* (endocarditis).

4. *H. influenzae* requires heme (X factor) and NAD (V factor) for growth. Although both are present in blood-containing media, sheep blood agar (the most commonly used blood agar in the United States) must be heated to destroy the inhibitors of V factor. This heated agar (chocolate agar) is used for the growth of *H. influenzae.* Some other species of *Haemophilus* (e.g., *H. ducreyi, H. aphrophilus*) do not require V factor and will grow on sheep blood agar.

5. *A. actinomycetemcomitans* is an important pathogen responsible for periodontitis and, less commonly, subacute bacterial endocarditis. This organism is a normal resident in the human oropharynx.

6. *P. multocida* is associated with animal bites, exacerbation of chronic pulmonary diseases, and systemic infections in immunocompromised patients (particularly patients with hepatic disease). This organism is part of the normal oral flora of dogs and cats.

Chapter 25 Enterobacteriaceae

1. *Escherichia coli,* peritonitis; part of intestinal flora that is introduced into the peritoneum after bowel perforation. *Klebsiella pneumoniae,* pneumonia; colonize the oropharynx; aspiration of oral secretions. *Proteus mirabilis,* urinary tract infection; introduced into the urethra by migration from the colon, then passed into the bladder in which the organisms can replicate.

2. *Salmonella,* gastroenteritis, part of fecal flora of chickens; *E. coli* 0157, gastroenteritis, part of fecal flora of cattle; *Yersinia pestis,* plague, colonizes rodents and is spread to humans by a flea bite.

3. *Salmonella* serotype Typhi, typhoid fever; *Shigella dysenteriae,* gastroenteritis.

CASE STUDY ANSWERS

1. GI infections have been associated with *Escherichia, Salmonella, Shigella,* and *Yersinia.* Both *Escherichia* and *Shigella* can cause hemorrhagic colitis.

2. STEC and *S. dysenteriae* produce Shiga toxin, which is an A-B exotoxin. The five B subunits in the toxin molecule bind to specific glycolipids on the host cell (Gb3). High concentrations of the receptor are on the intestinal villi and renal endothelial cells. The A subunit is internalized, cleaved into two molecules, with one subunit binding to 28S rRNA and disrupting protein synthesis. A serious complication of this disease is HUS. In this situation, the glomerular endothelial cells are destroyed. Damage to the endothelial cells leads to platelet activation and thrombin deposition. This results in decreased glomerular filtration and acute renal failure.

3. *E. coli* can produce gastroenteritis in a variety of ways. STEC is described earlier in the chapter. ETEC produce two classes of enterotoxins: heat-labile toxins (LT-I, LT-II) and heat-stable toxins (STa, STb). These toxins produce increased levels of cAMP or cGMP, with a subsequent hypersecretion of fluids (i.e., watery diarrhea).

EPEC attach to the epithelial cells of the small intestine and produce destruction of the microvillus (A/E pathology). EAEC also produce a watery diarrhea by autoagglutinating over the epithelium of the small intestine. EIEC invade and destroy the colonic epithelium. The initial disease is characterized by watery diarrhea, but this can progress to colonic ulcers and a dysentery form of disease (fever, abdominal cramps, and blood and leukocytes in stools).

4. *Salmonella* infections can result in asymptomatic carriage, gastroenteritis, septicemia, or enteric fever (typhoid or paratyphoid fever).

5. Disease caused by *Salmonella* Typhi begins after ingestion of the organism. The bacteria pass through the cells lining the intestines and are engulfed by macrophages. The bacteria are then taken to the liver, spleen, and bone marrow, in which they are able to replicate in the macrophages. Within 2 weeks of the initial infection, the patient becomes febrile, with nonspecific complaints of headache, myalgias, malaise, and anorexia. The bacteria are able to spread from the liver to the gallbladder and then into the intestines, where a diarrheal disease will develop. *S. sonnei* infection is typically restricted to the intestine, in which the bacteria attach to the M cells located in Peyer patches. The bacteria initiate intracellular multiplication and spread directly from cell to cell. With death of the infected host cells, the integrity of the intestinal wall is destabilized, leading to localized tissue destruction and a hemorrhagic colitis.

6. Two forms of *Y. pestis* infections are recognized: sylvatic plague and urban plague. In sylvatic plague, disease is established in squirrels, rabbits, field rats, and some domestic animals. Infection is spread among the reservoir animals by flea vectors, and elimination of this form of plague is difficult, if not impossible. Humans are accidental hosts when the infected animals are in close proximity to humans and an infected flea bites an individual. Urban plague is maintained in rat populations and is spread among rats or between rats and humans by infected fleas. Instituting rodent control measures in cities can control this form of disease.

Chapter 26 *Vibrio* and Related Bacteria

1. The Enterobacteriaceae and *Vibrio* and *Aeromonas* are gram-negative rods capable of aerobic and anaerobic growth (facultative anaerobe) on a variety of media and able to ferment many different carbohydrates. In contrast to the Enterobacteriaceae, *Vibrio* and *Aeromonas* have a single polar flagellum for motility (not typically assessed for identification) and are oxidase positive (readily measured by rapid "spot" tests).

2. *V. cholerae* serogroups O1 and O139 produce cholera toxin consisting of five B subunits that mediate binding to receptors on intestinal epithelial cells and one A subunit that is transported into the cell. These interact with G proteins that control adenylate cyclase, leading to the conversion of adenosine triphosphate (ATP) to cyclic adenosine monophosphate (cAMP), resulting in hypersecretion of water and electrolytes. *Escherichia coli* that produce heat-labile enterotoxin (enterotoxigenic *E. coli* [ETEC]) produce a morphologically and functionally similar toxin.

3. *V. vulnificus* produces wound infections and septicemia that are associated with a high mortality rate, particularly in patients with underlying hepatic disease.

4. *Aeromonas* causes three types of disease: diarrheal disease in healthy individuals, wound infections associated with trauma, and opportunistic systemic disease in immunocompromised patients.

CASE STUDY ANSWERS

1. *V. cholerae* infections can range from asymptomatic carriage to severe watery diarrhea. A typical course of disease begins 2 to 3 days after ingestion of the bacteria and is characterized by an abrupt onset of watery diarrhea and vomiting. The diarrhea is profuse, leading to dehydration, metabolic acidosis, hypokalemia, and hypovolemic shock caused by potassium loss. Symptoms can resolve spontaneously after a few days of diarrhea.

2. The most important virulence factor responsible for cholera is the cholera toxin (A-B toxin). The five B subunits in the toxin molecule bind to the GM_1 receptor on the intestinal epithelial cells, forming a pore that facilitates transport of the A subunit into the cell. The A subunit interacts with G proteins that control adenylate cyclase, leading to the catabolic conversion of ATP to cAMP. This results in a hypersecretion of water and electrolytes. Other virulence factors in *V. cholerae* include the TCP, zonula occludens toxin, accessory cholera enterotoxin, and a colonization factor.

3. The patient most likely acquired the infection by ingestion of contaminated water or foods. A high infectious dose is required to establish infection, so disease is primarily restricted to communities in which the sanitary conditions are poor. Infections with *V. parahaemolyticus* and *V. vulnificus* are primarily caused by consumption of raw or improperly cooked seafood, particularly oysters.

4. Cholera is controlled in endemic areas by improving the sanitation of the community (e.g., sewage management, use of purification systems to eliminate contamination of the water supply, implementation of appropriate steps to prevent contamination of foods).

Chapter 27 *Pseudomonas* and Related Bacteria

1. All organisms are ubiquitous in nature and commonly contaminate moist hospital sites, such as sinks, showers, and respirators.

2. Exotoxin A (ETA) disrupts protein synthesis by blocking peptide chain elongation.

3. *B. cepacia* causes pulmonary infections in patients with cystic fibrosis or chronic granulomatous disease.

4. *P. aeruginosa* is generally susceptible to the carbapenems and always resistant to trimethoprim-sulfamethoxazole; *S. maltophilia* is usually susceptible to trimethoprim-sulfamethoxazole and always resistant to the carbapenems.

CASE STUDY ANSWERS

1. *P. aeruginosa* is an opportunistic pathogen. Patients with medical conditions that compromise their immunity (e.g., leukemia, immunosuppressive therapy) are at increased risk of infection with this organism. Likewise, because *P. aeruginosa* is resistant to many antibiotics, prior treatment with broad-spectrum antibiotics can select for colonization and subsequent infection with *P. aeruginosa.*

2. *P. aeruginosa* possesses a variety of virulence factors that make it a particularly effective opportunistic pathogen. The bacteria can adhere to host cells by pili and nonpilus adhesins. The capsule also can function as an adhesion factor and interfere with phagocytosis. Similar to all gram-negative bacteria, *P. aeruginosa* organisms possess an endotoxin. Additionally, the bacteria produce ETA, which disrupts protein synthesis and has been implicated in the tissue damage observed in cutaneous, ocular, and pulmonary infections. A variety of other enzymes (exoenzymes S and T, elastases, alkaline protease, and phospholipase C) contribute to the tissue damage characteristic of *Pseudomonas* infections. Antibiotic resistance makes this organism difficult to treat.

3. Mutation of porin proteins can interfere with the penetration of many classes of antibiotics through the outer membrane and into the bacterial cell. *Pseudomonas* also produces a variety of β-lactamases that can inactivate β-lactam antibiotics, including carbapenems such as imipenem and meropenem. Less commonly, *P. aeruginosa* can enhance antibiotic efflux from the cell, reducing the intracellular antibiotic concentration to ineffective levels.

4. ***B. cepacia* complex** is a complex of species that have been associated with respiratory infections in patients with CF or CGD, UTIs in catheterized patients, septicemia in patients with intravascular catheters, and opportunistic infections in immunocompromised patients. Infections can be treated with TMP-SMX. ***S. maltophilia*** is an opportunistic pathogen that primarily causes infections (bacteremia, pneumonia, wound infections, UTIs) in debilitated patients with impaired host defenses. Antibiotic resistance is common in this organism, and TMP-SMX is the most effective antibiotic. Levofloxacin and ceftazidime also can be used to treat infections. ***A. baumannii*** is also an opportunistic pathogen that primarily causes respiratory tract infections. This organism also has been implicated in wound infections and UTIs. Resistance to many antibiotics has been reported, so effective therapy requires in vitro susceptibility tests. Empirical therapy for serious infections should use a combination of a broad-spectrum β-lactam (e.g., ceftazidime, imipenem) and an aminoglycoside. ***M. catarrhalis*** organisms are a common cause of bronchitis and bronchopneumonia in elderly patients with chronic pulmonary disease, sinusitis, and otitis. Although most isolates are resistant to penicillins, the bacteria are uniformly susceptible to other antibiotics.

Chapter 28 *Campylobacter* and *Helicobacter*

1. *Campylobacter* is thin, at the resolving limits of light microscopy, and is not typically observed in Gram-stained specimens. Growth of *C. jejuni* and *C. coli* requires incubation at an elevated temperature and in a microaerophilic atmosphere supplemented with carbon dioxide. *Helicobacter* is also difficult to grow, requiring enriched media, a microaerophilic atmosphere, and prolonged incubation.

2. Guillain-Barré syndrome; reactive arthritis.

3. *H. pylori* blocks acid production in the stomach by production of acid-inhibitory proteins and neutralizes gastric acids with the ammonia produced by urease activity. The bacteria are actively motile and rapidly penetrate through the gastric mucus and adhere to gastric epithelial cells, followed by penetration into the cells.

CASE STUDY ANSWERS

1. *C. jejuni* infections have been associated with a large variety of food products; however, the most common source of infections is contaminated poultry. Completely cooking all poultry and disinfecting all surfaces where uncooked poultry is prepared can avoid infections.

2. The three species of *Campylobacter* most commonly associated with gastroenteritis are *C. jejuni, C. coli,* and *C. upsaliensis. C. fetus* is the species most commonly associated with septicemia.

3. Diseases caused by *H. pylori* include gastritis, peptic ulcers, gastric adenocarcinoma, and gastric MALT B-cell lymphomas. *H. cinaedi* and *H. fennelliae* colonize the GI tract and have been associated with proctitis, proctocolitis, and enteritis in homosexual males.

4. *H. pylori* produce an acid-inhibitory protein that induces hypochlorhydria during acute infection by blocking acid secretion from parietal cells. Urease produced by *H. pylori* also neutralizes gastric acids by degrading urea to ammonia. *H. pylori* produces a variety of adhesins that mediate binding to the gastric epithelium, including sialic acid–binding adhesion, Lewis blood group adhesion, and various other hemagglutinins. Mucinase and phospholipases disrupt the gastric mucus, and superoxide dismutase and catalase interfere with phagocytic killing.

Chapter 29 Miscellaneous Gram-Negative Rods

1. *B. quintana* causes disease in immunocompromised patients, particularly patients with human immunodeficiency virus (HIV) infections, presenting as recurrent fevers with bacteremia or bacillary angiomatosis. *B. henselae* is also responsible for bacillary angiomatosis, as well as cat-scratch disease, which is a chronic regional lymphadenopathy.

2. *B. pertussis* is found only in humans, so disease is spread person to person.

3. *B. pertussis* is extremely sensitive to drying and frequently will die quickly unless a specimen is rapidly delivered to the laboratory and cultured. In addition, specialized culture media must be used as well as extended incubation. Even when optimum culture techniques are used, molecular-based tests such as polymerase chain reaction (PCR) are significantly more sensitive.

4. A number of animals serve as reservoirs for *Francisella,* but most infections are associated with exposure to infected rabbits or ticks. *Brucella* infections are also zoonotic, with specific species associated with specific reservoirs: goats and sheep *(B. melitensis);* cattle and bison *(B. abortus);* swine, reindeer, and caribou *(B. suis);* and dogs, foxes, and coyotes *(B. canis)*. Laboratory-acquired infections are a significant risk when both genera are handled.

5. Endocarditis.

6. *Legionella* is a short coccobacillus that does not stain well with Gram stain reagents, so a Gram stain of respiratory specimens is typically not useful. The organism can only grow on media supplemented with cysteine and iron, so culture is not useful unless the appropriate medium is selected.

CASE STUDY ANSWERS

1. Most cases of cat-scratch disease are caused by *B. henselae.* In general, very few organisms are present in the involved tissues, so microscopy and culture are usually not helpful. This is in contrast with *B. henselae* infections in HIV-infected patients, in which culture has been valuable in confirming *Bartonella*-mediated bacillary angiomatosis and septicemia. The definitive diagnosis of cat-scratch disease is made by serologic evidence of a recent infection. Cross-reactions with *Coxiella* and *Chlamydia* can occur.

2. *B. quintana* causes trench fever (5-day fever), subacute bacterial endocarditis (SBE), and bacillary angiomatosis. *B. henselae* causes cat-scratch disease, bacillary angiomatosis, peliosis hepatis, SBE, and chronic bacteremia in immunocompromised patients. Cat-scratch disease (as the name implies) is associated with cat exposures (scratches, bites, contact with cat fleas). *Bartonella* is in the oropharynx of cats and transferred to their claws while cleaning and grooming. No animal reservoir exists for *B. quintana*–produced trench fever; rather, infections are spread person to person through the human body louse.

3. Microscopy, culture, nucleic acid amplification (PCR), and serology have been used to confirm the clinical diagnosis of pertussis. The most sensitive and specific test is PCR, and it is the diagnostic test of choice. Microscopy has a limited value. The Gram stain is not useful and should not be performed because the bacteria (gram-negative coccobacillus) are difficult to detect in clinical specimens. A direct fluorescent antibody (DFA) test is helpful but has a sensitivity of approximately 50%, and cross-reactions with other organisms have been reported. Culture is limited by the quality of the collected specimen (need a nasopharyngeal aspirate) and the medium (must use Regan-Lowe charcoal medium). Fewer than half the patients with pertussis have their disease confirmed with a positive culture. Serology is also of limited value because an antibody rise must be documented, which can take weeks to months.

4. After a 7- to 10-day incubation period, the disease progresses through three stages. The catarrhal stage resembles a common cold. After 1 to 2 weeks, the paroxysmal stage begins and is characterized by the classic whooping cough paroxysms (a series of repetitive coughs followed by an inspiratory whoop). After 2 to 4 weeks, the convalescent stage begins, in which the paroxysms diminish but secondary complications can occur. Disease is prevented by vaccination of susceptible individuals. Persistence of immunity has been questioned, and booster vaccination of adults is under consideration. This is complicated by the higher rate of vaccine complications in older individuals.

5. The clinical diagnosis of tularemia can be confirmed by microscopy, culture, PCR-based assays, or serology. Microscopy is limited because organisms are extremely small and frequently overlooked in clinical specimens. A DFA test is available but rarely used in clinical laboratories. Culture has been described as insensitive; however, in the authors' experience, the test is sensitive if the appropriate media are used (BCYE agar, chocolate agar) with extended incubation. Care must be used in handling these cultures because the organisms are extremely infectious. PCR-based assays are sensitive and specific but not widely available. Most diagnoses are made retrospectively using serologic methods. Cross-reactions do occur (e.g., with *Brucella*), but this is generally not a diagnostic problem.

6. The most common sources of tularemia in the United States are handling infected animals (e.g., rabbits) or infected ticks. Ticks require prolonged feeding to transmit the bacteria, and animal exposure can include ingestion as well as exposure to infectious aerosols during the dressing of an animal.

7. A variety of laboratory tests have been used to diagnose *Legionella* infections, including microscopy, culture, antigen tests, NAATs, and serology. A Gram stain (as used in this case) is usually negative because the gram-negative rods are too thin to be seen in clinical specimens. DFA tests have been used in the past but have been abandoned by most laboratories because the tests are insensitive and can cross-react with non-*Legionella* organisms. Culture on appropriate media (e.g., BCYE agar with or without antibiotics to make the media selective) with extended incubation is a sensitive and specific test. Most patients will have a positive culture if the cultures are incubated for at least 1 week. Because these bacteria require L-cysteine and iron salts for primary isolation, no growth will occur on blood or chocolate agars. A sensitive and specific urinary antigen test has been developed for *L. pneumophila* serogroup 1. This is the most common serogroup implicated in disease. The assay will react with some other serogroups but should not be used in the absence of other diagnostic tests (e.g., culture, NAAT). NAAT assays are sensitive and specific and are the diagnostic test of choice; however, many laboratories do not currently offer this test. Serology can be used to confirm prior exposure to *Legionella* or current infection if a significant rise in antibodies can be documented. Documentation of seroconversion can take as long as 6 months. Cross-reactions may also occur, so serology has limited value in confirming an infection with *Legionella.*

Chapter 30 *Clostridium*

1. *C. perfringens* produces a large number of toxins and hydrolytic enzymes. The most important toxin is alpha toxin, which is a lecithinase that lyses erythrocytes, platelets, leukocytes, and endothelial cells.

2. *C. perfringens* produces a heat-labile enterotoxin that binds to receptors on the brush border membrane of the small intestine epithelium. This leads to altered membrane permeability and fluid loss. Disease is characterized by a short incubation period, abdominal cramps and watery diarrhea, and relatively short duration (1 to 2 days). In contrast, food poisoning with *C. botulinum* is characterized as a neurologic disease. The *C. botulinum* toxin binds to specific receptors on the surface of motor neurons and stimulates endocytosis of the toxin molecule. The toxin then inactivates the proteins that regulate release of acetylcholine, blocking neurotransmission at peripheral cholinergic synapses, resulting in a flaccid paralysis.

3. *C. septicum* causes nontraumatic myonecrosis in patients with occult colon cancer, leukemia, or diabetes.

CASE STUDY ANSWERS

1. The diagnosis of tetanus is based on the clinical presentation and history (e.g., history of a penetrating injury in a nonimmune individual). Laboratory tests that can be used to confirm the diagnosis include microscopy (useful if positive, but generally organisms are not observed in the wound) and culture (relatively insensitive because the organisms are extremely oxygen sensitive). Serology is not useful (antibodies to the toxin do not develop).

2. If tetanus is suspected, treatment should begin immediately. This requires debridement of the primary wound, use of metronidazole, passive immunization with human tetanus immunoglobulin, and vaccination with tetanus toxoid. Wound debridement and antibiotic therapy eliminate the vegetative cells producing toxin, passive immunization inactivates free toxin (bound toxin cannot be eliminated), and vaccination protects the patient from future exposure to toxin. The prognosis is determined by the site of the initial injury, rate of onset of disease, and rapidity of appropriate management. Mortality in the United States is relatively low because the diagnosis is typically made quickly and effective support measures are generally available. In less developed countries, the mortality associated with tetanus is high.

3. Tetanospasmin and botulinum toxin are both A-B toxins. The B subunit of tetanospasmin binds to specific sialic acid receptors and adjacent glycoproteins on the surface of motor neurons. The combined toxin is then internalized in endosomal vesicles and transported in the neuron axon to motor neuron soma located in the spinal cord. At this site, the endosome becomes acidified, resulting in a conformation change in the B chain, which facilitates transport of the A chain into the cell cytosol. The A chain is an endopeptidase that degrades proteins that regulate the inhibitory neurotransmitters glycine and GABA. This leads to unregulated excitatory synaptic activity in motor neurons. Botulinum toxin also binds to specific sialic acid receptors and glycoproteins on the surface of motor neurons (different targets than tetanospasmin) and is internalized. *Botulinum* toxin remains in the endosome at the neuromuscular junction (versus travel to the spinal cord), where after acidification, the endopeptidase A chain inactivates the proteins that regulate release of acetylcholine. Because acetylcholine is not released, neurotransmission is blocked, resulting in flaccid paralysis.

4. *C. perfringens* produces numerous toxins and cytotoxic enzymes. The most important toxin is alpha toxin, which is a phospholipase that is responsible for lysis of erythrocytes, platelets, leukocytes, and endothelial cells. This will lead to massive hemolysis and tissue destruction that is characteristic of the overwhelming disease caused by this organism. Other cytotoxic toxins produced by *C. perfringens* include beta, epsilon, and iota toxins. This organism also produces collagenase, proteases, hyaluronidase, deoxyribonucleases, neuraminidase, and enterotoxin.

5. *C. perfringens* causes a variety of diseases, including soft-tissue infections (cellulitis, fasciitis, myonecrosis), food poisoning, necrotizing enteritis, and primary septicemia.

6. *C. difficile* is the etiologic agent of GI diseases ranging from antibiotic-associated diarrhea to life-threatening pseudomembranous colitis. Infections can be difficult to

manage. Although the vegetative forms of the bacilli are uniformly susceptible to metronidazole or vancomycin, the nonreplicating spores are resistant. Thus treatment may eliminate the vegetative forms, but the spores can persist in the intestines and germinate into actively replicating, toxin-producing vegetative cells when antibiotic therapy is discontinued. Furthermore, spores can contaminate hospital rooms and serve as a focus of infection for other patients.

Chapter 31 Non–Spore-Forming Anaerobic Bacteria

1. Anaerobic bacteria responsible for pelvic abscesses include anaerobic gram-positive cocci, *Actinomyces, Fusobacterium, Prevotella, Porphyromonas,* and *Bacteroides.*

2. Infections with *Actinomyces* are characteristically chronic, requiring weeks to months to develop. The organisms also grow slowly in culture and respond slowly to antibiotic treatment.

3. Infections caused by *B. fragilis* are characterized by abscess formation. Although this organism has been implicated in infections of the lungs and brain, intraabdominal and skin and soft-tissue infections are the most common.

4. Metronidazole, carbapenems, and combinations of β-lactams and β-lactamase inhibitors.

CASE STUDY ANSWERS

1. The diagnosis of actinomycosis can be difficult to confirm. Specimens that avoid oral contamination must be collected because *Actinomyces* are part of the normal oropharyngeal flora. Furthermore, relatively few organisms may be present in the specimen because this is a chronic infection, and cultures may need to be incubated for a week or more. For these reasons, many diagnoses of actinomycosis are not confirmed. Granules present in the specimens (referred to as "sulfur granules") should be crushed and examined microscopically. Gram-positive rods embedded in amorphous mineral deposits should be observed.

2. *Actinomyces* colonize the oropharynx, GI tract, and vagina. Infections with these organisms are commonly chronic, developing slowly after trauma to the colonized mucosa introduces the organisms into deep tissues. Infection is characterized by the development of chronic granulomatous lesions that become suppurative and form abscesses connected by sinus tracts. Pelvic actinomycosis is frequently associated with the presence of an intrauterine device. This patient's poor oral hygiene predisposed him or her to cervicofacial actinomycosis.

3. *Cutibacterium* (*Propionibacterium*) *acnes* is responsible for acne and opportunistic infections in patients with prosthetic devices or intravascular lines. This organism colonizes the surface of the skin and mucosal membranes.

4. Abscess formation in this clinical situation is most likely caused by *B. fragilis.* The polysaccharide capsule stimulates leukocyte migration and abscess formation.

5. *B. fragilis* colonizes the colon in relatively small numbers. However, this organism is highly virulent and has been implicated in diseases in many body sites, including lungs (pulmonary abscess), central nervous system (brain abscess), abdomen (intraabdominal abscess), genitourinary tract (pelvic abscess), GI tract (gastroenteritis), cardiovascular system (thrombophlebitis, septicemia), and soft tissues (myonecrosis).

6. Metronidazole is uniformly active against *Bacteroides,* and carbapenems (e.g., imipenem, meropenem) are active against most strains. *E. coli* is generally susceptible to the carbapenems and broad-spectrum cephalosporins. Treatment of serious enterococcal infections requires use of a cell wall–active antibiotic (e.g., β-lactam, vancomycin) with an aminoglycoside.

7. Other anaerobic gram-negative rods associated with human disease include *Prevotella, Porphyromonas,* and *Fusobacterium.*

Chapter 32 *Treponema, Borrelia,* and *Leptospira*

1. Primary syphilis is characterized by a painless ulcer (chancre) at the site of penetration of the spirochete. If this is on the shaft of the penis or external genitalia, then the lesion should be obvious; however, if it is on the inside of the vagina, then the infection may not be noticed. In addition, the ulcer spontaneously resolves, so the infected individual may have a false sense of relief. The secondary stage of syphilis is a disseminated rash that also spontaneously resolves. Late manifestations of syphilis develop months to years later, but at that time, irreversible damage has occurred.

2. *B. burgdorferi* is the etiologic agent of Lyme disease. The major reservoirs for Lyme disease in the United States are the white-footed mouse and white-tailed deer. The white-footed mouse is the primary host of larval and nymph forms of *Ixodes* ticks, which are the vectors of Lyme disease. Because the nymph form of the ticks is responsible for most human infections, mice are the important reservoir.

3. The clinical presentation of early Lyme disease with the skin lesions (erythema migrans) is characteristic. Laboratory diagnosis at this stage is difficult because the organism is typically not seen in the lesion by microscopy, most laboratories do not have experience culturing the organism, nucleic acid amplification tests are generally insensitive, and many patients have not developed antibodies to the infection. By the time the patient develops arthritis or other signs of systemic disease, antibodies are almost universally present, so a serologic diagnosis is reliable.

4. The diagnosis of leptospirosis is typically made by serologic testing; however, spirochetes can be cultured from the blood using specialized techniques during the first 10 days of clinical illness and from urine only after the first week and up to 3 months in the clinical illness.

CASE STUDY ANSWERS

1. Onset of the early stages of Lyme disease is characterized by a small macule (typically at the site of the tick bite) that enlarges over the next few weeks. The lesion has a flat border with central clearing, although erythema, vesicle formation, or necrosis may also occur. This rash (erythema migrans [migrans because additional lesions may develop]) is accompanied by malaise, fatigue, headache, fever, chills, musculoskeletal pains, myalgias, and lymphadenopathy. These signs and symptoms can progress in untreated patients to include cardiac dysfunction (e.g., heart block, myopericarditis, congestive heart failure) and neurologic signs (e.g., facial palsy, meningitis, encephalitis). Late manifestations of Lyme disease typically present as arthritis involving one or more joints intermittently.

2. Laboratory confirmation of the clinical diagnosis of Lyme disease is problematic. Relatively few organisms are present in the blood or tissues of infected patients, so microscopy is of no practical value. Culture of *B. burgdorferi* has met with limited success. Culture requires use of specialized media and is only sensitive during the initial stage of erythema migrans; however, this lesion is pathognomonic, so laboratory confirmation is unnecessary. The clinical dilemma of diagnosis is when a patient presents with arthritis and no history of the early manifestations of Lyme disease. At this stage, cultures are invariably negative. Nucleic acid amplification tests are also insensitive. Serologic tests in patients with the late manifestations of disease are usually strongly positive if the patient has not received a course of antimicrobial therapy. However, serology is less reliable in the early stages of disease. Cross-reactions can occur but primarily in patients with other spirochetal diseases, such as syphilis. Observing the borreliae in the patient's blood primarily makes the laboratory diagnosis of relapsing fever. Culture and serology are not useful for these bacteria.

3. Laboratory diagnosis of syphilis is made most commonly using a sensitive screening nontreponemal serology test and confirmed by a more specific treponemal test. The VDRL and RPR tests are examples of nontreponemal tests, and the FTA-ABS and TP-PA tests are examples of the specific treponemal tests. The nontreponemal tests have a sensitivity of 75% to 85% for patients with primary syphilis and almost 100% for patients with secondary and latent syphilis. The sensitivity of these tests is lower (≈70%) for patients with late manifestations of syphilis. The treponemal tests have a sensitivity of approximately 85% for primary syphilis and almost 100% for all other stages, including late syphilis.

4. The reservoir for syphilis is humans. Transmission is either through sexual contact or congenitally. Exposure to contaminated blood is now an uncommon source. Endemic relapsing fever is a zoonotic disease, and rodents, small mammals, and soft ticks are the main reservoirs. The vectors of this disease are infected ticks. The reservoir for epidemic or louse-borne relapsing fever is humans, with person-to-person spread mediated by infected lice. The primary reservoirs for Lyme disease in the United States are the white-footed mouse and white-tailed deer. Hard ticks are the vectors. The reservoir hosts for leptospires are rodents and other small mammals. Disease is spread to humans by exposure to urine-contaminated water or occupational exposure to infected animals.

5. The diagnosis of leptospirosis is problematic. Leptospires are too thin to be observed by brightfield microscopy. Darkfield microscopy can be used to examine the blood of an infected person; however, this is a relatively insensitive test, and artifacts in the blood can lead to diagnostic errors. For this reason, microscopy is not recommended. Leptospires can be cultured for blood, CSF, or urine if specialized media and prolonged incubation (up to 4 months) are used. Because these procedures are not practical for routine diagnostic testing, serology is the diagnostic test of choice. The reference method is the MAT. However, this procedure requires using live leptospires, so this is restricted to reference laboratories. Alternative agglutination and ELISA tests are more broadly available but are less sensitive and specific.

Chapter 33 *Mycoplasma*

1. Mycoplasmas lack a cell wall, and their cell membrane contains sterols. The absence of a cell wall renders the bacteria resistant to antibiotics that interfere with cell wall synthesis (e.g., penicillins, cephalosporins, carbapenems, vancomycin).

2. *M. pneumoniae* causes respiratory infections (tracheobronchitis, pharyngitis, pneumonia); *M. genitalium* is implicated in urethritis, cervicitis, and pelvic inflammatory disease; *M. hominis* is implicated in infections of the respiratory tract and urinary tract, as well as systemic infections in immunocompromised patients.

3. Laboratory diagnosis of *M. pneumoniae* infections is problematic because culture is not performed in most laboratories, microscopy has no value for diagnosis, and serology is insensitive. The best diagnostic test is PCR for species-specific targets.

CASE STUDY ANSWERS

1. This patient has atypical pneumonia caused by *M. pneumoniae*. The organism can be cultured from throat washings, bronchial washings, or expectorated sputum. Because the patients generally do not have a productive cough (as with this patient), collection of expectorated sputum is not possible. The throat washings would be a sensitive, noninvasive specimen. Culture has a relatively

low sensitivity and requires incubation for as long as 6 weeks. For this reason, few laboratories rely on this procedure. Serology (as used in this case) is the most commonly used diagnostic procedure but is also insensitive. The diagnostic test of choice currently is the PCR-based nucleic acid amplification test; however, PCR tests are not widely available at this time.

2. Pneumonia caused by *M. pneumoniae* occurs throughout the year. Although it is most common in school-age children and young adults, it can occur in all age groups. Infection occurs by person-to-person spread via infectious respiratory secretions. The age of this patient and her clinical presentation is characteristic of *M. pneumoniae* infection.

Chapter 34 *Rickettsia, Ehrlichia,* and Related Bacteria

1. Rickettsial infections are treated with tetracyclines (e.g., doxycycline) or fluoroquinolones (e.g., ciprofloxacin). Although chloramphenicol has in vitro activity, a high incidence of relapse is associated with this antibiotic. β-Lactam antibiotics (e.g., penicillins, cephalosporins, carbapenems), aminoglycosides, and trimethoprim-sulfamethoxazole are inactive.

2. Ticks are vectors for the following rickettsiae and their diseases: *R. rickettsii,* Rocky Mountain spotted fever; *R. africae,* African tick bite fever; *R. australis,* Australian tick typhus; *R. conorii,* Mediterranean spotted fever; *R. japonica,* Japanese spotted fever; and *R. sibirica,* Siberian tick typhus. Only *R. rickettsii* is commonly recovered in the United States. Lice are associated with *R. prowazekii* (endemic typhus), mites are associated with *R. akari* (rickettsialpox) and *Orientia tsutsugamushi* (scrub typhus), and fleas are associated with *R. typhi* (murine typhus).

3. Rickettsiae are small and stain poorly with the Gram stain because the peptidoglycan layer is minimal.

4. *E. chaffeensis,* the etiologic agent of human monocytic ehrlichiosis, infects blood monocytes and mononuclear phagocytes in tissues and organs. Approximately 1 to 3 weeks after exposure, patients develop a flulike illness with high fever, headache, malaise, and myalgias. A rash develops in about one-third of patients. *A. phagocytophilum,* the agent of human anaplasmosis (formerly called human granulocytic ehrlichiosis), infects granulocytes (neutrophils, eosinophils, basophils). Approximately 5 to 11 days after exposure, a similar flulike illness develops, but a rash is uncommon. In both diseases, more than half of the infected persons require hospitalization, and recovery is prolonged.

5. The majority of infections with *C. burnetii* are asymptomatic or present with mild flulike symptoms. Severe diseases include pneumonia, hepatitis, or isolated fever; however, the most common presentation is subacute endocarditis.

CASE STUDY ANSWERS

1. The diagnosis of infection caused by *C. burnetii* can be made by culture, PCR-based NAAT, or serology. *Coxiella* stain poorly with the Gram stain, and relatively few organisms would be found in the blood, so this test has no value for diagnosis. *Coxiella* is an obligate intracellular pathogen, so culture requires the use of tissue culture cells. This procedure presents some risk to laboratory personnel, and as a result, relatively few laboratories perform cultures. PCR tests are sensitive and specific for acute infections and are the diagnostic test of choice in areas in which these infections are endemic. However, because relatively few organisms are present in the blood of patients with endocarditis, the sensitivity of this test is poor for this infection. Therefore serology is the diagnostic test of choice for patients with endocarditis. Because this is a chronic infection, high titers of antibodies are present when the diagnosis is suspected. *Coxiella* undergoes phase variation during replication, so antibodies will be stimulated against antigens exposed in both phases. In patients with endocarditis, higher antibody titers are detected against the phase I antigens. Cross-reactions can be detected in patients with *Bartonella* infections, so specific serology tests should also be performed against this organism to exclude this infection.

2. *Coxiella* produces zoonotic infections with farm animals such as sheep, cattle, and goats, which are the most common sources for human infections. Domestic animals and rabbits also can be associated with human infections. The bacteria reach a high concentration in the placenta of infected livestock. Dried placentas left on the ground after parturition, as well as feces and urine, can contaminate the soil. The bacteria are relatively stable and can remain viable for long periods. Humans acquire their infections when they inhale aerosolized bacteria. Ticks are an important source of animal infections but play an insignificant role in human infections.

3. Doxycycline is used to treat *Coxiella* infections. For chronic infections, as in this patient, a combination of antibiotics should be used for treatment, such as rifampin with either doxycycline or trimethoprim-sulfamethoxazole. Successful treatment requires prolonged therapy.

Chapter 35 *Chlamydia*

1. Respiratory disease is caused by *C. trachomatis, C. psittaci,* and *C. pneumoniae*; ocular and genital diseases are caused by *C. trachomatis.*

2. *C. trachomatis* serotype A (as well as serotypes B, Ba, and C) cause trachoma. This disease develops from the vigorous inflammatory response to recurrent infections, eventually leading to scarring of the cornea and blindness.

3. The most reliable tests for diagnosis of infections with *Chlamydia* are species-specific NAATs.

CASE STUDY ANSWERS

1. Previously it was thought that chlamydiae were resistant to cell wall–active antibiotics because they lacked a peptidoglycan layer; however, this has been demonstrated in actively replicating RBs. It is likely that these antibiotics are ineffective because they cannot reach the peptidoglycan target. This patient's infection can be treated with azithromycin or doxycycline.

2. The developmental cycle of *Chlamydia* involves two stages of the bacteria: the metabolically inactive, stable, infectious EBs and the metabolically active, labile, noninfectious RBs. Patients are infected with the EB forms, which bind to receptors on the host cells and are internalized. Within phagosomes, the EBs convert to RBs and initiate replication by binary fission. After 18 to 24 hours of replication, the RBs reorganize into EBs, and the cell lyses and releases the infectious EBs.

3. Three species of *Chlamydia* are clinically important: *C. trachomatis, C. pneumoniae,* and *C. psittaci. C. trachomatis* and *C. pneumoniae* are primarily human pathogens, and *C. psittaci* is primarily an animal pathogen, with humans as secondary hosts. *C. trachomatis* has two biovars (LGV and trachoma), *C. pneumoniae* has one biovar (TWAR), and *C. psittaci* has many biovars. The morphology of the EBs of *C. pneumoniae* differs from the other two species, and a single iodine-staining inclusion body is observed in cells infected with *C. trachomatis,* compared with multiple nonstaining inclusion bodies in cells infected with the other species. Only *C. trachomatis* is susceptible to sulfonamides.

4. Respiratory infections caused by *C. trachomatis* are primarily observed in infants who are infected at the time of birth. Rhinitis is initially observed, followed by a characteristic staccato cough. *C. pneumoniae* is an important cause of bronchitis, pneumonia, and sinusitis, with infections most common in adults. Most infections are asymptomatic or mild with malaise and a persistent cough. More severe lobar pneumonia also can occur. *C. psittaci* also produces a respiratory infection with the initial symptoms of headache, high fever, chills, malaise, and myalgia. Pulmonary signs include a nonproductive cough, rales, and consolidation.

Chapter 36 Viral Classification, Structure, and

ANSWERS

1. a. Both are picornaviruses and have similar structures and modes of replication, but unlike poliovirus, rhinoviruses are acid and temperature labile.
   b. Polio and rotaviruses are capsid viruses that are spread by the fecal-oral route. Polio has a (+) RNA genome; rotaviruses are larger and have a double capsid and a double-stranded RNA genome.
   c. Polio and WEE viruses have positive-stranded RNA genomes, and their genomes are infectious. WEE is a togavirus that can generate early and late proteins from full-length or partial-length mRNA. WEE is enveloped and spread in mosquito saliva and blood and unlike poliovirus would be inactivated by detergents and the conditions for fecal-oral transmission.
   d. Yellow fever virus and dengue virus are flaviviruses that are enveloped (+) RNA viruses, both of which are spread by mosquitoes in blood and mosquito saliva.
   e. EBV and CMV are herpesviruses that have large DNA genomes enclosed in an icosadeltahedral capsid surrounded by an envelope. These viruses have complex replication schemes that are controlled at the transcription level by some cells. Both viruses are strictly human viruses, but EBV infects B lymphocytes, whereas CMV has a broader tissue tropism.

2. The viruses matched with their properties are identified by the capital letter indicated in this list.

Properties	Match	Viruses
a. Are resistant to detergents	A, F, I, J, M, N	A. Picornaviruses
b. Are resistant to drying	A, F, I, J, M	B. Togaviruses
c. Genome replication in the nucleus	C, G, H, I, J, L[a]	C. Orthomyxoviruses
d. Genome replication in the cytoplasm	A, B, D, E, F, K, L, M, N	D. Paramyxoviruses
e. Can be released from the cell without cell lysis	B, C, D, E, G, H, L, N	E. Rhabdoviruses
f. Provide targets for approved antiviral drug action	C, G, H, J, L	F. Reoviruses
g. Undergo reassortment on coinfection with two strains	C, F	G. Retroviruses
h. Make DNA from an RNA template	G, L	H. Herpesviruses
i. Use a (+) RNA template to replicate the genome	C, D, E, F, L[a]	I. Papillomaviruses
j. Genome translated into a polyprotein	A, B, G[b], M,N	J. Adenoviruses
		K. Poxviruses
		L. Hepadnaviruses
		M. Caliciviruses
		N. Coronaviruses

[a]First step in hepadnavirus replication occurs in the nucleus (production of RNA template), but DNA genome is produced in the cytoplasm.
[b]Retroviruses encode mRNAs from the gag, pol, and env genes which are translated into polyproteins that are cleaved on assembly of the virus.

3. Adenovirus, picornavirus, calicivirus, reovirus, and papillomavirus are naked capsid viruses and resistant to detergents. Coronaviruses, although enveloped, can withstand detergents due to the 'corona' formed by the glycoproteins around the envelope.

4. POLYMERASES: DNA-dependent DNA polymerases: *adenovirus, herpes, poxviruses*; RNA-dependent DNA polymerase: *hepadnavirus, retroviruses*; RNA-dependent RNA polymerase: *all the RNA viruses, except retrovirus;* DNA-dependent RNA polymerase: *poxvirus. No polymerase encoded: papilloma, parvovirus*

5. Complementation: An HSV-2 gene provides the missing activity that allows replication of the mutant to occur. Transcapsidation may occur to put the HSV-1 genome into an HSV-1 or HSV-2 capsid but with an envelope that has HSV-2 glycoproteins so that it is recognized by HSV-2 antibody which blocks (neutralizes the virus) infection. Recombination between HSV-1 and HSV-2 may have occurred because these viruses share enough similarity to allow recombination of the two genomes and the generation of a hybrid virus that would have most of an HSV-1 genome but also HSV-2 genes for glycoprotein antigens that can be recognized by antibody to HSV-2.

6. The early genes, including the polymerase, of **togaviruses** are translated from the infecting (+) RNA genome (42S). Later, a subgenomic mRNA (26S), including genes for structural proteins, is transcribed from the replicative intermediate ([−] RNA) that encodes the late structural proteins. The **polyomavirus** genome is circular; the early genes, including cell growth activating genes, are transcribed in one direction, and the late genes, encoding the capsid proteins, are transcribed in the opposite direction. Expression of the late genes requires the action of the T antigen, which is an early gene. The herpesvirus immediate early genes are activated by host DNA-binding proteins and include proteins that facilitate early gene expression and takeover of the cell. The early genes are activated by viral proteins and encode the polymerase and other enzymes. Different combinations of viral proteins activate the late genes for translation after replication is initiated. The late proteins include glycoproteins, other structural proteins, and enzymes.

7. a. EBV polymerase: no virus production
   b. HSV thymidine kinase: inefficient virus production, especially in neurons
   c. HIV reverse transcriptase: no virus production
   d. Influenza B virus NA: very inefficient virus production
   e. Rabies virus (rhabdovirus) G-protein: no virus production

Chapter 37 Mechanisms of Viral Pathogenesis

ANSWERS

Answers

1. See table below

2. Varicella is inhaled; initiates replication in the lung; activates interferon and local inflammatory responses; initiates viremia and spreads to T cells and lymphatics, liver, and spleen; initiates viremia by infecting T cells; T cells transmit virus to skin cells; skin and lung cells produce virus that can be transmitted to other people; and blister-like lesions form on skin.

3. Protective antibody is generated against the viral attachment protein or structure as follows:
   Adenovirus: fiber protein
   Influenza A virus: hemagglutinin
   Poliovirus: capsid structure forming a valley
   Rabies virus: G glycoprotein

4. IFN-α and IFN-β: promote expression of proteins for the antiviral state (e.g., PKR, 2′5′A polymerase) that are activated by viral infection. They also increase expression of MHC molecules to enhance target recognition and promote stimulation of CD8 T cells. They also activate NK cells.

   IFN-γ: activates macrophage to become a killer cell and producer of IL-12, which is an inducer of T helper 1 (TH1) responses.

Route	Barriers	Examples of Viruses
Oral	Saliva, IgA, mucus	Poliovirus, rotavirus, norovirus
Respiratory	IgA, mucus	Influenza, parainfluenza, respiratory syncytial virus, measles, varicella-zoster virus,
Contact	Skin, mucus	HSV, human papillomavirus, molluscum contagiosum
Sexual	Female: IgA, IgG, mucus; male: skin	HSV, HIV, human papillomavirus, hepatitis B and C viruses
Injection, blood products, transplant	Antibody, T cells	Cytomegalovirus, HIV, HTLV, hepatitis B, C, D
Insect or animal bite (zoonoses)	Antibody, interferon	Eastern equine encephalitis virus, yellow fever virus, rabies
Maternal-neonatal	Maternal antibody	Rubella, cytomegalovirus, HIV

HIV, Human immunodeficiency virus; *HSV,* herpes simplex virus; *HTLV,* human T-cell lymphotropic virus; *Ig,* immunoglobulin.

Macrophage: antigen-presenting cell, which on activation by IFN-γ will promote inflammatory killing of internalized microbes; for viral infections, the macrophage produces cytokines that promote inflammation or facilitate repair of the infectious tissue damage.

NK cells: MHC-independent killing of infected cells; antibody-dependent cellular cytotoxicity killing of infected cells.

CD4 T cells: helper T cells that promote the antiviral response by producing cytokines; promote apoptosis of infected cells through Fas-FasL (ligand) interaction.

CD8 T cells: MHC I–restricted killing of infected cells and production of IFN-γ.

Antibody: neutralization of virus; opsonization of virus.

5. IFN-α and IFN-β are produced by the infected cell and activate an antiviral response in surrounding cells, activate NK cells, and also enhance immune responses. IFN-γ is produced later by NK or T cells as part of the cellular innate or immune responses.

6. The nucleoprotein of influenza virus is the predominant viral protein that is degraded by the proteasome of dendritic cells and converted into small peptides to pass through the transporter associated with antigen processing (TAP) into the endoplasmic reticulum to fill the antigenic peptide cleft of the MHC I molecule. Binding of an antigenic peptide is required for the movement of the MHC I molecule to the cell surface to present antigen as part of a CD8 T-cell response.

7. During the prodrome of a respiratory virus infection, the virus replicates in the lung, and IFN-α and IFN-β are produced, which cause flulike symptoms and tiredness. The virus replicates and spreads to other sites in the lung. Tissue damage is repaired after the virus has been controlled by innate and immune responses. For St. Louis encephalitis virus, the virus is injected into the blood by a mosquito and initiates a viremia and interferon responses, with similar flulike symptoms The viremia brings the virus to the meninges and then to the brain.

8. Viral characteristics that promote transmission.

Method of Transmission	Viral Characteristics That Promote Transmission
Fecal-oral	Capsid structure that is impervious to acid and bile of gastrointestinal tract; replication in oral or intestinal cells or released into gastrointestinal tract (e.g., hepatitis A virus)
Arthropods	Establishment of sufficient viremia to allow arthropod to acquire virus during a blood meal
Fomites	Stability to drying and heat, as for a naked capsule
Mother's milk	Secretion by epithelial cells into milk
Sexual activity	Long asymptomatic period of virus shedding to allow transmission before knowledge of infection

9. Fast oncogenesis: incorporation of a viral encoded oncogene into the host chromosome to stimulate cell growth (no human viruses act in this manner); example: Rous sarcoma virus of chickens

Slow oncogenesis: integration near a growth-promoting gene to allow the promoters in the LTR of the virus to induce overexpression of these genes and stimulate growth; example: HTLV-1

Transactivation of growth-promoting genes; example: IL-2 and IL-2 receptor by HTLV-1

Action of viral encoded or virus induced cytokines to chronically stimulate cell growth: HCV, HHV-8

Chapter 39 Laboratory Diagnosis of Viral Diseases

ANSWERS

1. Rabies virus infection can be identified by observation of Negri inclusion bodies and the presence of viral proteins by immunofluorescence. A tissue extract can also be analyzed by RT-PCR for viral genome.

2. The papillomavirus genome can be detected and typed by in situ hybridization and by PCR analysis using strain-specific DNA probes and primers. Immunofluorescence is not used because viral proteins may only be expressed in rare cells.

3. HSV-1 and HSV-2 can be distinguished with PCR tests for the viral genome or antigen detection tests using antibody specific for each virus type. The antibody can be used in a virus neutralization test, but better approaches are immunofluorescence or ELISA tests of cells infected by either virus using type-specific antibody. Different strains of virus can be distinguished by PCR of variable regions of the genome or by restriction fragment length polymorphism.

4. The figure shows that the titer of the convalescent serum taken 3 weeks after the acute serum is only different by one dilution tube (twofold). A significant difference in the titer of the antibody requires at least a fourfold difference. Therefore the patient was not infected by the H3N2 virus.

5. Recent infection is indicated by detection of a large concentration of the HIV genome as performed by RT-PCR or a related technique. These techniques amplify the genome that may be present in the sample. The presence of the viral protein p24 is a good indication of recent infection. It is too early for the person to provide a dependable indication of infection by the presence of antibodies to HIV.

Chapter 40 Antiviral Agents and Infection Control

ANSWERS

1. Steps in viral replication that depend on cellular processes are generally poor antiviral drug targets. These

include protein synthesis and processing (glycosylation, phosphorylation) and mRNA synthesis and processing (e.g., splicing, capping).

2. Treatable viruses:
DNA viruses
HSV (treatable with nucleoside analogs)
VZV (treatable with nucleoside analogs)
CMV (treatable with nucleoside analogs)
Adenovirus (treatable with nucleoside analogs)
Hepatitis B (treatable with nucleoside analogs)
RNA viruses
Influenza A and B (treatable with neuraminidase or polymerase inhibitor)
Respiratory syncytial virus (treatable with a nucleoside analog [ribavirin])
HCV (treatable with a nucleoside analog [ribavirin])
HIV (treatable with nucleoside analogs)

3. ACV: DNA polymerase, thymidine kinase of HSV or VZV
Phosphonoformate: DNA polymerase of herpesviruses (e.g., CMV)
Amantadine: M_2 protein of influenza A
AZT: RNA-dependent DNA polymerase of HIV

4. Amantadine and rimantadine inhibit influenza A virus replication by preventing uncoating of the virus in the cytoplasm. Oseltamivir and zanamivir are neuraminidase inhibitors that inhibit both influenza A and B viruses by preventing proper release of the virus. Baloxavir marboxil inhibits a subunit of the polymerase of influenza A and B viruses. These drugs are effective as prophylactics and, while the virus is replicating, during the first days of infection. Later, the inflammatory and immune responses cause the disease signs. Therapy is not appropriate unless the infection is definitely caused by influenza and treated within the first 3 days of infection. It is unlikely that any of these drugs would be effective on the sixth day after symptoms have started.

5. HAV and rhinovirus are picornaviruses with very different requirements for disinfection. HAV is an enterovirus and resistant to detergents and acid. Disinfection requires rigorous treatment for disinfection, such as 2% glutaraldehyde (a protein cross-linking fixative), toilet bowl cleaner with 23% hydrochloric acid and quaternary ammonium compounds, or ≈10% bleach (sodium hypochlorite). Autoclaving is also appropriate. In contrast, rhinoviruses can be disinfected by mild acid, including citric acid and the treatments described for HAV. For an enveloped virus such as HSV, detergent, 70% isopropanol or ethanol, acid, greater than 3% hydrogen peroxide, ≈10% bleach, and iodophors will inactivate the virus. Although enveloped, HBV disinfection requires rigorous methods. Universal blood and body fluid precautions should be used with HBV. HBV is less susceptible to detergents but can be disinfected with the other treatments listed for HSV.

6. For HBV and influenza A, the best protection is vaccination. Aerosol spread of influenza A is so contagious that prior immunity is the best prevention. Prophylactic antiviral treatment is expensive, difficult to administer, has side effects, and selects for resistance. For HBV, as for HIV and HCV, universal precautions for preventing transmission and contact with blood-borne infections must be used. All human blood is treated as if infected with these viruses. Universal precautions include wearing protective clothes, gloves, and eye shields, and not bending, recapping, or removing contaminated needles and other contaminated sharps. Contaminated items must be discarded or disinfected as described in question 5. For HSV, gloves must be worn to prevent infection. There is no vaccine for HSV.

Chapter 41 Papillomaviruses and Polyomaviruses

1. HPV-16 and HPV-18 are the most common high-risk strains for cervical and laryngeal cancer, but there are another 12 strains that also have the potential to integrate into the host chromosome and cause cancer. Their E6 and E7 proteins bind and inactivate the cellular growth-suppressor (transformation-suppressor) proteins p53 and the *p105* retinoblastoma gene product (p105RB), and the E5 protein enhances cell growth by stabilizing the epidermal growth factor receptor to make the cell more sensitive to growth signals. Integration inactivates viral genes necessary for its replication. Without virus replication to kill the cell and without p53 to error-check mutations, there is a greater potential for abnormal, uncontrolled growth of cells, as well as for mutation and the development of carcinoma.

2. The virus is transmitted by direct contact (warts) and on fomites (towels) or mixing and matching of mucous membranes and sharing mucous and skin (oral and genital papillomas).

3. The virus is harbored in the basal keratinocytes, little virus protein expression occurs, and the infected cells escape recognition. CD8 T cells can eventually be stimulated to resolve the infection (get rid of the wart). Virions are produced as the cells terminally differentiate and are released from cells that are programmed to die and be shed (skin and mucous epithelium), and therefore unless vaccinated, little antibody is produced. Vaccination promotes production of immunoglobulin (Ig)G which is secreted and can prevent infection.

4. Transmission can be prevented by using condoms during sex. Immunization with the HPV vaccine can prevent establishment of an infection and disease development and is suggested for girls and boys aged 11 to 25 years to be given before potential exposure to this ubiquitous virus on sexual experience.

5. JCV is a DNA virus that establishes latent and chronic infection of kidney cells, monocytes, lymphocytes, oligodendrocytes, and astrocytes. The virus is maintained in a latent state by cell-mediated immunity. Decrease in immune control by T cells allows the virus to replicate and spread. Infection of astrocytes results in abnormal growth and appearance; production of virus in oligodendrocytes is lytic and causes demyelination. The target cells, outcome of virus production, and the inflammatory response result in PML.

6. Individuals whose T-cell functions are compromised are at risk for PML. This includes organ transplant recipients; chemotherapy patients; and interestingly, people who are treated with natalizumab, which blocks the interaction of α4-integrin on immune cells with vascular cell adhesion molecule 1. This prevents T-cell interactions with antigen-presenting cells and their ability to cross the blood-brain barrier. The absence of proper T-cell function, either caused by immunosuppression or blockage by antibody, allows activation of JCV from latency and access to and replication in the brain. The immunocompromised state during AIDS allows the virus to be activated from latency, replicate, and spread.

CASE STUDY ANSWERS

1. The HPV that causes warts is spread by contact with other skin surfaces and would only initiate a wart at another site by contact with the primary site. The virus from a particular wart does not spread systemically.

2. Although the wart may disappear, the viral genome may remain in cells at the base of the wart site.

3. HPVs are controlled by host transcriptional machinery and require a replicating cell to provide deoxyribonucleotide substrates and a DNA polymerase to replicate the genome. Nongrowing cells cannot support virus genome replication. Also, expression of the late (capsid) mRNA and proteins is controlled by the same promoters as certain keratin genes; therefore they are tied to the differentiation stages of the keratinocyte. Thus complete virion particles are only made in the terminally differentiated skin cells and virus are released as these cells die and become the surface layer of skin. For the polyomaviruses, T cells control the replication of these viruses in an unknown manner.

4. The best way to identify an HPV type is by analysis of the genome using PCR, real-time PCR, or in situ hybridizations using DNA primers or probes that are specific for the different HPV types.

5. It is unlikely that the common wart virus is associated with human cancer. HPV-16 and HPV-18 (cervical carcinoma) are the most predominant types associated with cancers.

Chapter 42 Adenoviruses

1. The predominant routes of transmission of adenovirus are as aerosols and by the fecal-oral route, but adenovirus is also transmitted by contact.

2. The most likely types are serotypes 4 and 7 but could also be 1, 2, 3, 5, 7, and 14.

3. Diseases include conjunctivitis (pinkeye) and keratoconjunctivitis, pharyngoconjunctival fever, sore throat, pneumonia, common coldlike syndrome, gastroenteritis, and systemic infection.

4. Replication of the virus will kill the infected cell, so antibody is sufficient to resolve most adenovirus diseases. Antibody to the fiber proteins is neutralizing. However, adenovirus can also establish chronic infection, and natural killer (NK) and T cells are important in killing and controlling the chronic and latent infection.

5. Adenovirus types 4 and 7 are common causes of acute respiratory disease that spreads quickly to individuals in close proximity and under stress (military barracks). Infection of military personnel would rapidly spread and debilitate entire units, which would compromise their ability to serve their country. An outbreak of adenovirus 14 at Lackland Air Force Base is described in Clinical Case 42.1.

CASE STUDY ANSWERS

1. The patient has disease signs consistent with pharyngoconjunctival fever.

2. The most likely source of this outbreak is the unchlorinated water in the camp pond. The virus is very hardy and can endure relatively harsh conditions.

3. The capsid of the adenovirus protects the virus from harsh conditions of drying and even the acid and bile of the gastrointestinal tract to allow the virus to be transmitted by fecal-oral and respiratory routes, through contact, and on fomites.

4. Contamination of the pond would be difficult to eliminate. There is no vaccine to protect the campers. However, greater care with sewage may prevent further contamination of the pond. Also, campers should not share towels or other items that may come into contact with virus.

5. An eye swab, a fecal sample, and a nasal wipe could be tested for the virus in the infected child. Pond water could be concentrated to allow detection of virus as a common source of the infection. The presence of adenovirus and its type would be analyzed by PCR.

Chapter 43 Human Herpesviruses

1. (a) HSV-1 and HSV-2. Both viruses cause similar presentations, and it depends on which virus was placed at the site.
   (b) Varicella-zoster virus (VZV)
   (c) EBV
   (d) HSV, CMV, and EBV

2. (a) HSV-1 and HSV-2 are very similar and can cause the same diseases, except HSV-2 is usually transmitted and occurs below the belt. Both viruses cause vesicular infections of the oral, genital, and anal mucosa. HSV-1 can cause encephalitis, and HSV-2 can cause meningitis. The two viruses can be discriminated antigenically and by protein patterns, restriction fragment polymorphism, and DNA sequence (polymerase chain reaction [PCR]).
   (b) VZV resembles HSV in that it is neurotropic and expresses a thymidine kinase. Unlike HSV, it is transmitted by aerosol, acquired in the lungs, and then spread by viremia to the target tissues (e.g., skin). Like HSV, VZV establishes latency in neurons, but unlike HSV, recurrence (zoster) results in replication and release along an entire dermatome, whereas HSV is released only at the terminus of the nerve.
   (c) EBV has a very specific receptor specificity, which defines its tropism to B cells and some epithelial cells. Once in the B cell, it uses the natural cell biology of the B cell to promote its latent, recurrent and productive cycles.
   (d) All herpesviruses establish lytic, latent, and recurrent infections. HSV is neurotropic; CMV and EBV are lymphotropic, but unlike EBV, CMV can infect many different cell types.

3. (a) The infection was initially acquired by contact with another person with an active lesion (kissing) or his or her saliva. This presentation is likely to be a recurrence of an HSV infection after exposure to ultraviolet B radiation in sunlight, which is a common trigger of recurrence.
   (b) The patient breathed in an aerosol containing VZV. The virus can also be obtained by contact with active lesions, but this route is not efficient.
   (c) EBV is acquired by sharing saliva (e.g., kissing), and in this case, it is acquired from the water bottle.
   (d) All of the disease presentations in this case are recurrences from latent virus: from neurons for HSV, from macrophages and other cells for CMV, and from B cells for EBV, as a result of the immunosuppression.

4. (a) Immunocompromised individuals are at risk for disseminated disease. For neonates, HSV infection can be lethal because of their limited cell-mediated immunity. Also, HSV spreads extensively in individuals with eczema because of their compromised skin.
   (b) Adults suffer more severe VZV disease than children and are prone to pneumonia during the initial infection stage of the lung. Immunocompromised individuals and neonates are at risk because of the lack of protective cell-mediated immunity.
   (c) Immunocompromised individuals are at risk for a leukemia/lymphoma-like disease of B cells because of the ability of EBV to immortalize these cells.
   (d) HSV and EBV cause disease in normal individuals, whereas CMV disease is usually asymptomatic except in the immunocompromised individual. The immunocompromised individual is at risk for serious disease for all herpesviruses.

5. (a) There is no vaccine for HSV, but there are antiviral drugs, including acyclovir, valacyclovir, penciclovir, and famciclovir.
   (b) There is a live attenuated vaccine for varicella, given on the same schedule as the measles-mumps-rubella vaccine. There are two vaccines for zoster: a stronger version of the live varicella vaccine and a subunit vaccine consisting of the glycoprotein E and an adjuvant. Both are administered to adults older than 50 years. There are antiviral drugs, including acyclovir, valacyclovir, penciclovir, and famciclovir.
   (c) There is no vaccine and no true antiviral drug for EBV.
   (d) There are no vaccines for these viruses. Reduction in immunosuppressive therapy will allow T-cell control of the EBV-associated lymphoma to resume. HSV and CMV can be treated with antiviral drugs; CMV can be treated with ganciclovir, valganciclovir, foscarnet, and cidofovir.

CASE STUDY ANSWERS

1. The diagnosis can be confirmed by taking a Tzanck smear and analyzing the cells taken from the base of a lesion for syncytia and Cowdry type A inclusion bodies. The sample can also be analyzed by immunofluorescence. A sample of vesicle fluid can be put into cell culture and the cells observed for CPEs, or the vesicle fluid or spent medium can be analyzed by PCR for the HSV genome.

2. Immunofluorescence using type-specific antibodies or PCR analysis of the samples indicated in question 1 can distinguish HSV-1 from HSV-2.

3. Innate responses, such as IFN-α and NK cells, are activated early to limit the spread of virus, followed later by T-cell responses and antibody. T cells are essential for resolution of infection, but antibody assists in the cleanup of the infection, although it is not sufficient for protection or control of the infection.

4. Latency is established in the trigeminal ganglia because of the site of infection. Future recurrences will be triggered by stresses such as ultraviolet B light and emotional or physical stress.

5. The child was infected by contact with lesion material from an infected person (e.g., a kiss) or by sharing and mouthing an item (e.g., spoon, pacifier, rattle, etc.) with someone bearing an active lesion.

6. Most of the effective anti-HSV drugs are nucleotide analogs that are activated by the viral-encoded

thymidine kinase and then will inhibit the viral DNA-dependent DNA polymerase. These drugs include valacyclovir, acyclovir, penciclovir, and famciclovir. They are not indicated for this child because the infection is not life-threatening, and the disease has progressed beyond the time within which the drugs would be effective.

7. The simplest test would be a heterophile antibody test, which is specific for EBV and not CMV. Serology for EBV antigens or PCR to detect the genome in a blood sample could confirm the diagnosis. During the course of disease, virus and antibodies to VCA and EA would be detected. Only on resolution will antibodies to EBNA be detected. These tests will also distinguish between a current and previous course of EBV disease.

8. The mononucleosis results from the expansion in numbers of T cells on stimulation by the EBV-infected B cells. Mononucleosis-like syndromes accompany other infections (e.g., CMV, HIV) of lymphocytes and myeloid cells, which are antigen-presenting cells.

9. Swollen glands and fatigue are caused by the large-scale activation of the immune response, as indicated by the expansion of the numbers of T cells.

10. Immunocompromised individuals are at risk for EBV-induced leukemia and lymphoma-like diseases because EBV-stimulated B cells will grow out of control in the absence of functional T cells. Boys with Duncan disease (X-linked immunodeficiency) die of leukemia-like immunoproliferation caused by the inability of their T cells to control the outgrowth of B cells (this function is normally used to limit the outgrowth of B cells in response to antigen).

    Thought Question: Herpesviruses are associated with many different diseases, including atherosclerosis, Alzheimer disease, inflammatory diseases, and cancer. In some cases, as with EBV and HHV-8, the connection is clear, but in other cases, it is not so clear. Because these viruses are ubiquitous, lifelong infection is the status quo, but each individual interacts with the infection in a different manner. In some, there is more inflammation, greater frequency of recurrences, infection of different sites, and different levels of symptoms. It is harder to know the subtle effects these viruses have on the **balance** between inflammation and maintenance (status quo) (think M1 versus M2 macrophages) that continues all the time. There are some who suggest that chronic infections (e.g., parasitic worms) educate T-regulator cells and immune control mechanisms, and others suggest that individuals whose bodies are shifted toward inflammation are more prone and likely to have more serious heart attacks. The latter argument has been raised to encourage individuals older than 65 years to be immunized for influenza and *Streptococcus pneumoniae* to prevent the inflammation that accompanies infection. Individuals with integrated and reactivatable HHV-6 are more prone to fatigue, cognitive dysfunction, and other problems. It is very hard to know the influence latent/recurrent herpesviruses have on us.

Chapter 44 Poxviruses

1. Orf virus is a poxvirus with a large DNA genome and a complex virion structure; it replicates in the cytoplasm and causes a vesicular lesion. Unlike smallpox, it is a zoonosis; it is transmitted by contact and does not spread from the site of infection.

2. Orf virus is the poxvirus of sheep and goats.

3. A poxvirus replicates in the cytoplasm and, as a result, must be able to transcribe its genome in the cytoplasm, which requires encoding of a DNA-dependent RNA polymerase and other enzymes present in the nucleus of the host.

4. Wild-type smallpox is strictly a human virus (no animal reservoirs), it always causes disease signs (allows identification of infected individuals), there is only one serotype, and an effective vaccine is available. Immunization with other poxviruses (e.g., vaccinia virus) protects against smallpox virus.

5. MCV, like smallpox, infects only human cells and like other poxviruses, replicates in the cytoplasm. Unlike other poxviruses, MCV is restricted to infecting keratinocytes and can stimulate the growth of cells rather than causing a lytic infection. It is released, like human papilloma virus, on shedding of the terminally differentiated keratinocytes or epithelium.

6. MCV is transmitted by contact with infected skin.

7. Although MCV is common in healthy people, the immunodepression caused by TNF-α antagonists or immunosuppression (reduction in cell-mediated immunity) during AIDS or by chemotherapy or immunotherapy puts an individual at higher risk for more frequent and larger lesions.

ANSWERS

1. Poxviruses have a large, complex structure with several membranes, lateral bodies, and other structures. Unlike other viruses with small interlocking capsid pieces, synthesis and assembly of complex structures require complex interactions to ensure that all the necessary enzymes and structures are included in final package.

2. Poxviruses are DNA viruses. Replication of a DNA virus in the cytoplasm requires that the virus supply and encode the enzymes required for mRNA synthesis (e.g., DNA-dependent RNA polymerase, capping enzymes) and for DNA synthesis (DNA-dependent DNA polymerase), which are enzymes that are normally present in the nucleus.

3. Immunity to smallpox infection develops from the local innate responses to the more systemic antibody and T-cell responses. The immune responses do not develop until 6 to 10 days after infection or later because of the virus' ability to evade host protections (too late to stop

its spread). Because the virus has spread throughout the body by this time and infected many tissues, the immune response (especially cell-mediated immunity and inflammation) can cause great damage when trying to eliminate the infected cells. In a vaccinated person, antibody is present in the bloodstream to block the spread of the virus by viremia. T-cell responses are activated within 1 to 4 days from memory cells, and these responses can successfully limit cell-cell spread, kill infected cells, and resolve the infection.

4. Elimination of smallpox was made possible by an excellent vaccine that leaves a scar as evidence of vaccination, a very active WHO, and because the virus has the following properties: exclusive human host range (no animal vectors to control); single serotype shared with animal viruses such as vaccinia; and presence of symptoms in every infected individual, which facilitated quarantine procedures.

5. Vaccinia has been developed into an attenuated virus that will not cause significant human disease (in immunocompetent hosts). The genome contains many genes that are not necessary for virus replication and that can be replaced with genes from other viruses or microbes. If the appropriate gene is incorporated into a vaccinia hybrid, then the vaccine would establish a natural immune response, including CD8 T cells and memory cells, which would be appropriate for those viruses requiring TH1 immune responses for immune control. The vaccinia hybrid vaccine would also be appropriate for viruses that cannot be grown in animal models or tissue culture as long as the relevant genes can be isolated, for viruses that would have questionable safety because of potential reversion, and for viruses that have oncogenic potential. Appropriate viruses include human immunodeficiency virus (HIV), herpes simplex virus (HSV), cytomegalovirus (CMV), Epstein-Barr virus (EBV), and other viruses.

6. Both HPV and molluscum contagiosum infect keratinocytes and stimulate the growth of the basal cell. Neither virus is cytolytic, and virus is released as the skin cell matures and dies. Both viruses evade host immune responses, HPV by limiting protein expression and virus production within the body, and molluscum contagiosum with approximately 30% of its genome dedicated to the purpose

Chapter 45 Parvoviruses

1. Chronic hemolytic anemia (e.g., sickle cell anemia) puts an individual at risk for serious disease with B19 parvovirus because it compounds the loss of erythrocyte production resulting from the virus' infection of erythroid precursors.

2. Erythroid precursors are the host cell for the virus. The virus requires a growing cell to replicate and targets the blood group P antigen (globoside) as a receptor on these cells.

3. Infection of an adult may result in acute polyarthritis caused by immune complex–mediated inflammatory reactions. Infection of the fetus can result in hydrops fetalis, which often results in fetal death. The virus infects the erythroid precursors of the fetus, killing them and causing anemia, edema, hypoxia, and congestive heart failure.

CASE STUDY ANSWERS

1. The biphasic nature of the disease and the slapped-face rash are notable symptoms but are not unique to B19. B19 also causes arthralgia in adults because of immune complexes. A somewhat similar course of disease would occur with human herpesvirus 6 induction of exanthema subitum (roseola), although the time course may be different.

2. The child was infectious during the initial disease signs and symptoms, which resemble a mild cold. The rash is immune mediated and occurs later after the contagion period is over.

3. The initial nonspecific disease signs are caused by interferon and other innate responses to the infection. The rash is caused by immune responses that are most likely associated with antibody and virion immune complexes.

4. The rash of the daughter and the arthralgia of the mother are caused by the presence of antibody, formation of immune complexes, and type 2 and 3 hypersensitivity reactions.

5. Individuals with chronic hemolytic anemia (e.g., sickle cell anemia) are at risk for serious disease because B19 replicates in erythrocyte precursors and prevents development of new erythrocytes or shortens their lifetime. Pregnant women are at risk for B19 infection, which causes hydrops fetalis and loss of the fetus.

6. Quarantine would not be effective because the virus is spread before the onset of the classic disease signs and symptoms of erythema infectiosum (fifth disease).

Chapter 46 Picornaviruses

1. The baby is likely to be infected with echovirus 11. Infection could have occurred on contact with fecal material from the mother but, just as likely, by contact with nasal secretions or an aerosol. The mother or another family member is likely to be the source of infection because echovirus 11 causes a common cold in adults.

2. The virus is a naked capsid virus and is impervious to acids, detergents, heat, and dryness. It can withstand the harsh conditions of the gastrointestinal tract and even insufficient sewage treatment. As a result, the virus is transmitted by the fecal-oral route, but it also can infect the upper respiratory tract and cause common coldlike symptoms and can be transmitted by contact or aerosols.

3. Echovirus 11 kills the infected cell it infects and then spreads to other cells. The most important immune response for protection is antibody, which will neutralize the released virus to prevent spread of the virus. If Mom had been infected at an earlier time, then transplacental immunoglobulin (Ig)G would have been provided to the infant from Mom for protection, but that is not the case. Antibody in the serum also prevents spread of the virus to the target tissue, which would be the meninges and brain.

CASE STUDY ANSWERS

1. The key signs and symptoms were sore throat, fever, faint rash, excessive napping, lethargy, headache, and pain on turning head (stiff neck). The presence of lymphocytes in the CSF and normal glucose and protein levels minimizes the diagnosis of a bacterial infection.

2. The differential diagnosis is aseptic meningitis that is likely caused by a virus such as an enterovirus, HSV, or lymphocytochoriomeningitis virus, or by an arboencephalitis virus from the Togaviridae, Flaviviridae, or Bunyaviridae families. *Cryptococcus neoformans* (fungus), *Mycobacterium tuberculosis,* and *Borrelia burgdorferi* are also possible. However, the presence of a rash and sore throat before signs of meningitis strengthen the likelihood of an enterovirus infection, such as coxsackievirus A, echovirus, or parechovirus. At an earlier time (30 years ago), polio would also be in the differential diagnosis.

3. The rash and sore throat in the prodrome period and the presence of lymphocytes in the CSF distinguish an enterovirus meningitis from other microbial causes.

4. An RT-PCR analysis would identify the enterovirus in the CSF and confirm the diagnosis.

5. Enteroviruses are spread by the fecal-oral and aerosol routes.

6. The initial target tissues for enteroviruses are the mucoepithelium, lymphoid tissue of the tonsils and pharynx, and Peyer's patches of the intestinal mucosa. The virus is cytolytic.

Chapter 47 Coronaviruses and Noroviruses

1. A common cold is an upper respiratory infection and most likely caused by a coronavirus or one of the many rhinoviruses. Other picornaviruses (coxsackievirus, echovirus), parainfluenza, respiratory syncytial virus, metapneumovirus, and even influenza virus can cause common coldlike symptoms.

2. Common coronaviruses and rhinoviruses replicate poorly or cannot replicate at 37° C and are restricted to the cooler environments of the upper respiratory tract.

3. They are transmitted primarily by contact with contaminated hands, surfaces, and fomites, as well as by aerosols.

4. There are multiple microbial causes of gastroenteritis, and the nature of the stool, the time course of onset, and the history of exposure are important clues to the cause of the disease. For a combination of vomiting and diarrhea, *Bacillus cereus,* rotavirus, and norovirus should be in the differential diagnosis. Onset from *B. cereus* should be within about 4 to 10 hours because it is the result of intoxication by preformed toxin present in the food. Norovirus requires sufficient time to replicate in a sufficient number of cells and cause sufficient damage to elicit the diarrhea.

5. Norovirus binds to blood group antigens (ABO) on the cell surface, the intestinal villi are compromised as indicated by broadening and blunting, and crypt cells are also compromised and inflammatory processes initiated. These changes cause the diarrhea. Delay in gastric emptying and reduced gastric mobility cause nausea and vomiting.

6. The symptoms are the best means of diagnosing the infection, but reverse transcriptase-polymerase chain reaction (RT-PCR) and quantitative real-time PCR are the methods that also can be used. There also are enzyme-linked immunosorbent assay (ELISA) tests for immunologic detection.

CASE STUDY ANSWERS

1. Rotavirus-induced gastroenteritis usually occurs in infants, not adults. This infection is likely caused by a norovirus such as Norwalk virus.

2. Viral transmission of this virus is fecal-oral and probably through food.

3. The noroviruses are capsid viruses. Their capsid is impervious to acid, detergent, and drying.

4. Handwashing after using the bathroom is the best means for limiting the spread of this virus.

Chapter 48 Paramyxoviruses

1. Measles binds to specific protein receptors; fuses its membrane with the cell's membrane; delivers its negative-strand genome and RNA-dependent RNA polymerase components into the cytoplasm, in which individual mRNAs are generated; a full-length copy (positive-sense template) of the genome is made; and new genomes are transcribed from the template. The proteins of the virus are translated, including glycoproteins. The glycoproteins are processed similarly to cellular glycoproteins and then inserted into the plasma membrane. The matrix protein associates with these proteins, and the nucleocapsid (genome plus polymerase components) associates with the matrix protein, which promotes the

budding of the virion from the membrane, causing it to leave the infected cell. The virus does not have to kill the cell to exit.

2. Cough, conjunctivitis, coryza, photophobia (CCCP) and Koplik spots and rash (KR).

3. Measles is transmitted by aerosols.

4. Either the boy never was vaccinated, he did not get a booster to ensure that he has sufficient immune protection, or he is immunocompromised and did not respond to the vaccine.

5. Pneumonia, which can also be a serious complication, accounts for 60% of the deaths caused by measles. Bacterial superinfection is common in patients with pneumonia caused by the measles virus. Encephalitis caused by the virus usually begins 7 to 10 days after the onset of illness, but infection can induce postinfectious encephalitis caused by immunopathologic reactions. Disease mortality increases if there is a vitamin A deficiency. Subacute sclerosing panencephalitis (SSPE) is a very late neurologic sequela of measles resulting from a mutant of measles that replicates slowly in neurons until a threshold level induces inflammation.

CASE STUDY ANSWERS

1. The three Cs (cough, conjunctivitis, and coryza), rash, and Koplik spots (white lesions in mouth) are characteristic of measles. Photophobia may also be present.

2. The diagnosis is usually made based on the disease signs. Laboratory tests that may confirm the diagnosis include an RT-PCR analysis of RNA to detect the viral genome or immunofluorescence to detect viral antigens in cells present in respiratory tract secretions, urine, or blood.

3. There are no antiviral drugs available for measles, but immunoglobulin can limit the severity of the disease.

4. The patient was contagious for approximately 7 days before and 3 to 4 days after the onset of disease symptoms.

5. Incidence of the disease has become rare because of an effective immunization program.

6. The patient had an insufficient immune response to prevent viremic spread of the measles virus and onset of disease. This could occur if the individual was not immunized or did not receive a booster immunization as a young teenager.

7. This disease is laryngotracheobronchitis (croup) and is caused by parainfluenza virus.

8. *Haemophilus influenzae* can cause an epiglottitis that would have similar symptoms. RSV, metapneumovirus, influenza virus, *Bordetella pertussis,* and adenovirus may also cause croup-like disease.

9. Nasal washings can grow in tissue culture cells and will fuse the cells into multinucleated giant cells (syncytia). RT-PCR can be used to detect and identify the virus in nasal washings.

10. There is no antiviral drug for this disease, but nebulized cold or hot steam can help open the airways.

11. The child is contagious during the symptomatic period. The virus is transmitted by the respiratory route.

Chapter 49 Orthomyxoviruses

1. She acquired the infection by breathing a contaminated aerosol.

2. Normally there is an abrupt onset of fever, chills, severe myalgias, loss of appetite, weakness and fatigue, sore throat, and a nonproductive cough within 2 days of infection. The fever persists for 3 to 8 days, and unless a complication occurs, recovery is complete within 7 to 10 days. This woman suffered ARDS.

3. Cell-mediated immunity is suppressed in pregnant women. This allowed the virus to replicate and spread to a greater extent and enhanced the pathogenicity of the infection.

4. This H1N1 strain is a reassortant of viral strains from humans, pigs, and ducks generated by subsequent infections of pigs with virus from duck and then human and other pig viruses. It created a unique H1N1 virus. This is shown in Fig. 49.5.

CASE STUDY ANSWERS

1. These symptoms can be caused by the parainfluenza, metapneumovirus, or respiratory syncytial paramyxoviruses or by adenovirus.

2. The diagnosis can be confirmed by enzyme-linked immunosorbent assay (ELISA) tests for virus antigen, RT-PCR analysis for the influenza genome, and detection of hemagglutinating activity in nasal washings with confirmation by hemagglutination inhibition with virus-specific antibody.

3. Amantadine and rimantadine inhibit the uncoating of the virus by blocking the M2 viral protein–derived channel that is inserted into the endosomal uptake vesicle. This prevents the flow of protons through the channel and the subsequent dissociation of the nucleocapsid. The M2 channel also prevents acidification of the Golgi. An acidified Golgi would cause the HA protein to change conformation and be inactivated. Antiinfluenza therapy with amantadine or neuraminidase inhibitors is effective before or within the first 48 hours of infection, when virus replication is occurring but before extensive tissue damage is caused by the virus and the host's immune response to the virus causes immunopathogenesis. Other individuals can take amantadine as a prophylactic drug. Amantadine and rimantadine are no longer the drugs of

choice due to the prevalence of resistant strains. Oseltamivir, zanamivir and baloxavir marboxil are preferred.

4. The patient was contagious approximately 1 day before and up to 5 days after the onset of disease signs. The virus is transmitted by the respiratory route.

5. Very young and very old family members are at greatest risk. The young are immunonaive, and the elderly may be immunodeficient or may not have been exposed; thus they lack a response to the current strain of influenza. Older individuals also have difficulty repairing the damage caused by the influenza virus or a bacterial superinfection of the lung (pneumonia) that often accompanies influenza infection.

6. Influenza readily undergoes mutation (drift) to produce new strains of influenza, and influenza A can undergo reassortment of its genome segments with animal (especially avian) influenza viruses to create new viruses (shift). Both shift and drift create new serotypes of virus. The composition of the influenza vaccine is reevaluated on an annual basis in an attempt to out-guess the changes in influenza that Mother Nature delivers.

Chapter 50 Rhabdoviruses, Filoviruses, and Bornaviruses

1. If possible, the biting animal is captured, killed, and analyzed for rabies. In animals, a brain biopsy is analyzed by direct immunofluorescence detection for rabies antigen or samples are taken for genetic analysis by reverse transcriptase-polymerase chain reaction (RT-PCR). For the patient, there is no method for analysis until late in the infection when antirabies antibody may be present (usually too late to be of help), and an enzyme-linked immunosorbent assay (ELISA) can be used for detection. Cerebrospinal fluid or saliva can be analyzed by RT-PCR for viral genome at this time.

2. After a long incubation period, initial symptoms are fever, malaise, headache, pain or paresthesia (itching) at the site of the bite; gastrointestinal symptoms; fatigue; and anorexia. This prodrome after the incubation period usually lasts 2 to 10 days after the incubation period, after which the neurologic symptoms specific to rabies appear. Hydrophobia (fear of water) triggered by the pain associated with the patient's attempts to swallow water, focal and generalized seizures, disorientation, and hallucinations are also common during the neurologic phase. The paralysis may lead to respiratory failure. The patient becomes comatose after the neurologic phase, which lasts from 2 to 10 days. This phase almost universally leads to death resulting from neurologic and pulmonary complications.

3. The antibody is detected late in the course of disease, after the infection has progressed to generate neurologic symptoms. Analysis is only useful to confirm the diagnosis, but it is not helpful to the patient. Knowing that tissue is contaminated with rabies allows prevention of its use for transplants.

4. After being bitten by an animal suspected of carrying rabies, the bite site is washed carefully and then instilled with rabies immunoglobulin. The patient then receives four immunizations with rabies antigen.

5. Ribavirin is a guanosine analog that promotes hypermutation of the viral genome, leading to production of noninfectious viruses.

CASE STUDY ANSWERS

1. Rabies is suggested by the boy's refusal to drink (hydrophobia), hallucinations, anxiety, salivation, difficulty breathing, and fever.

2. Rabies has a long incubation period because it is not very cytolytic, replicates slowly until it reaches the brain, and once it enters the neuron it is relatively hidden from immune responses. The characteristic disease signs occur only when the virus has reached the brain, replicates, and causes damage.

3. Immediately after the dog bite, the bite site should have been washed and the child should have been injected with rabies-specific immunoglobulin as close to the site as possible. A course of immunization with the inactivated rabies vaccine should have also been initiated as soon as possible.

4. Unlike other neurologic viral diseases, rabies infection is undetectable until it reaches the brain (too late for treatment), and then it infects the salivary gland, causing painful swallowing and potential infection of others.

Chapter 51 Reoviruses

1. Because this is a watery diarrhea, norovirus, adenovirus, and bacterial agents such as cholera and toxigenic *Escherichia coli* must be considered. These other agents would also cause diarrhea in adults, whereas rotavirus is more likely to cause diarrhea in children.

2. Rotavirus can be detected in stool by enzyme-linked immunosorbent assay (ELISA). The rotavirus ELISA was one of the first commercially available ELISAs. Reverse transcriptase- polymerase chain reaction (RT-PCR) can also be used.

3. The virus is transmitted by the fecal-oral route. The patient is contagious during and for 2 to 5 days after the onset of diarrhea.

4. The baby, because of his small size, is at high risk for dehydration.

CASE STUDY ANSWERS

1. Commercially available ELISAs detect rotavirus in stool.

2. The NSP4 protein of rotavirus has a toxin-like (e.g., cholera) activity to promote secretory diarrhea, and the virus has a cytolytic action on the mucosal epithelium.

3. Treatment is fluid replacement.

4. There are two commercially available vaccines administered as early as possible during the first year of life.

5. Dehydration occurs very rapidly in babies because of their small size and the rapid fluid loss. Lack of access to a hospital and inability to rapidly rehydrate put this baby at greater risk.

6. Protection from rotavirus disease requires the continued presence of virus-specific secretory IgA in the intestine and IgG in the tissue. Even if maternal IgG were present, it would not be protective in the lumen of the intestine. Infection of the mucosa is the only mechanism to elicit an IgA this response. The vaccines are live attenuated and ingested to elicit this response. The protection must be generated as early as possible because babies are exposed and at highest risk for serious disease.

Chapter 52 Togaviruses and Flaviviruses

1. Dengue is a mosquito-borne virus.

2. Dengue, dengue hemorrhagic fever (DHF), and dengue shock syndrome (DSS).

3. Neutralizing antibody is protective, but a nonneutralizing antibody (possibly elicited to another strain of dengue) can facilitate uptake into macrophages, in which the virus replicates and travels throughout the body. In addition, immune responses are more intense and exacerbate inflammatory responses with the second infection.

4. Dengue is prevalent where the *Aedes* mosquito vector is prevalent, in tropical regions of the world, including regions of the United States.

CASE STUDY ANSWERS

1. The diagnosis of dengue virus infection is indicated by the disease signs of high fever, severe headache, and joint and back pain. His trip to Malaysia would have increased his risk of exposure to *Aedes* mosquitoes carrying the virus.

2. The *Aedes* mosquito is endemic in Malaysia and is a carrier of dengue virus, which is prevalent in Malaysia.

3. The virus was transmitted independently by different mosquitoes to the father and son.

4. Petechiae and ecchymoses are indicators of hemorrhagic disease.

5. The diagnosis of rubella infection is suggested by the arthralgia and especially the mild rash. These immune-mediated responses occur after viral replication and viremic spread, which induces interferon, causing the flulike syndrome.

6. Exposure to rubella in the United States is unlikely because of the effective vaccine program there.

7. If the man had been immunized with the MMR vaccine and received his booster immunization prior to 15 years of age, he should have been protected against rubella disease.

8. Rubella is the only togavirus that is transmitted by aerosols as a respiratory virus.

9. All unimmunized individuals are at risk for this infection. However, the most serious outcomes occur to the fetus of women who are infected before the 20th week of pregnancy. Rubella causes severe congenital defects.

10. Immunization of the populace (especially children) for rubella prevents congenital defects in babies.

Chapter 53 Bunyaviridae and Arenaviridae

1. Lassa fever is carried by small mammals (e.g., mice) and is transmitted by inhalation of aerosols, consumption of contaminated food, or contact with fomites contaminated with mouse saliva, feces, or urine.

2. Arenaviruses have nonfunctional ribosomes in the virion, and the genome consists of two single-strand ambisense RNAs.

3. Like arenaviruses, the bunyaviruses have multiple single-strand ambisense RNAs that are surrounded by an envelope but without ribosomes. Hantaviruses are transmitted in mouse saliva, feces, and urine, but the other bunyaviruses are transmitted by arthropods.

CASE STUDY ANSWERS

1. The severe headache, stiff neck, and photophobia are symptoms of meningitis, accompanied by the systemic interferon-induced flulike symptoms caused by a viremia.

2. The virus was transmitted in the feces and urine of the rodents that lived in her house. It is likely that she breathed in contaminated aerosols.

3. This virus infection requires cell-mediated responses (TH1) to control the infection, but antibody can limit viremic spread.

4. La Crosse encephalitis virus is suggested by the meningoencephalitic symptoms, the presence of inflammatory cells in cerebrospinal fluid (which were probably predominantly lymphocytes and accompanied by normal glucose levels), the time of year, and the fact that she spent time in the environment of the *Culex* mosquito carrier of the La Crosse virus.

5. The differential diagnosis would include other viral encephalitides such as eastern and western equine

encephalitis viruses, West Nile encephalitis virus, LCM virus, and also herpes simplex virus. Her recovery from the episode minimizes the possibility that she experienced herpes simplex encephalitis, which usually causes permanent and severe damage.

6. The patient was infected by the bite of a *Culex* mosquito.

7. Transmission could be prevented by reducing exposure to the mosquito vector (e.g., get out of the woods), spraying to kill the mosquitoes, and draining the breeding spots for these mosquitoes (too difficult).

8. Screening programs for birds carrying the encephalitis virus (host) and mosquitoes (vector) can help identify the presence of La Crosse virus in the environment of the summer camp. Blood from the birds can be analyzed for the presence of antibody, and blood from the birds and the mosquitoes can be analyzed by RT-PCR for evidence of the viral genome.

Chapter 54 Retroviruses

1. HIV infects cells expressing CD4 and either the CCR5 or the CXCR4 chemokine receptors. This includes CD4 T cells, macrophages, and dendritic cells.

2. After binding to cell-surface receptors, the virus fuses its envelope with the cell membrane and delivers the virion contents and genome into the cytoplasm. The positive-strand (+) RNA genome is reverse transcribed into DNA, which integrates into the host chromosome and is then transcribed similar to a very active host gene. Genome length mRNAs are transcribed that can become new viral genomes or can be processed into several mRNAs. Smaller mRNAs are also transcribed. The virion assembles on glycoprotein-modified membranes, the virus buds out of the cell, and then the viral protease cleaves the virion proteins into individual proteins to form the nucleocapsid within the envelope.

3. The woman is susceptible to other intracellular bacteria (e.g., *Mycobacterium avium-intracellulare* complex, *Salmonella*), viruses (especially herpesviruses), fungal infections, and malignancies such as lymphoma and Kaposi sarcoma.

4. HIV is transmitted by unprotected sexual contact and exposure to contaminated blood and blood products and intravenous (IV) drug abuse.

5. Initial virus detection (screening) is currently detected by enzyme-linked immunoassay (ELISA) for both a viral antigen (p24) and for antiviral antibodies. Earlier approaches required confirmation with Western Blot analysis for viral antigens. Initial detection and virus load (amount of virus in the blood) can be determined by real time reverse transcription-polymerase chain reaction (RT-PCR). The increase in viral load caused by poor compliance to antiviral therapy or viral resistance to therapy would be detected using real time RT-PCR.

6. Highly active antiretroviral therapy (HAART) combines multiple antiretroviral drugs to limit the potential selection of resistant mutants. The drugs target the reverse transcriptase, integrase, protease, CCR5 co-receptor, or block the fusion event.

CASE STUDY ANSWERS

1. A diagnosis of AIDS is confirmed by demonstrating the presence of HIV and a CD4 T-cell level less than 200/μL. The presence of HIV is demonstrated by antibodies to HIV by ELISA and the presence of the p24 protein, and if necessary, confirmation by Western blot analysis, or the presence of the genome by RT-PCR, or similar genomic analysis. CD4 T-cell levels are usually demonstrated by flow cytometry.

2. The high-risk behaviors of this man are heroin addiction and sharing needles at a shooting gallery. Unsafe sex and sex with many partners are also major risk factors.

3. The reduction in CD4 T cells reduces the body's ability to support TH17 and TH1 responses that produce IL-17, tumor necrosis factor, and IFN-γ, respectively. TH17 responses activate epithelial cells and neutrophils, and TH1 responses activate macrophages and CD8 T cells that are necessary to control viral, fungal, and intracellular bacterial infections.

4. The samples should be handled with universal blood precautions. Workers should wear gloves and protective eyewear and clothes.

5. Spread of HIV is limited by not reusing or sharing needles and by using condoms during sex. Individuals at high risk for infection can take one-a-day prophylactic antiviral treatment (PrEP).

6. The most important viral component to be incorporated into a vaccine to generate protective antibody is the gp120 glycoprotein (or the gp160 glycoprotein precursor). The gp120 is the viral attachment protein, and antibodies to this protein will neutralize the virus. Of interest, cytotoxic T-cell responses (CD8 T cells) are generated against other proteins, such as the Gag proteins. Such a vaccine would be appropriate for persons at risk for infection, including health care workers, promiscuous MSM, heterosexual men and women, and drug addicts. The large number of clades and rapid mutation rates make it difficult to develop an effective vaccine.

Chapter 55 Hepatitis Viruses

1. Common symptoms of hepatitis are nausea and abdominal discomfort, slight fever, dark yellow urine, jaundice (including yellowish sclera), and distended and tender abdomen. The time course of disease, possibility for chronic infection (unlikely for hepatitis A virus [HAV] or hepatitis E virus [HEV], very likely for HCV), and the serology of infection are different for HBV.

2. The presence or absence of antigens in the blood and the progression of the antibody response to specific hepatitis viral antigens correlate with disease progression. Most importantly, the presence of HBsAg (surface antigen) indicates unresolved infection, whereas antibody to HBsAg indicates resolved infection or prior immunization with vaccine. Anti-HAV IgG indicates that she had an HAV infection at some time in the past.

3. HBV is transmitted in contaminated blood products, tissues, and semen.

4. Spread of HBV can be prevented by screening the blood supply to prevent transmission by this route, by safe sex, by not sharing or reusing syringe needles, and by abiding by universal blood precautions. Vaccination is the best means of preventing disease. Chronic HBV disease can be treated with reverse transcriptase inhibitors such as lamivudine, entecavir, tenofovir, or adefovir dipivoxil.

5. No, this person has never been infected with HBV but has been immunized and developed antibodies to HBsAg in the vaccine for HBV. Antibodies to other HBV antigens, specifically HBc or HBe, would be present if this person had been previously infected with HBV.

6. This patient has an acute HCV episode that may resolve but is more likely to establish a chronic infection (70% of patients).

7. Treatment with a combination of direct acting antivirals (DAA) is able to resolve the disease and infection in many patients. The DAAs include protease inhibitors, nucleoside, and nonnucleoside inhibitors of the polymerase, and inhibitors of the NS5A protein, which are a component of the polymerase and inhibitor of interferon activity. Prior treatments used pegylated interferon and ribavirin.

CASE STUDY ANSWERS

1. In each case, the time course and nature of the onset of disease would help in distinguishing the hepatitis viruses. Hepatitis A and E have an acute onset of disease, whereas the onset of hepatitis B and C are slower and more insidious.

2. Serologic tests would be helpful to determine recent exposure for all three hepatitis viruses and the stage of disease for hepatitis B. Genomic assays for HBV and HCV can also be performed (PCR [HBV], RT-PCR [HCV]).

3. Patient A probably has hepatitis A infection obtained from food. Patient B may have hepatitis B or C infection acquired from sharing contaminated syringe needles. Patient C is likely to have obtained HCV (but possibly HBV) from a blood transfusion obtained before the screening of the blood supply.

4. Disease from hepatitis A or hepatitis B can be prevented by immunization of the individual. The risk for infection by hepatitis B and C can be reduced by careful screening of the blood and organ supply and use of new syringe and needles and carefully sterilized surgical equipment. Attention to proper hygiene for food service workers and others, and properly disinfected water supplies, are important to limit HAV and HEV dissemination.

5. Patient B (HBV), and especially patient C (HCV), are susceptible to chronic disease. Most individuals infected with HCV experience chronic infection.

6. Acute and chronic HBV disease are discriminated serologically. The presence of HBsAg combined with the inability to detect antibodies to anti-HBsAg is a good indicator of chronic HBV.

7. HBV infection can be prevented by proper blood handling procedures; by not sharing needles when taking drugs; and by practicing safe, protected sex.

Chapter 56 Prion Diseases

1. Myoclonus (muscle twitching) and other neurologic signs without immunologic or virologic evidence of infection support a diagnosis of a prion disease.

2. Prions are an alternate conformation of a normal mammalian protein that forms multimers. Most disinfection procedures disrupt nucleic acid or protein structure. There is no genetic information to be inactivated and the protein is in a tight conformation that could be considered to be already denatured from its normal functional form.

3. Prions are an alternate conformation of a normal mammalian protein, and the host immune response does not recognize them as foreign proteins.

CASE STUDY ANSWERS

1. The disease signs and slow onset suggest the possibility of a spongiform encephalopathy caused by a prion (e.g., CJD). The absence of inflammation distinguishes this disease from progressive multifocal leukoencephalopathy (PML) caused by the JC polyomavirus. The differential diagnosis would also include Alzheimer disease, stroke, viral encephalitis, and autoimmune and neoplastic diseases.

2. The lack of inflammation and the vacuolation of the brain are strong indicators of prion diseases.

3. The lack of swelling or inflammation distinguishes the prion diseases from virus diseases.

4. Prions are very resistant to most disinfection procedures. The pathologist should follow standard blood precautions; all infected materials should be disinfected in 5% hypochlorite solution or autoclaved for at least 1 hour.

Chapter 57 Fungal Classification, Structure, and Replication

ANSWERS

1. Fungi differ from bacteria in several ways. Generally, fungi are 10- to 100-fold larger than bacteria. Fungi are eukaryotic microorganisms, whereas bacteria are prokaryotes. Thus fungi contain a well-defined nucleus and cytoplasmic organelles, such as mitochondria, Golgi, and endoplasmic reticulum (see Fig. 57.1). Most fungi exhibit aerobic respiration, although some are facultatively anaerobic, and others are strictly anaerobic. Relative to bacteria, fungi are slow growing with doubling times in terms of hours rather than minutes.

2. In contrast to other eukaryotic (e.g., mammalian) cells, the plasma membranes of fungi contain ergosterol rather than cholesterol as the principal membrane sterol.

3. In contrast to molds, yeasts are usually unicellular; reproduce by budding or by fission; and produce round, pasty, or mucoid colonies on agar. Molds, on the other hand, are multicellular organisms consisting of threadlike tubular structures, called *hyphae* (see Fig. 57.2), which elongate at their tips by a process called *apical extension.* The hyphae combine to produce a matlike structure called a *mycelium.* The colonies formed by molds are often described as filamentous, hairy, or wooly. The hyphae may also produce specialized asexual reproductive elements known as *spore* or *conidia* (see Fig. 57.3).

4. The form of the fungus producing sexual spores is termed the *teleomorph,* and the form producing asexual spores is termed the *anamorph.* In clinical situations, it is common to refer to organisms by their asexual designations. This is because the anamorphic (asexual) state is isolated from clinical specimens, and the sexual or teleomorphic phase occurs only under very specialized conditions in the laboratory.

Chapter 58 Pathogenesis of Fungal Disease

ANSWERS

1. Primary pathogens are capable of initiating infection in a normal, apparently immunocompetent host. Primary pathogens possess putative virulence factors that allow them to actively breach host defenses that ordinarily restrict the invasive growth of other microbes. In contrast, opportunistic pathogens generally only cause infection when there are disruptions in the protective barriers of the skin and mucous membranes or when defects in the host immune system allow them to penetrate, colonize, and reproduce the host.

2. Each of the primary systemic fungal pathogens is an agent of respiratory infections. Each has a saprobic phase that is characterized by filamentous septate hyphae typically found in soil or decaying vegetation that produces the airborne infectious cells. Likewise, the parasitic phase of each fungus is adapted to grow at 37° C and to reproduce asexually in the alternative environmental niche of the host respiratory mucosa. This ability to exist in alternate morphogenic forms (dimorphism) is one of several special characteristics (virulence factors) that allow these fungi to cope with hostile environmental conditions of the hosts.

3. The most important line of defense against the endemic dimorphic fungi is the pulmonary macrophage.

4. Both primary and opportunistic fungal pathogens are capable of replication at 37° C.

Chapter 60 Laboratory Diagnosis of Fungal Disease

1. Knowledge of the specific etiologic agent may have important prognostic implications and may directly influence the choice of antifungal therapy.

2. The identification of yeastlike fungi to the species level often requires the determination of the biochemical and physiologic profile of the organism in addition to the assessment of the microscopic morphology. In contrast, the identification of a mold is based almost entirely on its microscopic morphology. Both yeasts and molds may require molecular or proteomic methods to establish a definitive identification.

3. The endemic dimorphic pathogens are identified by their microscopic morphologic features, by the demonstration of thermal dimorphism, and by exoantigen and nucleic acid probe tests. Nucleic acid sequence analysis and MALDI-TOF MS also have been used to identify these pathogenic fungi.

4. The advantages of direct microscopic examination of clinical material for the diagnosis of fungal infection include low cost and speed of diagnosis. In certain instances, the fungus may be not only detected but identified by microscopy because it possesses a distinctive morphology. Microscopic detection of fungi in tissue serves to guide the laboratory in selecting the most appropriate means to culture the specimen and is helpful in determining the significance of culture results.

Chapter 61 Antifungal Agents

1. The echinocandin antifungal agents inhibit the 1,3-β-glucan synthesis enzyme complex, resulting in deficient cell wall production. Because mammalian cells do not contain 1,3-β-glucans, this class of agents is selective in its toxicity for fungi. Most of the other systemically active antifungal agents act on targets that to some extent are shared by mammalian cells and thus may exhibit toxicity to the host and the infecting fungus.

2. Azole resistance in *C. albicans* can be caused by overexpression or mutation of 14-α-demethylase and by overexpression of efflux pumps, such as *CDR* and *MDR* genes.

3. The attraction of combination therapy is that, by using combinations of antifungal agents, one may be able to achieve a better clinical outcome than with monotherapy. Synergy may be achieved by combining two agents, such as terbinafine and an azole, which both attack the sterol pathway at different points, resulting in a more effective inhibition of ergosterol synthesis and disruption of the fungal cell membrane.

Chapter 62 Superficial and Cutaneous Mycoses

1. Both subjects appear to be suffering from a dermatophytosis. Given the clinical and epidemiologic evidence, one might expect infection with a zoophilic pathogen, such as *Microsporum canis* or a *Trichophyton* species.

2. The first step in making the diagnosis would be to examine both skin scrapings and hair using KOH and calcofluor white. A specific etiologic diagnosis requires culture of hair and skin scrapings, followed by assessment of the gross and microscopic appearance of the cultured fungus. In the case of dermatophytes, further identification may be accomplished by assessing the nutritional requirements of the fungus using special dermatophyte test media.

3. This infection, tinea barbae, will require therapy with an agent such as terbinafine or itraconazole. Further oral-to-muzzle contact should be discouraged.

4. The usual transmission of a zoophilic dermatophyte is from animal to human.

CASE STUDY ANSWERS

1. b. Cuddling with the family cat

2. a. *M. canis*

3. a. Microscopic examination of a skin scraping treated with KOH

Chapter 63 Subcutaneous Mycoses

1. The differential diagnosis of this process includes a subacute bacterial process caused by common aerobic and anaerobic gram-positive and gram-negative bacteria or infection caused by nontuberculous mycobacteria, an actinomycotic mycetoma, or a eumycotic mycetoma.

2. The list of most likely fungi involved in such a process is extensive and includes *Acremonium, Fusarium, Scedosporium, Madurella,* and *Exophiala* species among others.

3. Evaluation of this process should include radiographs of the extremity plus direct microscopic examination of any drainage. If sinus tracts are present, then they should be examined for the presence of any granules. In the absence of drainage or granules, a deep surgical biopsy should be obtained. Routine hematoxylin and eosin (H&E), Gram, acid-fast, and fungal stains (e.g., periodic acid–Schiff [PAS] or Gomori methenamine silver [GMS]) should be performed. Drainage, granules, and biopsy material should be cultured for routine bacteria, acid-fast bacilli, and fungi (selective and nonselective media).

4. Treatment of eumycotic mycetomas is usually unsuccessful, whereas medical therapy (with antibacterial agents) is usually effective in cases of actinomycotic mycetoma. Progression of a eumycotic mycetoma may be slowed by administration of systemically active antifungal agents, such as amphotericin B, terbinafine, ketoconazole, itraconazole, or posaconazole. Amputation is the only definitive treatment but should be balanced against the rate of progression, symptomatology, the availability of adequate prosthesis, and the individual circumstances of the patient. More recently posaconazole seems to be a promising agent for the treatment of mycetoma with clinical cure or improvement of several mycetoma patients.

CASE STUDY ANSWERS

1. c. *Sporothrix* spp.

2. The general approach would be to obtain a biopsy of the lesion and submit it for both histopathology (with fungal stains) and fungal cultures. Whereas histopathology rarely reveals the organism in lymphocutaneous sporotrichosis, it may rule out other pathogens, such as *Nocardia,* which may cause similar lesions. Culture provides the best yield, although it may be delayed. Serology is not usually available and is not especially helpful. In the future, polymerase chain reaction may be useful.

3. b. Itraconazole

Chapter 64 Systemic Mycoses Caused by Dimorphic Fungi

1. In their travels, they were exposed to *Histoplasma capsulatum* (caves in Missouri and chicken coops in Iowa), *Blastomyces dermatitidis* (Wisconsin), and *Coccidioides posadasii* (*immitis*) (Arizona).

2. Dimorphic fungi are organisms that exist in a mold form in nature or in the laboratory at 25° C to 30° C (saprobic phase) and in a yeast or spherule form in tissues or when grown on enriched medium in the laboratory at 37° C (parasitic phase).

3. In addition to dimorphism, all of the agents of the endemic mycoses share the ability to replicate at 37° C.

4. In general, the life cycles of all dimorphic pathogens involve the inhalation of the infective spores in nature, followed by transformation within the lung into the yeast phase, which evades killing by phagocytic cells and replicates both intracellularly and extracellularly. The specifics of each are shown in Figs. 64.5, 64.6, 64.12, and 64.14.

5. Jane's pneumonia most likely represents acute pulmonary histoplasmosis. The diagnosis may be made by serology (detection of antigen in urine and/or antibodies in serum), culture of respiratory secretions, and microscopic examination of sputum or bronchoalveolar lavage fluid.

6. Most acute infections resolve with supportive care and do not require specific antifungal therapy. In rare instances, usually after heavy exposure, acute respiratory distress syndrome may be seen. Specific antifungal therapy with itraconazole plus supportive care may be necessary in such severe cases.

7. The differential diagnosis of Joan's lung nodule includes cancer, histoplasmosis (single nodules are rare), coccidioidal granuloma (common), or a nodule caused by the dog heartworm *Dirofilaria immitis.* Tuberculosis may also be a consideration. Because of the possibility of malignancy, biopsy coupled with histopathology is required. Culture for fungi and mycobacteria should be performed but may not be necessary if characteristic fungal elements are seen on histopathologic exam. Given her exposures, the nodule most likely represents coccidioidomycosis (coccidioidal granuloma). She does not require antifungal therapy.

CASE STUDY ANSWERS

1. d. Acute pulmonary histoplasmosis

2. The diagnosis of histoplasmosis may be made by direct microscopy of respiratory secretions; histopathologic examination of tissue biopsy, culture of blood, bone marrow, or other clinical material; and by serologic studies, including antigen detection in blood and urine. In acute pulmonary histoplasmosis in otherwise immunocompetent individuals, serologic studies using ID and CF tests provide the optimal sensitivity and specificity.

3. In most instances, acute pulmonary histoplasmosis is self-limited and requires only supportive care. In more severe cases, itraconazole is the antifungal agent of choice. Amphotericin B is generally reserved for cases marked by acute respiratory distress syndrome or disseminated disease.

Chapter 65 Opportunistic Mycoses

1. The differential diagnosis of fever, pneumonia, and sinusitis in a BMT patient with GVHD is very broad and includes bacterial infection, viral infection (especially cytomegalovirus), and fungal infection. The combination of sinusitis and a wedge-shaped infiltrate in such a patient receiving voriconazole prophylaxis is strongly suggestive of infection caused by a mold other than *Aspergillus.* Possibilities include infection caused by a mucormycete or another hyaline mold with decreased susceptibility to voriconazole, such as *Fusarium.* The localized pneumonia plus sinusitis makes infection with *Pneumocystis jirovecii* unlikely.

2. Fungi with decreased susceptibility to voriconazole include *C. glabrata,* the Mucormycetes, *Lomentospora prolificans,* and some strains of *Fusarium.*

3. If at all possible, a tissue diagnosis should be made. Material from the sinus and lung should be obtained and examined microscopically. Culture for fungi should also be performed, although it is often negative in this setting, especially if the infection is caused by a member of the Mucormycetes.

4. Therapy should include decreasing the immunosuppression, if possible, coupled with surgical excision of infected material and systemic therapy with amphotericin B. If the infection is caused by Mucormycetes, posaconazole or isavuconazole may be useful based on case reports.

CASE STUDY ANSWERS

1. b. Aspergilloma

2. Although examination and culture of sputum may yield an organism, the most direct approach would be bronchoscopy and biopsy of the mass. Examination of the tissue will show branching septate hyphae consistent with a fungus ball. Culture is necessary to determine the specific involvement with *Aspergillus.*

3. In general, aspergillomas are not managed with specific antifungal therapy. Symptomatic treatment of the underlying COPD is important, but aspergillomas do not usually respond to antifungal therapy. In the event of pulmonary hemorrhage, which may be severe and life-threatening, surgical excision of the cavity and fungus ball may be indicated.

Chapter 66 Fungal and Fungal-Like Infections of Unusual or Uncertain Etiology

1. The differential diagnosis of a solitary lung nodule includes cancer, mycobacterial infection, dirofilariasis (dog heartworm), and fungal (e.g., *Aspergillus, C. immitis, H. capsulatum*), or fungal-like (e.g., adiaspiromycosis) processes.

2. These three entities may be differentiated by diameter of the spherule, thickness of the wall, presence and size of endospores, host reaction, and staining with mucicarmine (see Table 66.2).

3. The conidia of *Adiaspiromyces crescens* are inhaled into the lungs, in which they transform into adiaconidia. The adiaconidia undergo massive enlargement but show no evidence of replication. The host response to the adiaconidia is fibrogranulomatous in nature, and the expanding granuloma may cause symptoms because of compression and displacement of the distal airways and alveolar parenchyma. The severity of the disease appears to be entirely a result of the number of conidia inhaled.

4. Only *Prototheca wickerhamii* can be identified by commercially available yeast identification systems. Neither *L. loboi* nor *R. seeberi* can be grown in culture, and *P. insidiosum* must be identified by demonstration of biflagellate zoospores.

CASE STUDY ANSWERS

1. c. *Prototheca wickerhamii*

2. On histopathologic examination of infected tissue, *Prototheca* spp. appear as sporangiospores that are wedge shaped and arranged in a radial or morula pattern. A wet mount of the culture material may be stained with lactophenol cotton blue to reveal the characteristic sporangia and sporangiospores. The organism in culture is quite metabolically active and may be identified to species using one of several commercially available yeast identification systems to determine the carbohydrate assimilation profile.

3. Treatment of cutaneous protothecosis with a variety of topical and systemic antibacterial, antifungal, and antiprotozoal agents has been largely unsuccessful. Antimycotic agents such as ketoconazole, itraconazole, fluconazole, and amphotericin B have been effective in some cases, as was the combination of amphotericin B and tetracycline. Surgical excision has been recommended for localized lesions.

Chapter 67 Parasitic Classification, Structure, and Replication

ANSWERS

1. Protozoa adapt to harsh conditions by developing into a cyst form that is less metabolically active. This cyst is surrounded by a thick external cell wall capable of protecting the organism from otherwise lethal physical and chemical insults.

2. The cyst form.

3. They avoid the host immune response by alteration of the antigenic properties of their external surfaces. This is accomplished in part by incorporating host antigens into their external cuticular layer.

4. They may be involved directly in causing invasive or superficial (infestation) disease processes or indirectly as intermediate hosts and vectors of many infectious agents. In addition, envenomation by biting and stinging arthropods can result in adverse reactions in human.

Chapter 68 Pathogenesis of Parasitic Diseases

ANSWERS

1. The most common modes of entry are oral ingestion or direct penetration through the skin or other surfaces (see Table 68.1).

2. Two important factors that determine the outcome of the interaction between parasite and host are the route of exposure and the inoculum size.

3. The galactose-inhibitable adherence lectin of *E. histolytica* is a good example of an adhesin that is directly related to the virulence of a parasite. Binding of this lectin to carbohydrates on the host cell surface is required for *E. histolytica* trophozoites to exert their cytolytic activity.

4. Three broad pathologic mechanisms in parasitic diseases are (1) the production of toxic parasite products, (2) mechanical tissue damage, and (3) immunopathologic reactions of the host (see Table 68.3).

5. Parasites can resist immunologic clearance by antigenic variation (e.g., trypanosomes, plasmodia), molecular mimicry (e.g., schistosomes), antigenic masking (e.g., filaria, schistosomes), intracellular location (e.g., plasmodia, leishmania), and immunosuppression (e.g., trypanosomes) (see Table 68.5).

6. The four types of immunopathologic reactions that occur in parasitic diseases are anaphylactic (type 1, helminth infection), cytotoxic (type 2, *Trypanosoma cruzi* infection), immune complex (type 3, malaria), and cell-mediated (type 4, leishmaniasis) (see Table 68.4).

Chapter 70 Laboratory Diagnosis of Parasitic Disease

ANSWERS

1. The life cycle of the parasite dictates both the form and the location of the parasite in the host. These features determine the type of specimen to be collected for diagnosis, when the specimen should be collected, and the type of diagnostic test that must be applied to the specimen.

2. Because the majority of parasitologic examinations and identifications are based entirely on recognizing the characteristic morphology of the organisms, conditions that

may obscure or distort the morphologic appearance of the parasite may result in an erroneous identification or missed diagnosis. For example, improper collection and handling of a specimen before its arrival in the laboratory may result in lysis of protozoan parasites, and contamination of stool specimens with urine may destroy motile trophozoites and cause helminth eggs to hatch. Stool specimens should not contain barium, bismuth, or medications containing mineral oil, antibiotics, antimalarials, or other chemical substances because such specimens compromise the detection of intestinal parasites.

3. Fecal specimens should be collected in clean, wide-mouthed waterproof containers with a tight-fitting lid to ensure and maintain adequate moisture. Specimens should be free of the interfering substances noted in the answer to question 2. Fresh fecal samples should be taken to the laboratory within 2 hours of collection or, if transport is delayed, be placed into preservatives such as 10% formalin, PVA, or SAF. Fecal specimens may be stored at 4° C but should not be incubated or frozen. For routine parasitic examination, a total of three separate specimens collected over a period of no more than 10 days is recommended. Parasitic examination of stools from patients with hospital-acquired diarrhea is not appropriate given the rare frequency of acquiring a parasitic infection in the hospital setting.

4. Parasites detected in blood include *Plasmodium, Babesia, Trypanosoma,* and filarial species.

5. Alternatives to microscopy include serology (antigen and antibody detection), molecular diagnostics, culture, animal inoculation, and xenodiagnosis.

Chapter 71 Antiparasitic Agents

ANSWERS

1. There are numerous obstacles to effective treatment and prevention of parasitic diseases in resource-poor countries, including toxic and ineffective drugs, need for prolonged administration, poor access to diagnostic testing, complex parasitic life cycles, presence of multiple infections and recurrent infections, large number of immunocompromised individuals, poverty, and poor hygiene and sanitation.

2. In many cases, the goal of antiparasitic therapy is similar to that of antibacterial therapy, which is to eradicate the organism rapidly and completely from the infected host. In contrast, in many cases in developing countries, the agents and treatment regimens used for parasitic diseases are designed simply to decrease the parasitic burden and to prevent systemic complications of chronic infection. The difference in treatment strategies is influenced by the severity of disease, the toxicity of the antiparasitic agents, and the likelihood of reinfection.

3. The major importance of the aminoquinoline analogs is in the prophylaxis and treatment of malaria, especially malaria caused by *P. falciparum.*

4. The strategy for the use of anthelmintic drugs is quite different from that for the use of drugs for treating most protozoal infections. Whereas drugs directed against protozoa target younger, more rapidly proliferating cells, most anthelmintic drugs are targeted at nonproliferating adult organisms. Thus many antiprotozoal agents exert a relatively rapid cidal activity against the parasite. In contrast, anthelmintic agents often impair neuromuscular and microtubule function, resulting in expulsion of the worm from the host or impairment of egg production and larval development.

Chapter 72 Intestinal and Urogenital Protozoa

1. The history and clinical picture suggests infection with *Cryptosporidium parvum.*

2. Given this patient's occupation, the most likely source was zoonotic acquisition from one of her animal patients.

3. In addition to cryptosporidiosis, HIV-infected patients are at risk for infection with *Entamoeba histolytica, Giardia, Cystoisospora, Cyclospora,* and Microsporidia. Both *Cystoisospora* species and Microsporidia produce a clinical picture similar to that of cryptosporidiosis.

4. Cryptosporidiosis may be diagnosed by immunofluorescent staining, antigen detection and by polymerase chain reaction (PCR) as part of a gastrointestinal or multiplex enteric panel.

5. In nonimmunocompromised individuals, cryptosporidiosis is self-limited and does not require specific antimicrobial therapy. Currently, there is no broadly effective therapy for cryptosporidiosis in immunocompromised patients. Nitazoxanide is the only drug approved by the U.S. Food and Drug Administration for the specific treatment of cryptosporidiosis in immunocompetent individuals. Spiramycin, azithromycin, and paromomycin all have some promise in different patient groups. In industrialized nations, the most effective treatment and prophylaxis for cryptosporidiosis in AIDs patients is the use of antiretroviral therapy for immune reconstitution. Therapy consists primarily of supportive measures to restore the tremendous fluid loss from watery diarrhea.

CASE STUDY ANSWERS

1. b. *Entamoeba histolytica.*

2. In this patient, the potential agents include *Cyclospora, Cryptosporidium, Cystoisospora,* and *Enterocytozoon bieneusi* or other microsporidia. Simply ordering a routine microscopic examination of stool for ova and parasites would miss all of these potential pathogens. Along with an appropriately collected stool specimen, the order should specify an antigen detection test for *Cryptosporidium,* a modified acid-fast stain for *Cryptosporidium, Cyclospora,* and *Cystoisospora,* and a modified trichrome

or chromotrope stain for microsporidia. A multiplex PCR-based gastrointestinal panel may also be ordered allowing the detection of *Cryptosporidium* and *Cyclospora.*

3. c. Fecal-oral.

Chapter 73 Blood and Tissue Protozoa

1. The differential diagnosis in this patient included central nervous system (CNS) lymphoma, a bacterial process, a fungal process, or toxoplasmosis. The most likely infectious process is toxoplasmosis.

2. The most appropriate test was the one performed. Serologic testing is also generally performed. Polymerase chain reaction (PCR) performed on spinal fluid may be considered if biopsy could not be performed.

3. Symptoms of headache, nausea, and vomiting clearly suggest a CNS process. These symptoms in a profoundly immunocompromised patient, such as a heart transplant patient, would lead one to be concerned about a CNS lymphoma or an infectious process. Toxoplasmosis would be a prime consideration.

4. In such a patient, decreasing the immunosuppressive therapy is really not an option. Long-term treatment with pyrimethamine plus sulfadiazine or trimethoprim-sulfamethoxazole will be required along with administration of corticosteroids, if indicated, to control cerebral edema. It is unlikely that this therapy will be curative given her persistent immunocompromised state. Long-term (e.g., indefinite) suppression will be required.

CASE STUDY ANSWERS

1. b. *Plasmodium knowlesi*

2. *Plasmodium knowlesi* exhibits a 24-hour asexual life cycle, which is the shortest of all known human and nonhuman primate malarias. This rapid cycle, coupled with the ability to infect RBCs at all stages of development is thought to contribute to the rapid development of a high parasite load.

3. Prompt diagnosis, treatment, and adjunctive management are essential to the management of patients with malaria caused by *Plasmodium knowlesi.* It appears to be susceptible to numerous alternative treatments, including chloroquine, mefloquine, quinine plus tetracycline, and atovaquone plus proguanil.

Chapter 74 Nematodes

1. The nematodes that may infect the intestinal tract of humans include *Ascaris, Enterobius vermicularis, Trichuris trichiura, Ancylostoma duodenale, Necator americanus,* and *Strongyloides stercoralis* (see Table 74.1).

2. The most likely nematode in the case presented is *Ascaris lumbricoides.* Among the intestinal nematodes, those presenting with worms in the stool include *E. vermicularis, A. lumbricoides, and S. stercoralis* (larval form). The eggs of *A. duodenale, N. americanus, T. trichiura, E. vermicularis, and A. lumbricoides* also may be found in stool.

3. The most likely means of acquisition is via the fecal-oral route.

4. Patients infected with *A. lumbricoides* are not at risk of autoinfection.

5. The life cycle of *Ascaris* includes shedding of the fertilized egg in stool, followed by a period of maturation in the soil. The latter is required for the egg to be infectious. The infective stage is then ingested, and the larval worm is released to migrate via the bloodstream to the liver, heart, and pulmonary circulation. The larvae break free in the alveoli of the lungs, in which they grow and molt and are finally coughed up, swallowed, and return to the small intestine. The male and female worms mature in the small intestine, mate, and initiate egg production.

6. Ascaris may produce a variety of extraintestinal symptoms, ranging from pneumonitis to intestinal obstruction and perforation. Migration of the adult worms to the biliary tract and liver can produce severe tissue damage and attendant symptomatology. Extraintestinal invasion may be stimulated in response to fever, drugs other than those used to treat ascariasis, and by anesthetics.

CASE STUDY ANSWERS

1. d. *Trichinella spiralis.*

2. The most characteristic diagnostic features of trichinosis are leukocytosis with eosinophilic predominance. Diagnosis largely depends on correlating the symptomatology and laboratory test results with a carefully taken history. Confirmation may be achieved by muscle biopsy or serologic detection of anti-*Trichinella* antibodies.

3. Treatment of trichinosis is primarily symptomatic because there are no good antiparasite agents for tissue larvae. Treatment of the adult worms in the intestine with mebendazole may halt production of new larvae. Steroids, along with thiabendazole or mebendazole, are recommended for severe symptoms.

Chapter 75 Trematodes

1. The differential diagnosis of hematuria in this individual includes bladder cancer, nephrolithiasis, urinary tuberculosis, and schistosomiasis.

2. The etiologic agent of this patient's urologic process was most likely *Schistosoma haematobium.*

3. As with other forms of schistosomiasis, infection with *S. haematobium* is acquired by contact with freshwater containing the appropriate snail intermediate host.

4. The major complications of this infection are obstructive uropathy and squamous cell cancer of the bladder.

5. The treatment of choice is praziquantel.

CASE STUDY ANSWERS

1. a. *Schistosoma mansoni.*

2. The pathogenesis is migration of eggs from the intestinal mucosa to the liver via the portal circulation, with subsequent inflammation leading to periportal fibrosis and portal hypertension.

3. The diagnosis of schistosomiasis is usually established by the demonstration of the characteristic eggs in feces. Serologic tests also are available.

Chapter 76 Cestodes

1. This patient presents with focal neurologic signs. The differential diagnosis is that of a mass lesion, including tumor, bacterial or fungal abscess, or cysticercosis.

2. The most likely parasite causing this condition is the pork tapeworm, *Taenia solium.*

3. The diagnostic tests include radiographic imaging showing calcified cysticerci. Central nervous system lesions such as this are generally not biopsied. Serologic studies demonstrating antibodies to *T. solium* may be useful.

4. The drug of choice for cysticercosis is either praziquantel or albendazole. Concomitant steroid administration may be necessary to minimize the inflammatory response to dying larvae. Given the multiple lesions, surgical excision is not a viable therapeutic option.

5. Cysticercosis is generally acquired by fecal-oral transmission (ingestion of eggs) or by autoinfection in which a gravid proglottid is regurgitated from the small intestine into the stomach, allowing the eggs to hatch and release the infectious oncosphere.

6. Other sites that may be involved include the eye and skeletal muscles. Ocular involvement may be detected by direct examination of the eye, and soft-tissue roentgenograms may detect the calcified cysticerci.

CASE STUDY ANSWERS

1. b. *Diphyllobothrium latum.*

2. The diagnosis is made by microscopic examination of stool to detect the characteristic bile-stained, operculated egg with its abopercular knob. Proglottids with the rosette uterine structure also may be found in stool specimens.

3. The drug of choice is niclosamide; praziquantel and paromomycin are acceptable alternatives. Vitamin B_{12} supplementation may be necessary in people with evidence of B_{12} deficiency (megaloblastic anemia).

Chapter 77 Arthropods

1. The clinical presentation is consistent with the diagnosis of scabies.

2. The definitive diagnosis of scabies depends on the demonstration of the mite in skin scrapings. Scrapings are made of the terminal portions of a fresh burrow. The scrapings are placed on a clean glass slide, cleared by the addition of 20% potassium hydroxide, covered with a coverslip, and examined under a low-power microscope.

3. The standard treatment for scabies is the application of 1% gamma benzene hexachloride (lindane) or a 5% permethrin cream (Elmite). Primary prevention of scabies is best achieved with good hygiene habits, personal cleanliness, and routine washing of clothing and bed linens.

4. The development of pustules associated with the scabies tracks suggests a secondary bacterial infection that may require antibiotic therapy.

5. Simultaneous treatment of all affected people and their contacts is necessary in an epidemic situation. Thorough cleansing of the day-care environment also will be necessary.

CASE STUDY ANSWERS

1. c. Tick paralysis

2. Tick paralysis is caused by the introduction of a neurotoxin into humans during the attachment and feeding by the females of several tick species.

3. The first step in treatment of tick paralysis is finding the tick and removing it. It is recommended that the tick be grasped close to the skin with curved forceps and removed with steady pressure. Forcible removal of a live tick may result in rapid dispersal of the toxin. Antitoxin is the usual treatment for paralyzed animals, but it is used sparingly in humans because of the risk of acute reactions and serum sickness. General supportive care, including respiratory support in severe cases, should be administered.
