Preface

Our knowledge about microbiology and immunology is constantly growing, and by building a good foundation of understanding in the beginning, it will be much easier to understand the advances of the future.

Medical microbiology can be a bewildering field for the novice. We are faced with many questions when learning microbiology: How do I learn all the names? Which infectious agents cause which diseases? Why? When? Who is at risk? Is there a treatment? However, all these concerns can be reduced to one essential question: **What information do I need to know that will help me understand how to diagnose and treat an infected patient?**

Certainly, there are a number of theories about what a student needs to know and how to teach it, which supposedly validates the plethora of microbiology textbooks that have flooded the bookstores in recent years. Although we do not claim to have the one right approach to teaching medical microbiology (there is truly no one perfect approach to medical education), we have founded the revisions of this textbook on our experience gained through years of teaching medical students, residents, and infectious disease fellows, as well as on the work devoted to the eight previous editions.

We have tried to present the basic concepts of medical microbiology clearly and succinctly in a manner that addresses different types of learners. The text is written in a straightforward manner with, it is hoped, uncomplicated explanations of difficult concepts. In this edition, we challenged ourselves to improve the learning experience even more. We are using the new technology on StudentConsult.com (e-version) to enhance access to the material. In the previous edition, we added **chapter summaries** and learning aids in the beginning of each of the microbe chapters, and on the e-version these are keyed to the appropriate sections in the chapter. In the e-version of the ninth edition, we added an **infectious disease chapter that lists the microbes by organ system and disease with hyperlinks to the appropriate chapter in the text.** This will facilitate access to the microbes for those in organ-system or disease/case-based curricula.

As in previous editions, there are new and enhanced **figures** to assist learning. **Details** are summarized in tabular format rather than in lengthy text, and there are colorful illustrations for the visual learner. **Clinical Cases** provide the relevance that puts reality into the basic science. **Important points** are emphasized in **boxes** to aid students, especially in their review, and the **study questions,** including Clinical Cases, address relevant aspects of each chapter. Each section (bacteria, viruses, fungi, parasites) begins with a chapter that summarizes microbial diseases, and this also provides **review material.**

Our understanding of microbiology and immunology is rapidly expanding, with new and exciting discoveries in all areas. We used our experience as authors and teachers to choose the most important information and explanations for inclusion in this textbook. Each chapter has been carefully updated and expanded to include new, medically relevant discoveries. In each of these chapters, we have attempted to present the material that we believe will help the student gain an interest in as well as a clear understanding of the significance of the individual microbes and their diseases.

With each edition of *Medical Microbiology* we refine and update our presentation. There are many changes to the ninth edition, both in the print and e-versions of the book. The book starts with a general introduction to microbiology and chapters on the human microbiome and epidemiology of infectious diseases. The human microbiome (that is, the normal population of organisms that populate our bodies) can now be considered as another organ system with 10 times as many cells as human cells. This microbiota educates the immune response, helps digest our food, and protects us against more harmful microbes. Additional chapters in the introductory section introduce the techniques used by microbiologists and immunologists and are followed by chapters on the functional immune system. Recent developments in rapid microbial identification are highlighted. The immune cells and tissues are introduced, followed by an enhanced chapter on innate immunity and updated chapters on antigen-specific immunity, antimicrobial immunity, and vaccines. Each of the sections on bacteria, viruses, fungi, and parasites is introduced by the relevant basic science chapters and then a summary chapter that highlights the specific microbial diseases before proceeding into descriptions of the individual microbes, "the bug parade."

Each chapter on the specific microbes begins with a summary (including trigger words), which is keyed to the appropriate part of the chapter in the e-version. As in previous editions, there are many summary boxes, tables, clinical photographs, and original clinical cases. **Clinical Cases** are included because we believe students will find them particularly interesting and instructive, and they are a very efficient way to present this complex subject. Each chapter in the "bug parade" is introduced by relevant questions to excite students and orient them as they explore the chapter. Finally, students are provided with access to the new Student Consult website, which provides links to additional reference materials, clinical photographs, animations, and answers to the introductory and summary questions of each chapter. Many of the figures are presented in step-by-step manner to facilitate learning. A very important feature on the website is access to more than 200 **practice exam questions** that will help students assess their mastery of the subject matter and prepare for their course and licensure exams. In essence, this edition provides an understandable text, details, questions, examples, and a review book all in one.

To Our Future Colleagues: The Students

On first impression, success in medical microbiology would appear to depend on memorization. Microbiology may seem to consist of only innumerable facts, but there is also a logic to microbiology and immunology. Like a medical detective, the first step is to know your villain. Microbes establish a niche in our bodies; some are beneficial and help us to digest our food and educate our immune system, while others may cause disease. Their ability to cause disease, and the disease that may result, depend on how the microbe interacts with the host and the innate and immune protective responses that ensue.

There are many ways to approach learning microbiology and immunology, but ultimately the more you interact with the material using multiple senses, the better you will build memory and learn. A **fun** and **effective** approach to learning is to **think like a physician and treat each microbe and its diseases as if it were an infection in your patient. Create a patient for each microbial infection and compare and contrast the different patients.** Perform role-playing and ask the seven basic questions as you approach this material: Who? Where? When? Why? Which? What? and How? For example: Who is at risk for disease? Where does this organism cause infections (both body site and geographic area)? When is isolation of this organism important? Why is this organism able to cause disease? Which species and genera are medically important? What diagnostic tests should be performed? How is this infection managed? Each organism that is encountered can be systematically examined.

Use the following acronym to create a clinical case and learn the essential information for each microbe: **DIVIRDEPTS.**

- How does the microbial ***d***isease present in the patient and the differential diagnosis?
- How would you confirm the diagnosis and ***i***dentify the microbial cause of disease?
- What are the ***v***irulence properties of the organism that cause the disease?
- What are the helpful and harmful aspects of the ***i***nnate and ***i***mmune response to the infection?
- What are the specific conditions or mechanisms for ***r***eplicating the microbe?
- What are all the ***d***isease characteristics and consequences?
- What is the ***e***pidemiology of infection?
- How can you ***p***revent its disease?
- What is its ***t***reatment?
- What social issues are caused by the microbial infection?

Answering the DIVIRDEPTS questions will require that you jump around in the chapter to find the information, but this will help you learn the material.

Get familiar with the textbook and its bonus materials and you will not only learn the material but also have a review book to work from in the future. For each of the microbes, learn three to five words or phrases that are associated with the microbe—words that will stimulate your memory (**trigger words,** provided in the chapter summary) and organize the diverse facts into a logical picture. Develop **alternative associations.** For example, this textbook presents organisms in the systematic taxonomic structure (frequently called a "bug parade," which the authors think is the easiest way to introduce the organisms). Take a given virulence property (e.g., toxin production) or type of disease (e.g., meningitis) and list the organisms that share this property. Pretend that an imaginary patient is infected with a specific agent and create the case history. Explain the diagnosis to your imaginary patient and also to your future professional colleagues. In other words, do not simply attempt to memorize page after page of facts; rather, use techniques that stimulate your mind and challenge your understanding of the facts presented throughout the text and **it will be more fun.** Use the summary chapter at the beginning of each organism section to **review** and help refine your "differential diagnosis" and classify organisms into logical "boxes."

No textbook of this magnitude would be successful without the contributions of numerous individuals. We are grateful for the valuable professional help and support provided by the staff at Elsevier, particularly Jeremy Bowes, Joanne Scott and Andrew Riley. We also want to thank the many students and professional colleagues who have offered their advice and constructive criticism throughout the development of this ninth edition of *Medical Microbiology*.

SECTION 1

Introduction

SECTION OUTLINE

1 Introduction to Medical Microbiology

Historical Perspective

Imagine the excitement felt by the Dutch biologist Anton van Leeuwenhoek in 1674 as he peered through his carefully ground microscopic lenses at a drop of water and discovered a world of millions of tiny "animalcules." Almost 100 years later, the Danish biologist Otto Müller extended van Leeuwenhoek's studies and organized bacteria into genera and species according to the classification methods of Carolus Linnaeus. This was the beginning of the taxonomic classification of microbes. In 1840, the German pathologist Friedrich Henle proposed criteria for proving that microorganisms were responsible for causing human disease (the "germ theory" of disease). Robert Koch and Louis Pasteur confirmed this theory in the 1870s and 1880s with a series of elegant experiments proving that microorganisms were responsible for causing anthrax, rabies, plague, cholera, and tuberculosis. Other brilliant scientists went on to prove that a diverse collection of microbes was responsible for causing human disease. The era of chemotherapy began in 1910, when the German chemist Paul Ehrlich discovered the first antibacterial agent, which was a compound effective against the spirochete that causes syphilis. This was followed by Alexander Fleming's discovery of penicillin in 1928, Gerhard Domagk's discovery of sulfanilamide in 1935, and Selman Waksman's discovery of streptomycin in 1943. In 1946, the American microbiologist John Enders was the first to cultivate viruses in cell cultures, leading the way to the large-scale production of virus cultures for vaccine development. Thousands of scientists have followed these pioneers, each building on the foundation established by his or her predecessors, and each adding an observation that expanded our understanding of microbes and their role in disease.

Our knowledge and practice of microbiology is undergoing a remarkable transformation founded in the rapid technologic advances in genome analysis. Molecular diagnostic tests have been simplified and are sufficiently inexpensive to allow rapid detection and identification of organisms. Previously unappreciated insights about pathogenic properties of organisms, taxonomic relationships, and functional attributes of the endogenous flora are being revealed. The complexity of the medical microbiology we know today rivals the limits of the imagination. We now know that there are thousands of different types of microbes that live in, on, and around us, hundreds of which cause serious human diseases. To understand this information and organize it in a useful manner, it is important to understand some of the basic aspects of medical microbiology. To start, microbes can be subdivided into the following five general groups: viruses, bacteria, archaebacteria, fungi, and parasites, with each having its own level of complexity. Archaebacteria do not seem to cause disease but arthropods may have a disease-causing relationship with man, and they are discussed in this book.

Viruses

Viruses are the smallest infectious particles, ranging in diameter from 18 to 600 nm (most viruses are <200 nm and cannot be seen with a light microscope). The genome of human viruses consists of either deoxyribonucleic acid (DNA) or ribonucleic acid (RNA). The viral nucleic acids required for replication are enclosed in a protein shell with or without a lipid membrane envelope. Viruses are true parasites, requiring host cells for replication. The cells they infect and the host response to the infection dictate the nature of the clinical manifestation. More than 2000 species of viruses have been described, with approximately 650 infecting humans and animals. Infection can lead either to rapid replication and destruction of the cell or to a long-term chronic relationship with possible integration of the viral genetic information into the host genome. The factors that determine which of these takes place are only partially understood.

Viral disease can range from the benign common cold to life-threatening Ebola, with acute, chronic, and even cancer-promoting presentations. The immune response provides both protection and pathology and may be the primary cause of illness. Often initiated with nonspecific flulike symptoms caused by host responses to the virus in the blood, viral disease is characterized by the target tissue(s) infected by the virus. Classic symptomatology guides diagnosis with confirmation by isolation in cell culture, detection of viral components, or antiviral immune responses with a prominent role for genetic detection and sequencing. Treatment has advanced so that there is now a tolerable cure for hepatitis C virus and lifelong maintenance of human immunodeficiency virus (HIV) infections. New vaccines have reduced the risk for several viruses, and vaccines for human papillomavirus and hepatitis B virus are also preventing cancers.

Bacteria

Bacteria are deceptively simple in structure. They are **prokaryotic** organisms, which are simple unicellular organisms with no nuclear membrane, mitochondria, Golgi bodies, or endoplasmic reticulum, that reproduce by asexual division. Most bacteria have either a gram-positive cell wall with a thick peptidoglycan layer, or a gram-negative cell wall with a thin peptidoglycan layer and an overlying outer membrane. Bacteria, such as *Mycobacterium tuberculosis* have more complex cell walls and others lack this cell wall structure and compensate by surviving only inside host cells or in a hypertonic environment. The size (1 to 20 μm or larger), shape (spheres, rods, and spirals), and spatial arrangement (single cells, chains, and clusters) of the cells are used for the preliminary classification of bacteria,

and the phenotypic and genotypic properties of the bacteria form the basis for the definitive classification.

We live in a microbial world with microbes in the air we breathe, the water we drink, and the food we eat, many of which are relatively avirulent but some of which are capable of producing life-threatening disease. The human body is inhabited by thousands of different bacterial species, with some living transiently and others living in a permanent parasitic relationship. This population of microbes residing in our intestines and on our skin and other mucoepithelial surfaces (called the "human microbiome") act almost as an organ of the body. Each of us harbor a unique microbiome, which, similar to a fingerprint, has similarities but individual differences. Although influenced by our genetics and policed by our immune system, the microbiome is sensitive to the environment, our diet, and the antibiotics and other drugs we take. As genetic analysis methods become faster and cheaper, the influences of specific types of microbes within the microbiome on our immune system, metabolism, drug metabolism, behavior, and general health are uncovered. The near future will see increased use of therapeutic manipulation of the intestinal microbiome with fecal transplants beyond the current treatment of recurrent *Clostridium difficile* colitis to correct inflammatory bowel disease, type 2 diabetes-associated metabolic syndrome, and other diseases.

Bacterial disease can result from the toxic effects of bacterial products (e.g., toxins) or when bacteria invade normally sterile body tissues and fluids. Some bacteria are always pathogenic, expressing virulence factors that cause tissue damage, whereas others cause disease by stimulating inflammation, and many do both. Proper identification of the infecting bacteria allows for prediction of the disease course and appropriate antimicrobial therapy. Unfortunately, inappropriate use of antimicrobials and other factors have led to the selection of multiply antimicrobial-resistant bacteria that cannot be treated.

Fungi

In contrast to bacteria, the cellular structure of fungi is more complex. These are **eukaryotic** organisms that contain a well-defined nucleus, mitochondria, Golgi bodies, and endoplasmic reticulum. Fungi can exist either in a unicellular form **(yeast),** which can replicate asexually, or in a filamentous form **(mold),** which can replicate asexually and sexually. Some fungi have a mold form in the environment and a spherical form in the body at 37° C. These are known as **dimorphic** fungi and include such organisms as *Histoplasma, Blastomyces,* and *Coccidiodes.*

Fungal infections range from benign skin infections to life-threatening pneumonias, sepsis, and disfiguring diseases. Most fungi are effectively controlled by host immunity and can reside within an individual for a lifetime, but these same fungi can cause serious disease in the immunocompromised host. Antimicrobial therapy addresses unique metabolic pathways and structures of the fungi but may be toxic and requires lengthy treatments. As with bacteria, extensive use of antifungal agents in the hospital setting has resulted in the emergence of yeasts and molds that express intrinsic and acquired resistance to several different classes of antifungal agents.

Parasites

Parasites are the most complex microbes. Although all parasites are classified as eukaryotic, some are unicellular and others are multicellular. They range in size from tiny protozoa as small as 4 to 5 μm in diameter (the size of some bacteria) to tapeworms that can measure up to 10 m in length and arthropods (bugs). Indeed, considering the size of some of these parasites, it is hard to imagine how these organisms came to be classified as microbes. Their life cycles are equally complex, with some parasites establishing a permanent relationship with humans and others going through a series of developmental stages in a progression of animal hosts. Parasitic disease is diagnosed by symptoms, a good patient history, and detection of the microbe. Helpful hints are obtained from the travel and dietary history of the patient, because many parasites are unique to different global regions. Therapies exist for some but not all parasites, and the development of resistance to antiparasitic agents complicates the prevention and treatment of many infections involving parasites.

Immunology

It is difficult to discuss human microbiology without also discussing the innate and immune responses to the microbes. Our innate and immune responses evolved to maintain our normal flora microbiome and protect us from infection by pathogens. Physical barriers prevent invasion by the microbe; innate responses recognize molecular patterns on the microbial components and activate local defenses; and specific adapted immune responses target invading microbes for eliminationand block their toxins. Unfortunately, the immune response is often too late or too slow to prevent or limit the spread of the infection. The ensuing war between the host protections and microbial invaders escalates and, even when successful, the inflammatory response that results often contributes to or may be the cause of the symptoms of the disease. To improve the human body's ability to prevent infection, the immune system can be augmented either through the passive transfer of antibodies present in immunoglobulin preparations or through active immunization with components of the microbes (vaccines). Ultimately, the innate and immune responses are the best prevention and cure for microbial disease.

Diagnostic Microbiology

The clinical microbiology laboratory plays an important role in the diagnosis and control of infectious diseases. Newer molecular, proteomic, and immunologic technologies are being used to enhance the information that the laboratory can provide.

Many of the diagnostic tests require viable samples, and the quality of the results depends on the quality of the specimen collected from the patient, the means by which it is transported from the patient to the laboratory, and the techniques used to demonstrate the microbe in the sample. In addition, the collected specimen must be representative

BOX 1.1 Four Questions Regarding an Infectious Disease Patient

1. Is it an infection?
2. Where is the infection?
3. Which microbe is causing the infection, and how is it causing the disease?
4. Should it be treated and if so, what is the best treatment?

of the site of infection and not contaminated during collection with other organisms that colonize skin and mucosal surfaces. Antimicrobial susceptibility determinations require viable and representative microbes purified from the clinical sample. Knowing the minimal inhibitory or biocidal concentrations for specific drugs is important for prescribing the best treatment.

The procedures for genome and antigen analysis have become less expensive and available for more pathogens. These procedures may not require viable samples. These assays are very sensitive and specific and can speed up the analysis.

TABLE 1.1 Indications of an Infection

• Fever
• High neutrophil count
• Pneumonia
• Diarrhea
• Rash
• Abscess
• Flulike symptoms
• Chills
• Lymphadenopathy
• Enlarged liver or spleen
• Unexplained weight loss
• Sore throat
• "itises"
• Sepsis
• "Hot joint"

Microbiology and Immunology in the Clinic

Relatively few organisms are classified as always pathogenic (e.g., rabies virus, *Bacillus anthracis*, *Shigella*, *Sporothrix schenckii*), whereas some establish disease only under well-defined circumstances or under certain conditions (e.g., opportunistic infections of immunocompromised individuals). Some diseases arise when a person is exposed to organisms from external sources, which is called an **exogenous infection** (e.g., influenza virus, *C. tetani, Neisseria gonorrhoeae, Coccidioides immitis,* and *Entamoeba histolytica),* but most human diseases are produced by organisms from the person's own microbial flora that spread to normally sterile body sites (e.g., blood, brain, lungs, peritoneal cavity) in which disease can ensue **(endogenous infections).** Some infections cause a single well-defined disease, which is oftentimes caused by the action of a virulence factor, such as a toxin (e.g., *C. tetani* [tetanus]), whereas others can cause several manifestations of disease (e.g., *Staphylococcus aureus* causes endocarditis, pneumonia, wound infections, food poisoning). The same disease can also be caused by different microbes (e.g., meningitis can be caused by viruses, bacteria, fungi, and parasites).

By understanding the characteristics of the microbe and the host's response to infection, a Sherlock Holmes–like approach can be applied to the microbial villain to solve the clinical infectious disease case. In addition, proper precautions can be taken to protect oneself and others from infection, and a sensible approach to prescribing appropriate therapy can be designed. When approaching a patient with an infectious disease, there are four questions that must be answered (Box 1.1).

Question 1 and the first step in treating an infectious disease is to recognize and distinguish an infection from other maladies. Infections are often accompanied by fever, inflammation, swollen lymph nodes, and other symptoms (Table 1.1). Many of these disease presentations are caused by the inflammatory response to the infection. These same presentations can be induced by other disease syndromes.

The next question is, where is the infection? Knowing the site of infection can provide clues as to the possible microbes causing the infection and is important in picking an antimicrobial that can reach the infected tissue or site.

The answers to Question 3 are the main subjects of this book: Which microbe is causing the infection and how is it causing the disease? Although the distinction of bacterial, viral, fungal, and parasitic infections can oftentimes be made from the history and physical presentations of the patient, certain laboratory tests can help focus the diagnosis. For example, bacterial infections are often accompanied by increases in serum levels of C-reactive protein and procalcitonin, which are components of an inflammatory response. Once a differential diagnosis (a list of most probable villains) is obtained, then confirmatory tests can identify the disease-causing microbe. Chapters 4 to 6 introduce the different types of tests and their application to each of the microbes to be discussed. In addition to knowing the most appropriate test for a microbe or microbial syndrome, it is also important to know the limitations, sensitivity, and specificity of the tests.

More and more individuals are living with immunodeficiencies caused by treatments for cancer, autoimmune diseases, or infections (e.g., AIDS). These individuals become susceptible to infections caused by less virulent or nonvirulent microbes that do not affect other individuals. The importance of the deficient immune response becomes very apparent for protections against these microbes.

Bacterial disease is usually determined by the microbe's virulence factors. For some, it is a one–one correspondence, such as for toxin-producing *Corynebacterium diphtheriae, Vibrio cholera,* and *C. botulinum*. For others, the disease may result from colonization, toxic by-products, or the immune and inflammatory responses to the microbe. Immune and inflammatory responses are triggered by structures of the microbe. Repetitive microbial structures provide

pathogen-associated molecular patterns that induce innate responses, whereas specific structures are recognized by the immune response. In addition, extracellular bacterial and fungal structures usually trigger the activation of a cascade of soluble proteins of the complement system, which recruits macrophages and neutrophils to the infection site, initiates inflammation, activates antibody production, and generates a molecular membrane pore in the microbe. Intracellular infections, including viruses, bacteria, fungi, and parasites, require a different immune response, and the consequences are also different. Human cells respond to an intracellular microbial infection by shutting down cellular processes and by activating cytolytic cellular responses (natural killer [NK] cell, T cell, and macrophage responses) that kill or wall off the infected cells. Antibody is generated to inactivate toxins, to prevent binding of the microbe, and to facilitate its uptake and clearance by macrophages and neutrophils. The nature of the disease and susceptibility of an individual to a pathogen is determined by how soon the protective response can act on the infection, the efficacy of the response, and the immunopathologic consequences of that response. Inflammation accompanies most immune responses and sometimes it is just as important to treat the inflammation as it is to treat the infection to reduce the severity of the disease.

The fourth question should take considerable thought: Should the microbe be treated and, if so, what is the best treatment? Designing appropriate therapy is necessary for those infections that do not resolve on their own. Although safe, antibiotic treatment can disrupt the normal flora which may allow more pathogenic bacteria or fungi to take their place. Proper therapy requires getting enough of the right antimicrobial drug to a sensitive target within the microbe at the site of infection in the body. The antimicrobial potency and spectrum of activity and the pharmacologic properties of the drug are determined by the structure and mode of action of the drug. Microbes may be naturally resistant, mutate, or acquire genetic information to make them resistant and those that are resistant to antibiotics will be selected and will endure. Initial antimicrobial choices may attempt to cover all possible pathogens, but on identification of the microbe and its antimicrobial susceptibilities, antibiotics that are more specific, less expensive, easier to administer, and with fewer side effects should be prescribed. Proper **antimicrobial stewardship** will reduce cost, side effects, and potential development of resistant strains. Antimicrobial drugs are discussed in Chapters 17, 40, 61, and 71.

In addition to the four questions relating to the patient, the care provider must also know how to protect themselves and others from infection. Key questions include: Is there a vaccine? What safety precautions should be taken? How can hands, objects and contaminated surfaces be disinfected? The best means to protect an individual from infection is to prevent exposure or contact, and the second best means is to be immunized against the microbe, by prior infection, or vaccine. Proper sanitation and disinfection techniques are discussed in Chapter 3, and vaccines are discussed in Chapter 11. Restricting access to infected individuals or areas by **quarantine** helped prevent the spread of the smallpox virus and with an effective vaccine and worldwide vaccination program, it led to the elimination of the virus.

Knowing the epidemiologic characteristics of the microbe helps determine the potential for exposure and identify who is at risk to infection. This includes the means of spread, the vector, if utilized, geographical distribution, and seasonal presence of the microbe, as well as the influence of personal health, genetics, habits, and lifestyle, which increases risk of infection and disease. Asking a patient whether they have traveled recently has become a key question in obtaining a diagnosis and is an indication of the globalization of disease.

Summary

It is important to realize that our knowledge of the microbial world is evolving continually. Just as the early microbiologists built their discoveries on the foundations established by their predecessors, present and future generations will continue to discover new microbes, new diseases, and new therapies. The following chapters are intended as a foundation of knowledge that can be used to build your understanding of microbes and their diseases.

2 Human Microbiome in Health and Disease

Up until the time of birth, the human fetus lives in a remarkably protected and for the most part sterile environment; however, this rapidly changes as the infant is exposed to bacteria, archaea, fungi, and viruses from the mother, other close contacts, and the environment. Over the next few years, communities of organisms (**microbiota** or **normal flora** [Table 2.1]) form on the surfaces of the skin, nares, oral cavity, intestines, and genitourinary tract. The focus of this chapter is to gain an understanding of the role these communities play in the metabolic and immunologic functions of healthy individuals, factors regulating the composition of these communities, and how disruption of these communities can result in disease states.

Human Microbiome Project

Our current knowledge of the **microbiome** is rooted in the successful completion of the Human Genome Project, which was a 13-year international effort initiated in 1990 that determined the sequences of the approximately 3 billion nucleotides that make up the 23,000 protein-encoding genes in human deoxyribonucleic acid (DNA). Much like efforts to send a man to the moon, the greatest legacy of this work was the development of technologies that allow the generation and analysis of tremendous amounts of DNA and ribonucleic acid (RNA) sequencing data.

The Human Genome Project was followed by the Human Microbiome Project, which was a 5-year multinational study to analyze the genetic composition of the microbial populations that live in and on healthy adults **(microbiome)**. To put the complexity of this program into perspective, it is estimated that bacterial cells outnumber human cells in the host by 10:1, and the bacterial population contributes at least 300-fold more unique protein genes.

The Human Microbiome Project was launched in 2007 with a collection of samples from the nose, mouth, skin, gut, and vagina from healthy adult volunteers. The microbes were identified by sequencing targeted regions of the 16S ribosomal RNA gene, and information about the gene content of the entire population was determined by sequencing the entire genome of a subset of specimens. These analyses showed that there is substantial variation in the species and gene composition for individuals and at different body sites. For example, bacteria colonizing the gut are different from those in the mouth, skin, and other body sites. The body site with the greatest taxonomic and genetic diversity was the intestine, and the vagina was the least complex. Microenvironments such as different regions of the mouth, gut, skin surface, and vagina also had their own unique microbiome (Fig. 2.1).

Core Microbiome

Most individuals share a **core microbiome,** arbitrarily defined as the species that are present at a specific site in 95% or more of individuals. The greatest numbers of shared

Table 2.1 Glossary of Terms

Term	Definition
Microbiota	Community of microbes that live in and on an individual; can vary substantially between environmental sites and host niches in health and disease
Normal flora	Microbiota
Microbiome	Aggregate collection of microbial genomes in the microbiota
Core microbiome	Commonly shared microbial species among individuals at specific body sites; although typically represented by a limited number of species, these comprise the largest proportion of the microbial population
Secondary microbiome	Microbial species that contribute to the unique diversity of individuals at specific body sites; typically present in proportionately small numbers
Functional redundancy	Required functions (e.g., metabolism of nutrients, regulation of the immune response) that are provided by the diverse members of the microbiota
Taxonomic diversity	Diverse number of species that comprise the microbiota
Proteomics	Study of the protein products of the microbiome population
Metabolomics	Study of metabolic activity of the microbiome population
Prebiotic	Food ingredient that supports the growth of one or more members of the microbiota
Probiotic	Live organism that, when ingested, is believed to provide benefit to the host

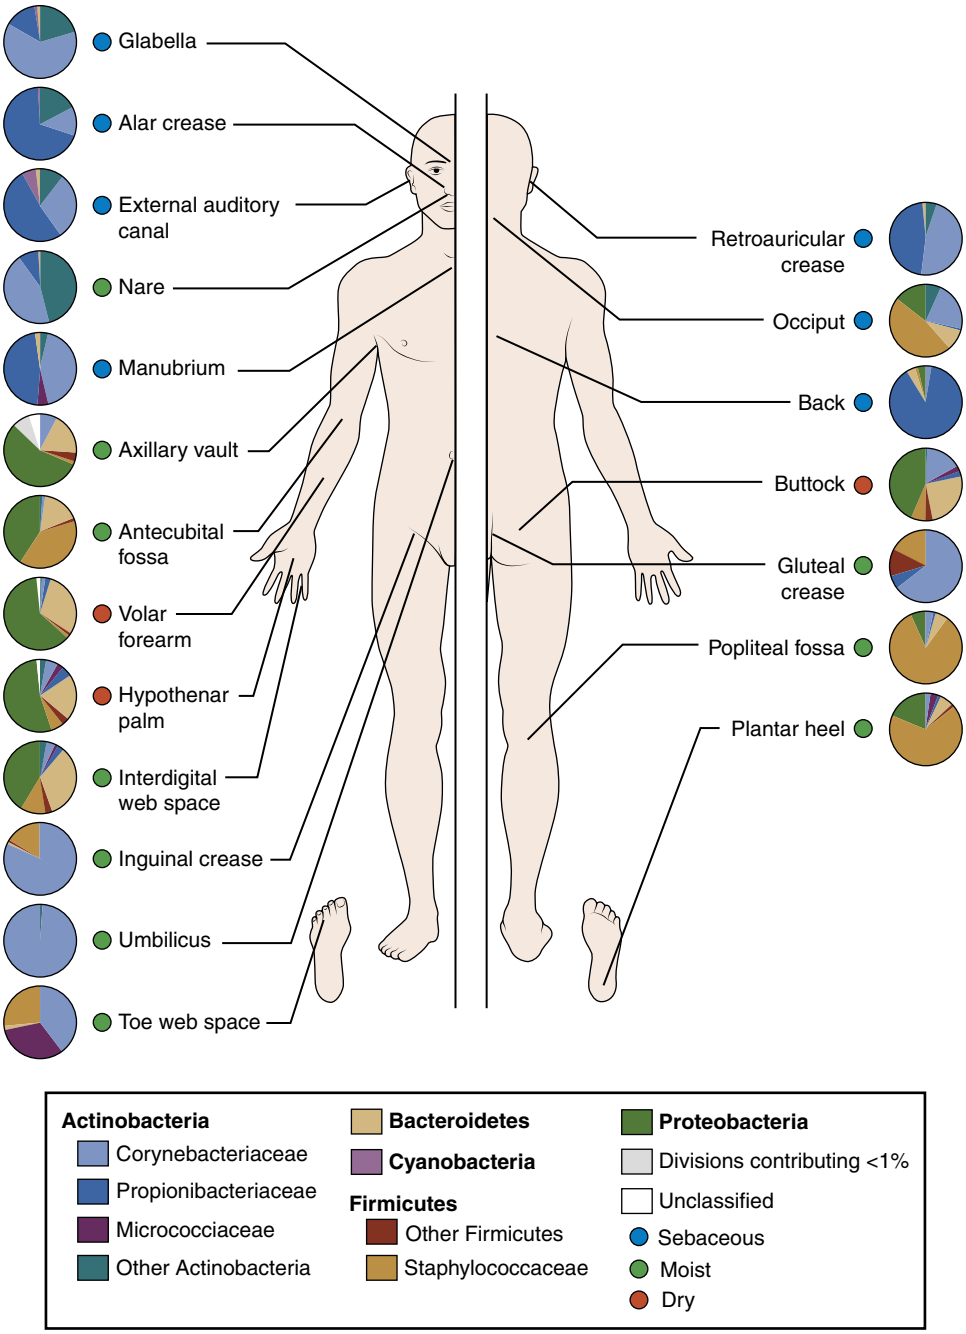

Fig. 2.1 Topographical distribution of bacteria on skin sites. As at other body sites, the distribution of the skin microbiome is dependent on the microenvironment of the sampled site, such as sebaceous or oily *(blue circles);* moist *(green circles);* and dry, flat surfaces *(red circles).* (From Grice, E., Segre, J. 2011. The skin microbiome. Nat. Rev. Microbiol. 9, 244–253.)

species are present in the mouth, followed by the nose, intestine, and skin, and the fewest shared species are found in the vagina. Additionally, the small numbers of species that comprise the core microbiome are the most numerous, representing the majority of the total population, whereas the remaining portion of the population **(secondary microbiome)** consists of small numbers of many species that may not be widely shared by individuals. This would imply that the members of the core microbiome are critically important, providing essential functions that must be retained for normal metabolic and immunologic activities, and the functions provided by the secondary microbiome are also critically important but can be provided by a variety of organisms. In other words, although there is tremendous variation of species among individuals, there is less variation in the genetic composition at each site. The **taxonomic diversity** of a population is great, but the functional properties are highly conserved **(functional redundancy)** in microbiomes associated with health. This is not surprising if we consider that the microbiome is a community that exists in a symbiotic relationship with its host, providing needed metabolic functions, stimulating innate immunity, and preventing colonization with unwanted pathogens. Thus interpersonal variations of the microbiome can exist in healthy individuals as long as the needed functions are satisfied.

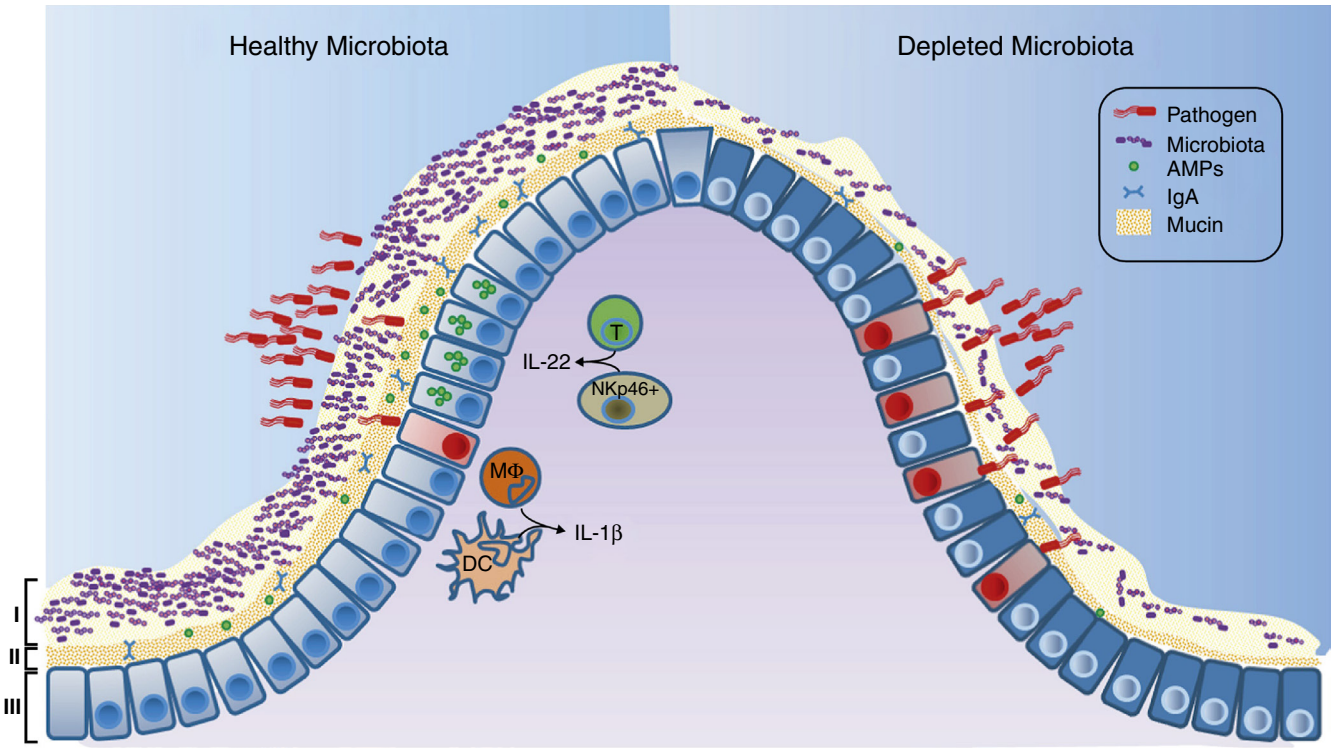

Fig. 2.2 Intestinal microbiota protection against enteric infections. (I) Saturation of colonization sites and consumption of nutrients limit pathogen access to host tissues; (II) the microbiota prime innate immunity by stimulating mucin production, immunoglobulin *(Ig)*A, and antimicrobial peptides *(AMPs);* and (III) the microbiota stimulate interleukin *(IL)*-22 expression, which increases epithelial resistance, and IL-1β production, which promotes recruitment of inflammatory cells. (From Khosravi, A., Mazmanian, S. 2013. Disruption of the gut microbiome as a risk factor for microbial infections. Curr. Opin. Microbiol. 16, 221–227.)

Evolution of the Microbiome and Normal Flora

The **normal flora** of a particular site of the body consists of a unique community of core and secondary microbiota that evolved through a symbiotic relationship with the host and a competitive relationship with other species. The host provides a place to colonize, nutrients, and some protection from unwanted species (innate immune responses). The microbes provide needed metabolic functions, stimulate innate and regulatory immunity, and prevent colonization with unwanted pathogens (Fig. 2.2). The ability to tolerate the amount of oxygen or lack thereof (redox state) and the pH and salt concentration, as well as to scavenge essential minerals and harvest and metabolize the available nutrients, determines the numbers and nature of the species that populate a site of the body. Anaerobic or facultative anaerobic bacteria colonize most of the sites of the body because of the lack of oxygen in sites such as the mouth, intestine, and genitourinary tract.

The composition of the microbiota is influenced by personal hygiene (e.g., use of soap, deodorants, mouthwash, skin peels, enemas, vaginal douches), diet, water source, medicines (especially antibiotics), and exposure to environmental toxins. Drinking well water versus chlorinated city water or a diet consisting of more or less fiber, sugar, or fats can select for different intestinal bacteria based on their ability to use the essential minerals (e.g., iron) and nutrients. Alteration of the environment with foods or medicines can also alter the microbiota (Fig. 2.3). These changes can be acceptable if the core microbiome and critical functional properties of the microbiome are maintained but can result in disease if these functions are lost. Historically, the greatest concern with the use of broad-spectrum antibiotics was the selection of resistant bacteria; however, a greater concern should be the disruption of the microbiome and loss of essential functions.

Of the approximately 200 unique species of bacteria that colonize the gut, most are members of Actinobacteria (e.g., *Bifidobacterium*), Bacteroidetes (e.g., *Bacteroides*), and Firmicutes (e.g., *Eubacterium, Ruminococcus, Faecalibacterium, Blautia*). Interestingly, the importance of many of these bacteria was not appreciated before gene sequencing was used to identify and quantitate the gut microbiota. Within the colon, some bacteria wage interspecies warfare to establish their niche with bacteriocins (e.g., colicins produced by *Escherichia coli*), other antibacterial proteins, and metabolites that deter other species from growing. These molecules also benefit the host by eliminating invading bacteria including *Salmonella, Shigella, Clostridium difficile, Bacillus cereus,* and other pathogens. The bacteria must also resist antimicrobial peptides and immunoglobulin (Ig) A produced by the host and released into the bowel.

Metabolism of nutrients plays a major role in the symbiotic relationship between the human host and microbe. Bacteria in the human gut are responsible for metabolizing complex carbohydrates (including cellulose) to provide small-chain fatty acids such as acetate, propionate, and butyrate that can be readily transported and used by the cells of our body. These acids also limit the growth of

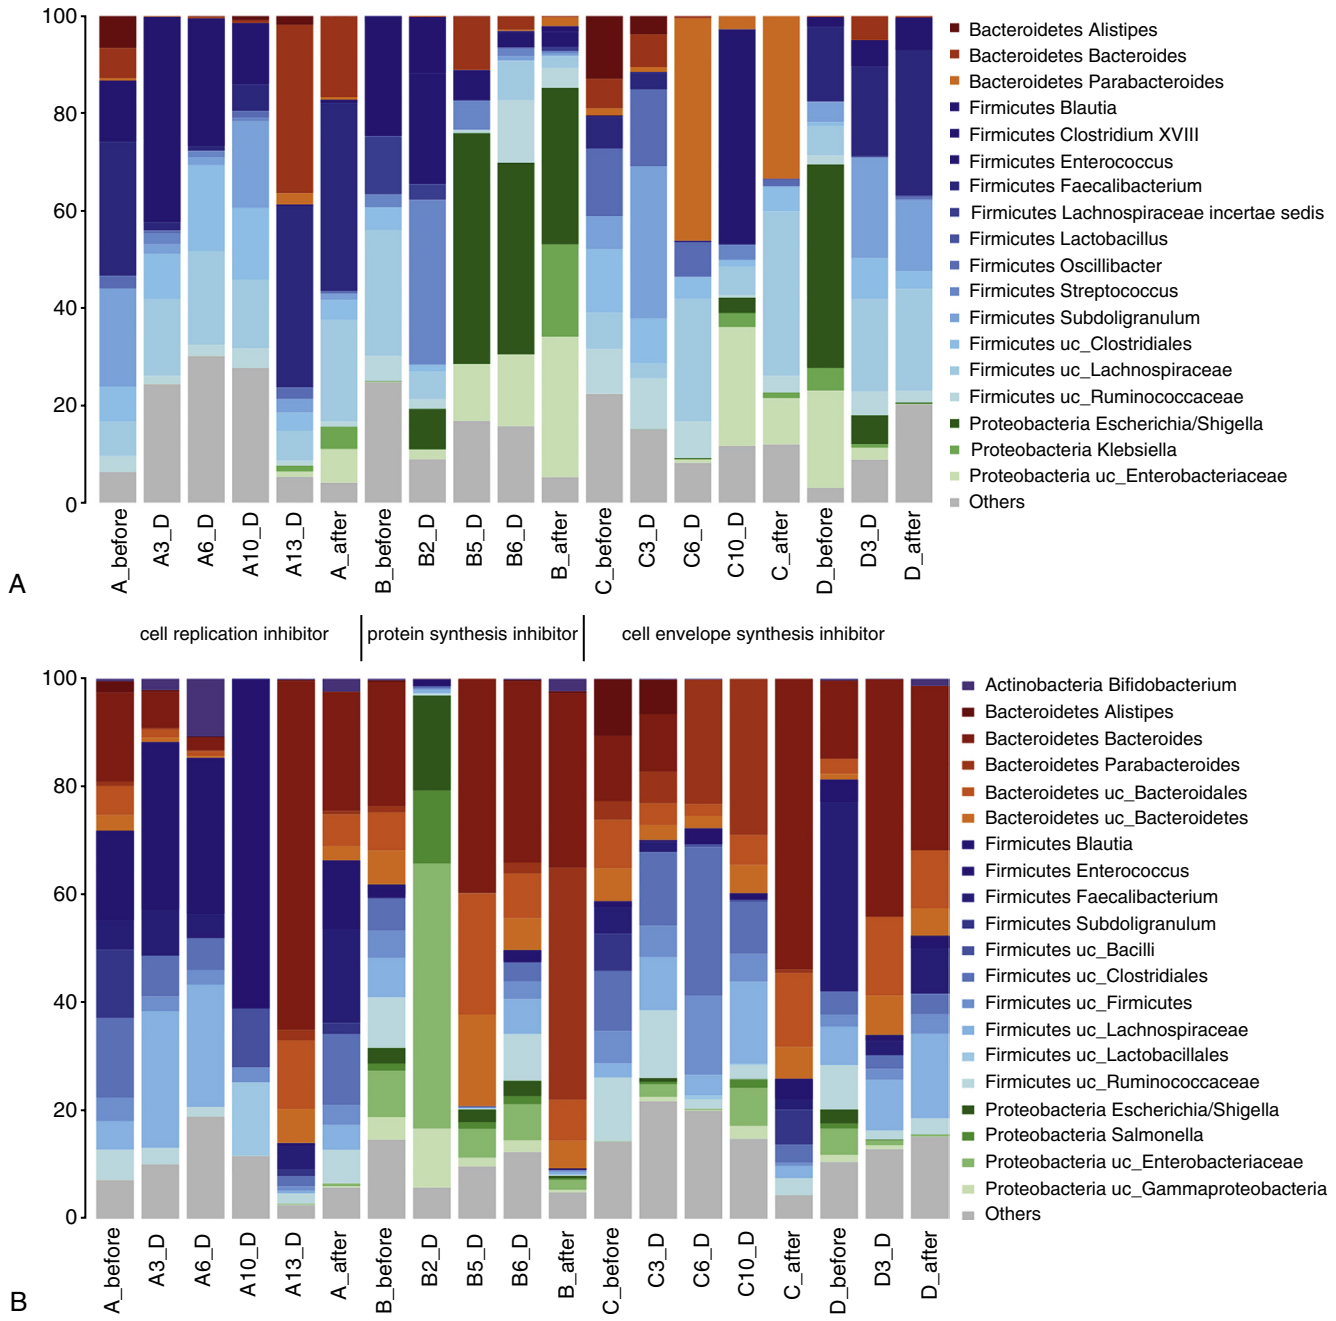

Fig. 2.3 Effect of antibiotics on the gut microbiota. Fecal samples were collected from four patients treated with antibiotics: patient A, moxifloxacin; patient B, penicillin + clindamycin; patient C, cefazolin followed by ampicillin/sulbactam; and patient D, amoxicillin. Fecal samples collected before, during (e.g., 3_D is day 3 of therapy), and after therapy were used to assess the total microbiota. Changes are noted both during therapy and after therapy is discontinued. **A,** Total microbiota (16S rRNA gene). **B,** Metabolically active microbiota (16S rRNA transcripts). (From Perez-Cobas, A. E., Artacho, A., Knecht, H., et al., 2013. Differential effects of antibiotic therapy on the structure and function of human gut microbiota. PLoS One 8, e80201.)

undesirable bacteria. Other bacteria graze on the carbohydrates, the mucins that line the epithelium, or the oils released in our sweat. Bacteroidetes and Firmicutes are more efficient than others at breaking down complex carbohydrates, including plant cell wall compounds (cellulose, pectin, and xylan) and host-derived carbohydrates, including those attached to the mucins or chondroitin sulfates of the protective mucous layer of the intestine. Increases in the ratio of these bacteria in the gut microbiome can lead to a higher efficiency in storage of the metabolic by-products. This can be a benefit for malnourished populations or patients with debilitating diseases such as cancer, or can lead to obesity in well-nourished populations.

Role of the Microbiome in Disease

If the normal microbiome characterizes health, then alterations in the microbiome can signify disease; this is a relationship we are only beginning to understand.

In 1884 Robert Koch and Friedrich Loeffler defined the relationship between an organism and infection. The **Koch postulates** were based on the concept of one organism:one disease. Microbiome research has introduced a new concept of disease caused by a community of organisms rather than a single species of bacteria, and the influence extends beyond traditional "infectious" diseases to include immunologic and metabolic disorders such as inflammatory bowel disease, obesity, type 2 diabetes, and celiac disease. We are now at the forefront of a new era of redefining the concept of infectious diseases.

Disruption of the normal microflora (commonly referred to as **dysbiosis**) can lead to disease by the elimination of needed organisms or allowing the growth of inappropriate bacteria. For example, following exposure to antibiotics and suppression of the intestinal normal flora, *C. difficile* is able to proliferate and express enterotoxins, leading to inflammation of the colon **(antibiotic-associated colitis).** Another disease of the colon, **ulcerative colitis,** is associated with an increased level of bacteria producing mucin-degrading sulfatases, leading to degradation of the protective mucosal lining of the intestinal wall and stimulation of inflammatory immune responses. Individuals with an intestinal microbiota that is more efficient at breaking down complex carbohydrates internalize rather than void these nutrients; therefore they are susceptible to **obesity** and a predisposition to metabolic syndromes such as **type 2 diabetes.** Not all patients genetically predisposed to **celiac disease,** which is an immune-mediated enteropathy precipitated by exposure to gluten proteins, are symptomatic. The intestinal microbiota of most individuals is composed of bacteria capable of digesting glutens, which may be sufficient to protect these genetically predisposed individuals. In the absence of these bacteria, disease may occur. Shifts in the skin microbiome are associated with progression to **chronic wound infections** and episodic exacerbations of **atopic dermatitis.** Alteration in the vaginal microbiome from relatively few predominant organisms to a heterogeneous mixed population is associated with the progression to **vaginitis.**

Diagnostics and Therapeutics

An understanding of the influence of dysbiosis on disease pathology can lead to both advanced diagnostic tests and paths for therapeutic intervention. Just as the presence of *Salmonella* or *Shigella* signifies disease, changes in the diversity and composition of the fecal microflora can also indicate susceptibility to or onset of disease. The most obvious example is *C. difficile* disease, which is a clinical disease preceded by a depletion of the normal flora because of antibiotic use. Interestingly, patients with chronic relapsing *C. difficile* infections are treated successfully by repopulating (some say **"repoopulating"**) the intestines with stool transplants from a healthy spouse or close relative, or with artificially created stool specimens consisting of a complex mixture of aerobic and anaerobic fecal organisms.

More subtle alterations in the gut microbiome may predict development of diseases such as **necrotizing enterocolitis (NEC),** inflammatory bowel disease, and a predilection for obesity. NEC is a devastating intestinal disease that afflicts preterm infants. Prospectively collected stool samples from infants younger than 29 weeks' gestational age who develop NEC demonstrate a distinct dysbiosis prior to the development of disease. Infants with early-onset disease have a dominance of Firmicutes (predominantly *Staphylococcus*), whereas infants with late-onset NEC have a dominance of Enterobacteriaceae.

The effects of microbiome alterations have also been described for the pathogenesis of inflammatory bowel disease and colorectal cancer. Proliferation of bacteria such as *Akkermansia muciniphila* that produce mucin-degrading sulfatases is responsible for degradation of the intestinal wall lining. Additionally, an increase in members of the anaerobic family Prevotellaceae leads to upregulation of chemokine-mediated inflammation. Enterotoxigenic *Bacteroides fragilis* can also induce T helper cell–mediated inflammatory responses that are associated with colitis and are a precursor to colonic hyperplasia and colorectal tumors. Finally, *Methanobrevibacter smithii,* a minor member of the gut microbiome, enhances digestion of dietary glycans by *B. thetaiotaomicron* and other core intestinal bacteria, leading to accumulation of fat.

Alterations of the microbiome leading to disease may not be characterized by the presence or absence of a specific microbe because more than one organism may provide the needed function. It is likely that future diagnostics will measure for the presence or absence of a specific gene product **(proteomics)** or metabolic function **(metabolomics)**.

Probiotics

Probiotics are mixtures of bacteria or yeast that when ingested colonize and proliferate, even temporarily, the intestine. Consumers of probiotics believe they act by rebalancing the microbiome and its functions, such as enhancing digestion of food and modulating the individual's innate and immune response. The most common reason people use over-the-counter probiotics is to promote and maintain regular bowel function and improve tolerance to lactose. Probiotics are commonly gram-positive bacteria (e.g., *Bifidobacterium, Lactobacillus*) and yeasts (e.g., *Saccharomyces*). Many of these microbes are found in ingestible capsules and as food supplements (e.g., yogurt, kefir). Probiotics have been used to treat *C. difficile*–associated diarrhea and inflammatory bowel disease, to provide protection from *Salmonella* and *Helicobacter pylori* disease, as therapy for pediatric atopic dermatitis and autoimmune diseases, and even for reduction in dental caries, although the value of probiotics for many of these conditions is unproven. Although probiotics are generally safe dietary supplements, many probiotics are ineffective. The species, mixture of species, and dose and viability of the probiotic organisms within a probiotic formulation influence its potency, efficacy, and therapeutic potential. What is clear is that much like the use of complex artificial mixtures of organisms to treat recurrent *C. difficile* disease, carefully designed "smart probiotics" will likely be an important adjunct to medical therapy in the future.

Perspective

In the near future, with faster and cheaper DNA sequencing procedures, analysis of a person's microbiome may become a routine diagnostic test for predicting and treating a wide range of diseases. However, a number of questions remain to be resolved: Can we predict disease in an individual by monitoring changes in the microbiome? Which changes are most important, taxonomic or genetic function? Can we prevent disease or treat disease by reestablishing a healthy microbiome? Can this be done by prescribing specific replacement microbes (e.g., fecal transplant) or with a universal mixture (probiotic)? Can the use of metabolic supplements **(prebiotics)** promote a healthy microbiota? Will use of antibiotics be replaced by use of "smart microbiome" therapies? Other questions include: What is the role of the host genome, environmental factors, and our hygienic practices in shaping the microbiome? What will be the informatic requirements for guiding diagnostics or therapeutics? Regardless of the answers to these and other questions, it is certain that we are witnessing the beginning of a new era of microbiology that can radically change our approach to prediction, diagnosis, and treatment of disease.

Questions

1. What is the relationship between the human genome and microbiome genetic material?
2. Explain the concepts of taxonomic diversity and genetic diversity.
3. Explain the concept of the core microbiome.
4. Give three examples of alterations of the microbiome (dysbiosis) that are associated with specific diseases.

3 Sterilization, Disinfection, and Antisepsis

An important aspect of the control of infections is an understanding of the principles of sterilization, disinfection, and antisepsis (Box 3.1).

Sterilization

Sterilization is the total destruction of all microbes, including the more resilient forms such as bacterial spores, mycobacteria, nonenveloped (nonlipid) viruses, and fungi. This can be accomplished using physical, gas vapor, or chemical sterilants (Table 3.1).

Saturated steam under pressure is a widely used, inexpensive, nontoxic, and reliable method of sterilization. Three parameters are critical: the time of exposure to steam, temperature, and amount of moisture. The most commonly used sterilization cycle is use of saturated steam heated at 121° C for 15 minutes. Maintaining the proper temperature is critical because a drop of 1.7° C increases the needed exposure time by 48%. If no moisture is present, then the temperature must reach 160° C. Dry heat sterilization requires prolonged exposure times and damages many instruments, so it is not currently recommended.

Ethylene oxide gas is used to sterilize temperature- or pressure-sensitive items. Treatment is generally for 4 hours, and sterilized items must be aerated for an additional 12 hours to eliminate the toxic gas before the items are used. Although ethylene oxide is highly efficient, strict regulations limit its use because it is flammable, explosive, and carcinogenic to laboratory animals. For these reasons, ethylene oxide sterilization is avoided if acceptable alternatives are available.

Hydrogen peroxide vapors are effective sterilants because of the oxidizing nature of the gas. This sterilant is used for the sterilization of instruments. A variation is **plasma gas sterilization,** in which hydrogen peroxide is vaporized, and then reactive free radicals are produced with either microwave-frequency or radiofrequency energy. Because this is an efficient sterilizing method that does not produce toxic by-products, plasma gas sterilization has replaced many of the applications for ethylene oxide. However, it cannot be used with materials that absorb hydrogen peroxide or react with it.

Two **chemical sterilants** have also been used: **peracetic acid** and **glutaraldehyde.** Peracetic acid, an oxidizing agent, has excellent activity, and its end products (i.e., acetic acid and oxygen) are nontoxic. In contrast, safety is a concern with glutaraldehyde, and care must be used when handling this chemical.

Disinfection

Microbes are also destroyed by disinfection procedures, although more resilient organisms can survive. Unfortunately, the terms *disinfection* and *sterilization* are casually interchanged and can result in some confusion. This occurs because disinfection processes have been categorized as high level, intermediate level, and low level. High-level disinfection can generally approach sterilization in effectiveness, whereas spore forms can survive intermediate-level disinfection, and many microbes can remain viable when exposed to low-level disinfection.

Even the classification of disinfectants (Table 3.2) by their level of activity is misleading. The effectiveness of these procedures is influenced by the nature of the item to be disinfected, number and resilience of the contaminating organisms, amount of organic material present (which can inactivate the disinfectant), type and concentration of disinfectant, and duration and temperature of exposure.

High-level disinfectants are used for items involved with invasive procedures that cannot withstand sterilization procedures (e.g., certain types of endoscopes and surgical instruments with plastic or other components that cannot be autoclaved). Disinfection of these and other items is most effective if cleaning the surface to remove organic matter precedes treatment. Examples of high-level disinfectants include treatment with moist heat and use of liquids such as glutaraldehyde, hydrogen peroxide, peracetic acid, and chlorine compounds.

BOX 3.1 Definitions

Antisepsis: Use of chemical agents on skin or other living tissue to inhibit or eliminate microbes; no sporicidal action is implied

Disinfection: Use of physical procedures or chemical agents to destroy most microbial forms; bacterial spores and other relatively resistant organisms (e.g., mycobacteria, viruses, fungi) may remain viable; disinfectants are subdivided into high-, intermediate-, and low-level agents

Germicide: Chemical agent capable of killing microbes; includes virucide, bactericide, sporicide, tuberculocide, and fungicide

High-level disinfectant: A germicide that kills all microbial pathogens except large numbers of bacterial spores

Intermediate-level disinfectant: A germicide that kills all microbial pathogens except bacterial endospores

Low-level disinfectant: A germicide that kills most vegetative bacteria and lipid-enveloped and medium-size viruses

Sterilization: Use of physical procedures or chemical agents to destroy all microbial forms, including bacterial spores

Table 3.1 Methods of Sterilization

Method	Concentration or Level
PHYSICAL STERILANTS	
Steam under pressure	121° C or 132° C for various time intervals
Filtration	0.22- to 0.45-μm pore size; HEPA filters
Ultraviolet radiation	Variable exposure to 254-nm wavelength
Ionizing radiation	Variable exposure to microwave or gamma radiation
GAS VAPOR STERILANTS	
Ethylene oxide	450-1200 mg/L at 29° C to 65° C for 2-5 hr
Hydrogen peroxide vapor	30% at 55° C to 60° C
Plasma gas	Highly ionized hydrogen peroxide gas
CHEMICAL STERILANTS	
Peracetic acid	0.2%
Glutaraldehyde	2%

HEPA, High-efficiency particulate air.

Table 3.2 Methods of Disinfection

Method	Concentration (Level of Activity)
HEAT	
Moist heat	75° C to 100° C for 30 min (high)
LIQUID	
Glutaraldehyde	2%-3.2% (high)
Hydrogen peroxide	3%-25% (high)
Chlorine compounds	100-1000 ppm of free chlorine (high)
Alcohol (ethyl, isopropyl)	70%-95% (intermediate)
Phenolic compounds	0.4%-5.0% (intermediate/low)
Iodophor compounds	30-50 ppm of free iodine per liter (intermediate)
Quaternary ammonium compounds	0.4%-1.6% (low)

ppm, Parts per million.

Intermediate-level disinfectants (i.e., alcohols, iodophor compounds, phenolic compounds) are used to clean surfaces or instruments on which contamination with bacterial spores and other highly resilient organisms is unlikely. These have been referred to as semicritical instruments and devices and include flexible fiberoptic endoscopes, laryngoscopes, vaginal specula, anesthesia breathing circuits, and other items.

Low-level disinfectants (i.e., quaternary ammonium compounds) are used to treat noncritical instruments and devices, such as blood pressure cuffs, electrocardiogram electrodes, and stethoscopes. Although these items come into contact with patients, they do not penetrate through mucosal surfaces or into sterile tissues.

The level of disinfectants used for environmental surfaces is determined by the relative risk these surfaces pose as a reservoir for pathogenic organisms. For example, a higher level of disinfectant should be used to clean the surface of instruments contaminated with blood than that used to clean surfaces that are "dirty," such as floors, sinks, and countertops. The exception to this rule is if a particular surface has been implicated in a nosocomial infection, such as a bathroom contaminated with *Clostridium difficile* (spore-forming anaerobic bacterium) or a sink contaminated with *Pseudomonas aeruginosa*. In these cases, a disinfectant with appropriate activity against the implicated pathogen should be selected.

Table 3.3 Antiseptic Agents

Antiseptic Agent	Concentration
Alcohol (ethyl, isopropyl)	70%-90%
Iodophors	1-2 mg of free iodine per liter; 1%-2% available iodine
Chlorhexidine	0.5%-4.0%
Parachlorometaxylenol	0.50%-3.75%
Triclosan	0.3%-2.0%

Antisepsis

Antiseptic agents (Table 3.3) are used to reduce the number of microbes on skin surfaces. These compounds are selected for their safety and efficacy. A summary of their germicidal properties is presented in Table 3.4. **Alcohols** have excellent activity against all groups of organisms except spores and are nontoxic, although they tend to dry the skin surface because they remove lipids. They also do not have residual activity and are inactivated by organic matter. Thus the surface of the skin should be cleaned before alcohol is applied. **Iodophors** are also excellent skin antiseptic agents, having a range of activity similar to that of alcohols. They are slightly more toxic to the skin than is alcohol, have limited residual activity, and are inactivated by organic matter. Iodophors and iodine preparations are frequently used with alcohols for disinfecting the skin surface. **Chlorhexidine** has broad antimicrobial activity, although it kills organisms at a much slower rate than alcohol. Its activity persists, although organic material and high pH levels decrease its effectiveness. The activity of **parachlorometaxylenol (PCMX)** is limited primarily to gram-positive bacteria. Because it is nontoxic and has residual activity, it has been used in handwashing products. **Triclosan** is active against bacteria but not against many other organisms. It is a common antiseptic agent in deodorant soaps and some toothpaste products.

Mechanisms of Action

The following section briefly reviews the mechanisms by which the most common sterilants, disinfectants, and antiseptics work.

MOIST HEAT

Attempts to sterilize items using boiling water are inefficient because only a relatively low temperature (100° C) can be

TABLE 3.4 Germicidal Properties of Disinfectants and Antiseptic Agents

Agents	Bacteria	Mycobacteria	Bacterial Spores	Fungi	Viruses
DISINFECTANTS					
Alcohol	+	+	–	+	+/–
Hydrogen peroxide	+	+	+/–	+	+
Phenolics	+	+	–	+	+/–
Chlorine	+	+	+/–	+	+

Triclosan	+	+/–	–	+/–	+

maintained. Indeed, spore formation by a bacterium is commonly demonstrated by boiling a solution of organisms and then subculturing the solution. Boiling vegetative organisms kills them, but the spores remain viable. In contrast, steam under pressure in an autoclave is a very effective form of sterilization; the higher temperature causes denaturation of microbial proteins. The rate of killing organisms during the autoclave process is rapid but is influenced by the temperature and duration of autoclaving, size of the autoclave, flow rate of the steam, density and size of the load, and placement of the load in the chamber. Care must be taken to avoid creating air pockets, which inhibit penetration of the steam into the load. In general, most autoclaves are operated at 121° C to 132° C for 15 minutes or longer. Including commercial preparations of *Bacillus stearothermophilus,* spores can help monitor the effectiveness of sterilization. An ampule of these spores is placed in the center of the load, removed at the end of the autoclave process, and incubated at 37° C. If the sterilization process is successful, the spores are killed and the organisms fail to grow.

ETHYLENE OXIDE

Ethylene oxide is a colorless gas (soluble in water and common organic solvents) that is used to sterilize heat-sensitive items. The sterilization process is relatively slow and is influenced by the concentration of gas, relative humidity and moisture content of the item to be sterilized, exposure time, and temperature. The exposure time is reduced by 50% for each doubling of ethylene oxide concentration. Likewise, the activity of ethylene oxide approximately doubles with each temperature increase of 10° C. Sterilization with ethylene oxide is optimal in a relative humidity of approximately 30%, with decreased activity at higher or lower humidity. This is particularly problematic if the contaminated organisms are dried onto a surface or lyophilized. Ethylene oxide exerts its sporicidal activity through the alkylation of terminal hydroxyl, carboxyl, amino, and sulfhydryl groups. This process blocks the reactive groups required for many essential metabolic processes. Examples of other strong alkylating gases used as sterilants are formaldehyde and β-propiolactone. Because ethylene oxide can damage viable tissues, the gas must be dissipated before the item can be used. This aeration period is generally 16 hours or longer. The effectiveness of sterilization is monitored with the *B. subtilis* spore test.

ALDEHYDES

As with ethylene oxide, aldehydes exert their effect through alkylation. The two best known aldehydes are **formaldehyde** and **glutaraldehyde,** both of which can be used as sterilants or high-level disinfectants. Formaldehyde gas can be dissolved in water, creating a solution called formalin. Low concentrations of formalin are bacteriostatic (i.e., they inhibit but do not kill organisms), whereas higher concentrations (e.g., 20%) can kill all organisms. Combining formaldehyde with alcohol can enhance this microbicidal activity. Exposure of skin or mucous membranes to formaldehyde can be toxic, and vapors may be carcinogenic. For these reasons, formaldehyde is now rarely used in health care settings. Glutaraldehyde is less toxic for viable tissues, but it can still cause burns on the skin or mucous membranes. Glutaraldehyde is more active at alkaline pH levels ("activated" by sodium hydroxide) but is less stable. Glutaraldehyde is also inactivated by organic material, so items to be treated must first be cleaned.

OXIDIZING AGENTS

Examples of oxidants include ozone, peracetic acid, and hydrogen peroxide, and the latter is the most common. **Hydrogen peroxide** effectively kills most bacteria at a concentration of 3% to 6% and kills all organisms, including spores, at higher concentrations (10% to 25%). The active oxidant form is not hydrogen peroxide; it is the free hydroxyl radical formed by the decomposition of hydrogen peroxide. Hydrogen peroxide is used to disinfect plastic implants, contact lenses, and surgical prostheses.

HALOGENS

Halogens, such as compounds containing iodine or chlorine, are used extensively as disinfectants. **Iodine compounds** are the most effective halogens available for disinfection. Iodine is a highly reactive element that precipitates proteins and oxidizes essential enzymes. It is microbicidal against virtually all organisms, including spore-forming bacteria and mycobacteria. Neither the concentration nor the pH of the iodine solution affects the microbicidal activity, although the efficiency of iodine solutions is increased in acid solutions because more free iodine is liberated. Iodine acts more rapidly than do other halogen compounds or quaternary ammonium compounds. However, the activity of iodine can be reduced in the presence of some organic and inorganic compounds, including serum, feces, ascitic fluid, sputum, urine, sodium thiosulfate, and ammonia. Elemental iodine can be dissolved in aqueous potassium iodide or alcohol, or it can be complexed with a carrier. The latter compound is referred to as an *iodophor* (*iodo* means iodine, and *phor* means carrier). Povidone-iodine (iodine complexed with polyvinylpyrrolidone) is used most often and is relatively stable and nontoxic to tissues and metal surfaces, but it is expensive compared with other iodine solutions.

Chlorine compounds are also used extensively as disinfectants. Aqueous solutions of chlorine are rapidly bactericidal, although their mechanisms of action are not defined. Three forms of chlorine may be present in water: elemental chlorine (Cl_2), which is a very strong oxidizing agent; hypochlorous acid (HOCl); and hypochlorite ion (OCl_2). Chlorine also combines with ammonia and other nitrogenous compounds to form chloramines, or *N*-chloro compounds. Chlorine can exert its effect by the irreversible oxidation of sulfhydryl (SH) groups of essential enzymes. Hypochlorites are believed to interact with cytoplasmic components to form toxic *N*-chloro compounds, which interfere with cellular metabolism. The efficacy of chlorine is inversely proportional to the pH, with greater activity observed at acid pH levels. This is consistent with greater activity associated with HOCl rather than with OCl_2 concentration. The activity of chlorine compounds also increases with concentration (e.g., a twofold increase in concentration results in a 30% decrease in time required for killing) and temperature (e.g., a 50% to 65% reduction in killing time with a 10° C increase in temperature). Organic matter and alkaline detergents can reduce the effectiveness of chlorine compounds. These compounds demonstrate good germicidal activity, although spore-forming organisms are 10- to 1000-fold more resistant to chlorine than are vegetative bacteria.

PHENOLIC COMPOUNDS

Phenolic compounds (germicides) are rarely used as disinfectants. However, they are of historical interest because they were used as a comparative standard for assessing the activity of other germicidal compounds. The ratio of germicidal activity by a test compound to that by a specified concentration of phenol yielded the phenol coefficient. A value of 1 indicated equivalent activity, greater than 1 indicated activity less than phenol, and less than 1 indicated activity greater than phenol. These tests are limited because phenol is not sporicidal at room temperature (but is sporicidal at temperatures approaching 100° C), and it has poor activity against non–lipid-containing viruses. This is understandable because phenol is believed to act by disrupting lipid-containing membranes, resulting in leakage of cellular contents. Phenolic compounds are active against the normally resilient mycobacteria because the cell wall of these organisms has a very high concentration of lipids. Exposure of phenolics to alkaline compounds significantly reduces their activity, whereas halogenation of the phenolics enhances their activity. The introduction of aliphatic or aromatic groups into the nucleus of halogen phenols also increases their activity. Bisphenols are two phenol compounds linked together. The activity of these compounds can also be potentiated by halogenation. One example of a halogenated bisphenol is **hexachlorophene,** which is an antiseptic with activity against gram-positive bacteria.

QUATERNARY AMMONIUM COMPOUNDS

Quaternary ammonium compounds consist of four organic groups covalently linked to nitrogen. The germicidal activity of these cationic compounds is determined by the nature of the organic groups, with the greatest activity observed with compounds having 8- to 18-carbon-long groups. Examples of quaternary ammonium compounds include **benzalkonium chloride** and **cetylpyridinium chloride.** These compounds act by denaturing cell membranes to release the intracellular components. Quaternary ammonium compounds are bacteriostatic at low concentrations and bactericidal at high concentrations; however, organisms such as *Pseudomonas, Mycobacterium,* and the fungus *Trichophyton* are resistant to these compounds. Indeed, some *Pseudomonas* strains can grow in quaternary ammonium solutions. Many viruses and all bacterial spores are also resistant. Ionic detergents, organic matter, and dilution neutralize quaternary ammonium compounds.

ALCOHOLS

The germicidal activity of alcohols increases with increasing chain length (maximum of five to eight carbons). The two most commonly used alcohols are **ethanol** and **isopropanol.** These alcohols are rapidly bactericidal against vegetative bacteria, mycobacteria, some fungi, and lipid-containing viruses. Unfortunately, alcohols have no activity against bacterial spores and have poor activity against some fungi and non–lipid-containing viruses. Activity is greater in the presence of water. Thus 70% alcohol is more active than 95% alcohol. Alcohol is a common disinfectant for skin surfaces and, when followed by treatment with an iodophor, is extremely effective for this purpose. Alcohols are also used to disinfect items such as thermometers.

Questions

1. Define the following terms and give three examples of each: sterilization, disinfection, and antisepsis.

2. Define the three levels of disinfection and give examples of each. When would each type of disinfectant be used?

3. What factors influence the effectiveness of sterilization with moist heat, dry heat, and ethylene oxide?

4. Give examples of each of the following disinfectants and their mode of action: iodine compounds, chlorine compounds, phenolic compounds, and quaternary ammonium compounds.

SECTION 2

General Principles of Laboratory Diagnosis

SECTION OUTLINE

4 Microscopy and In Vitro Culture

The foundation of microbiology was established in 1676 when Anton van Leeuwenhoek, using one of his early microscopes, observed bacteria in water. It was not until almost 200 years later that Pasteur was able to grow bacteria in the laboratory in a culture medium consisting of yeast extract, sugar, and ammonium salts. In 1881, Hesse used agar from his wife's kitchen to solidify the medium in the dishes that Petri made, which then permitted the growth of macroscopic colonies of bacteria. Over the years, microbiologists have returned to the kitchen to create hundreds of culture media that are now routinely used in all clinical microbiology laboratories. Although tests that rapidly detect microbial antigens and nucleic acid–based molecular assays have replaced microscopy and culture methods for the detection of many organisms, the ability to observe microbes by microscopy and grow microbes in the laboratory remains an important procedure in clinical laboratories. For many diseases, these techniques remain the definitive methods to identify the cause of an infection. This chapter will provide an overview of the most commonly used techniques for microscopy and culture, and more specific details will be presented in the chapters devoted to laboratory diagnosis in the individual organism sections.

Microscopy

In general, microscopy is used in microbiology for two basic purposes: the initial detection of microbes and the preliminary or definitive identification of microbes. The microscopic examination of clinical specimens is used to detect bacterial cells, fungal elements, parasites (eggs, larvae, or adult forms), and clumps of viruses (viral inclusions) present in infected cells. Characteristic morphologic properties can be used for the preliminary identification of most bacteria and are used for the definitive identification of many fungi and parasites. The microscopic detection of organisms stained with antibodies labeled with fluorescent dyes or other markers has proved to be very useful for the specific identification of many organisms. Five general microscopic methods are used (Box 4.1).

MICROSCOPIC METHODS

Brightfield (Light) Microscopy

The basic components of light microscopes consist of a light source used to illuminate the specimen positioned on a stage, a condenser used to focus the light on the specimen, and two lens systems **(objective** and **ocular)** used to magnify the image of the specimen. In brightfield microscopy the specimen is visualized by transillumination, with light passing up through the condenser to the specimen. The image is then magnified, first by the objective lens and then by the ocular lens. The total magnification of the image is the product of the magnifications of the objective and ocular lenses. Three different objective lenses are commonly used: low power (10-fold magnification), which can be used to scan a specimen; high dry (40-fold), which is used to look for large microbes such as parasites and filamentous fungi; and oil immersion (100-fold), which is used to observe bacteria, yeasts (single-cell stage of fungi), and the morphologic details of larger organisms and cells. Ocular lenses further magnify the image (generally 10- to 15-fold). Thus using an oil immersion lens (100-fold) with a 10-fold ocular lens provides a total magnification of 1000-fold that is generally necessary to see bacteria in a specimen.

The limitation of brightfield microscopy is the resolution of the image (i.e., the ability to distinguish that two objects are separate and not one). The **resolving power** of a microscope is determined by the wavelength of light used to illuminate the subject and the angle of light entering the objective lens (referred to as the **numerical aperture**). The resolving power is greatest when oil is placed between the objective lens (typically the 100× lens) and the specimen because oil reduces the dispersion of light. The best brightfield microscopes have a resolving power of approximately 0.2 μm, which allows most bacteria, but not viruses, to be visualized. Although most bacteria and larger microorganisms can be seen with brightfield microscopy, the **refractive indices** of the organisms and background are similar. Thus organisms must be stained with a dye so they can be observed, or an alternative microscopic method must be used.

Darkfield Microscopy

The same objective and ocular lenses used in brightfield microscopes are used in darkfield microscopes; however, a special **condenser** is used that prevents transmitted light from directly illuminating the specimen. Only oblique scattered light reaches the specimen and passes into the lens systems, which causes the specimen to be brightly illuminated against a black background. The advantage of this method is that the resolving power of darkfield microscopy is significantly improved compared with that of brightfield microscopy (i.e., 0.02 μm versus 0.2 μm), which makes it possible to detect extremely thin bacteria such as *Treponema*

BOX 4.1 Microscopic Methods

Brightfield (light) microscopy
Darkfield microscopy
Phase-contrast microscopy
Fluorescent microscopy
Electron microscopy

pallidum (etiologic agent of syphilis) and *Leptospira* spp. (leptospirosis). The disadvantage of this method is that light passes around rather than through organisms, making it difficult to study their internal structure.

Phase-Contrast Microscopy

Phase-contrast microscopy enables the internal details of microbes to be examined. In this form of microscopy, as parallel beams of light are passed through objects of different densities, the wavelength of one beam moves out of "phase" relative to the other beam of light (i.e., the beam moving through the more dense material is retarded more than the other beam). Through the use of **annular rings** in the condenser and the objective lens, the differences in phase are amplified so that in-phase light appears brighter than out-of-phase light. This creates a three-dimensional image of the organism or specimen and permits more detailed analysis of the internal structures.

Fluorescent Microscopy

Some compounds called **fluorochromes** can absorb short-wavelength ultraviolet or ultrablue light and emit energy at a higher visible wavelength. Although some microorganisms show natural fluorescence **(autofluorescence),** fluorescent microscopy typically involves staining organisms with fluorescent dyes and then examining them with a specially designed fluorescent microscope. The microscope uses a high-pressure mercury, halogen, or xenon vapor lamp that emits a shorter wavelength of light than that emitted by traditional bright-field microscopes. A series of filters are used to block the heat generated from the lamp, eliminate infrared light, and select the appropriate wavelength for exciting the fluorochrome. The light emitted from the fluorochrome is then magnified through traditional objective and ocular lenses. Organisms and specimens stained with fluorochromes appear brightly illuminated against a dark background, although the colors vary depending on the fluorochrome selected. The contrast between the organism and background is great enough that the specimen can be screened rapidly under low magnification, and then the material is examined under higher magnification once fluorescence is detected.

Electron Microscopy

Unlike other forms of microscopy, **magnetic coils** (rather than lenses) are used in electron microscopes to direct a beam of electrons from a tungsten filament through a specimen and onto a screen. Because a much shorter wavelength of light is used, magnification and resolution are improved dramatically. Individual viral particles (as opposed to viral inclusion bodies) can be seen with electron microscopy. Samples are usually stained or coated with metal ions to create contrast. There are two types of electron microscopes: **transmission electron microscopes,** in which electrons such as light pass directly through the specimen, and **scanning electron microscopes,** in which electrons bounce off the surface of the specimen at an angle and a three-dimensional picture is produced. Today, electron microscopy is used more as a research tool than a diagnostic aid, and highly sensitive and specific nucleic acid amplification assays are the primary diagnostic test in current use.

EXAMINATION METHODS

Clinical specimens or suspensions of microorganisms can be placed on a glass slide and examined under the microscope (i.e., direct examination of a wet mount). Although large organisms (e.g., fungal elements, parasites) and cellular material can be seen using this method, analysis of the internal detail is often difficult. Phase-contrast microscopy can overcome some of these problems; alternatively, the specimen or organism can be stained by a variety of methods (Table 4.1).

Direct Examination

Direct examination methods are the simplest for preparing samples for microscopic examination. The sample can be suspended in water or saline **(wet mount),** mixed with alkali to dissolve background material **(potassium hydroxide [KOH] method),** or mixed with a combination of alkali and a contrasting dye (e.g., **lactophenol cotton blue, iodine**). The dyes nonspecifically stain the cellular material, increasing the contrast with the background, and permit examination of the detailed structures. A variation is the **India ink method,** in which the ink darkens the background rather than the cell. This method is used to detect capsules surrounding organisms, such as the yeast *Cryptococcus* (the dye is excluded by the capsule, creating a clear halo around the yeast cell) and encapsulated *Bacillus anthracis*.

Differential Stains

A variety of differential stains are used to stain specific organisms or components of cellular material. The **Gram stain** is the best known and most widely used stain and forms the basis for the phenotypic classification of bacteria; yeasts can also be stained with this method (yeasts are gram-positive). The **iron hematoxylin** and **trichrome** stains are invaluable for identifying protozoan parasites, and the **Wright-Giemsa** stain is used to identify blood parasites and other selected organisms. Stains such as methenamine silver and toluidine blue O have largely been replaced by more sensitive or technically easier differential or fluorescent stains.

Acid-Fast Stains

At least three different acid-fast stains are used, each exploiting the fact that some organisms retain a primary stain even when exposed to strong decolorizing agents such as mixtures of acids and alcohols. The **Ziehl-Neelsen** is the oldest method used but requires heating the specimen during the staining procedure. Many laboratories have replaced this method with either the cold acid-fast stain **(Kinyoun method)** or the fluorochrome stain **(auramine-rhodamine method).** The fluorochrome method is the stain of choice because a large area of the specimen can be examined rapidly by simply searching for fluorescing organisms against a black background. Some organisms are "partially acid-fast," retaining the primary stain only when they are decolorized with a weakly acidic solution. This property is characteristic of only a few organisms (see Table 4.1), making it quite valuable for their preliminary identification.

Table 4.1 Microscopic Preparations and Stains Used in the Clinical Microbiology Laboratory

Staining Method	Principle and Applications
DIRECT EXAMINATION	
Wet mount	Unstained preparation is examined by brightfield, darkfield, or phase-contrast microscopy
10% KOH	KOH is used to dissolve proteinaceous material and facilitate detection of fungal elements that are not affected by strong alkali solution; dyes such as lactophenol cotton blue can be added to increase contrast between fungal elements and background
India ink	Modification of KOH procedure in which ink is added as contrast material; dye primarily used to detect *Cryptococcus* spp. in cerebrospinal fluid and other body fluids; polysaccharide capsule of *Cryptococcus* spp. excludes ink, creating a halo around the yeast cell
Lugol iodine	Iodine is added to wet preparations of parasitology specimens to enhance contrast of internal structures; this facilitates differentiation of amoebae and host white blood cells
DIFFERENTIAL STAINS	
Gram stain	Most commonly used stain in microbiology laboratory, forming the basis for separating major groups of bacteria (e.g., gram-positive, gram-negative); after fixation of specimen to glass slide (by heating or alcohol treatment), specimen is exposed to crystal violet and then iodine is added to form a complex with primary dye; during decolorization with alcohol or acetone, the complex is retained in gram-positive bacteria but lost in gram-negative organisms; counterstain safranin is retained by gram-negative organisms (hence their red color); the degree to which organism retains stain is function of organism, culture conditions, and staining skills of the microscopist
Iron hematoxylin stain	Used for detection and identification of fecal protozoa; helminth eggs and larvae retain too much stain and are more easily identified with wet-mount preparation
Methenamine silver	In general, performed in histology laboratories rather than in microbiology laboratories; used primarily for stain detection of fungal elements in tissue, although other organisms (e.g., bacteria) can be detected; silver staining requires skill because nonspecific staining can render slides incapable of being interpreted
Toluidine blue O stain	Used primarily for detection of *Pneumocystis* organisms in respiratory specimens; cysts stain reddish-blue to dark purple on light blue background; background staining is removed by sulfation reagent; yeast cells stain and are difficult to distinguish from *Pneumocystis* cells; trophozoites do not stain; many laboratories have replaced this stain with specific fluorescent stains
Trichrome stain	Alternative to iron hematoxylin for staining protozoa; protozoa have bluish-green to purple cytoplasms with red or purplish-red nuclei and inclusion bodies; specimen background is green
Wright-Giemsa stain	Used to detect blood parasites, viral and chlamydial inclusion bodies, and *Borrelia, Toxoplasma, Pneumocystis,* and *Rickettsia* spp.; this is a polychromatic stain that contains a mixture of methylene blue, azure B, and eosin Y; Giemsa stain combines methylene blue and eosin; eosin ions are negatively charged and stain basic components of cells orange to pink, whereas other dyes stain acidic cell structures various shades of blue to purple; protozoan trophozoites have a red nucleus and grayish-blue cytoplasm; intracellular yeasts and inclusion bodies typically stain blue; rickettsiae, chlamydiae, and *Pneumocystis* spp. stain purple
ACID-FAST STAINS	
Ziehl-Neelsen stain	Used to stain mycobacteria and other acid-fast organisms; organisms are stained with basic carbolfuchsin and resist decolorization with acid-alkali solutions; background is counterstained with methylene blue; organisms appear red against light blue background; uptake of carbolfuchsin requires heating specimen (hot acid-fast stain).
Kinyoun stain	Cold acid-fast stain (does not require heating); same principle as Ziehl-Neelsen stain
Auramine-rhodamine	Same principle as other acid-fast stains, except that fluorescent dyes (auramine and rhodamine) are used for primary stain, and potassium permanganate (strong oxidizing agent) is the counterstain and inactivates unbound fluorochrome dyes; organisms fluoresce yellowish-green against a black background
Modified acid-fast stain	Weak decolorizing agent is used with any of three acid-fast stains listed; whereas mycobacteria are strongly acid-fast, other organisms stain weaker (e.g., *Nocardia, Rhodococcus, Tsukamurella, Gordonia, Cryptosporidium, Isospora, Sarcocystis, Cyclospora*); these organisms can be stained more efficiently by using a weak decolorizing agent; organisms that retain this stain are referred to as partially acid-fast
FLUORESCENT STAINS	
Acridine orange stain	Used for detection of bacteria and fungi in clinical specimens; dye intercalates into nucleic acid (native and denatured); at neutral pH, bacteria, fungi, and cellular material stain reddish-orange; at acid pH (4.0), bacteria and fungi remain reddish-orange, but background material stains greenish-yellow
Auramine-rhodamine stain	Same as acid-fast stains
Calcofluor white stain	Used to detect fungal elements and *Pneumocystis* spp.; stain binds to cellulose and chitin in cell walls; microscopist can mix dye with KOH (many laboratories have replaced traditional KOH stain with this stain)
Direct fluorescent antibody stain	Antibodies (monoclonal or polyclonal) are complexed with fluorescent molecules; specific binding to an organism is detected by the presence of microbial fluorescence; technique has proved useful for detecting or identifying many organisms (e.g., *Streptococcus pyogenes, Bordetella, Francisella, Legionella, Chlamydia, Pneumocystis, Cryptosporidium, Giardia*, influenza virus, herpes simplex virus); sensitivity and specificity of test are determined by the number of organisms present in the test sample and quality of antibodies used in reagents.

KOH, Potassium hydroxide.

Fluorescent Stains

The auramine-rhodamine acid-fast stain is a specific example of a fluorescent stain. Numerous other fluorescent dyes have also been used to stain specimens. For example, the **acridine orange stain** can be used to stain bacteria and fungi, and **calcofluor white** stains the chitin in fungal cell walls. Although the acridine orange stain is rather limited in its applications, the calcofluor white stain has replaced the KOH stains. Another procedure is the examination of specimens with specific antibodies labeled with fluorescent dyes **(fluorescent antibody stains).** The presence of fluorescing organisms is a rapid method for both detection and identification of the organism.

In Vitro Culture

The success of culture methods is defined by the biology of the organism, the site of the infection, the patient's immune response to the infection, and the quality of the culture media. The bacterium *Legionella* is an important respiratory pathogen; however, it was never grown in culture until it was recognized that recovery of the organism required using media supplemented with iron and L-cysteine. *Campylobacter,* an important enteric pathogen, was not recovered in stool specimens until highly selective media were incubated at 42° C in a microaerophilic atmosphere. *Chlamydia,* an important bacterium responsible for sexually transmitted diseases, is an obligate intracellular pathogen that must be grown in living cells. *Staphylococcus aureus,* the cause of staphylococcal toxic shock syndrome, produces disease by release of a toxin into the circulatory system. Culture of blood will almost always be negative, but culture of the site in which the organism is growing will detect the organism. In many infections (e.g., gastroenteritis, pharyngitis, urethritis), the organism responsible for the infection will be present among many other organisms that are part of the normal microbial population at the site of infection. Many media have been developed that suppress the normally present microbes and allow easier detection of clinically important organisms. The patient's innate and adaptive immunity may suppress the pathogen, so highly sensitive culture techniques are frequently required. Likewise, some infections are characterized by the presence of relatively few organisms. For example, most septic patients have less than one organism per milliliter of blood, so recovery of these organisms in a traditional blood culture requires inoculation of a large volume of blood into enrichment broths. Finally, the quality of media must be carefully monitored to demonstrate that they will perform as designed.

Relatively few laboratories prepare their own media today. Most media are produced by large commercial companies with expertise in media production. Although this has obvious advantages, it also means that media are not "freshly produced." This is generally not a problem, although it can affect the recovery of some fastidious organisms (e.g., *Bordetella pertussis*). Thus laboratories that perform sophisticated testing frequently have the ability to make a limited amount of specialized media. Dehydrated formulations of most media are available, so this can be accomplished with minimal difficulty. Please refer to the references in the Bibliography for additional information about the preparation and quality control of media.

TYPES OF CULTURE MEDIA

Culture media can be subdivided into four general categories: (1) enriched nonselective media, (2) selective media, (3) differential media, and (4) specialized media (Table 4.2). Some examples of these media are summarized in the following.

Enriched Nonselective Media

These media are designed to support the growth of most organisms without fastidious growth requirements. The following are some of the more commonly used media:

Blood agar. Many types of blood agar media are used in clinical laboratories. These media contain two primary components: a basal medium (e.g., tryptic soy, brain heart infusion, *Brucella* base) and blood (e.g., sheep, horse, rabbit). Various other supplements can also be added to extend the range of organisms that can grow on the media.

Chocolate agar. This is a modified blood agar medium. When blood or hemoglobin is added to the heated basal media, it turns brown (hence the name). This medium supports the growth of most bacteria, including some that do not grow on blood agar (i.e., *Haemophilus,* some pathogenic *Neisseria* strains).

Mueller-Hinton agar. This is the recommended medium for routine antibiotic susceptibility testing of bacteria. It has a well-defined composition of beef and casein extracts, salts, divalent cations, and soluble starch that is necessary for reproducible test results.

Thioglycolate broth. This is one of a variety of enrichment broths used to recover low numbers of aerobic and anaerobic bacteria. Various formulations are used, but most formulations include casein digest, glucose, yeast extract, cysteine, and sodium thioglycolate. Supplementation with hemin and vitamin K will enhance the recovery of anaerobic bacteria.

Sabouraud dextrose agar. This is an enriched medium consisting of digests of casein and animal tissue supplemented with glucose that is used for the isolation of fungi. A variety of formulations have been developed, but most mycologists use the formulation with a low concentration of glucose and neutral pH. By reducing the pH and adding antibiotics to inhibit bacteria, this medium can be made selective for fungi.

Selective Media and Differential Media

Selective media are designed for the recovery of specific organisms that may be present in a mixture of other organisms (e.g., an enteric pathogen in stool). The media are supplemented with inhibitors that suppress the growth of unwanted organisms. These media can be made differential by adding specific ingredients that allow identification of an organism in a mixture (e.g., addition of lactose and a pH indicator to detect lactose-fermenting organisms). The following are some examples of selective and differential media:

MacConkey agar. This is a selective agar for gram-negative bacteria and differential for differentiation of lactose-fermenting and lactose-nonfermenting bacteria.

Table 4.2 Types of Culture Media

Type	Media (Examples)	Purpose
Nonselective	Blood agar	Recovery of bacteria and fungi
	Chocolate agar	Recovery of bacteria including *Haemophilus* and *Neisseria gonorrhoeae*
	Mueller-Hinton agar	Bacterial susceptibility test medium
	Thioglycolate broth	Enrichment broth for anaerobic bacteria
	Sabouraud dextrose agar	Recovery of fungi
Selective, differential	MacConkey agar	Selective for gram-negative bacteria; differential for lactose-fermenting species
	Mannitol salt agar	Selective for staphylococci; differential for *Staphylococcus aureus*
	Xylose-lysine deoxycholate agar	Selective, differential agar for *Salmonella* and *Shigella* in enteric cultures
	Lowenstein-Jensen medium	Selective for mycobacteria
	Middlebrook agar	Selective for mycobacteria
	CHROMagar	Selective, differential for selected bacteria and yeasts
	Inhibitory mold agar	Selective for molds
Specialized	BCYE agar	Recovery of *Legionella* and *Nocardia*
	Cystine-tellurite agar	Recovery of *Corynebacterium diphtheriae*
	Lim broth	Recovery of *Streptococcus agalactiae*
	MacConkey sorbitol agar	Recovery of *Escherichia coli* O157
	Regan-Lowe agar	Recovery of *Bordetella pertussis*
	TCBS agar	Recovery of *Vibrio* species

BYCE, Buffered charcoal yeast extract; *TCBS,* thiosulfate citrate bile salts sucrose.

The medium consists of digests of peptones, bile salts, lactose, neutral red, and crystal violet. The bile salts and crystal violet inhibit gram-positive bacteria. Bacteria that ferment lactose produce acid that precipitates the bile salts and causes a red color in the neutral red indicator.

Mannitol salt agar. This is a selective medium used for the isolation of staphylococci. The medium consists of digests of casein and animal tissue, beef extract, mannitol, salts, and phenol red. Staphylococci can grow in the presence of a high salt concentration, and *S. aureus* can ferment mannitol, producing yellow-colored colonies on this agar.

Xylose-lysine deoxycholate (XLD) agar. This is a selective agar used for the detection of *Salmonella* and *Shigella* in enteric cultures. This is an example of a very clever approach to detecting important bacteria in a complex mixture of insignificant bacteria. The medium consists of yeast extract with xylose, lysine, lactose, sucrose, sodium deoxycholate, sodium thiosulfate, ferric ammonium citrate, and phenol red. Sodium deoxycholate inhibits the growth of the majority of nonpathogenic bacteria. Those that do grow typically ferment lactose, sucrose, or xylose, producing yellow colonies. *Shigella* does not ferment these carbohydrates, so the colonies appear red. *Salmonella* ferments xylose but also decarboxylates lysine, producing the alkaline diamine product cadaverine. This neutralizes the acid fermentation products; thus the colonies appear red. Because most *Salmonella* produce hydrogen sulfide from sodium thiosulfate, the colonies will turn black in the presence of ferric ammonium citrate, thus differentiating *Salmonella* from *Shigella.*

Lowenstein-Jensen (LJ) medium. This medium, used for the isolation of mycobacteria, contains glycerol, potato flour, salts, and coagulated whole eggs (to solidify the medium). Malachite green is added to inhibit gram-positive bacteria.

Middlebrook agar. This agar medium is also used for the isolation of mycobacteria. It contains nutrients required for the growth of mycobacteria (i.e., salts, vitamins, oleic acid, albumin, catalase, glycerol, glucose) and malachite green for the inhibition of gram-positive bacteria. In contrast with LJ medium, it is solidified with agar.

CHROMagar. These selective differential agars are used for the isolation and identification of a variety of bacteria (e.g., *S. aureus,* enteric bacteria) and yeasts. An example of the design of these media is the one developed for *Candida* species. This medium has chloramphenicol to inhibit bacteria and a mixture of proprietary chromogenic substrates. The different species of *Candida* have enzymes that can use one or more of the substrates, releasing the color compound and producing colored colonies; thus *Candida albicans* forms green colonies, *C. tropicalis* forms purple colonies, and *C. krusei* forms pink colonies.

Inhibitory mold agar. This medium is an enriched selective formulation used for the isolation of pathogenic fungi other than dermatophytes. Chloramphenicol is added to suppress the growth of contaminating bacteria.

Specialized Media

A large variety of specialized media have been created for the detection of specific organisms that may be fastidious or typically present in large mixtures of organisms. The more commonly used media are described in the specific organism chapters in this textbook.

CELL CULTURE

Some bacteria and all viruses are **strict intracellular microbes;** that is, they can only grow in living cells. In 1949, John Franklin Enders described a technique for cultivating mammalian cells for the isolation of poliovirus. This technique has been expanded for the growth of most strict intracellular organisms. The cell cultures can either be cells that grow and divide on a surface (i.e., **cell monolayer**) or grow suspended in broth. Some cell cultures are well established and can be maintained indefinitely. These cultures are commonly commercially available. Other cell cultures must be prepared immediately before they are infected with the bacteria or viruses and cannot be maintained in the laboratory for more than a few cycles of division **(primary cell cultures).** Entry into cells is frequently regulated by the presence of specific receptors, so the differential ability to infect specific cell lines can be used to predict the identity of the bacterium or virus. Additional information about the use of cell cultures is described in the following chapters.

Questions

1. Explain the principles underlying brightfield, darkfield, phase-contrast, fluorescent, and electron microscopy. Give one example in which each method would be used.
2. List examples of direct microscopic examinations, differential stains, acid-fast stains, and fluorescent stains.
3. Name three factors that affect the success of a culture.
4. Give three examples of enriched nonselective media.
5. Give three examples of selective differential media.

5 Molecular Diagnosis

Like the evidence left at the scene of a crime, the deoxyribonucleic acid (DNA), ribonucleic acid (RNA), or proteins of an infectious agent in a clinical sample can be used to help identify the agent. In many cases, the agent can be detected and identified even if it cannot be isolated in culture or detected by immunologic means. Additionally, molecular techniques such as nucleic acid sequencing and protein analysis by mass spectrometry are rapidly replacing traditional methods such as biochemical tests for identification of bacteria and fungi isolated in culture.

The subject matter in this chapter is presented commonly in comprehensive books, so this chapter is only a broad overview of the methods and applications of molecular diagnostics. The methods encompass techniques for detecting microbial nucleic acids and proteins, and the applications are for the detection, identification, or characterization of the microbes. Detection of microbes (viruses, bacteria, fungi, and parasites) primarily is performed directly with clinical specimens, whereas identification and characterization can be from clinical specimens or with organisms isolated in culture. Examples of the use of molecular diagnostic tests are summarized in Table 5.1.

Nonamplified Nucleic Acid Probes

DNA or RNA oligonucleotides (generally less than 50 nucleotides in length) labeled with reporter signal molecules bind to specific complementary microbial nucleic acid sequences for the detection of the organism in a clinical specimen or for the identification of the organism isolated in culture. Large numbers of the target sequence must be present for these probes to be useful. Generally these are not used for the direct detection of organisms in clinical specimens because the test sensitivity is too low (i.e., too few organisms are present for reliable detection). However, they can be used to identify organisms isolated in culture such as mycobacteria, dimorphic fungi, and viruses because large numbers of organisms will be present. Another use of molecular probes is to detect specific sequences amplified by the methods listed next.

TABLE 5.1 Examples of Applications of Molecular Diagnostic Tests

Test	Molecular Assay	Alternative Diagnostic
HAI tests	MSSA, MRSA	Culture more sensitive but slower
	Clostridium difficile	Immunoassay offered but insensitive; molecular test of choice
	Carbapenem-resistant gram-negative bacteria	Culture is more sensitive but slower
Reproductive health tests	*Chlamydia trachomatis*	Tissue culture or serology; molecular test of choice
	Neisseria gonorrhoeae	Culture; molecular test of choice
	Trichomonas vaginalis	Culture or microscopy; molecular test of choice
	Group B *Streptococcus*	Culture; molecular test of choice
	Bacterial vaginosis	Microscopy; molecular test of choice
Molecular multiplex panels	Respiratory infections (bacteria, viruses)	Culture or immunoassay for selected viruses and bacteria; molecular test of choice for most agents
	Enteric infections (bacteria, viruses, parasites)	Culture or immunoassays for selected bacteria; immunoassays for selected viruses; molecular test of choice for most agents
	Positive blood culture (bacteria, yeasts)	Rapid ID by MALDI; molecular tests complement culture (not replacement)
	Meningitis (bacteria, viruses)	No alternative for viruses; complements culture for bacteria (not replacement)
Blood-based viral tests	HIV	Immunoassay; molecular test of choice
	Hepatitis viruses (A, B, C)	Immunoassay; molecular test of choice
	HPV	Cytology; molecular test of choice
	Miscellaneous viruses	Molecular test of choice
Miscellaneous tests	*Mycobacterium tuberculosis*	Culture and/or microscopy
	Group A *Streptococcus*	Replaces immunoassays or culture

NUCLEIC ACID AMPLIFICATION METHODS

Nucleic acid amplification (NAA) methods are now widely used in clinical laboratories for the direct detection of pathogens in clinical specimens. A variety of NAA methods have been developed, but only four commonly used methods are described here: polymerase chain reaction (PCR) and modifications of PCR, transcription-mediated amplification (TMA), strand displacement amplification (SDA), and loop-mediated amplification (LAMP).

Polymerase Chain Reaction

DNA polymerase is used to synthesize a specific sequence of microbial DNA (target sequence). Two oligonucleotide primers flank the double-stranded DNA to be sequenced by binding to the complementary strands of DNA. Amplification occurs by heating the DNA to separate the double strands, cooling the reaction to allow the primers to bind to the two DNA strands, and then extending the sequences from the primers with DNA polymerase. This cycle of heating, cooling, and polymerization proceeds through a number of cycles, each time exponentially increasing the number of copies of the target DNA (Fig. 5.1). PCR is the most common NAA technique used in clinical laboratories for the detection of pathogens in clinical specimens. There also are a number of PCR variations. **Reverse transcriptase-PCR** (RT-PCR) was developed to amplify RNA targets. **Nested PCR** increases the sensitivity of PCR by performing two sequential amplification reactions using two pairs of primers and PCR reactions. The first pair of primers is used for a traditional PCR amplification. The second pair of primers amplifies an internal sequence of the first reaction product.

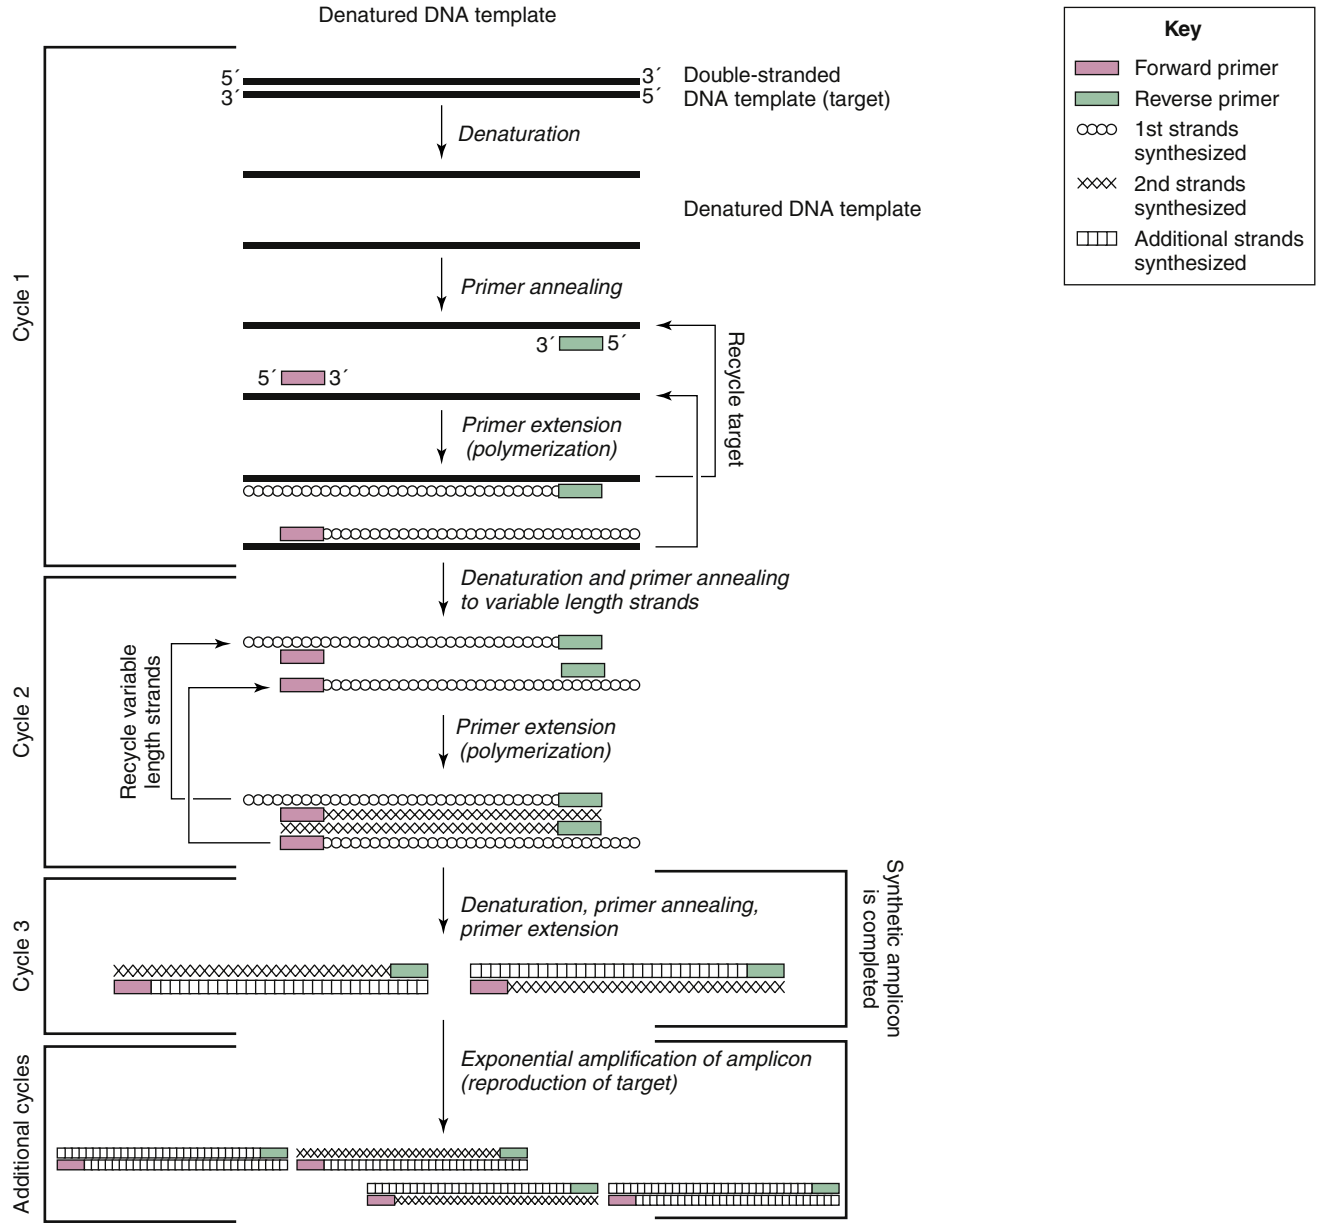

Fig. 5.1 Polymerase chain reaction target amplification. (From Wolk, D., Mitchell, S., Patel, R., 2001. Principles of molecular microbiology testing methods. Infect. Dis. Clin. North Am.15 (4) [Fig. 1].)

This process increases both the sensitivity and specificity of the PCR amplification. **Multiplex PCR** uses multiple pairs of primers to amplify multiple gene targets simultaneously. **Real-time PCR** allows both amplification of the target nucleic acid sequence and simultaneous detection of the amplification product, decreasing the time to detect a positive reaction.

Transcription-Mediated Amplification

TMA is an isothermal (performed at a constant temperature) RNA amplification method. The RNA target is transcribed into complementary DNA (cDNA) and then RNA copies are transcribed using RNA polymerase (Fig. 5.2). The advantages of TMA include rapid kinetics, elimination of the need for heating and cooling with a thermocycler, and the single-stranded RNA product does not need to be denatured before detection. A disadvantage of this technique is the relatively poor performance with DNA targets.

Strand Displacement Amplification

SDA is an isothermal amplification method for detection of specific RNA and DNA sequences (Fig. 5.3). The double-strand DNA target (or DNA-RNA hybrid) is denatured and then hybridized to two pairs of primers. The amplification primer pair hybridizes at the 5′ end of the target sequence and contains a restriction endonuclease sequence. The second primer pair binds just outside the 3′ end of the target sequence. The complementary strands are simultaneously extended, creating double-strand copies of the target sequence. Amplification of the target occurs when endonuclease creates a nick at the 5′ end and then DNA polymerase binds to the nick site and synthesizes a new strand while

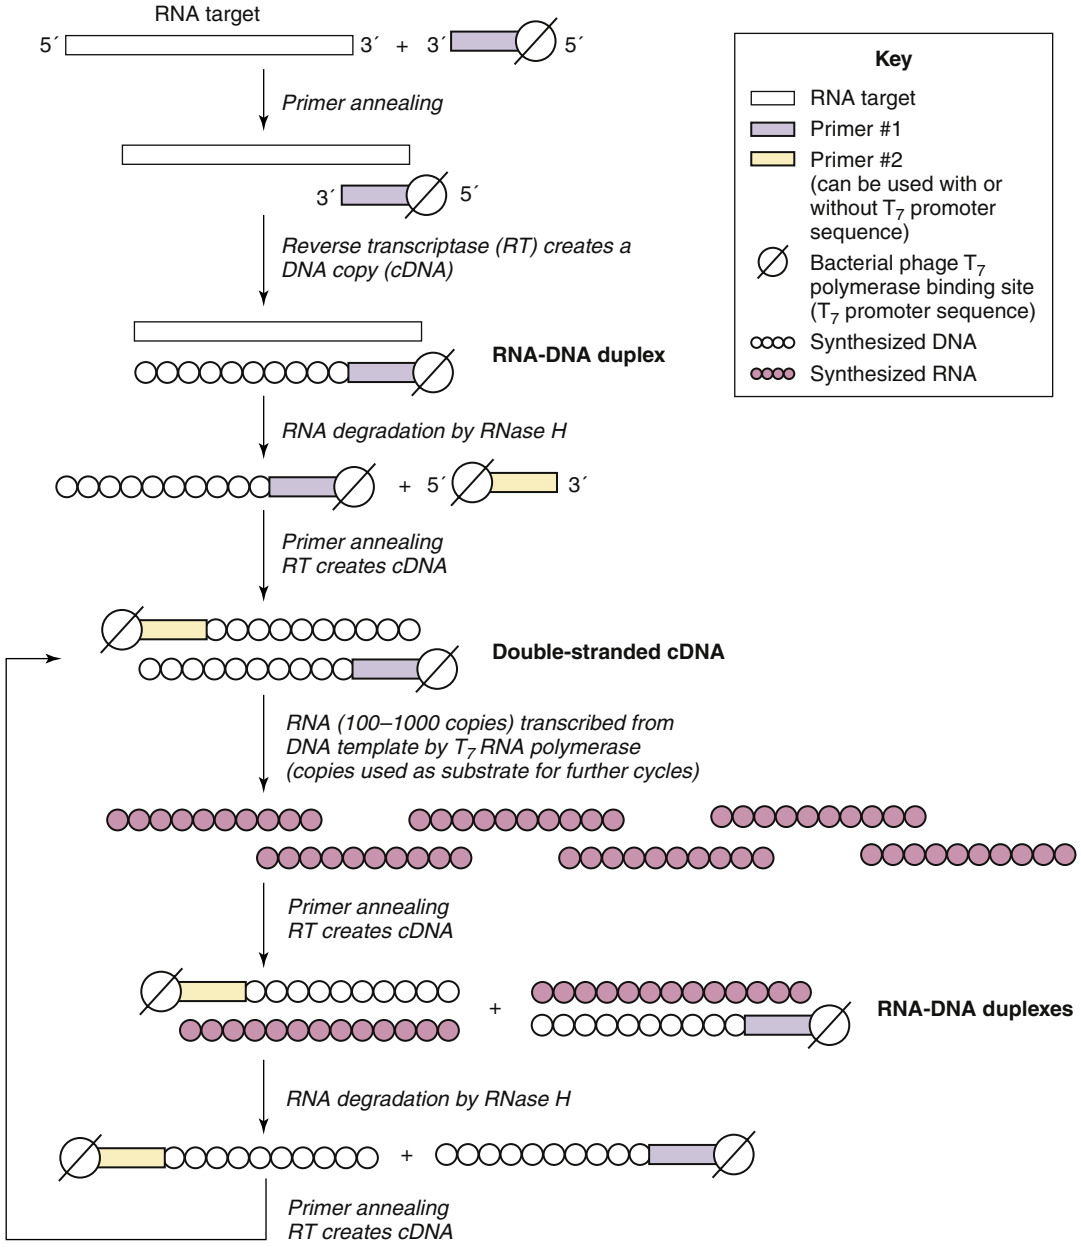

Fig. 5.2 Transcription based target amplification. (From Wolk, D., Mitchell, S., Patel, R., 2001. Principles of molecular microbiology testing methods. Infect. Dis. Clin. North Am. 15 (4) [Fig. 6].)

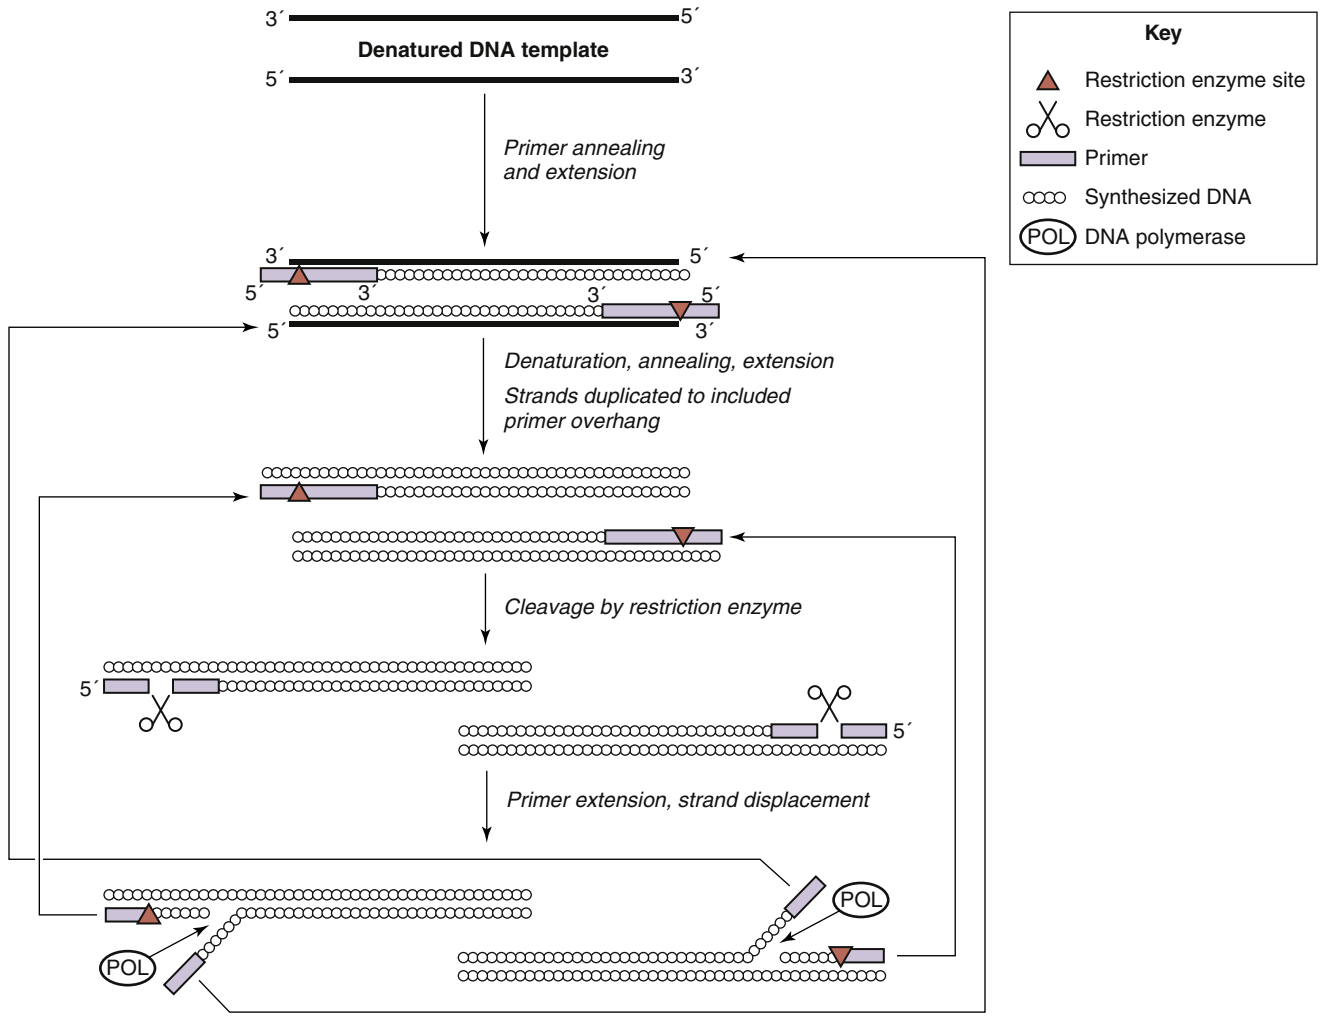

Fig. 5.3 Strand displacement target amplification. (From Wolk, D., Mitchell, S., Patel, R., 2001. Principles of molecular microbiology testing methods. Infect. Dis. Clin. North. Am. 15 (4) [Fig. 7].)

displacing the downstream strand. This process repeats creating exponential amplification of the target sequence. This isothermal amplification has very high sensitivity, but nonspecific primer hybridization can occur in complex mixtures of organisms.

Loop-Mediated Amplification

LAMP is an isothermal variation of SDA using four to six primer pairs to amplify the target DNA or RNA sequence. The amplified products are monitored in real time by measuring the turbidity of the magnesium pyrophosphate precipitate produced during the amplification reaction. This amplification method is particularly attractive because it is rapid and does not require expensive instrumentation.

Nucleic Acid Analysis

Much like letters, words, sentences, and paragraphs in a book, the sequences of nucleic acids in DNA and RNA tell a story about the genetic capabilities of an isolated organism. At the highest level, a sequence of DNA or RNA can be selected that is used to identify an organism at the genus or species level, or characterize a gene encoding a virulence marker or antibiotic resistance. At a deeper level, the sequences of DNA can be used to subtype an organism for epidemiologic purposes. In this section, the most commonly used techniques for identification and epidemiologic subtyping organisms are discussed.

NUCLEIC ACID SEQUENCING

Sequencing can be subdivided into targeted sequencing in which a specific region of DNA or RNA is sequenced, and whole genome sequencing (WGS), in which the entire microbial genome is sequenced. Targeted sequencing is used primarily to identify an organism or detect a virulence gene or antibiotic resistance gene, whereas WGS is used for subtyping or genotyping organisms. Sequencing the ribosomal RNA genes is a common procedure for the definitive identification of bacteria and fungi because portions of these genes are highly conserved and useful for identification at the genus level, whereas other sequences of the ribosomal RNA genes are species specific. Likewise, comparison of the genome sequences of individual bacteria is a common method for assessing their degree of relatedness. With each replication, one or more mutations is introduced in the genomes of the bacterial progeny. Thus the

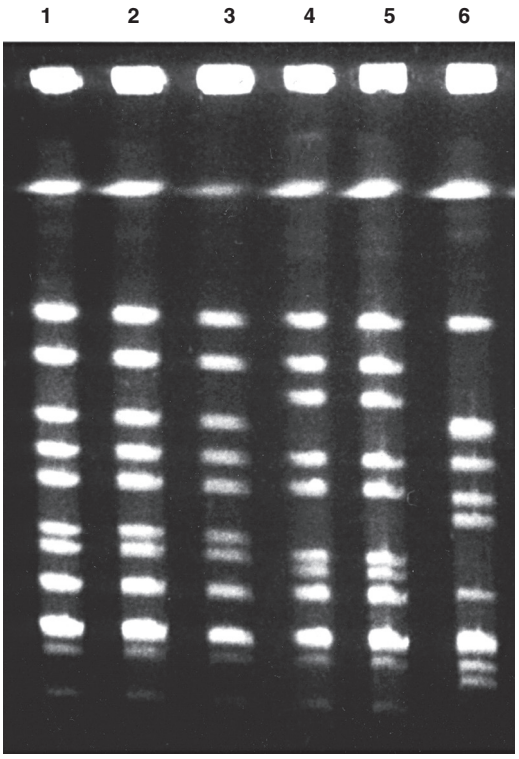

Fig. 5.4 Restriction fragment length polymorphism distinction of DNA from bacterial strains separated by pulsed-field gel electrophoresis. Lanes 1 to 3 show Sma 1 restriction endonuclease-digested DNA from bacteria from two family members with necrotizing fasciitis and from their physician (pharyngitis). Lanes 4 to 6 are from unrelated *Streptococcus pyogenes* strains. (Courtesy Dr. Joe DiPersio, Akron, Ohio.)

more mutations (single nucleotide polymorphisms [SNPs]) that are present in the genomes, the more distantly related are the two organisms. This procedure has become the gold standard for investigations of infectious outbreaks. However, even though the process of WGS, including sequencing long nucleic acid fragments and then assembly into complete genomes, has become relatively simple and inexpensive in recent years, most laboratories still do not have the technical expertise to use these tools. Thus a variety of other methods are used for epidemiologic classification, with the most commonly used method described here.

RESTRICTION FRAGMENT LENGTH POLYMORPHISM

Specific strains of microorganisms (primarily bacteria and viruses) can be distinguished on the basis of DNA fragments produced when the genomic DNA is cleaved by specific restriction endonucleases **(restriction enzymes)** that recognize specific DNA sequences. The cleavage of DNA samples from different strains with a restriction endonuclease can yield fragments of many different lengths. This pattern of DNA fragments (restriction fragment length polymorphism [RFLP]) is used to determine the relatedness of different strains (Fig. 5.4). DNA fragments of different sizes or structures can be distinguished by their electrophoretic mobility in an agarose or polyacrylamide gel. The DNA fragment moves through the mazelike structure of an agarose gel at different speeds, allowing their separation. The DNA can be visualized by staining with ethidium bromide. Smaller fragments (<20,000 base pairs), such as those from bacterial plasmids or viruses, can be separated and distinguished by normal electrophoretic methods. Larger fragments, such as those from whole bacteria, can be separated by using a special electrophoretic technique called **pulsed-field gel electrophoresis.** The procedure for this technique is similar to standard gel electrophoresis except the current that moves the DNA fragments through the gel is alternated periodically. By doing this, very large fragments of DNA can move through the gel and be separated by size. RFLP is a labor-intensive procedure that does not have the resolving power of WGS and SNP analysis; thus it is likely that this procedure will be discontinued in the next decade as sequencing techniques become more widely adopted in clinical microbiology laboratories.

Protein Analysis

WESTERN BLOT

Western blot or protein immunoblot is a technique to detect specific microbial proteins or patient antibodies to the proteins. This technique is a variation of Southern blot developed by Edwin Southern to detect DNA, and Northern blot developed for the detection of RNA. Although this technique has been replaced by other infectious diagnostic tests for most organisms, it is still used for diseases such as Lyme disease, prion-mediated Creutzfeldt-Jacob disease and HIV. In the case of Lyme disease, the Western blot test is used to confirm an initial positive immunoassay result. Microbial proteins (either purified or whole cell proteins) are denatured with a strong reducing agent and then separated by size on a polyacrylamide gel by electrophoresis. The proteins are then transferred to a nitrocellulose sheet by "blotting" (blocked with milk proteins to prevent nonspecific reactions) and then overlaid with the patient's serum. After binding with the patient's antibodies, the nitrocellulose is washed and stained to detect antibody binding to specific microbial proteins. The pattern of binding can differentiate specific reactivity or nonspecific (or negative) reactions.

MATRIX-ASSISTED LASER DESORPTION/ IONIZATION–TIME OF FLIGHT

It is rare that a technology can fundamentally alter well-established diagnostic testing methods, but that is precisely what the use of matrix-assisted laser desorption/ionization–time of flight (MALDI-TOF) mass spectrometry has done. This technology is now widely used for the identification of bacteria, mycobacteria, yeasts, and molds, replacing biochemical and morphologic tests that were the cornerstone of diagnostic microbiology for more than 100 years. The reason for this transformation is that the technology is highly accurate, technically simple to perform, rapid, and inexpensive. Bacterial and yeast colonies are removed from the agar culture plates, transferred to a target plate, dissolved with a strong organic acid (e.g., formic acid), mixed with an excess of ultraviolet (UV)-absorbing matrix, and dried on the target plates (Fig. 5.5). The dried preparations are exposed to laser pulses, resulting in energy transfer from the matrix to the nonvolatile protein molecules, with

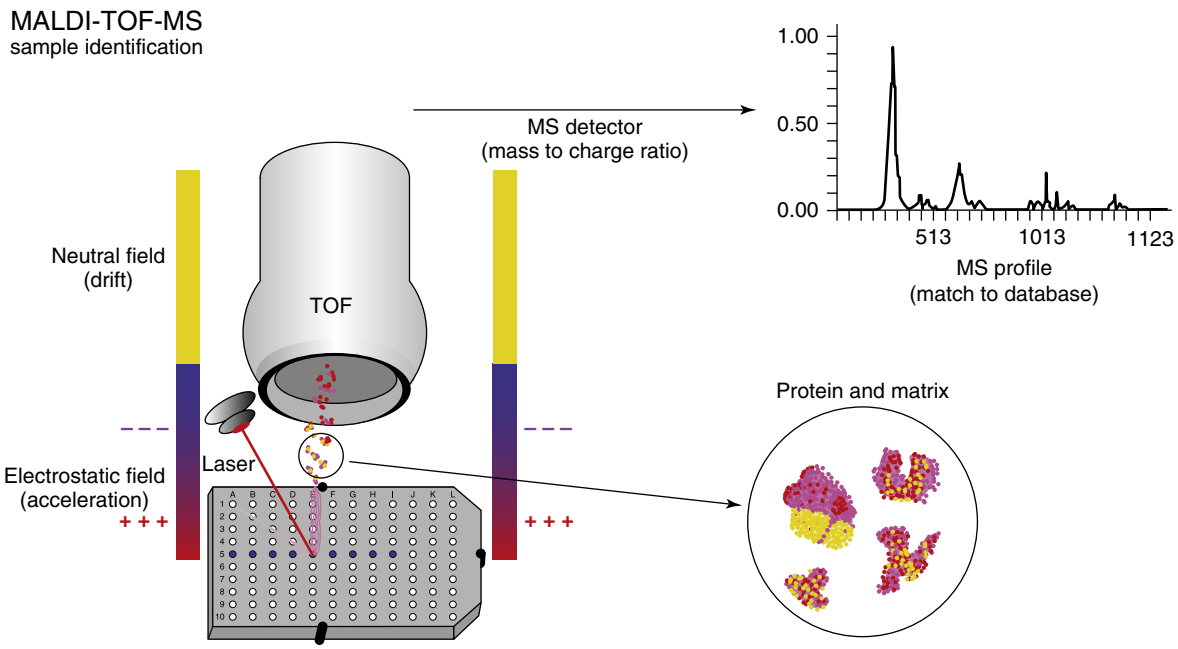

Fig. 5.5 Microorganism identification by matrix-assisted laser desorption ionization–time of flight (MALDI-TOF) mass spectrometry. (From Wolk, D.M., Clark, A.E. MALDI-TOF mass spectrometry. Clin. Lab. Med. 38, 471–486.)

the desorption (removal) of the proteins into the gas phase. The ionized molecules are accelerated by electric potentials through a flight tube to the mass spectrometer, with separation of the proteins determined by the mass/charge ratio (m/z; z typically is 1), with smaller proteins moving more rapidly than larger proteins. The profile of proteins is compared with profiles of well-characterized organisms permitting the identification of most organisms at the species or subspecies level. Using MALDI-TOF for identification of mycobacteria and molds is only slightly more complex, resulting in highly accurate identifications is less than 1 hour. Selection of the matrix influences the specific biomarkers that are detected (e.g., proteins phospholipids, cyclic lipopeptides) with α–cyano-4-hydroxy-cinnamic acid used preferentially for detection of protein biomarkers. The entire process takes minutes and is equivalent to identifying organisms by sequencing hundreds of genes because a single amino acid change will shift the protein profile. Applications of MALDI-TOF has recently been expanded for the detection of protein markers for antibiotic resistance and virulence, as well as the direct identification of some organisms in clinical specimens.

Questions

Which procedure(s) can be used for the following analyses and why would that procedure be used?

1. Comparison of the major bacterial species present in the normal flora of a thin and an obese individual.

2. Comparison of the normal bacterial flora associated with chronic oral abscesses.

3. A 37-year-old man has flulike symptoms. A viral infection is suspected. The agent needs to be identified from a nasal wash sample.

4. The efficacy of antiretroviral therapy in an HIV-infected individual can be evaluated by quantitating the number of viral genomes in her blood.

5. A Pap smear is suspected to contain human papillomavirus (HPV) infection. How can HPV be detected in the sample?

6. A baby is born with microcephaly, and cytomegalovirus (CMV) is suspected. Urine contains cells with a characteristic CMV-infected morphology. How can CMV infection be verified?

7. Antiviral resistance and disease severity are analyzed for hepatitis C virus isolates from intravenous drug users.

6 Serologic Diagnosis

Immunologic techniques are used to detect, identify, and quantitate antigen in clinical samples, as well as to evaluate the antibody response to infection and a person's history of exposure to infectious agents. The specificity of the antibody-antigen interaction and the sensitivity of many of the immunologic techniques make them powerful laboratory tools (Table 6.1). *In most cases, the same technique can be adapted to evaluate antigen and antibody*. Because many serologic assays are designed to give a positive or negative result, quantitation of the antibody strength is obtained as a titer. The **titer** of an antibody is defined as the greatest dilution of the sample that retains a detectable activity.

Antibodies

Antibodies can be used as sensitive and specific tools to detect, identify, and quantitate soluble antigens and antigens in a cell from a virus, bacterium, fungus, or parasite. Specific antibodies may be obtained from convalescent patients (e.g., antiviral antibodies) or prepared in animals. These antibodies are **polyclonal;** that is, they are heterogeneous antibody preparations that can recognize many epitopes on a single antigen. **Monoclonal** antibodies recognize individual epitopes on an antigen. Monoclonal antibodies for many antigens are commercially available, especially for lymphocyte cell surface proteins.

The development of monoclonal antibody technology revolutionized the science of immunology. For example, because of the specificity of these antibodies, lymphocyte subsets (e.g., CD4 and CD8 T cells) and lymphocyte cell surface antigens were identified. Monoclonal antibodies are usually produced from hybrid cells generated by the fusion and cloning of a B cell and a myeloma cell, which produces a hybridoma. The myeloma provides immortalization to the antibody-producing B cells. *Each hybridoma clone is a factory for one antibody molecule, yielding a monoclonal antibody that recognizes only one epitope*. Monoclonal antibodies can also be prepared and manipulated through genetic engineering and "humanized" for therapeutic usage.

The advantages of monoclonal antibodies are that (1) their specificity can be confined to a single epitope on an antigen and (2) they can be prepared in "industrial-sized" tissue culture preparations. A major disadvantage of monoclonal antibodies is that they are often too specific, such that a monoclonal antibody specific for one epitope on a viral antigen of one strain may not be able to detect that molecule from different strains of the same virus.

Methods of Detection

Antibody-antigen complexes can be detected directly, by precipitation techniques, or by labeling the antibody with a radioactive, fluorescent, or enzyme probe, or they can be detected indirectly through measurement of an antibody-directed reaction, such as complement fixation.

PRECIPITATION AND IMMUNODIFFUSION TECHNIQUES

Specific antigen-antibody complexes and cross-reactivity can be distinguished by immunoprecipitation techniques. Within a limited concentration range for both antigen and antibody, termed the **equivalence zone,** the antibody cross-links the antigen into a complex that is too large to stay in solution and therefore precipitates. This technique is based on the multivalent nature of antibody molecules (e.g., immunoglobulin [Ig]G has two antigen-binding domains). The antigen-antibody complexes are soluble at concentration ratios of antigen to antibody that are above and below the equivalence concentration.

Various immunodiffusion techniques make use of the equivalence concept to determine the identity of an antigen or the presence of antibody (Fig. 6.1). **Single radial immunodiffusion** can be used to detect and quantify an antigen. In this technique, antigen is placed into a well and allowed to diffuse into antibody-containing agar. The higher the concentration of antigen, the farther it diffuses before it reaches equivalence with the antibody in the agar and precipitates as a ring around the well.

The **Ouchterlony immuno–double-diffusion** technique is used to determine the relatedness of different antigens, as shown in Fig. 6.1. In this technique, solutions of antibody and antigen are placed in separate wells cut into agar, and the antigen and antibody are allowed to diffuse toward each other to establish rings of concentration gradients of each substance. A visible precipitin line occurs where the concentrations of antigen and antibody reach equivalence. On the basis of the pattern of the precipitin lines, this technique can also be used to determine whether samples are identical, share some but not all epitopes (partial identity), or are distinct. This technique is used to detect antibody and fungal antigens (e.g., *Histoplasma* species, *Blastomyces* species, and coccidioidomycoses).

In other immunodiffusion techniques, the antigen may be separated by electrophoresis in agar and then reacted with antibody (immunoelectrophoresis); it may be pushed into agar that contains antibody by means of electrophoresis (rocket electrophoresis), or antigen and antibody may be placed in separate wells and allowed to move electrophoretically toward each other (countercurrent immunoelectrophoresis).

TABLE 6.1 Selected Immunologic Techniques

Technique	Purpose	Clinical Examples
Ouchterlony immuno–double-diffusion	Detect and compare antigen and antibody	Fungal antigen and antibody
Immunofluorescence	Detection and localization of antigen	Viral antigen in biopsy (e.g., rabies, herpes simplex virus)
EIA	Same as immunofluorescence	Same as immunofluorescence
Immunofluorescence flow cytometry	Population analysis of antigen-positive cells	Immunophenotyping
ELISA	Quantitation of antigen or antibody	Viral antigen (rotavirus); viral antibody (anti-HIV)
Western blot	Detection of antigen-specific antibody or antigen	Confirmation of anti-HIV seropositivity (antibody)
RIA	Same as ELISA	Same as for ELISA
Complement fixation	Quantitate specific antibody titer	Fungal, viral antibody
Hemagglutination inhibition	Antiviral antibody titer; serotype of virus strain	Seroconversion to current influenza strain; identification of influenza
Latex agglutination	Quantitation and detection of antigen and antibody	Rheumatoid factor; fungal antigens; streptococcal antigens

EIA, Enzyme immunoassay; *ELISA,* enzyme-linked immunosorbent assay; *HIV,* human immunodeficiency virus; *RIA,* radioimmunoassay.

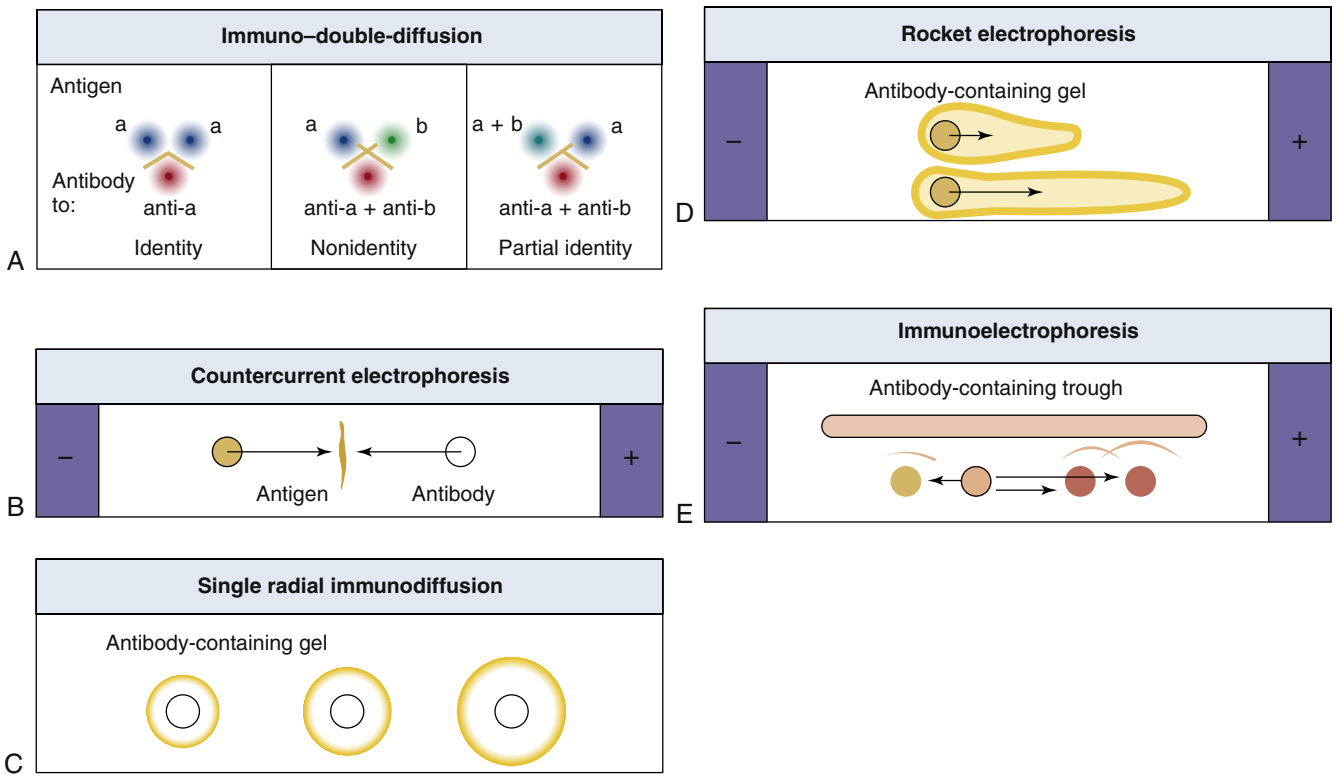

Fig. 6.1 Analysis of antigens and antibodies by immunoprecipitation. The precipitation of protein occurs at the equivalence point, at which multivalent antibody forms large complexes with antigen. (A) Ouchterlony immuno–double-diffusion. Antigen and antibody diffuse from wells, meet, and form a precipitin line. If identical antigens are placed in adjacent wells, then the concentration of antigen between them is doubled, and precipitation does not occur in this region. If different antigens are used, two different precipitin lines are produced. If one sample shares antigen but is not identical, then a single spur results for the complete antigen. (B) Countercurrent electrophoresis. This technique is similar to the Ouchterlony method, but antigen movement is facilitated by electrophoresis. (C) Single radial immunodiffusion. This technique involves the diffusion of antigen into an antibody-containing gel. Precipitin rings indicate an immune reaction, and the area of the ring is proportional to the concentration of antigen. (D) Rocket electrophoresis. Antigens are separated by electrophoresis into an agar gel that contains antibody. The length of the "rocket" indicates concentration of antigen. (E) Immunoelectrophoresis. Antigen is placed in a well and separated by electrophoresis. Antibody is then placed in the trough, and precipitin lines form as antigen and antibody diffuse toward each other.

Immunoassays for Cell-Associated Antigen (Immunohistology)

Antigens on the cell surface or within the cell can be detected by **immunofluorescence** and **enzyme immunoassay (EIA).** In **direct immunofluorescence,** a fluorescent molecule is covalently attached to the antibody (e.g., fluorescein-isothiocyanate [FITC]-labeled rabbit antiviral antibody). In **indirect immunofluorescence,** a second fluorescent antibody specific for the primary antibody (e.g., FITC-labeled goat anti-rabbit antibody) is used to detect the primary antiviral antibody and locate the antigen (Figs. 6.2 and 6.3). In EIA, an enzyme such as horseradish peroxidase or alkaline

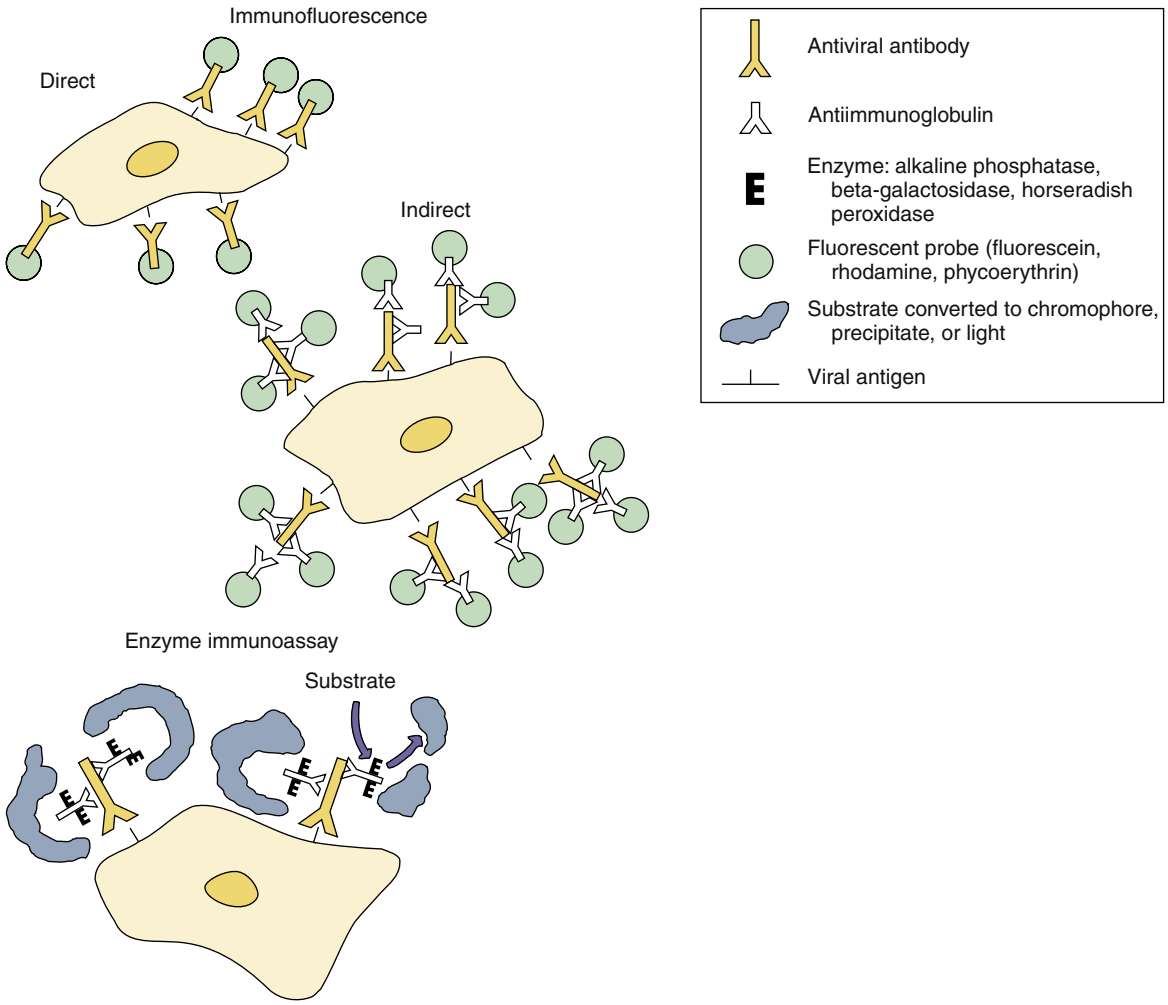

Fig. 6.2 Immunofluorescence and enzyme immunoassays for antigen localization in cells. Antigen can be detected by *direct* assay with antiviral antibody modified covalently with a fluorescent or enzyme probe, or by *indirect* assay using antiviral antibody and chemically modified antiimmunoglobulin. The enzyme converts substrate to a precipitate, chromophore, or light.

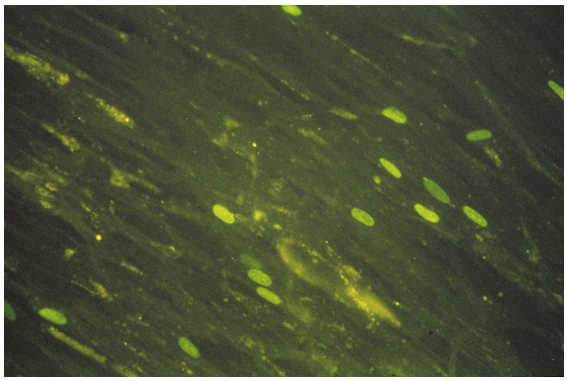

Fig. 6.3 Immunofluorescence localization of herpes simplex virus–infected nerve cells in a brain section from a patient with herpes encephalitis. (Modified from Male, D., Cooke, A., Owen, M., et al., 1996. Advanced Immunology, third ed. Mosby, St Louis, MO.)

phosphatase is conjugated to the antibody and converts a substrate into a chromophore to mark the antigen. Alternatively, an antibody modified by the attachment of a **biotin** (the vitamin) molecule can be localized by the very high-affinity binding of avidin or streptavidin molecules. A fluorescent molecule or an enzyme attached to the avidin and streptavidin allows detection. These techniques are useful for the analysis of tissue biopsy specimens, blood cells, and tissue culture cells.

The **flow cytometer** can be used to analyze the immunofluorescence of cells in suspension and is especially useful for identifying and quantitating lymphocytes (immunophenotyping) (Fig. 6.4). A laser is used in the flow cytometer to excite the fluorescent antibody attached to the cell and to determine the size and the granularity of the cell by means of light-scattering measurements. Use of antibodies labeled with different fluorescent dyes allows simultaneous analysis of multiple molecules with instruments that can analyze up to 12 different fluorescent colors and parameters. The cells flow past the laser at rates of more than 5000 cells per second, and analysis is performed electronically. The **fluorescence-activated cell sorter (FACS)** is a flow cytometer that can also isolate specific subpopulations of cells for tissue culture growth on the basis of their size and immunofluorescence. Variations on this approach use instruments that image and analyze every cell as they flow or on a slide.

The data obtained from a flow cytometer are usually presented in the form of a histogram, with the fluorescence intensity on the *x*-axis and the number of cells on the *y*-axis, or in the form of a dot plot, in which more than one parameter is compared for each cell. The flow

cytometer can perform a differential analysis of white blood cells. As shown in Fig. 6.4, all cells expressing a specific parameter (e.g., size, granularity and the CD3 T-cell marker) can be electronically identified by marking their graphic region and then chosen **(gated)** for further analysis (e.g., expression of CD4 and CD8) in subsequent graphs. Flow cytometry is also useful for analyzing cell growth after the fluorescent labeling of deoxyribonucleic acid (DNA) and other fluorescent applications.

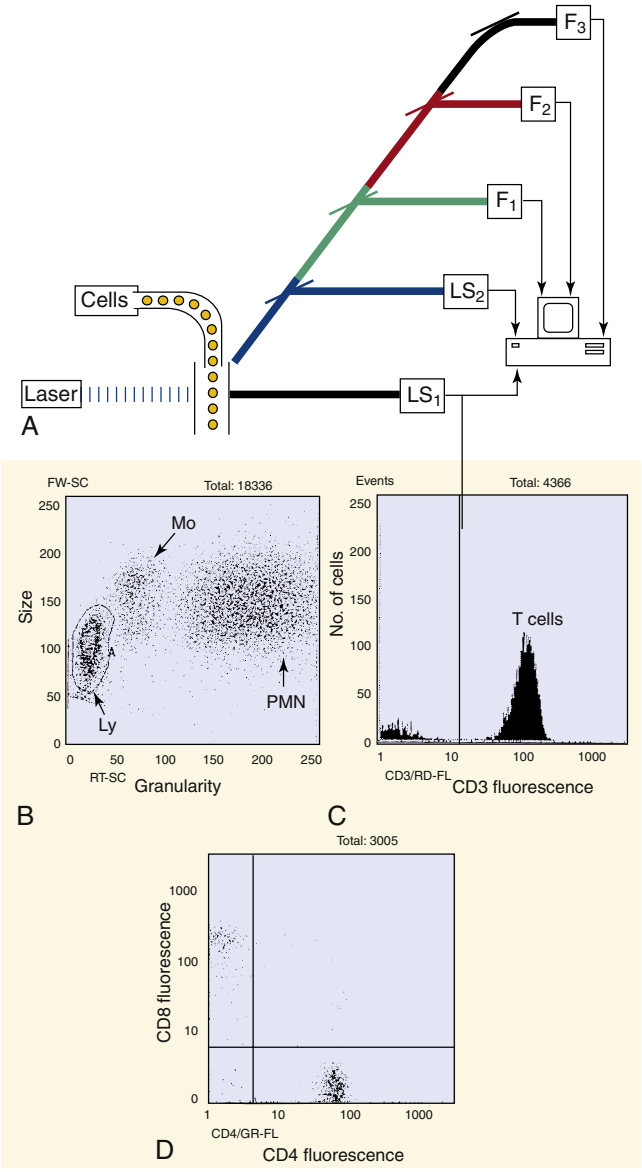

Fig. 6.4 Flow cytometry. (A) The flow cytometer evaluates individual cell parameters as the cells flow past a laser beam at rates of more than 5000 per second. Cell size and granularity are determined by light scattering *(LS)*, and antigen expression is evaluated by immunofluorescence *(F)*, using antibodies labeled with different fluorescent probes. Graphs B to D depict T-cell analysis of a normal patient. (B) Light-scatter analysis was used to define the lymphocytes *(Ly)*, monocytes *(Mo)*, and polymorphonuclear (neutrophil) leukocytes *(PMN)*. The Ly were "gated" for further analysis. (C) The T lymphocytes were identified by CD3 expression (presented in a histogram) and then analyzed for D, CD4, and CD8 T cells. Each dot represents one or a multiple of cells. (Data courtesy Dr. Tom Alexander, Akron, Ohio.)

Immunoassays for Antibody and Soluble Antigen

The **enzyme-linked immunosorbent assay (ELISA)** uses antigen immobilized on a plastic surface, bead, or filter to capture and separate the specific antibody from other antibodies in a patient's serum (Fig. 6.5). An antihuman

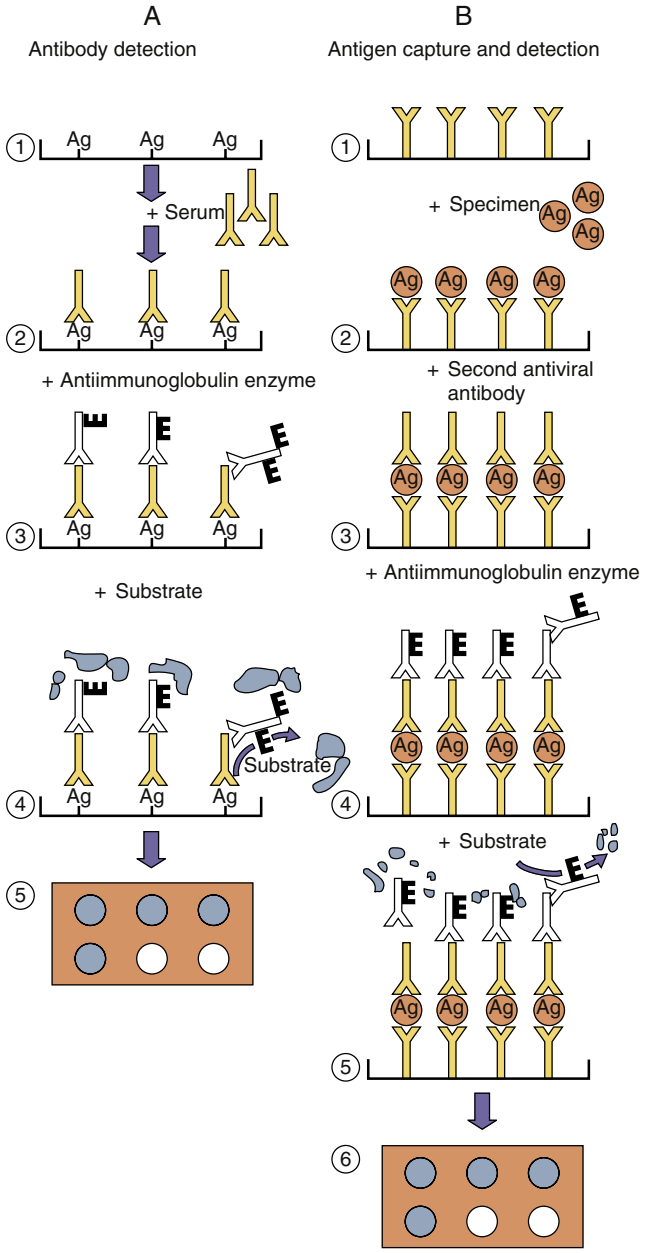

Fig. 6.5 Enzyme immunoassays for quantitation of antibody or antigen. (A) Antibody detection. *1,* Viral antigen *(Ag)* obtained from infected cells, virions, or genetic engineering is affixed to a surface. *2,* Patient serum is added and allowed to bind to the antigen. Unbound antibody is washed away. *3,* Enzyme-conjugated antihuman antibody *(E)* is added, and unbound antibody is washed away. *4,* Substrate is added and converted *(5)* into chromophore, precipitate, or light. (B) Antigen capture and detection. *1,* Antiviral antibody is affixed to a surface. *2,* A specimen that contains antigen is added, and unbound antigen is washed away. *3,* A second antiviral antibody is added to detect the captured antigen. *4,* Enzyme-conjugated anti-antibody is added, washed, and followed by substrate *(5)*, which is converted *(6)* into a chromophore, precipitate, or light.

antibody with a covalently linked enzyme (e.g., horseradish peroxidase, alkaline phosphatase, β-galactosidase) then detects the affixed patient antibody. It is quantitated spectrophotometrically according to the optical density of the color produced in response to the enzyme conversion of an appropriate substrate. The actual concentration of a specific antibody can be determined by comparison with the reactivity of standard human antibody solutions.

ELISAs can also be used to quantitate the soluble antigen in a patient's sample. In these assays, soluble antigen is captured and concentrated by an immobilized antibody and then detected with a different antibody labeled with the enzyme. The many variations of ELISAs differ in the way in which they capture or detect antibody or antigen.

Western blot analysis is a variation of ELISA. In this technique, viral proteins separated by electrophoresis according to their molecular weight or charge are transferred (blotted) onto a filter paper (e.g., nitrocellulose, nylon). When exposed to a patient's serum, the immobilized proteins capture virus-specific antibody and are visualized with an enzyme-conjugated antihuman antibody. This technique shows the proteins recognized by the patient's serum. Western blot analysis has been used to confirm ELISA results in patients suspected to be infected with the human immunodeficiency virus (HIV; Fig. 6.6; also see Fig. 39.7).

Rapid tests for home usage, such as the home pregnancy test for the human chorionic gonadotropin hormone, use a **lateral flow visual assay**. A dipstick is placed into urine or other fluid and the antigen-containing fluid wicks through a section containing enzyme-labeled antibodies and then continues to another section that captures and concentrates the complex and has substrate for the enzyme to give a display.

In **radioimmunoassay (RIA),** radiolabeled (e.g., with iodine-125) antibody or antigen is used to quantitate antigen-antibody complexes. Antibody in a patient's serum can be quantitated by its ability to compete with and replace a laboratory-prepared radiolabeled antibody in precipitated antigen-antibody complexes. The radioallergosorbent assay (RAST) is a variation of an RIA assay in which patient antibody competes with radiolabeled anti-IgE in binding to immobilized allergen, but this assay has been replaced with ELISA tests.

Complement fixation is a standard but technically difficult serologic test (Box 6.1). In this test, the patient's serum sample is reacted with laboratory-derived antigen and extra complement. Antibody-antigen complexes bind, activate, and fix (use up) the complement. The residual complement is then assayed through the lysis of red blood cells coated with antibody. A variation of this test can also be used to identify genetic deficiencies in complement components.

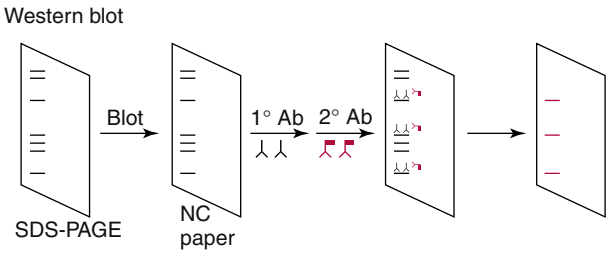

Fig. 6.6 Western blot analysis. Proteins are separated by sodium dodecyl sulfate–polyacrylamide gel electrophoresis *(SDS-PAGE),* electroblotted onto nitrocellulose *(NC)* paper, and incubated with antigen-specific antisera or the patient's antisera *(1 Ab)* and then enzyme-conjugated antihuman serum *(2 Ab).* Enzyme conversion of substrate identifies the antigen.

Antibody inhibition assays make use of the specificity of an antibody to prevent infection **(neutralization)** or other activity **(hemagglutination inhibition)** to identify the strain of the infecting agent, usually a virus, or to quantitate antibody responses to a specific strain of virus. For example, hemagglutination inhibition is used to distinguish different strains of influenza A and the potency of antibody developed by new vaccines for influenza. These tests are discussed further in Chapter 49.

Latex agglutination is a rapid, technically simple assay for detecting antibody or soluble antigen. Virus-specific antibody causes latex particles coated with viral antigens to clump. Conversely, antibody-coated latex particles are used to detect soluble viral antigen. In **passive hemagglutination**, antigen-modified erythrocytes are used as indicators instead of latex particles.

Serology

The humoral immune response provides a history of a patient's infections. Serology can be used to identify the infecting agent, evaluate the course of an infection, or determine the nature of the infection, such as whether it is a primary infection or a reinfection, and whether it is acute or chronic. The antibody type and titer and the identity of the antigenic targets provide serologic data about an infection. Serologic testing is used to identify viruses and other agents that are difficult to isolate and grow in the laboratory or that cause diseases that progress slowly (Box 6.2).

The relative antibody concentration is reported as a titer. A **titer** is the inverse of the greatest dilution (lowest concentration [e.g., dilution of 1:64 = titer of 64]) of a patient's serum that retains activity in one of the immunoassays just described.

Box 6.2 Viruses Diagnosed by Serology[a]

Epstein-Barr virus
Rubella virus
Hepatitis A, B, C, D, and E viruses
Human immunodeficiency virus
Human T-cell leukemia virus
Arboviruses (encephalitis viruses)

[a]Serologic testing is also used to determine a person's immune status with regard to other viruses.

The amount of IgM, IgG, IgA, or IgE reactive with antigen can also be evaluated through the use of a labeled second antihuman antibody that is specific for the antibody isotype.

Serology is used to determine the time course of an infection. **Seroconversion** occurs when antibody is produced in response to a primary infection. *Specific IgM antibody found during the first 2 to 3 weeks of a primary infection is a good indicator of a recent primary infection.* Reinfection or recurrence later in life causes an **anamnestic** (secondary or booster) response. Antibody titers may remain high in patients whose disease recurs frequently (e.g., herpesviruses). Seroconversion or reinfection is indicated by the finding *of at least a fourfold increase in the antibody titer between serum obtained during the acute phase of disease and that obtained at least 2 to 3 weeks later during the convalescent phase.* For example, a twofold serial dilution will not distinguish between samples with 512 and 1023 units of antibody, both of which would give a reaction on a 512-fold dilution but not on a 1024-fold dilution, and both results would be reported as titers of 512. On the other hand, samples with 1020 and 1030 units are not significantly different but would be reported as titers of 512 and 1024, respectively.

Serology can also be used to determine the stage of a slower or chronic infection (e.g., hepatitis B or infectious mononucleosis caused by Epstein-Barr virus) based on the presence of antibody to specific microbial antigens. The first antibodies to be detected are those directed against antigens most available to the immune system (e.g., on the surface of the virion, on infected cells, or secreted). Later in the infection, when cells have been lysed by the infecting virus or the cellular immune response, antibodies directed against the intracellular proteins and enzymes are detected.

Questions

Describe the diagnostic procedure or procedures (molecular or immunologic) that would be appropriate for each of the following applications:

1. Determination of the apparent molecular weights of the HIV proteins
2. Detection of human papillomavirus 16 (a nonreplicating virus) in a Papanicolaou (Pap) smear
3. Detection of herpes simplex virus (HSV) (a replicating virus) in a Pap smear
4. Presence of *Histoplasma* fungal antigens in a patient's serum
5. CD4 and CD8 T-cell concentrations in blood from a patient infected with HIV
6. The presence of antibody and the titer of anti-HIV antibody
7. Genetic differences between two HSVs (DNA virus)
8. Genetic differences between two parainfluenza viruses (ribonucleic acid virus)
9. Amount of rotavirus antigen in stool
10. Detection of group A streptococci and their distinction from other streptococci

SECTION 3

Basic Concepts in the Immune Response

SECTION OUTLINE

7 Elements of Host Protective Responses

We live in a microbial world, and a microbial world lives on and within us as normal flora. Our bodies are constantly being exposed to bacteria, fungi, parasites, and viruses (Box 7.1) and must restrict the normal flora from entering into sterile tissue sites, discriminate between friend and foe, and defend against invading microbes. Our bodies' defenses are similar to a sanitation department and military defense. Most of the time they are protecting the borders of the body and cleaning up cellular and molecular trash. The initial defense mechanisms are **barriers** such as the skin, acid and bile of the gastrointestinal tract, and mucus that inactivate and prevent entry of the foreign agents. If these barriers are compromised or the agent gains entry in another way, then the local militia of **innate responses** must quickly rally to the challenge and prevent expansion of the invasion. Initially, toxic molecules (defensins and other peptides, and complement) are thrown at the microbe whereas other molecules make them sticky (complement, lectins, and antibodies), facilitating the ingestion and destruction of the microbial trash by neutrophils and macrophages. Once activated, these responses also send an alarm (complement, cytokines, and chemokines) to other cells and open the vasculature (complement and cytokines) to provide access to the site. The innate responses then activate a major campaign specifically directed against the invader by **antigen-specific immune responses** (B cells, antibody, and T cells) at whatever cost (energy and immunopathogenesis). Finally, the infected tissue must be repaired and the system returned to the status quo and a normal regulated balance. Knowledge of the characteristics of the enemy (antigens) through prior exposure or vaccination enables the body to mount a faster, more effective response (activation of memory B and T cells) on rechallenge.

The different elements of the immune system interact and communicate using soluble molecules and by direct cell-to-cell interaction. These interactions provide the mechanisms for activation and control of the protective responses. Unfortunately, the protective responses to some infectious agents are insufficient or too slow; in other cases, the response to the challenge is excessive and causes peripheral damage. In either case, disease occurs.

Soluble Activators and Stimulators of Innate and Immune Functions

Innate and immune cells communicate by cell–cell interactions and with soluble molecules, including complement cleavage products, cytokines, interferons (IFNs), and chemokines. **Cytokines** are hormone-like proteins that act on cells to activate and regulate the innate and immune response (Table 7.1 and Box 7.2). **IFNs** are also cytokines that are produced in response to viral and other infections (IFN-α and IFN-β) or on activation of the immune response (IFN-γ); they promote antiviral and antitumor responses and stimulate immune responses (see Chapter 8). **Chemokines** are small proteins (≈8000 Da) that attract specific cells to sites of inflammation and other immunologically important sites. Neutrophils, basophils, natural killer (NK) cells, monocytes, and T cells express receptors and can be activated by specific chemokines. The chemokines and other proteins (e.g., the C3a and C5a products of the complement cascade) are chemotactic factors that establish a chemical path to attract white blood cells to the site of infection. The triggers that stimulate the production of these soluble molecules and the consequences of the interactions with their receptors on specific cells determine the nature of the innate and immune response. *For each of the cytokines know **STAT** (**s**ource [cell], **t**rigger, **a**ction, **t**arget [receptor and cell]), and for the response, **TICTOC** (**t**rigger, **i**nducer, **c**ells [producer and responder], **t**ime course, **o**utcome, **c**ytokines).*

Cells of the Immune Response

Immune responses are mediated by specific cells with defined functions. Characteristics of these cells, their appearances, and numbers are presented in Fig. 7.1 and in Tables 7.2 and 7.3. *For each of the cells know **CARP**: **c**ell-surface markers (e.g., CD4, TCR, etc.), **a**ctions (kill, suppress, activate, etc.), **r**ole (type of response), and **p**roducts (cytokines, antibody, etc.).* The white blood cells can be distinguished on the basis of (1) morphology, (2) histologic staining, (3) immunologic functions, and (4) intracellular and cell-surface markers. B and T lymphocytes can be distinguished by expression of antigen receptors on their surfaces, immunoglobulin for B cells, and T-cell receptors (TCRs) for T cells. Other cell-surface proteins distinguish subsets of these and other types of cells. These marker proteins are identified with monoclonal antibodies. They are defined within **clusters of differentiation** (as determined by all of the monoclonal antibodies that recognize the same molecule [e.g., CD4]) or group of molecules (e.g., CD3) and the markers indicated by **"CD"** (cluster of differentiation) numbers (Table 7.4). In addition, **all nucleated cells express class I major histocompatibility complex (MHC I) antigens** (human: HLA-A, HLA-B, HLA-C).

A special class of cells that are **antigen-presenting cells (APCs) express class II MHC antigens** (HLA-DR, HLA-DP, HLA-DQ). Cells that present antigenic peptides to T cells include dendritic cells (DCs), macrophage family cells, B lymphocytes, and a limited number of other cell types.

BOX 7.1 Overview of the Immune Response

- There is a natural balance in the body between repair and debris removal and inflammation and attack; this balance is regulated by components of the innate and antigen-specific immune responses.
- The immune system is trained to ignore its own proteins and tolerate normal flora that stays in its normal habitat.
- Tissue damage and infection trigger host responses, each of which provides molecules (DAMP and PAMP) recognized by host receptors on immune and other cells that activate innate and inflammatory responses.
- Soluble effectors are released or activated in response to tissue damage or infection before phagocytes or immune cells become involved (soluble before cellular).
- The host response progresses from innate to antigen specific.
- The immune response facilitates, enhances, and regulates the innate responses.

DAMP, Damage-associated molecular patterns; *PAMP,* pathogen-associated molecular patterns.

HEMATOPOIETIC CELL DIFFERENTIATION

Differentiation of a common progenitor cell, termed the **pluripotent stem cell,** gives rise to all blood cells. Differentiation of these cells begins during development of the fetus and continues throughout life. The pluripotent stem cell differentiates into stem cells (sometimes referred to as *colony-forming units*) for different lineages of blood cells, including the lymphoid (T and B cells), myeloid, erythrocytic, and megakaryoblastic (source of platelets) lineages (see Fig. 7.1). The stem cells reside primarily in the bone marrow but can be isolated from the fetal blood in umbilical cords and as rare cells in adult blood. Differentiation of stem cells into the functional blood cells is triggered by specific cell-surface interactions with the stromal cells of the marrow and specific cytokines produced by these and other cells.

The bone marrow and thymus are considered **primary lymphoid organs** (Fig. 7.2 and Box 7.3). These sites of initial lymphocyte differentiation are essential to the development of the immune system. The thymus is essential at birth for T-cell development but shrinks with aging, and other tissues adopt its function later in life. **Secondary lymphoid organs** include the **lymph nodes, spleen, skin**, and **mucosa-associated lymphoid tissue (MALT);** the latter also includes gut-associated lymphoid tissue (GALT) (e.g., Peyer patches) and bronchus-associated lymphoid tissue (BALT) (e.g., lung). These sites are where DCs, innate lymphoid cells (ILCs), B and T lymphocytes, and other cells reside and respond to antigenic challenges. The primary and secondary lymphoid organs produce chemokines and express cell-surface adhesion molecules **(addressins)** that interact with homing receptors **(cell adhesion molecules)** to attract and retain these cells.

The spleen and lymph nodes are encapsulated organs with designated areas for B and T cells. These locations facilitate interactions that promote immune responses to antigen (Fig. 7.3). Proliferation of the lymphocytes in response to infectious challenge causes these tissues to swell (i.e., "swollen glands").

The **lymph nodes** are kidney-shaped organs, 2 to 10 mm in diameter, that filter the fluid that passes from intercellular spaces into the lymphatic system, almost like a sewage processing plant. The lymph node is constructed to optimize the meeting of the innate (DCs and macrophages) and the immune response (B and T) cells to initiate and expand specific immune responses. A lymph node consists of three layers:

1. The cortex: The outer layer contains mainly B cells, some T cells, follicular DCs, and macrophages arranged in structures called *follicles* and, if activated, in germinal centers.
2. The paracortex: Contains T cells and DCs and the DCs present antigens to the T cells to initiate immune responses.
3. The medulla: Contains B and T cells and antibody-producing plasma cells, as well as channels for the lymph fluid.

The **spleen** is a large organ that acts like a lymph node and also filters antigens, encapsulated bacteria, and viruses from blood and removes aged blood cells and platelets (Fig. 7.4). The spleen consists of two types of tissue, the white pulp and the red pulp. The white pulp consists of arterioles surrounded by lymphoid cells (periarteriolar lymphoid sheath) in which the **T cells** surround the central arteriole. **B cells** are organized into primary unstimulated or secondary stimulated follicles that have a germinal center. The germinal center contains memory cells, macrophages, and follicular DCs. The red pulp is a storage site for blood cells and the site of turnover of aged platelets and erythrocytes. *A hint for remembering this: There is no T in follicle or germinal center but there are Ts in paracortex and periarteriolar lymphoid sheet.*

The **epidermis of skin** contains keratinocytes and Langerhans cells, and the **dermis** contains DCs, B and T lymphocytes, macrophages, and mast cells. Large numbers of memory T cells continuously circulate into these layers of the skin. Keratinocytes in the epidermis are part of the innate antimicrobial defense system.

MALT contains less structured aggregates of lymphoid cells (Fig. 7.5). For example, the **Peyer patches** along the intestinal wall have special cells in the epithelium (M cells) that deliver antigens from the lumen into this mini lymph node–like structure containing DCs and lymphocytes in defined regions (T [interfollicular] and B [germinal]). DCs, T cells, and B cells also reside in the lamina propria layer just under the epithelium. Once thought to be expendable, the **tonsils** are an important part of the MALT. These lymphoepithelial organs sample the microbes in the oral and nasal area. The tonsils contain a large number of mature and memory B cells (50% to 90% of the lymphocytes) that use their antibodies to sense specific pathogens and, with DCs and T cells, can initiate immune responses. Swelling of the tonsils may be caused by infection or a response to infection.

POLYMORPHONUCLEAR LEUKOCYTES

Polymorphonuclear leukocytes (neutrophils) are short-lived cells that constitute 50% to 70% of circulating white blood cells (see Fig. 7.1) and are a primary **phagocytic defense** against bacterial and fungal infection and a major component of the **inflammatory response. Neutrophils**

TABLE 7.1 Cytokines and Chemokines

Factor	Major Sources	Major Target	Function
INNATE AND ACUTE-PHASE RESPONSES			
IFN-α, IFN-β	Leukocytes, DCs, fibroblasts, and other cells	Virally infected cells, tumor cells, NK cells	Induction of antiviral state; activation of NK cells, enhancement of cell-mediated immunity
IL-1α, IL-1β	Macrophages, DCs, fibroblasts, epithelial cells, endothelial cells	T cells, B cells, PMNs, tissue, central nervous system, liver, and so forth	Many actions: promotion of inflammatory and acute-phase responses, fever, activation of T cells and macrophages
TNF-α (cachectin)	Similar to IL-1	Macrophages, T cells, NK cells, epithelial and many other cells	Similar to IL-1, and also antitumor, wasting (cachexia, weight loss) functions, sepsis, endothelial activation
IL-6	DCs, macrophages, T and B cells, fibroblasts, epithelial cells, endothelial cells	T and B cells, hepatocytes	Stimulation of acute-phase and inflammatory responses, T- and B-cell growth and development
IL-12, IL-23	DCs, macrophage	NK cells, CD4 TH1, TH17 cells	Activation of T-cell–mediated and inflammatory responses, promotes IFN-γ or IL-17 production
GROWTH AND DIFFERENTIATION			
Colony-stimulating factors (e.g., GM-CSF)	T cells, stromal cells	Stem cells	Growth and differentiation of specific cell types, hematopoiesis
IL-3	CD4 T cells, keratinocytes	Stem cells	Hematopoiesis
IL-7	Bone marrow, stroma	Precursor cells and stem cells	Growth of pre–B cell, thymocyte, T cell, and cytotoxic lymphocyte
TH1 AND TH17 RESPONSES			
IL-2	CD4 T cells (TH0, TH1)	T cells, B cells, NK cells	T- and B-cell growth, NK activation
IFN-γ	CD4 TH1 cells, NK cells, ILC1	Macrophages,[a] DCs, T cells, B cells	Activation of macrophage, inflammation and TH1 and promotion of IgG class switch but inhibition of TH2 responses
TNF-β	CD4 TH1 cells	PMN, tumors	Lymphotoxin: tumor killing, activation of PMN, endothelial activation
IL-17	CD4 TH17 cells, ILC3	Epithelial, endothelial, and fibroblast cells; neutrophils	Activate tissue to promote inflammation even in the presence of TGF-β.
IL-22	CD4 TH17 cells, ILC3	Epithelial cells	Growth and repair of epithelial cells; antibacterial peptide production with IL-17
TH2 RESPONSES			
IL-4	CD4 T cells (TH0, TH2), ILC2	B and T cells	T- and B-cell growth; IgG, IgA, and IgE production; TH2 responses
IL-5	CD4 TH2 cells, ILC2	B cells, eosinophils	B-cell growth and differentiation; IgG, IgA, and IgE production; eosinophil production; allergic responses
IL-10	CD4 TH2, ILCreg, Tr1 and Treg cells	B cells, CD4 TH1 cells	B-cell growth, inhibition of TH1 response
REGULATORY RESPONSE			
TGF-β (also IL-10)	CD4 Treg, Tr1 cells, ILCreg	B cells, T cells, macrophages	Immunosuppression of B, T, and NK cells and macrophages; promotion of oral tolerance, wound healing, IgA production
CHEMOKINES			
α-Chemokines: CXC chemokines, two cysteines separated by one amino acid (IL-8; IP-10; GRO-α, GRO-β, GRO-γ)	Many cells	Neutrophils, T cells, macrophages	Chemotaxis, activation
β-Chemokines: CC chemokines, two adjacent cysteines (MCP-1; MIP-α; MIP-β; RANTES)	Many cells	T cells, macrophages, basophils	Chemotaxis, activation

[a]Applies to one or more cell types of the monocyte-macrophage lineage.

CD, Cluster of differentiation; *DCs*, dendritic cells; *GM-CSF,* granulocyte-macrophage colony-stimulating factor; *GRO-γ,* growth-related oncogene-γ; *IFN-α, -β, -γ,* interferon-α, -β, -γ; *Ig,* immunoglobulin; *IL,* interleukin; *ILC,* innate lymphoid cells; *ILCreg,* regulatory innate lymphoid cell; *IP,* interferon-α protein; *MCP,* monocyte chemoattractant protein; *MIP,* macrophage inflammatory protein; *NK,* natural killer cells; *PMN,* polymorphonuclear leukocyte; *RANTES,* regulated on activation, normal T expressed and secreted; *TGF-β,* transforming growth factor-β; *TH,* T helper (cell); *TNF-α,* tumor necrosis factor-α; *Treg,* regulatory T cell; *Tr1*, Type 1 regulatory cell.

are 9 to 14 μm in diameter, lack mitochondria, have a granulated cytoplasm in which granules stain with both acidic and basic stains, and have a multilobed nucleus. Neutrophils leave the blood and concentrate at the site of infection in response to chemotactic factors. During infection, the neutrophils are recruited from the bone marrow to increase the numbers in blood and these will include precursor forms. These precursors are termed **band forms,** which is in contrast to the terminally differentiated and **segmented neutrophils (segs).** The finding of such an increase and change in neutrophils by a blood count is sometimes termed *a left shift with an increase in bands versus segs*. Neutrophils ingest bacteria by phagocytosis and expose the bacteria to antibacterial substances and enzymes contained in **primary (azurophilic)** and **secondary (specific) granules.** Primary granules are reservoirs for enzymes such as myeloperoxidase, β-glucuronidase, elastase, and cathepsin G. Specific granules serve as reservoirs for lysozyme and lactoferrin. Dead neutrophils release a sticky antimicrobial net of deoxyribonucleic acid (DNA) and other fibers, termed **neutrophil extracellular trap (NET)**, and dead neutrophils are the major component of **pus.**

Eosinophils are heavily granulated cells (11 to 15 μm in diameter) with a bilobed nucleus that stains with the acid dye eosin Y. They are also phagocytic, motile, and granulated. The granules contain acid phosphatase, peroxidase, and eosinophilic basic proteins. Eosinophils play a role in the defense against **parasitic infections.** The eosinophilic basic proteins are toxic to many parasites. **Mast cells** and

BOX 7.2 Major Cytokine-Producing Cells

Innate (Acute-Phase Responses)

Dendritic cells, macrophages, other: IL-1, TNF-α, IL-6, IL-12, IL-18, IL-23, GM-CSF, chemokines, IFN-α, IFN-β

Immune: T Cells (CD4 and CD8)

TH1 cells: IL-2, IFN-γ, TNF-α, TNF-β, IL-3, GM-CSF
TH2 cells: IL-4, IL-5, IL-6, IL-10, IL-3, IL-9, IL-13, GM-CSF, TNF-α
TH17 cells: IL17, IL21, IL22, GM-CSF, TNF-α
Treg cells: TGF-β and IL-10

CD, Cluster differentiation; *GM-CSF,* granulocyte-macrophage colony-stimulating factor; *IFN-α, -β, -γ,* interferon-α, -β, -γ; *IL,* interleukin; *TGF-β,* transforming growth factor-β; *TH,* T helper (cell); *TNF-α,* tumor necrosis factor-α; *Treg,* T regulator.

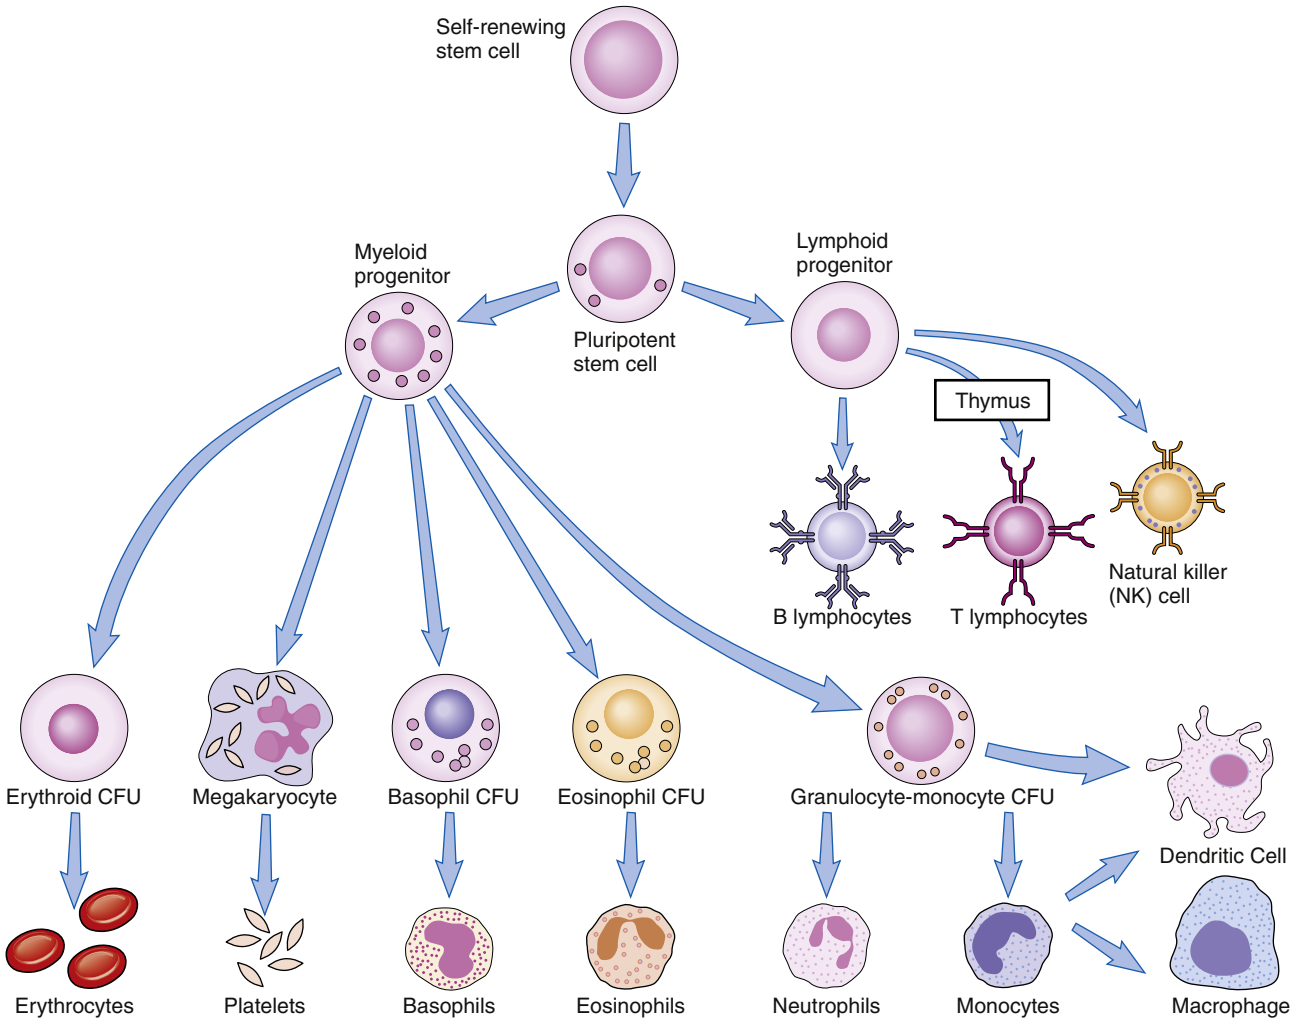

Fig. 7.1 Morphology and lineage of cells involved in the immune response. Pluripotent stem cells and colony-forming units *(CFUs)* are long-lived cells capable of replenishing the more differentiated functional and terminally differentiated cells. (Modified from Abbas, A.K., Lichtman, A.H., Pillai, S., et al., 2015. Cellular and Molecular Immunology, eighth ed. Elsevier, Philadelphia, PA.)

TABLE 7.2 Cells of the Immune Response

Cells	Characteristics and Functions
ILCs	Produce cytokines in response to microbial and other triggers
NK cells (ILC1)	Large, granular lymphocytes Markers: Fc receptors for antibody, KIR **Kill antibody-decorated cells and virus-infected or tumor cell** (no MHC restriction)
PHAGOCYTIC CELLS	
Neutrophils	Granulocytes with short life span, multilobed nucleus and granules, segmented band forms (more immature) **Phagocytose** and **kill bacteria** (polymorphonuclear leukocytes)
Eosinophils	Bilobed nucleus, heavily granulated cytoplasm, stains with eosin Involved in parasite defense and allergic response
APCs	Marker: class II MHC-expressing cells Process and present antigen to CD4 T cells
Monocytes[a]	Horseshoe-shaped nucleus, lysosomes, granules *Precursors to macrophage-lineage and dendritic cells*, cytokine release
Immature dendritic cells	Blood and tissue Cytokine response to infection, process antigen
Dendritic cells[a]	Lymph nodes, tissue Most potent APC; initiates and determines nature of T-cell response
Langerhans cells[a]	**Present in skin** **Same as immature dendritic cell**
Macrophages[a]	Possible residence in tissue, spleen, lymph nodes, and other organs; activated by IFN-γ and TNF Markers: large, granular cells; Fc and C3b receptors (M2) Remove debris, maintain normal tissue function, and facilitate repair, APC (M1) Activated cells initiate inflammatory and acute-phase response; **activated cells are antibacterial, APC**
ANTIGEN-RESPONSIVE T CELLS	
T cells (all)	Mature in thymus; large nucleus, small cytoplasm Markers: CD2, CD3, TCR
α/β TCR CD4 T cells	Helper cells; **activation** by APCs through **class II MHC antigen presentation** Produce cytokines; activate APCs; stimulate T- and B-cell growth; promote B-cell differentiation (class switching, antibody production) **TH1 subtype** (IL-2, IFN-γ, LT production): activate macrophages and local and systemic cell-mediated defenses (including DTH, CD8 T killer cells) and antibody production **TH2 subtype** (IL-4, IL-5, IL-6, IL-10 production): promote humoral (antibody) responses (systemic) **TH17 subtype** (IL-17, TNF-α, IL-21, IL-22): stimulate epithelial cells and neutrophils and inflammation **Treg, Tr1 cells** (TGF-β, IL-10): control activation of CD4 and CD8 T cells and other cells; important for immunotolerance
α/β NKT cells	Markers: NK cell receptors, α/β TCR for glycolipids on CD1 Rapid response to infection, cytokine release
α/β MAIT cells	Markers: α/β TCR for vitamin B2 from bacteria bound to MR-1 Rapid response to infection, cytokine release
γ/δ TCR T cells	Markers: CD2, CD3, γ/δ TCR Early sensor of some bacterial infections and cell stress, cytokine release
α/β CD8 T cells	Recognition of antigen presented by **class I MHC antigens** on all cells Kill viral, tumor and nonself-transplanted cells; secrete cytokines
ANTIBODY-PRODUCING CELLS	
B cells	Mature in bone marrow, Peyer patches Large nucleus, small cytoplasm; activation by antigens and T-cell factors Markers: surface antibody, **class II MHC antigens** Produce antibody and present antigen
Plasma cells	Small nucleus, large cytoplasm Terminally differentiated, antibody factories
OTHER CELLS	
Basophils/mast cells	Granulocytic Marker: Fc receptors for IgE Release histamine, provide allergic response, are antiparasitic
Platelets	Release clotting factors, antimicrobial peptides, chemokines and cytokines on activation

[a]Monocyte/macrophage lineage.

APC, Antigen-presenting phagocytic cells; *DTH,* delayed-type hypersensitivity; *Fc,* fragment crystallizable region of immunoglobulin; *IFN-γ,* interferon-γ; *Ig,* immunoglobulin; *IL,* interleukin; *ILC,* innate lymphoid cells; *KIR,* killer cell immunoglobulin-like receptors; *LT,* lymphotoxin; *MAIT,* mucosal-associated invariant T-cell; *MHC,* major histocompatibility complex; *MR-1,* MHC-related protein 1; *NK,* natural killer; *NKT,* natural killer T cell; *TCR,* T-cell receptor; *TGF-β,* transforming growth factor-β; *TH,* T helper (cell); *TNF-α,* tumor necrosis factor-α; *Treg,* T regulator; *Tr1,* Type 1 regulatory cell.

TABLE 7.3 Normal Blood Cell Counts

Cell Type	Mean Number per Microliter	Normal Range
White blood cells (leukocytes)	7400	4500–11,000
Neutrophils	4400	1800–7700
Eosinophils	200	0–450
Basophils	40	0–200
Lymphocytes	2500	1000–4800
Monocytes	300	0–800

Modified from Abbas, A.K., Lichtman, A.H., Pillai, S., et al., 2015. Cellular and Molecular Immunology, eighth ed. Elsevier, Philadelphia, PA.

basophils are nonphagocytic granulocytes that release the contents of their granules in response to inflammatory triggers and during allergic responses (type 1 hypersensitivity).

MONONUCLEAR PHAGOCYTE SYSTEM

The **mononuclear phagocyte system** has myeloid cells and consists of monocytes (see Fig. 7.1) in the blood, **macrophages**, and **DCs. Monocytes** are 10 to 18 μm in diameter, with a single-lobed, kidney bean–shaped nucleus. They represent 3% to 8% of peripheral blood leukocytes. Monocytes follow neutrophils into tissue as an early cellular component of inflammation. Monocytes can differentiate into macrophages and DCs.

TABLE 7.4 Selected Cluster Differentiation Markers of Importance

CD Markers	Identity and Function	Cell
CD1 (a–d)	MHC I–like, glycolipid antigen presentation	DC, macrophage
CD2 (LFA-3R)	Erythrocyte receptor, adhesion	T cells
CD3	TCR subunit (γ, δ, ε, ζ, η); activation	T cells
CD4	Class II MHC receptor	T-cell subset, monocytes, some DCs
CD8	Class I MHC receptor	T-cell subset
CD11b (CR3)	C3b complement receptor 3 (α chain)	NK, myeloid cells
CD14	LPS-binding protein receptor	Myeloid cells (monocytes, macrophages)
CD16 (Fc-γ RIII)	Phagocytosis and ADCC	NK-cell marker, macrophages, neutrophils
CD21 (CR2)	C3d complement receptor, EBV receptor, B-cell activation	B cells
CD25	IL-2 receptor (α chain), early activation marker, marker for regulatory cells	Activated T and B cells, regulatory T cells
CD28	Receptor for B7 co-stimulation: activation	T cells
CD40	Stimulation of B cell, DC, and macrophage	B cell, macrophage
CD40 L	Ligand for CD40	T cell
CD45RO	Isoform (on memory cells)	T cell, B cell
CD56 (NKH1)	Adhesion molecule	NK cell
CD69	Marker of cell activation	Activated T, B, and NK cells and macrophages
CD80 (B7-1)	Co-stimulation of T cells	DC, macrophages, B cell
CD86 (B7-2)	Co-stimulation of T cells	DC, macrophages, B cell
CD95 (Fas)	Apoptosis inducer	Many cells
CD152 (CTLA-4)	Receptor for B7; tolerance	T cell
CD178 (FasL)	Fas ligand: apoptosis inducer	Killer T and NK cells
ADHESION MOLECULES		
CD11a	LFA-1 (α chain)	—
CD29	VLA (β chain)	—
VLA-1, VLA-2, VLA-3	α Integrins	T cells
VLA-4	α_4-Integrin homing receptor	T cell, B cell, monocyte
CD50	ICAM-3	Lymphocytes and leukocytes
CD54	ICAM-1	—
CD58	LFA-3	—

Modified from Male, D., Cooke, A., Owen, M., et al., 1996. Advanced Immunology, third ed. Mosby, St Louis, MO.

ADCC, Antibody-dependent cellular cytotoxicity; *CD,* cluster of differentiation; *CTLA-4,* cytotoxic T-lymphocyte–associated protein-4; *DC,* dendritic cell; *EBV,* Epstein-Barr virus; *ICAM-1, -3,* intercellular adhesion molecule-1, -3; *IL,* interleukin; *LFA-1, -3R,* leukocyte function–associated antigen-1, -3R; *LPS,* lipopolysaccharide; *MHC,* major histocompatibility complex; *NK,* natural killer cell; *TCR,* T-cell antigen receptor; *VLA,* very late activation (antigen).

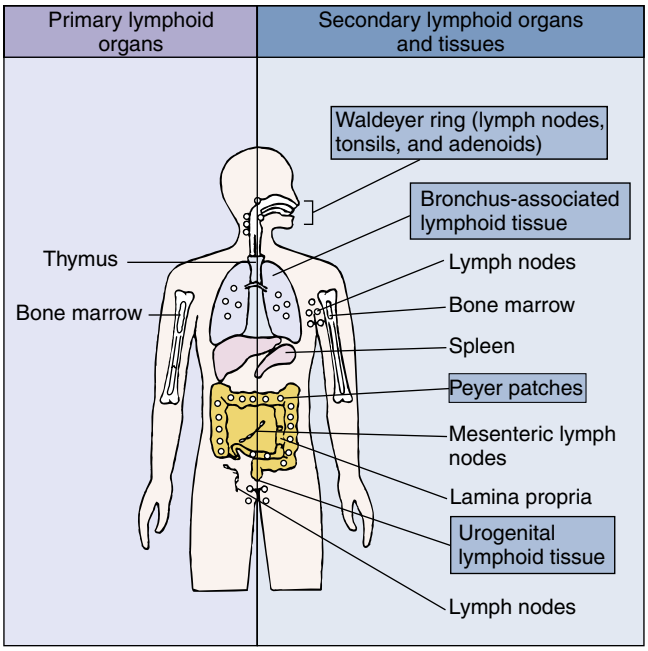

Fig. 7.2 Organs of the immune system. Thymus and bone marrow are primary lymphoid organs. They are sites of maturation for T and B cells, respectively. Cellular and humoral immune responses develop in the secondary (peripheral) lymphoid organs and tissues; effector and memory cells are generated in these organs. The spleen responds predominantly to blood-borne antigens. Lymph nodes mount immune responses to antigens in intercellular fluid and in the lymph, absorbed either through the skin (superficial nodes) or from internal viscera (deep nodes). Tonsils, Peyer patches, and other mucosa-associated lymphoid tissues *(blue boxes)* respond to antigens that have penetrated the surface of mucosal barriers. (From Male, D., Brostoff, J., Roth, D.B., et al., 2013. Immunology, eighth ed. Elsevier, Philadelphia, PA.)

BOX 7.3 Immune Organs

Thymus

Required at birth for T-cell development
Site of T-cell maturation and development of central tolerance

Bone Marrow

Source of stem cells
B-cell maturation and development of central tolerance

Lymph Node

Follicle: B-cell zone
  Germinal center: site of B-cell proliferation and plasma and memory cell development
Paracortex: T-cell zone

Spleen

White pulp
  Follicles: B-cell zone
  PALS; T-cell zone
Red pulp
  Macrophage-rich region for filtering blood, removal of damaged cells and microbes

Mucosa-Associated Lymphoid Tissue

Skin

PALS, Periarteriolar lymphoid sheath.

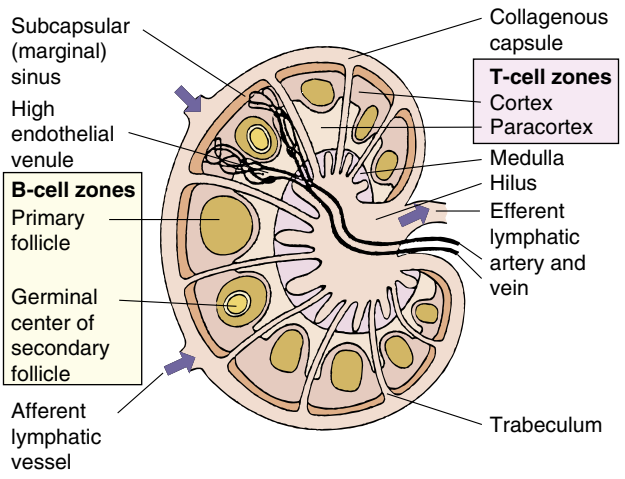

Fig. 7.3 Organization of the lymph node. Beneath the collagenous capsule is the subcapsular sinus, which is lined with phagocytic cells. Lymphocytes and antigens from surrounding tissue spaces or adjacent nodes pass into the sinus via the afferent lymphatic system. The cortex contains B cells grouped in primary follicles and stimulated B cells in secondary follicles (germinal centers). The paracortex contains mainly T cells and dendritic cells (antigen-presenting cells). Each lymph node has its own arterial and venous supplies. Lymphocytes enter the node from the circulation through the specialized high endothelial venules in the paracortex. The medulla contains both T and B cells and most of the lymph node plasma cells organized into cords of lymphoid tissue. Lymphocytes can leave the node only through the efferent lymphatic vessel. (From Male, D., Brostoff, J., Roth, D.B., et al., 2013. Immunology, eighth ed. Elsevier, Philadelphia, PA.)

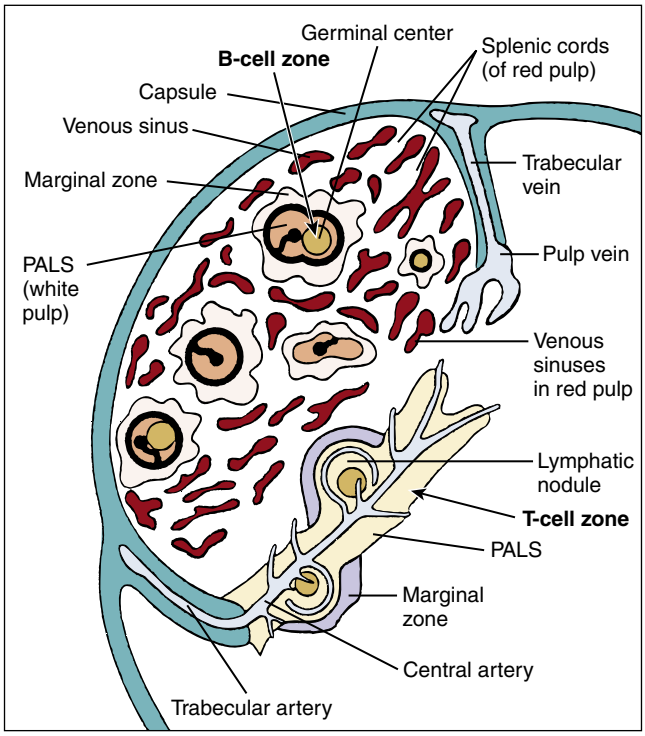

Fig. 7.4 Organization of lymphoid tissue in the spleen. The white pulp contains germinal centers and is surrounded by the marginal zone, which contains numerous macrophages, antigen-presenting cells, slowly recirculating B cells, and natural killer cells. The T cells reside in the periarteriolar lymphoid sheath *(PALS).* The red pulp contains venous sinuses separated by splenic cords. Blood enters the tissues via the trabecular arteries, which give rise to the many branched central arteries. Some arteries end in the white pulp, supplying the germinal centers and mantle zones, but most empty into or near the marginal zones. (From Male, D., Brostoff, J., Roth, D.B., et al., 2013. Immunology, eighth ed. Elsevier, Philadelphia, PA.)

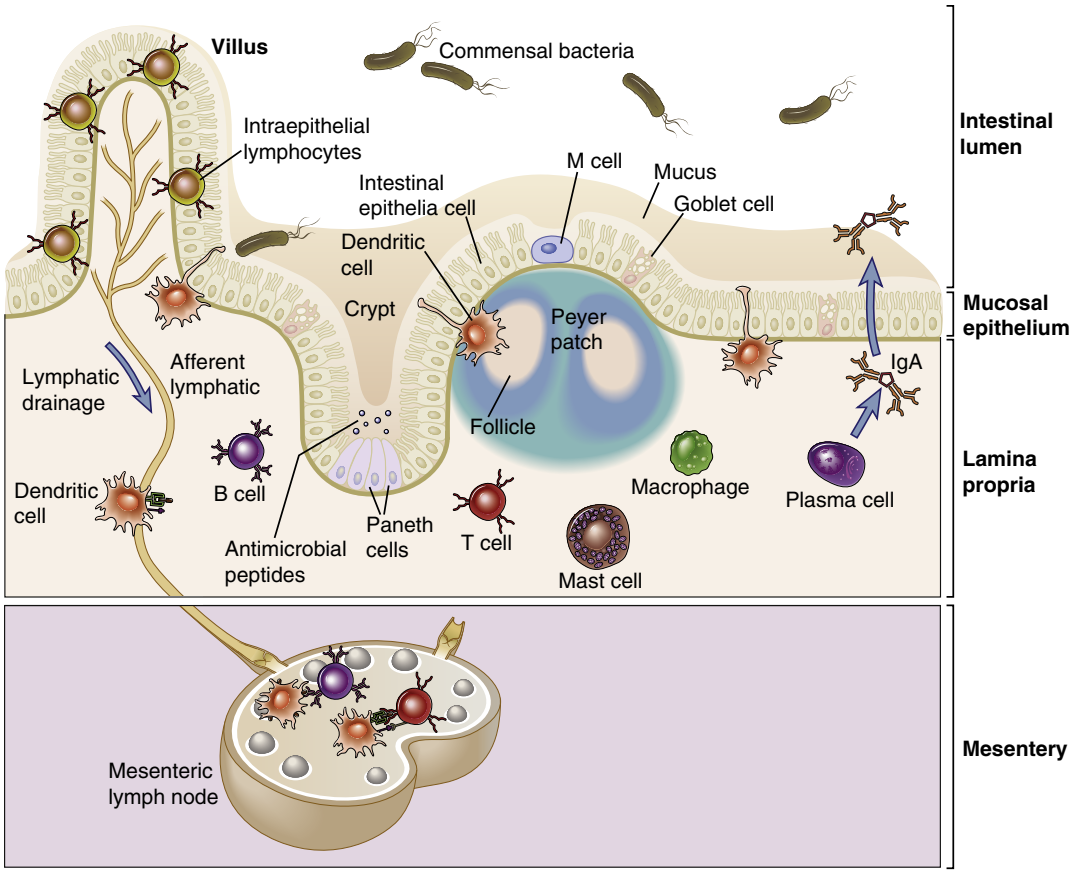

Fig. 7.5 Lymphoid cells stimulated with antigen in Peyer patches (or lungs or another mucosal site) migrate via the regional lymph nodes and thoracic duct into the bloodstream and then to the lamina propria of the gut and probably other mucosal surfaces. Thus lymphocytes stimulated at one mucosal surface may become distributed throughout the mucosa-associated lymphoid tissue system. *IgA,* Immunoglobulin A. (Modified from Abbas, A.K., Lichtman, A.H., Pillai, S., et al., 2015. Cellular and Molecular Immunology, eighth ed. Elsevier, Philadelphia, PA.)

Macrophages are long-lived cells that may be resident in tissues and derived from the embryonic yolk sack or derived from monocytes that are recruited to the tissue and are bone marrow derived. They are phagocytic, contain lysosomes, and, unlike neutrophils, have mitochondria. Macrophages have the following basic functions: (1) phagocytosis and degradation of debris and microbes, (2) antigen presentation (APC) to T cells to expand specific immune responses, and (3) secretion of cytokines to either maintain normal tissue function and repair **(M2 macrophages)** or be antimicrobial and promote inflammation (**M1 macrophages**) (Fig. 7.6; see Fig. 8.3). Macrophages express cell-surface receptors for the Fc portion of immunoglobulin (Ig) G **(Fc-γ RI, Fc-γ RII, Fc-γ RIII)** and for the C3b product of the complement cascade **(CR1, CR3).** These receptors facilitate the phagocytosis and clearance of antigen, dead cells, bacteria, or viruses coated with these proteins. **Toll-like and other pattern-recognition receptors** recognize pathogen-associated molecular patterns and activate protective responses. Macrophages also express the **class II MHC antigen,** which allows these cells to present antigen to CD4 helper T cells to expand the immune response. Macrophages secrete **interleukin (IL)-1, IL-6, tumor necrosis factor (TNF)-α, IL-12, IL-23,** and other molecules on sensing bacteria, which stimulates immune and inflammatory responses, including fever.

Tissue resident macrophages include alveolar macrophages in the lungs, Kupffer cells in the liver, intraglomerular mesangial cells in the kidney, histiocytes in connective tissue, osteoclasts, synovial cells, and microglial cells in the brain. These macrophages are descended from cells of the yolk sac and are primarily involved in tissue maintenance, angiogenesis, and repair functions **(M2 macrophages)**. The mature forms of these cells have different morphologies corresponding to their ultimate tissue location and function and may express a subset of macrophage activities or cell-surface markers.

Recruited monocytes and macrophages activated by a T-cell–derived cytokine, **IFN-γ,** generate **M1 macrophages.** These macrophages have enhanced phagocytic, killing, and antigen-presenting capabilities and produce cytokines that promote inflammation.

DENDRITIC CELLS

DCs have octopus-like tendrils and a large surface area to interact with lymphocytes. There are three functional types of DCs: follicular, myeloid, and plasmacytoid.

Follicular DCs localize to B-cell regions of lymph nodes and spleen, are *not* hematopoietic in origin, and *do not process antigen* but have tendrils (dendrites) and a "sticky" surface to concentrate and *display antigens to B cells.*

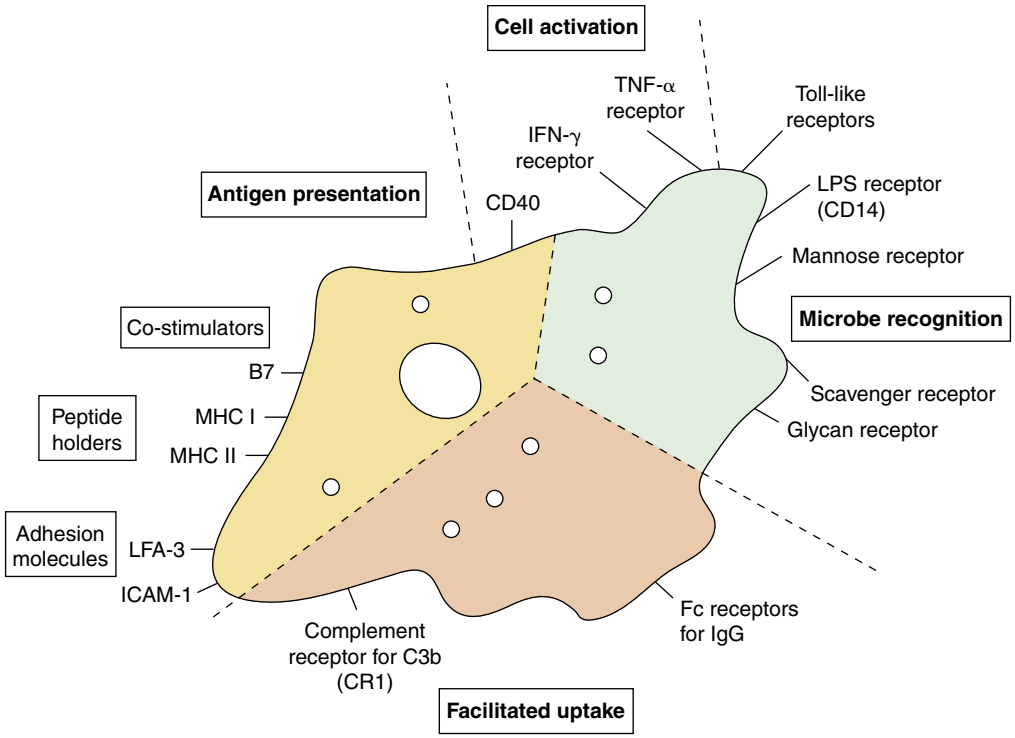

Fig. 7.6 Macrophage surface structures mediate cell function. Receptors for bacterial components, antibody, and complement (for opsonization) promote activation and phagocytosis of antigen; other receptors promote antigen presentation and activation of T cells. The dendritic cell shares many of these characteristics. *ICAM-1,* Intercellular adhesion molecule-1; *IFN-γ,* interferon-γ; *Ig,* immunoglobulin; *LFA-3,* leukocyte function–associated antigen-3; *LPS,* lipopolysaccharide; *MHC,* major histocompatibility antigen I or II; *TNF-α,* tumor necrosis factor-α.

Plasmacytoid DCs have a plasma cell–like appearance, are present in blood, and produce large amounts of IFN-α and cytokines in response to viral and other infections and can also present antigen to T cells.

Myeloid-derived DCs are professional **APCs for T cells** that can also produce cytokines. Different types of immature and mature DCs are found in tissue and blood, and they include **Langerhans cells** in the skin; **dermal interstitial cells; splenic marginal DCs**; and DCs in the **liver, thymus, germinal centers of the lymph nodes,** and **blood.** DCs may be derived from myeloid stem cells or monocytes. **Immature DCs** capture and phagocytose antigen efficiently and release cytokines to activate and steer the subsequent immune response. On maturation, DCs move to lymph node regions rich in T cells to present antigen on class I and class II MHC antigens. *DCs are the only APCs that can initiate an immune response with a naive T lymphocyte and they direct (D for director) the nature of the subsequent T-cell response* (TH1, TH2, TH17, Treg).

LYMPHOCYTES

Lymphocytes are 6 to 10 μm in diameter, making them smaller than leukocytes. There are three classes of lymphocytes: **T cells, B cells, and ILCs.** These cells have a large nucleus and smaller, agranular cytoplasm. Although their morphologic features are similar, they can be distinguished on the basis of function and surface markers (Table 7.5).

T cells acquired their name because they develop in the *thymus*. T cells have the following two major functions in response to foreign antigen:

1. Regulate, suppress (when necessary), and activate immune and inflammatory responses with cell-to-cell interactions and by releasing cytokines
2. Directly kill virally infected cells, foreign cells (e.g., tissue grafts), and tumors by promoting apoptosis

T cells make up 60% to 80% of peripheral blood lymphocytes. T cells were initially distinguished from B cells on the basis of their ability to bind and surround themselves (forming rosettes) with sheep erythrocytes through the CD2 molecule. All T cells express an antigen-binding **TCR,** which resembles but differs from antibody, and **CD2-** and **CD3-associated** proteins on their cell surface (Fig. 7.7). T cells are divided into major groups on the basis of the type of TCR and by the cell-surface expression of two proteins, CD4 and CD8. Most T cells express the α/β **TCR. CD4-expressing T cells are T helper cells** and primarily cytokine-producing cells that help initiate, direct, and regulate innate and immune responses. The CD4 T cells can be further divided into TH0, TH1, TH2, TH17, Treg, Tr1, and other subgroups according to the spectrum of cytokines they secrete and the type of immune response they promote. TH1 cells promote local antibody and cellular inflammatory responses, whereas TH2 cells promote antibody production. TH17 cells activate epithelial cell and neutrophil-driven inflammation and other responses, and Treg and inducible Tr1 cells regulate the immune response to maintain balance and tolerance of self. The **CD8 T cells** also release cytokines but are better known for their ability to recognize and kill (through apoptosis) virally infected cells, foreign tissue transplants (nonself-grafts), and tumor cells as **cytotoxic T cells**. T cells also produce **memory cells** that express CD45RO. Other α/β TCR T cells include the mucosal-associated invariant T cell (**MAIT**) and NK T cell (**NKT**) and the **γ/δ T cells**, which express the γ/δ TCR but not CD4 or CD8. These cells generally reside in skin and mucosa and are important cytokine-producing cells that help initiate and maintain immune responses.

TABLE 7.5 Comparison of B and T Cells

Property	T Cells	B Cells
Origin	Bone marrow	Bone marrow
Maturation	Thymus	Bone marrow, Peyer patches
Functions	Varied (see section Subsets)	**Antibody production** Antigen presentation to T cells
Protective response	Enhance and control innate and immune responses; resolution of intracellular and fungal infections	Antibody protects against rechallenge; blocks spread of agent in blood, opsonize, etc.
Products[a]	Cytokines, growth factors, cytolytic substances (perforin, granzymes)	IgM, IgD, IgG, IgA, or IgE
Distinguishing surface markers	CD2 (sheep red blood cell receptor), TCR, CD3	Surface antibody, complement receptors, class II MHC antigens
Subsets	**CD4 TH0:** helper precursor **CD4 TH1:** activates B-, T-, and NK-cell growth; activates macrophages, CTLs, DTH responses, and IgG production **CD4 TH2:** activates B- and T-cell growth; promotes IgG, IgE, and IgA production **CD4 TH17:** antibacterial, inflammation **CD4 Treg, Tr1:** suppression and regulation **CD8:** cytotoxic T cells (CTL), cytokine production **NKT, MAIT, γδT;** rapid response to infection **Memory cells:** long-lived, anamnestic response	**B cells (IgM, IgD):** antibody, antigen presentation **B cells (IgG or IgE or IgA):** antibody, antigen presentation **B-1, Marginal zone B cells:** natural antibody production **Plasma cell:** terminally differentiated antibody factories **Memory cells:** long-lived, anamnestic response

[a]Depending on subset.

CD, Cluster of differentiation; *CTL,* cytotoxic lymphocyte; *DTH,* delayed-type hypersensitivity; *Ig,* immunoglobulin; *MAIT,* Mucosal associated invariant T cells; *MHC,* major histocompatibility complex; *NKT,* natural killer T (cell); *TCR,* T-cell receptor; *TH,* T helper (cell); *Treg,* regulatory T cell; *Tr1,* Type 1 regulatory cell.

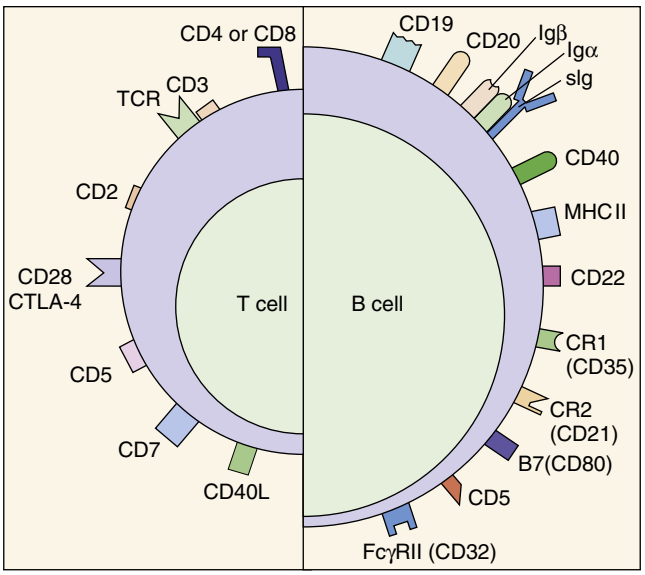

Fig. 7.7 Surface markers of human B and T cells.

The primary function of **B cells** is to **make antibody,** and most B cells also internalize antigen, process the antigen, and present the antigen to T cells to request T cell help and expand the immune response. These B cells can be identified by the presence of immunoglobulins, class II MHC molecules, and receptors for the C3b and C3d products of the complement cascade (CR1, CR2) on their cell surfaces (see Fig. 7.7). The B-cell name is derived from its site of differentiation, the *b*ursa of Fabricius in birds, and the *b*one marrow of mammals. Activated B cells either apoptose; develop into **memory cells,** which express the CD45RO cell-surface marker and circulate until activated by specific antigen; or terminally differentiate into plasma cells. **Plasma cells** have small nuclei and a large cytoplasm. Plasma cells are factories for production of antibody. More primitive B cells include **B-1 cells** and **marginal zone B cells. B-1 cells** are derived from fetal liver and constantly produce antibody but of low affinity against bacterial polysaccharides, ABO blood groups, and even self-antigens. **Marginal zone B cells** are found in the spleen. B-1 cells and marginal zone B cells are especially important for generating antibody against the capsular polysaccharides of bacteria and fungi.

ILCs are non-B, non-T lymphocytes that resemble T cells in some characteristics and include the **NK cells.** These cells are distinguished as ILC1, ILC2 or ILC3 by the cytokines that they produce and can initiate, maintain, and regulate host responses. In the gut, these cells produce cytokines that regulate the epithelial cell and lymphocyte response to the intestinal flora and facilitate antiparasitic worm protection. **NK cells** (ILC1s) are **large, granular lymphocytes** that resemble CD8 T cells in cytolytic function toward virally infected and tumor cells, but they differ in the mechanism for identifying the target cell. NK cells are also capable of antibody-dependent killing; hence they are also called **antibody-dependent cellular cytotoxicity (ADCC or K) cells.** The cytoplasmic granules contain cytolytic proteins to mediate the killing.

Questions

A professor was teaching an introductory course and described the different immune cells with the following nicknames. Explain why the nicknames are appropriate or why they are not.

1. Macrophage: Pac-Man (a computer game character who normally eats dots but eats bad guys when activated)
2. Lymph node: police department or sewage processing plant
3. CD4 T cell: desk sergeant/dispatch officer
4. CD8 T cell: "cop on the beat"/patrol officer
5. B cell: product design and building company
6. Plasma cell: factory
7. Mast cell: activatable chemical warfare unit
8. Neutrophil: trash collector and disinfector
9. Dendritic cell: billboard display

8 Innate Host Responses

Animations for this chapter are available on StudentConsult.com.

Innate host responses are continuously working to keep the normal flora in their appropriate places and rapidly react to invading and inappropriate microbes and cells. The body protects itself from microbial invasion in ways that are similar to those used to protect a country from invasion. Barriers such as skin, mucosal surfaces, and the acid of the stomach restrict bacteria to the outer surfaces and the lumen of the gastrointestinal tract and prevent invasion by most microbes. The microbes are bombarded with soluble antimicrobial molecules such as defensins; scavenger molecules of essential elements, such as iron; complement components; and lectins. If invasion occurs, a local militia of cells of the innate response, including immature dendritic cells (iDCs), Langerhans cells, dendritic cells (DCs), innate lymphoid cells (ILCs), and innate T cells (natural killer T cell [NKT], mucosal-associated invariant T cell [MAIT], and γδ T cells) are alerted by microbial structures, metabolites, and stress molecules, and then neutrophils and monocytes are attracted to the site by chemokines. Monocytes mature to macrophages, and neutrophils and macrophages ingest and kill the invaders. All of these cells produce cytokines and chemokines to instruct, activate, and call in additional forces. Often these innate responses are sufficient to control the infection. Later, more sophisticated antigen-specific responses support, enhance, and control the cell-mediated innate responses (Box 8.1).

Innate protections are activated by direct contact with repetitive structures of the microbial surface or their genome termed *pathogen-associated molecular patterns* (PAMPs) and by molecules released on stress or cell damage from microbes or human cells termed *damage-associated molecular patterns* (DAMPS). In contrast, the antigen-specific responses sense and are activated by unique small structures termed *epitopes* on larger molecules.

Barriers to Infection

The **skin** and **mucous membranes** serve as barriers to most infectious agents (Fig. 8.1), with few exceptions (e.g., papillomavirus, dermatophytes ["skin-loving" fungi]). Free fatty acids produced in sebaceous glands and by organisms on the skin surface, lactic acid in perspiration, and the low pH and relatively dry environment of the skin all form unfavorable conditions for the survival of most organisms.

The mucosal epithelium covering the orifices of the body is protected by mucus secretions and cilia. In the upper respiratory tract, large airborne particles get caught in the mucus, which is continuously transported toward the mouth by an escalator of ciliated epithelial cells and then swallowed to be inactivated in the stomach. Small particles (0.05 to 3 μm, the size of viruses or bacteria) that reach the alveoli are phagocytosed by macrophages and transported out of the airspaces. Some bacteria and viruses (e.g., *Bordetella pertussis*, influenza virus), cigarette smoke, or other pollutants can interfere with this clearance mechanism by damaging the ciliated epithelial cells, rendering the patient susceptible to secondary bacterial pneumonia. Antimicrobial substances (cationic peptides **[defensins],** lysozyme, and lactoferrin) found in secretions at mucosal surfaces (e.g., tears, mucus, saliva) also provide protection. Lysozyme induces lysis of bacteria by cleaving the polysaccharide backbone of the peptidoglycan of gram-positive bacteria. Lactoferrin, an iron-binding protein, deprives microbes of the free iron they need for growth (Table 8.1).

The **acidic environment** of the stomach, bladder, and kidneys and the **bile** of the intestines inactivate many viruses and bacteria. **Urinary flow** also limits the establishment of infection.

Body temperature, especially **fever,** limits or prevents the growth of many microbes, especially viruses. In addition, the immune response is more efficient at elevated temperatures.

Soluble Components of Innate Responses

ANTIMICROBIAL PEPTIDES AND CHELATORS

Defensins, bactericidal/permeability-increasing peptides (BPIs), and cathelicidins are peptides produced by neutrophils, epithelial cells, and other cells that disrupt microbial membranes and are toxic to bacteria and fungi. Defensins are small (≈30 amino acids) cationic peptides; cathelicidins and BPIs are larger and cleaved to produce microbiocidal peptides. When secreted by Paneth and other cells in the bowel, they limit and regulate the bacteria living in the lumen. Production of these antimicrobial peptides may be constitutive or stimulated by microbial products or cytokines, including interleukin (IL)-17 and IL-22.

Metal ion–binding proteins that bind iron (e.g., lactoferrin, transferrin, ferritin, siderocalin) or bind zinc and manganese (e.g., calprotectin) sequester these essential ions to prevent growth of bacteria and yeast. Unfortunately, many pathogens have developed alternate means for acquiring these ions.

COMPLEMENT

The complement system is an alarm and a weapon against infection and is especially important against bacterial

BOX 8.1 Innate Host Responses

Constitutive

Barriers: skin, stomach acid, bile, mucus
Body temperature
Antimicrobial peptides: defensins, cathelicidins
Enzymes: lysozyme
Metal ion scavengers: lactoferrin, transferrin, hepcidin
Complement
Epithelial cell responses

Recruitment

Complement C3a, C5a
Chemokines from epithelium and macrophages

Pathogen-Responsive Innate Cells

Granulocytes/neutrophils
Macrophages
Langerhans/dendritic cells
Innate lymphoid cells (NK cells)
γ/δ T cells, MAIT, NKT cells
B1 B cells

Acute-Phase/Inflammatory Cytokines

IL-1: fever, diapedesis, inflammation
TNF-α: fever, diapedesis, inflammation, vascular permeability, tissue remodeling, metabolism, maintenance of macrophage activation, cachexia
IL-6: acute-phase protein synthesis by liver, lymphocyte activation

Other Cytokines and Activators

IL-12: promotes TH1 response and activates NK cells
IL-23: promotes TH17 response from memory cells
Type 1 IFNs: antiviral effect, fever, promotes CD8 T-cell response
IFN-γ: activation of macrophages, dendritic cells, T and B cells
Lipid mediators (prostaglandins and leukotrienes): acts on many cells

Acute-Phase Proteins from the Liver

C-reactive protein, mannose-binding protein, fibrinogen, complement

IFN, Interferon; *IL,* interleukin; *NK,* natural killer; *MAIT,* mucosal-associated invariant T cells; *TNF,* tumor necrosis factor; *TH,* T helper (cell).

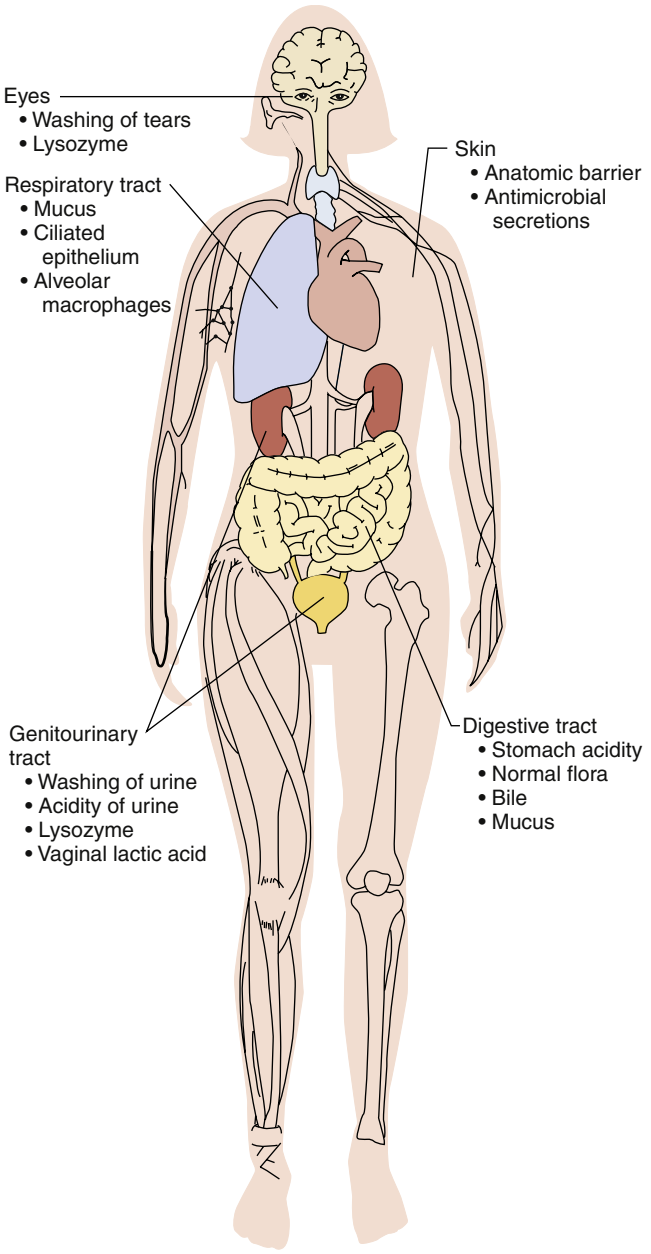

Fig. 8.1 Barrier defenses of the human body.

infections. The complement system is activated directly by fungal and bacterial surfaces and bacterial products **(alternate or properdin pathway),** by lectin binding to sugars on the bacterial or fungal cell surface **(mannose-binding protein),** or by complexes of antibody and antigen **(classical pathway)** (Fig. 8.2; Animation 1). The three activation pathways of complement coalesce at a common junction point, which is the activation of the C3 component. Activation by either pathway initiates a cascade of proteolytic events that cleave the proteins into **"a," "b,"** and other subunits. *The **a** subunits (C3a and C5a) **a**ttract (chemotactic factors) phagocytic and inflammatory cells to the site, **a**llow **a**ccess to soluble molecules and cells by increasing vascular permeability (**a**naphylactic C3a, C4a, and C5a), and **a**ctivate responses. The **b** subunits are **b**igger and **b**ind to the agent to promote their phagocytosis **(opsonization)** and elimination, and they **b**uild a molecular drill that can directly kill the infecting agent.*

Alternate Pathway

The alternate pathway can be activated before the establishment of an immune response to the infecting bacteria because it does not depend on antibody and does not involve the early complement components (C1, C2, and C4). C3 is spontaneously cleaved in serum and can covalently bind to bacterial surfaces. *Properdin factor B* binds to the C3b and *properdin factor D* splits *factor B* in the complex to yield the *Bb active fragment* that remains linked to *C3b (activation unit)*. The complement cascade then continues in a manner analogous to the classical pathway.

Lectin Pathway

The lectin pathway is a bacterial and fungal defense mechanism independent of antibody. The **mannose-binding protein** is a large serum protein that binds to nonreduced mannose, fucose, and glucosamine on bacterial, fungal, and other cell surfaces. Mannose-binding protein resembles and replaces the C1q component of the classical pathway and, on binding to microbial surfaces, activates the

TABLE 8.1 Soluble Innate Defense Mediators

Factor	Function	Source
Lysozyme	Catalyzes hydrolysis of bacterial peptidoglycan	Tears, saliva, nasal secretions, body fluids, lysosomal granules
Lactoferrin, transferrin, hepcidin, calprotectin	Bind iron, manganese, or zinc to sequester from microorganisms	Tears, saliva, nasal secretions, body fluids, specific granules of PMNs
Lactoperoxidase	Generates bleachlike antimicrobials	Tears, saliva, nasal secretions, body fluids
β-lysine	Is effective mainly against gram-positive bacteria	Thrombocytes, normal serum
Chemotactic factors	Induce directed migration of PMNs, monocytes, and other cells	Complement and chemokines
Properdin	Promotes complement activation in the absence of antibody-antigen complex	Normal plasma
Lectins	Bind to carbohydrates to promote microbial phagocytosis	Normal plasma
Cationic peptides (defensins, etc.)	Antimicrobials to disrupt membranes, block cell transport activities	Polymorphonuclear granules, epithelial cells, and so forth

PMNs, Polymorphonuclear neutrophils (leukocytes).

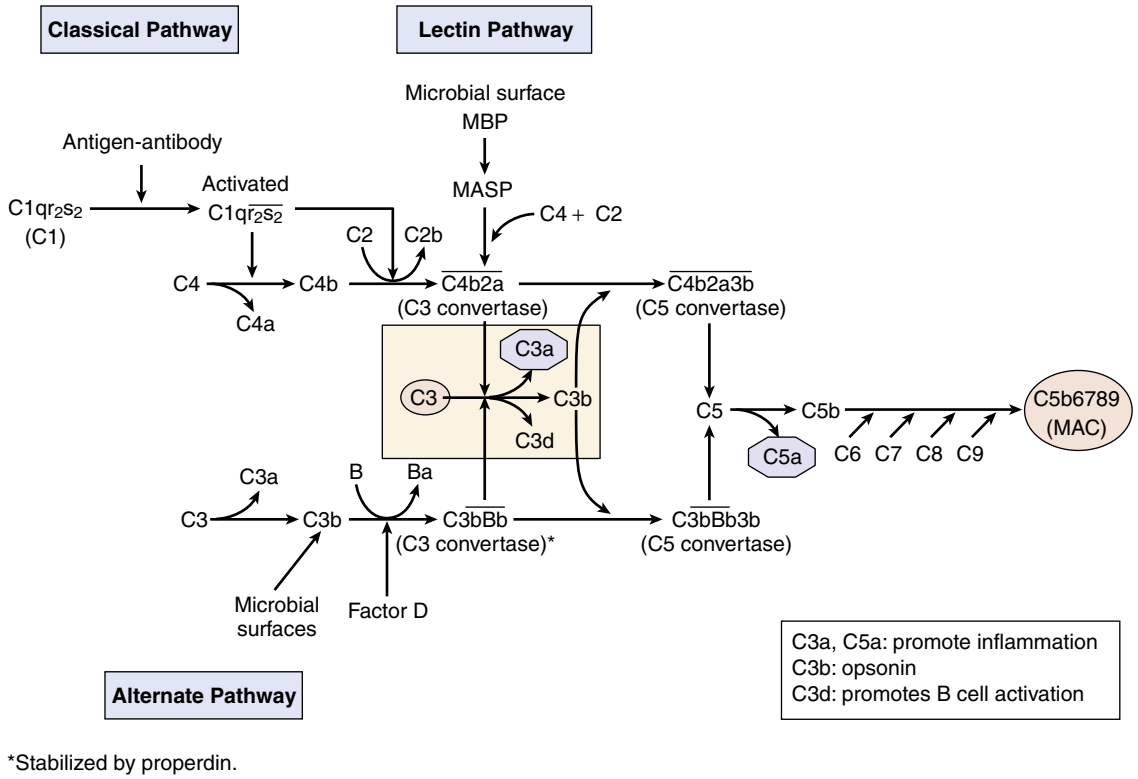

Fig. 8.2 Classical, lectin, and alternate complement pathways. Despite different activators, all three pathways converge toward the cleavage of C3 and C5 to provide chemoattractants and anaphylatoxins *(C3a, C5a),* an opsonin *(C3b)* that adheres to membranes, and a B-cell activator *(C3d)* and to initiate the membrane attack complex *(MAC)* to kill cells. C9 resembles perforin (natural killer cells and cytotoxic T cells) to promote apoptosis in the target cell. *MASP,* MBP-associated serine protease; *MBP,* mannose-binding protein. (Redrawn from Rosenthal, K.S., Tan, M. 2010. Rapid Review Microbiology and Immunology, third ed. Mosby, St Louis, MO.)

cleavage of the mannose-binding protein–associated serine protease. Mannose-binding protein–associated serine protease cleaves the C4 and C2 components to produce the C3 convertase, which is the junction point of the complement cascade.

Classical Pathway

The classical complement cascade is initiated by the binding of the first component, C1, to the Fc portion of antibody **(immunoglobulin [Ig]G or IgM, not IgA or IgE),** when it is bound to cell-surface antigens or to an immune complex with soluble antigens. C1 consists of a complex of three separate proteins designated C1q, C1r, and C1s (see Fig. 8.2). C1q binds to the Fc portion, leading to activation of the proteolytic activities of C1r and C1s. C1s then cleaves C4 to C4a and C4b, and C2 to C2a and C2b. The union of C4b and C2a produces **C4b2a,** which is known as **C3 convertase.** This complex binds to the cell membrane and cleaves C3 into C3a and C3b fragments. The C3b protein has a unique thioester bond that will covalently attach

C3b to a cell surface or be hydrolyzed. The C3 convertase amplifies the response by splitting many C3 molecules. The interaction of C3b with C4b2a bound to the cell membrane produces **C4b3b2a,** which is termed **C5 convertase.** This activation unit splits C5 into C5a and C5b fragments and represents yet another amplification step.

Biological Activities of Complement Components

The products of cleavage of the C3 and C5 components are essential for antibacterial responses, enhance clearance of the infectious agent, and promote inflammation. Complement fragments **C3a, C4a,** and **C5a** serve as powerful **anaphylatoxins** that stimulate mast cells to release histamine and tumor necrosis factor (TNF)-α, which enhances vascular permeability and smooth muscle contraction and promotes inflammation. **C3a** and **C5a** also act as attractants **(chemotactic factors)** for neutrophils and macrophages, facilitating their exit from the capillary near the infection. These proteins are powerful promoters of inflammatory reactions. C3b is an **opsonin** that promotes clearance of microbes by binding directly to the cell to make the cell more recognizable to phagocytic cells, such as neutrophils and macrophages, which have receptors for C3b. C3b can be cleaved further to generate C3d, which is an activator of B lymphocytes. For gram-positive and most other bacterial infections, these responses provide the major antimicrobial function of the complement system.

The complement system also interacts with the clotting cascade. Activated coagulation factors can cleave C5a, and a protease of the lectin pathway can cleave prothrombin to result in production of fibrin and activation of the clotting cascade.

Membrane Attack Complex

The terminal stage of the classical pathway involves creation of the **membrane attack complex (MAC),** which is also called the **lytic unit** (see Fig. 8.2). The five terminal complement proteins (C5 through C9) assemble into a MAC on target cell membranes to mediate injury. Initiation of the MAC assembly begins with C5 cleavage into C5a and C5b fragments. A $(C5b,6,7,8)_1(C9)_n$ complex forms and drills a hole in the membrane, leading to apoptosis or the hypotonic lysis of cells. The C9 component is similar to perforin, which is produced by cytolytic T cells and NK cells.

Neisseria bacteria are very sensitive to this manner of killing, whereas gram-positive bacteria are relatively insensitive. The peptidoglycan of gram-positive bacteria limits access of the complement components to the plasma membrane target unless disrupted by lysozyme. Unlike other gram-negative bacteria, the outer membrane of *Neisseria* bacteria contains lipooligosaccharide (LOS), which lacks O-antigenic side chains, and similar to stubble, it allows access of complement to the membrane surface.

Regulation of Complement Activation

Humans have several mechanisms for preventing generation of the C3 convertase to protect against inappropriate complement activation including C1 inhibitor, C4 binding protein, factor H, factor I, and the cell-surface proteins decay-accelerating factor (DAF) and membrane cofactor protein. In addition, CD59 (protectin) prevents formation of the MAC. Most infectious agents lack these protective mechanisms and remain susceptible to complement. A genetic deficiency in these protection systems can result in disease.

INTERFERONS

Interferons (IFNs) are small, cytokine-like proteins that can interfere with virus replication, and they have systemic effects (*described in more detail in Chapter 10*). The major type I IFNs are α and β. The type I IFNs are primarily a very early antiviral response triggered by the double-stranded ribonucleic acid (RNA) intermediates of virus replication and other structures that bind to Toll-like receptors (TLRs), retinoic acid–inducible gene 1 (RIG-1), and other PAMP receptors (PAMPRs). Plasmacytoid DCs produce large amounts of IFN-α in response to viral infection, especially during viremia, but other cells can also make IFN-α. IFN-β is made primarily by fibroblasts. The type I IFNs promote transcription of antiviral proteins in cells that become activated by viral infection. They also activate systemic responses, including fever, and enhance T-cell activation. Type I IFNs will be discussed further with respect to the response to viral infections.

Type 3 interferons λ act like Type 1 interferons and are also important for virus infections but act locally to inhibit virus replication and promote healing rather than activating systemic and inflammatory responses.

IFN-γ is a type II IFN and differs in biochemical and biological properties from type I IFNs. IFN-γ is primarily a cytokine produced by natural killer (NK) and T cells as part of TH1 immune responses and activates macrophages and myeloid cells. IFN-γ will be discussed further with respect to T-cell responses.

Cellular Components of Innate Responses

NEUTROPHILS

Neutrophils play a major role in antibacterial and antifungal protections and a lesser role in antiviral protections. The neutrophil surface is decorated with receptors that directly bind microbes, such as lectins and scavenger receptors, and **opsonin receptors.** Different opsonin receptors bind the Fc portion of immunoglobulin, C3b, or other opsonins, which are bound to specific structures on a molecule or microbial surface. These receptors promote phagocytosis of the microbe and their subsequent killing, as described later. Neutrophils have many granules that contain antimicrobial proteins and substances and can produce reactive oxygen molecules. These cells are terminally differentiated, spend less than 3 days in the blood, and on death during infection release a sticky deoxyribonucleic acid (DNA) net and **become pus**.

MAST CELLS, BASOPHILS, AND EOSINOPHILS

Mast cells, basophils, and eosinophils have cytoplasmic granules containing antimicrobial substances and mediators of inflammation. Mast cells are present in skin, mucoepithelial tissue, and the lining of small blood vessels and nerves. Basophils are like mast cells but circulate in the blood, and their granules stain with basic dyes. Mast cells and basophils bind IgE, complement, and microbial products

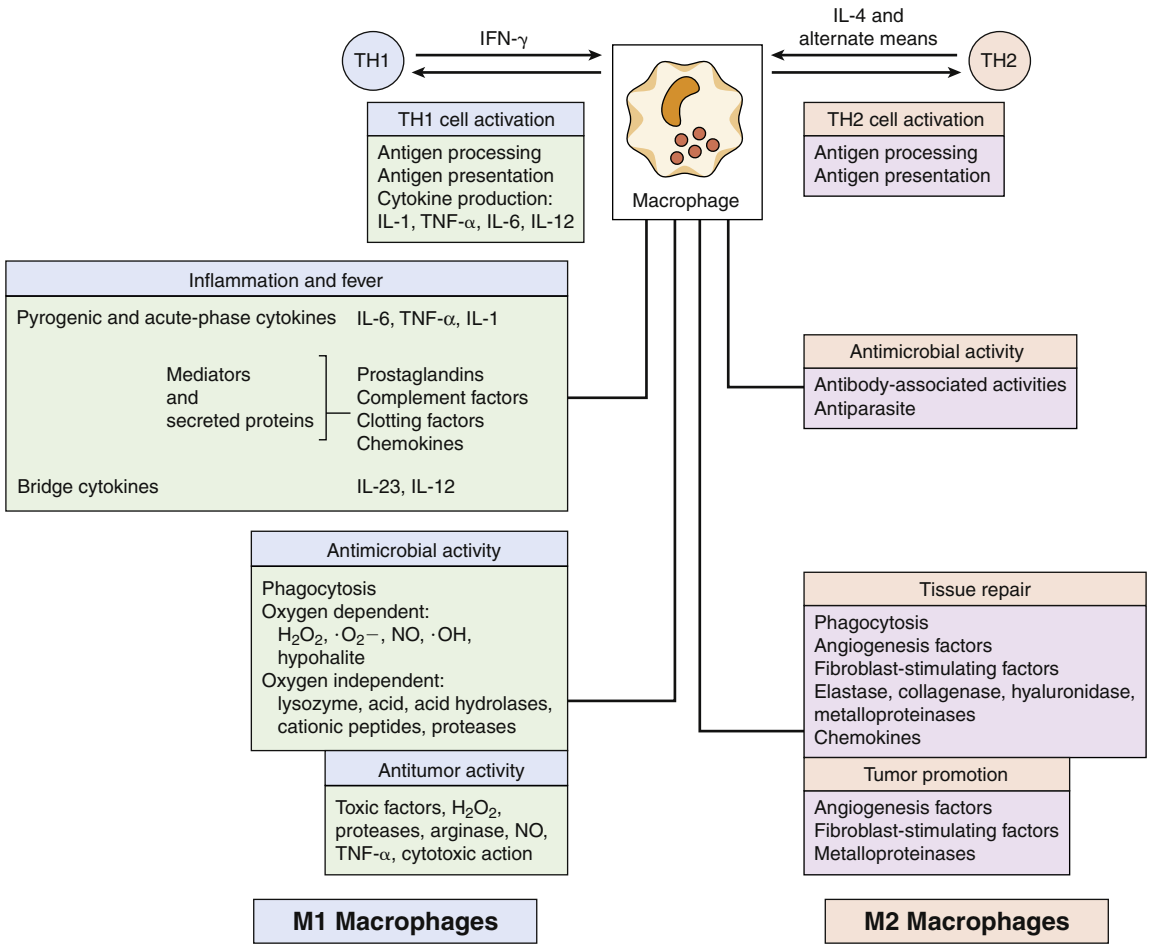

Fig. 8.3 The many functions of macrophages and members of the macrophage family. M2 macrophages maintain the status quo and facilitate wound healing by removal of debris and promoting angiogenesis and tissue repair. M1 macrophages promote antimicrobial killing and inflammation. *H_2O_2,* Hydrogen peroxide; *IFN-γ,* interferon-γ; *IL,* interleukin; *NO,* nitric oxide; *·O^-,* oxygen radical; *·OH,* hydroxyl radical; *TH,* T helper (cell); *TNF-α,* tumor necrosis factor-α.

and release histamine and cytokines as part of allergic and inflammatory responses. Eosinophils circulate in the blood, their granules stain with acidic dyes (e.g., eosin), and they are important in antiparasitic responses.

CELLS OF THE MONOCYTE-MACROPHAGE LINEAGE

Monocytes originate in the bone marrow and circulate in the blood. During infection or injury, chemokines attract them into the tissue where they differentiate into inflammatory macrophages (M1) or DCs.

Macrophages may originate from bone marrow–derived monocytes or from embryonic yolk sac. The latter reside in tissue, such as the Kupffer cells in the liver. Similar to neutrophils, macrophages are phagocytes, but unlike neutrophils, they are long lived, can divide, present antigenic peptides to CD4 T cells on major histocompatibility complex (MHC) II molecules, and must be activated to efficiently kill the phagocytosed bacteria.

The primary role of tissue macrophages is to remove debris and promote tissue repair and remodeling **(M2 macrophages).** Sometimes called alternatively activated macrophages, these cells can be further activated by the TH2-related cytokines, IL-4 and IL-13, to support antiparasitic responses. M2 macrophages are also present in tumors and reinforce the growth of tumor cells and promote angiogenesis (Fig. 8.3).

To promote inflammatory responses and be able to kill phagocytosed bacteria, macrophages are activated to become **M1 macrophages** by lipopolysaccharide, TNF-α, IFN-γ, and granulocyte-macrophage colony-stimulating factor (GM-CSF). The cytokines are produced by ILC1 cells and CD4 and CD8 T cells as part of the TH1 response**.** Activated M1 macrophages produce reactive oxygen species (ROS) and nitric oxide (NO), enzymes, and other molecules to promote antimicrobial function (Box 8.2) and reinforce local inflammatory reactions by producing chemokines to attract neutrophils, iDCs, NK cells, and activated T cells, and acute-phase cytokines (IL-1, TNF-α, IL-6) to promote the response. Macrophages get help by presenting antigen to CD4 TH1 cells, which produce IFN-γ as long as the antigen is present. In the absence of IFN-γ, the M1 macrophages may transition to M2 to facilitate healing and resolution of the infection and its damage.

In the case of an unresolved mycobacterial infection, continuous (chronic) stimulation of macrophages by T cells promotes fusion of the macrophages into **multinucleated giant cells** and large macrophages called **epithelioid cells**, surround the infection and form a **granuloma.**

BOX 8.2 The Many Functions of Macrophages

Status Quo (Peacetime): M2 Macrophages

Phagocytosis and degradation of debris
Production of enzymes and factors for tissue growth and repair
Production of angiogenesis factors

During Infection and Inflammation (At War): M1 Macrophages (Activated by PAMPs, TNF-α, GM-CSF, and IFN-γ)

Phagocytosis and oxygen-dependent and -independent antimicrobials
Acute-phase cytokines: IL-6, TNF-α, and IL-1 (endogenous pyrogens)
Other cytokines: IL-12, GM-CSF, G-CSF, M-CSF, IFN-α
Arachidonic acid metabolites
Prostaglandin, thromboxane, leukotrienes
Enzymes, complement components, coagulation factors

G-CSF, Granulocyte colony-stimulating factor; *GM-CSF,* granulocyte-macrophage colony-stimulating factor; *IFN-α,* interferon-α; *IL,* interleukin; *M-CSF,* macrophage colony-stimulating factor; *PAMP,* pathogen-associated molecular pattern; *TNF-α,* tumor necrosis factor-α.

BOX 8.3 Dendritic Cells

Myeloid and Plasmacytoid (for T cells)

Morphology: octopus-like with tendrils
Activities
- Immature DCs
- In blood and tissue
- Danger sensors, phagocytosis, cytokine production, antigen processing
- Mature DCs
- T-cell areas of lymph node and spleen
- Only cell that can initiate a new T-cell response
- Process antigenic proteins into peptides
- Increased expression of molecules for antigen presentation
  - MHC I-peptide: CD8 T cells
  - CD1-glycolipids: CD8 T cells
  - MHC II-peptide: CD4 T cells
  - B7-1 and B7-2 and other coreceptors
- Produce cytokines to initiate and direct T-cell response

Follicular DCs (for B cells)

In B-cell areas of lymphoid tissues
Express sticky receptors to display antigen to B cells (Fc and CR1, CR2, and CR3 complement receptors, lack MHC II)

CD, Cluster differentiation; *DC,* dendritic cell; *MHC,* major histocompatibility complex.

MYELOID AND PLASMACYTOID DENDRITIC CELLS

DCs provide the bridge between the innate and the immune responses. The cytokines they produce determine the nature of the T-cell response *(**D**endritic cells **d**irect the **T** cells as to what to **t**ell other cells to do)*. Monocytes and precursor myeloid DCs circulate in the blood and then differentiate into immature DCs (iDCs) in tissue and lymphoid organs. The **iDCs** have many dendritic arms, are phagocytic, and on activation by danger signals, they release an early cytokine-mediated warning and then mature into DCs. The iDCs express different combinations of danger sensors (DAMP receptors [DAMPRs]) that can detect tissue trauma (adenosine triphosphate [ATP], adenosine, ROS, heat shock proteins) and infection (PAMPRs), including **TLRs** and other receptors (see later). **Mature DCs** are the ultimate antigen-presenting cells; they are the only antigen-presenting cells that can initiate an antigen-specific T-cell response (Box 8.3). **Langerhans cells** are a type of iDC that remains in the epidermis of the skin until activated and then becomes a mature DC. **Plasmacytoid DCs** are in the blood and generate large amounts of type 1 IFN and cytokines in response to viral and other infections and can present antigen to T cells.

The **follicular DC** cannot process nor present antigen to T cells, but it acquires its name by its presence in the B-cell–rich follicles of lymph nodes and spleen and its multiarmed appearance. Antigens stick to its surface and are displayed to B cells.

INNATE LYMPHOID CELLS, NATURAL KILLER CELLS, γ/δ T CELLS, MUCOSAL-ASSOCIATED INVARIANT T CELLS, AND NATURAL KILLER T CELLS

ILCs resemble and produce cytokines similar to CD4T cells instead of responding through a T-cell antigen receptor (TCR), they respond to PAMPR and DAMPR stimulation. They are distinguished by the expression of T-cell–like transcriptional regulators and cytokines. ILC1 cells express the T-bet transcription factor and produce IFN-γ and TNF-α, similar to CD4 Th1 cells; ILC2 cells express GATA-3 and produce IL-4, IL-5, IL-9, and IL-13, similar to CD4 Th2 cells and are important for initiating the response to intestinal parasites; ILC3 cells express RORγt and produce IL-17 and IL-22, similar to Th17 cells; and ILCreg cells are similar to CD4 Treg-ulator (Treg) cells and produce TGF-β and IL-10. ILCs are present throughout the body, especially near mucosal epithelial cells in which their cytokines help regulate responses to normal flora but provide rapid responses to pathogenic infection.

NK cells are **ILC1s** that provide an early cellular response to a viral infection, have antitumor activity, and amplify inflammatory reactions after bacterial infection. NK cells are also responsible for **antibody-dependent cellular cytotoxicity (ADCC),** in which they bind and kill antibody-coated cells. NK cells are large granular lymphocytes (LGLs) that share many characteristics with T cells, except the mechanism for target cell recognition. NK cells do not express a TCR or CD3 and cannot make IL-2. They neither recognize a specific antigen nor require presentation of antigen by MHC molecules. The NK system does not involve memory or require sensitization and cannot be enhanced by specific immunization.

NK cells are activated by (1) type 1 IFNs (produced early in response to viral and other infections); (2) TNF-α; (3) IL-12, IL-15, and IL-18 (produced by DCs and activated macrophages); and (4) IL-2 (produced by CD4 TH1 cells). The functional receptors include the **FasL [Fas ligand]**), the **Fc receptor for IgG** (CD16) and complement receptors for ADCC, and NK-specific inhibitory receptors, and activating receptors (including NK immunoglobulin-like receptors **[KIRs]**). Activated NK cells produce IFN-γ, IL-1, and GM-CSF. The granules in an NK cell contain **perforin,** which is a pore-forming protein, and **granzymes** (esterases), which

are also present in the granules of a CD8 cytotoxic T lymphocyte (CTL). These molecules promote the **apoptotic** death of the target cell.

The NK cell sees every cell as a potential victim, especially those that appear in distress, and will kill unless it receives an inhibitory signal from the target cell. NK cells bind to carbohydrates and surface proteins on a distressed cell. Interaction of sufficient numbers of class I MHC molecules with KIR **inhibitory receptors** acts as a secret password, indicating that all is normal, to activate an inhibitory signal to prevent NK killing of the target cell. Virus-infected cells and tumor cells express "stress-related molecules" and are often deficient in MHC I molecules and become NK-cell targets. Binding of the NK cell to antibody-coated target cells (ADCCs) also initiates killing, but this is not controlled by an inhibitory signal. The **killing mechanisms** are similar to those of CD8 cytotoxic T cells. A synapse (pocket) is formed between the NK and target cell, and **perforin and granzymes** are released to disrupt the target cell and induce apoptosis. In addition, the interaction of the **FasL** on the NK cell with **Fas** protein on the target cell can also induce **apoptosis.**

NKT cells, MAIT, and γ/δ **T cells** reside primarily in tissue and differ from other T cells because they have a limited repertoire of TCRs. Unlike other T cells, NKT, MAIT, and γ/δ T cells can sense nonpeptide antigens, including glycolipids, vitamin B derivatives, phosphorylated amine metabolites and stress molecules produced by some microbes, and even human cells. NKT cells also express KIR receptors (Table 8.2). Similar to the ILCs, these T cells produce cytokines to regulate and activate host protective responses by other cells.

Activation of Innate Cellular Responses

The cells of the innate response are activated by cytokines, chemokines, stress molecules, and direct interaction with microbes and microbial components. These cells express different combinations of danger (PAMPRs) and damage (DAMPRs) sensors for microbes and cell trauma, including the **TLR** family of proteins and other receptors. The TLRs include at least 10 different cell-surface and intracellular proteins that bind repetitive structures that form **PAMPs** (Fig. 8.4 and Table 8.3). These patterns are present within the endotoxin component of lipopolysaccharides (LPS) and in lipoteichoic acid (LTA), flagella, fungal glycans, unmethylated cytosine-guanosine units of DNA (CpG oligodeoxynucleotides [ODNs]) commonly found in bacteria, double-stranded RNA produced during the replication of some viruses, and other molecules. In addition to the TLRs, other cell-surface PAMPRs include C-type lectins for microbial carbohydrates and glucans, and scavenger receptors. Cytoplasmic sensors of bacterial peptidoglycan include nucleotide-binding oligomerization domain protein 1 (NOD1), NOD2, and cryopyrin and, for nucleic acids, RIG-1, melanoma differentiation–associated gene 5 (MDA5), and others. Binding of PAMPs to TLRs and other PAMPRs activate adaptor proteins that trigger cascades of protein kinases and other responses that result in the

TABLE 8.2 Ligands Recognized by Innate T cells

T Cell	Receptor	Ligand
NKT cells	CD1	Glycolipids
MAIT cells	MR1	Riboflavin (vitamin B) analogues and metabolites
γ/δ T cells	—	Cellular stress molecules Alkylamines Bisphosphonates Organic phosphoantigens (e.g., hydroxy-methyl-butyl-pyrophosphate)
	Other receptors	Butyrate Vitamin A and retinoic acid Vitamin D AhR ligands (tryptophan metabolites: indole-3-lactic acid)

MAIT, Mucosal-associated invariant T cell; *NKT,* natural killer T cell.

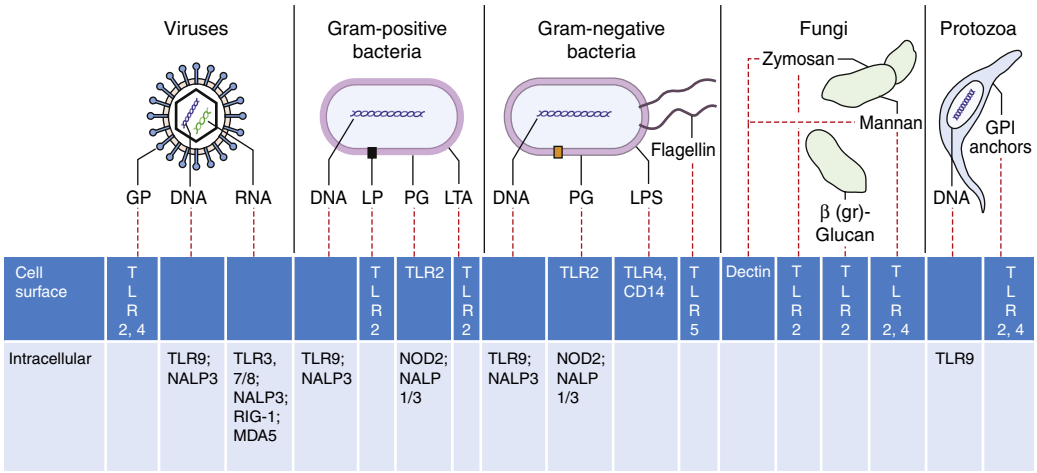

Fig. 8.4 Recognition of pathogen-associated molecular patterns (PAMPs). Microbial structures, RNA, and DNA bind to specific PAMP receptors on the cell surface, in vesicles, or in the cytoplasm to activate innate responses. *GP,* Glycoproteins; *GPI,* phosphatidylinositol glycan–anchored proteins; *LP,* lipoproteins; *LPS,* lipopolysaccharide; *LTA,* lipoteichoic acid; *MDA5,* melanoma differentiation–associated gene 5; *NALP3,* Nacht, leucine-rich repeat, and pyrin domain–containing protein 3; *NOD2,* nucleotide-binding oligomerization domain protein 2; *PG,* peptidoglycan; *RIG-1,* retinoic acid–inducible gene-1; *TLR9,* Toll-like receptor 9. (Modified from Mogensen, T.H. 2009. Pathogen recognition and inflammatory signaling in innate immune defenses. Clin. Microbiol. Rev. 22, 240–273.)

TABLE 8.3 Pathogen Pattern Receptors

Receptor[a]	Microbial Activators	Ligand
CELL SURFACE		
TLR1	Bacteria, mycobacteria *Neisseria meningitidis*	Lipopeptides Soluble factors
TLR2	Bacteria Fungi Cells	LTA, LPS, PG, and so forth Zymosan Necrotic cells
TLR4	Bacteria, parasites, host proteins Viruses, parasites, host proteins	**LPS,** fungal mannans, viral glycoproteins, parasitic phospholipids, host heat shock proteins, LDL
TLR5	Bacteria	Flagellin
TLR6	Bacteria Fungi	LTA, lipopeptides, zymosan
Lectins	Bacteria, fungi, viruses	Specific surface carbohydrates (e.g., mannose)
N-Formyl methionine receptor	Bacteria	Bacterial proteins
ENDOSOME		
TLR3	Viruses	dsRNA
TLR7	Viruses	Single-stranded RNA Imidazoquinolines
TLR8	Viruses	Single-stranded RNA Imidazoquinolines

[a]Information about Toll-like receptors from Takeda, A., Kaisho, T., Akira, S. 2003. Toll-like receptors. Annu. Rev. Immunol. 21, 335–376; Akira, S., Takeda, K. 2003. Toll-like receptor signalling. Nat. Rev. Immunol. 4, 499–511.

Activators: *DAI,* DNA-dependent activator of interferon regulatory factors; *dsRNA,* double-stranded RNA; *LDL,* minimally modified low-density lipoprotein; *LPS,* lipopolysaccharide; *LTA,* lipoteichoic acid; *MDA5,* melanoma differentiation–associated gene 5; *NALP3,* Nacht, leucine-rich repeat and pyrin domain–containing protein 3; *NOD,* nucleotide-binding oligomerization domain; *PG,* peptidoglycan; *RIG-1,* retinoic acid–inducible gene 1; *TLR,* Toll-like receptor.

activation of the cell and production of specific cytokines and chemokines, which can include proinflammatory cytokines (IL-1, TNF-α, and IL-6) and type 1 IFNs (IFN-α and IFN-β).

In response to PAMPs and other stimuli, epithelial cells, DCs, macrophages, and other cells can assemble an **inflammasome** (Fig. 8.5). This multiprotein complex is activated by assembly of several of the adaptor proteins induced in response to PAMPs, tissue damage, or on proteolysis of some of its components. Proteases released on uric acid crystal (gout) or asbestos puncture of phagosomes and lysosomes can also activate inflammasome formation. The inflammasome activates the caspase 1 protease, which then cleaves, activates, and promotes the release of IL-1β and IL-18. These activated cytokines promote local inflammation. The activated inflammasome can also initiate pyroptosis, which is an inflammatory apoptosis-like cell death for cells bearing intracellular bacterial infections.

CHEMOTAXIS AND LEUKOCYTE MIGRATION

Chemotactic factors produced in response to infection and inflammatory responses, such as complement components (C3a and C5a), bacterial products (e.g., formyl-methionyl-leucyl-phenylalanine [f-met-leu-phe]), and chemokines, are powerful chemoattractants for neutrophils, monocytes, and macrophages, and later in the response, lymphocytes. **Chemokines** are small cytokine-like proteins that direct the migration of white blood cells to the site of infection or inflammation or to different tissue locations. Most chemokines are either CC (adjacent cysteines) or CXC (cysteines separated by one amino acid) chemokines and bind to specific G-protein–coupled receptors. The chemokines establish a chemically lighted "runway" to guide these cells to the site of an infection and also activate them. Combined with TNF-α, the chemokines cause the endothelial cells lining the capillaries (near the inflammation) and the leukocytes passing by to express complementary adhesion

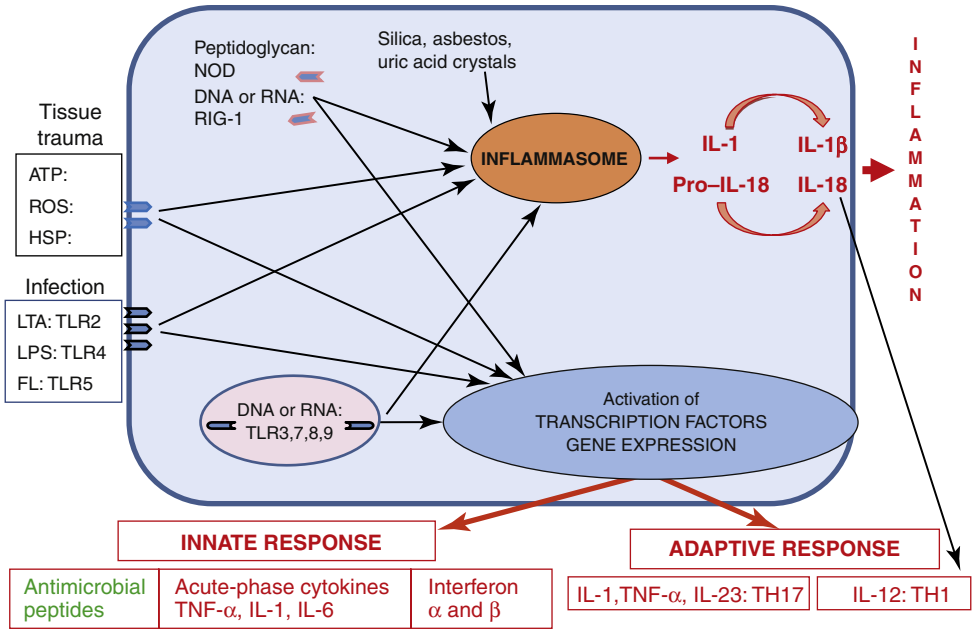

Fig. 8.5 Induction of inflammatory responses. Receptors for pathogen-associated molecular patterns and damage-associated molecular pattern receptors at the cell surface, in vesicles, and in the cytoplasm (1) activate signal cascades that (2) produce adaptor proteins that (3) activate local inflammatory responses. The adaptor proteins trigger the transcription of cytokines and initiate the assembly of the inflammasome. Cytokines activate innate and promote antigen-specific responses. The assembled inflammasome is a protease that cleaves and activates IL-1 and pro–IL-18 and these cytokines promote inflammation. Asbestos and other materials also activate the inflammasome after lysing lysosomes and releasing proteases that cleave precursors to initiate its assembly and activation. *ATP,* Adenosine triphosphate; *FL,* flagellin; *HSP,* heat shock protein; *IL,* interleukin; *LPS,* lipopolysaccharide; *LTA,* lipoteichoic acid; *NOD,* nucleotide-binding oligomerization domain protein; *RIG-1,* retinoic acid–inducible gene 1; *ROS,* reactive oxygen species; *TLR,* Toll-like receptor; *TNF-α,* tumor necrosis factor-α.

molecules (molecular "Velcro"). The leukocytes slow, roll, attach to the lining, and then extravasate across (i.e., pass through) the capillary wall to the site of inflammation (a process called *diapedesis*) (Fig. 8.6). TNF-α and histamine released by mast cells lining the vessel also make the walls leaky.

PHAGOCYTIC RESPONSES

Polymorphonuclear neutrophils (PMNs) are the first cells to arrive at the site in response to infection; they are followed later by monocytes and macrophages. **Neutrophils** provide the major antibacterial and antifungal response and contribute to inflammation. An increased number of neutrophils in the blood, body fluids (e.g., cerebrospinal fluid), or tissue usually indicates a bacterial infection. The infection recruits the release of immature **band forms** from the bone marrow described as a "left shift" (*left* refers to the beginning of a chart of neutrophil development).

Phagocytosis of bacteria or a fungus by macrophages and neutrophils involves three steps: attachment, internalization, and digestion (Fig. 8.7). **Attachment** to the microbe or molecule is mediated by receptors for cell-surface carbohydrates (**lectins** [specific sugar-binding proteins]); fibronectin receptors (especially for *Staphylococcus aureus*); and **receptors for opsonins,** including complement (C3b), mannose-binding protein, and the Fc portion of antibody. After attachment, a section of plasma membrane surrounds the particle to form a **phagocytic vacuole** around the microbe. This vacuole fuses with the **primary lysosomes** (macrophages) or **granules** (PMNs) to allow inactivation and digestion of the vacuole contents.

Phagocytic killing may be oxygen independent or oxygen dependent (Box 8.4). *Neutrophils do not need special activation to kill internalized microbes,* but their response is reinforced by IL-17 and TNF-α. *Activation of macrophages is required for efficient killing of internalized microbes.* Activation is promoted by IFN-γ (best), which is produced early in the infection by ILC1 cells and NKT cells and later by CD4 and CD8 T cells, and sustained by TNF-α and lymphotoxin (TNF-β).

Oxygen-dependent killing is mediated by reactive oxygen species (ROS), hypochlorous ions, and NO (see Box 8.4). **NADPH oxidase** is used to produce superoxides and convert water into hydrogen peroxide. **Myeloperoxidase** transforms chloride ions and hydrogen peroxide into hypochlorous ions (chlorine bleach). **NO** has antimicrobial activity and is also a major second messenger molecule that enhances the inflammatory and other responses.

The **neutrophil** also can mediate **oxygen-independent killing** on fusion of the phagosome with azurophilic granules containing cationic proteins (e.g., cathepsin G) and other granules containing lysozyme and lactoferrin. These proteins kill gram-negative bacteria by disrupting their cell membrane integrity, but they are far less effective against gram-positive bacteria and fungi, which are killed principally through the oxygen-dependent mechanism.

The neutrophils also promote inflammation. Prostaglandins and leukotrienes, which increase vascular permeability, are released, causing swelling (edema) and stimulating pain receptors. In addition, during phagocytosis, the granules may leak their contents to cause tissue damage. The neutrophils have short lives; on death at the site of infection, they release their DNA and granule contents to form a sticky net to catch and kill microbes **(neutrophil extracellular traps [NETs])** and dead neutrophils become **pus.**

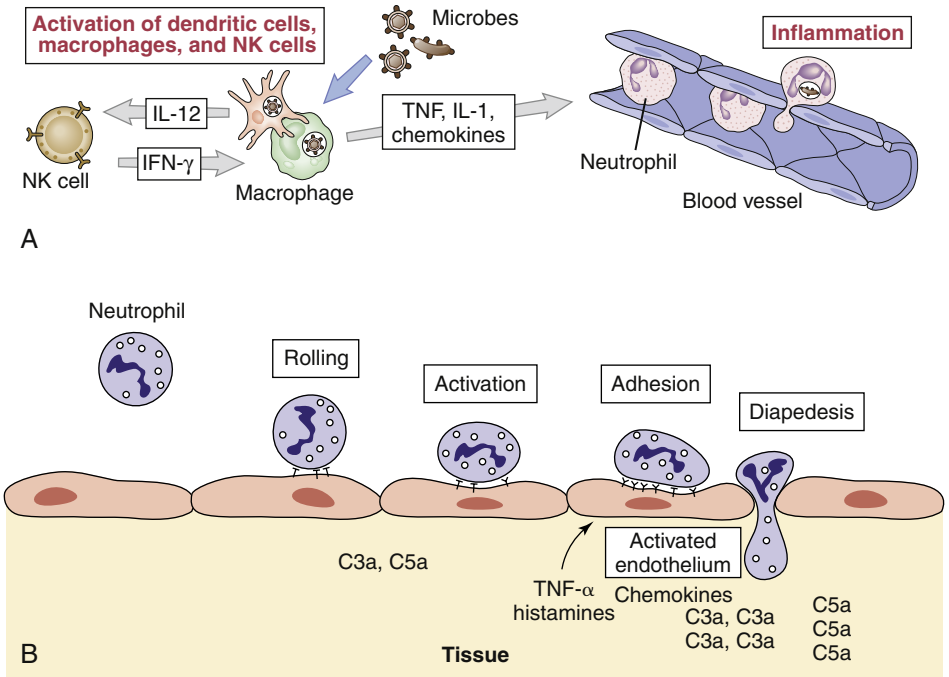

Fig. 8.6 (A and B) Neutrophil diapedesis in response to inflammatory signals. Tumor necrosis factor *(TNF)*-α and chemokines activate the expression of selectins and intercellular adhesion molecules on the endothelium near the inflammation and their ligands on the neutrophil: integrins, L-selectin, and leukocyte function–associated antigen-1 (LFA-1). The neutrophil binds progressively tighter to the endothelium until it finds its way through the endothelium. Epithelial cells, Langerhans cells, and macrophages activated by microbes and interferon *(IFN)*-γ make TNF-α and other cytokines and chemokines to enhance diapedesis. *IL,* Interleukin; *NK,* natural killer. (A, From Abbas, A.K., Lichtman, A.H. 2012. Basic Immunology: Functions and Disorders of the Immune System, fourth ed. WB Saunders, Philadelphia, PA.)

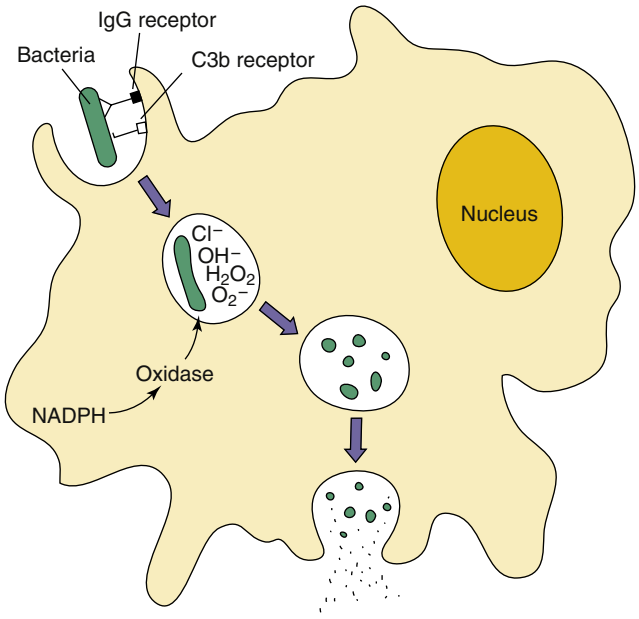

Fig. 8.7 Phagocytosis and killing of bacteria. Bacteria are bound directly or are opsonized by mannose-binding protein, immunoglobulin *(Ig)*G, and/or C3b receptors, promoting their adherence and uptake by phagocytes. Within the phagosome, oxygen-dependent and oxygen-independent mechanisms kill and degrade the bacteria. *NADPH,* Nicotinamide adenine dinucleotide phosphate reduced.

Resting and tissue **macrophages** (M2 macrophages) are phagocytic and will internalize microbes, but unlike neutrophils, they do not have the preformed granules of antimicrobial molecules to kill them. Intracellular infection can occur upon infection of a resting macrophage or

BOX 8.4 Antibacterial Compounds of the Phagolysosome

Oxygen-Dependent Compounds
- Hydrogen peroxide, superoxide, hydroxyl radicals (·OH^-): NADPH oxidase and NADH oxidase
- Activated halides (Cl^-, I^-, Br^-): myeloperoxidase (neutrophil)
- Nitric oxide: nitric oxide synthase

Oxygen-Independent Compounds
- Acids
- Lysozyme (degrades bacterial peptidoglycan)
- Lactoferrin (chelates iron)
- Defensins and other cationic proteins (damage membranes)

Proteases: Elastase, cathepsin G, and so forth

NADH, Nicotinamide adenine dinucleotide reduced; *NADPH,* nicotinamide adenine dinucleotide phosphate reduced.

if the microbe can counteract the antimicrobial activities of an activated macrophage. **Activation of the macrophage by IFN-γ (M1 macrophages),** making the macrophages "angry," promotes production of inducible NO synthase (iNOS) and NO, other ROSs, and antimicrobial enzymes to kill internalized microbes. Activated macrophages also make acute-phase cytokines (IL-1, IL-6, and TNF-α) and possibly IL-23 or IL-12. Macrophages have a long life, and with T-cell help they can maintain the inflammatory response.

Splenic macrophages are important for clearing bacteria, especially encapsulated bacteria, from blood. Asplenic (congenitally or surgically) individuals are highly susceptible to pneumonia, meningitis, and other manifestations of *Streptococcus pneumoniae, Neisseria meningitidis,* and other encapsulated bacteria and yeast.

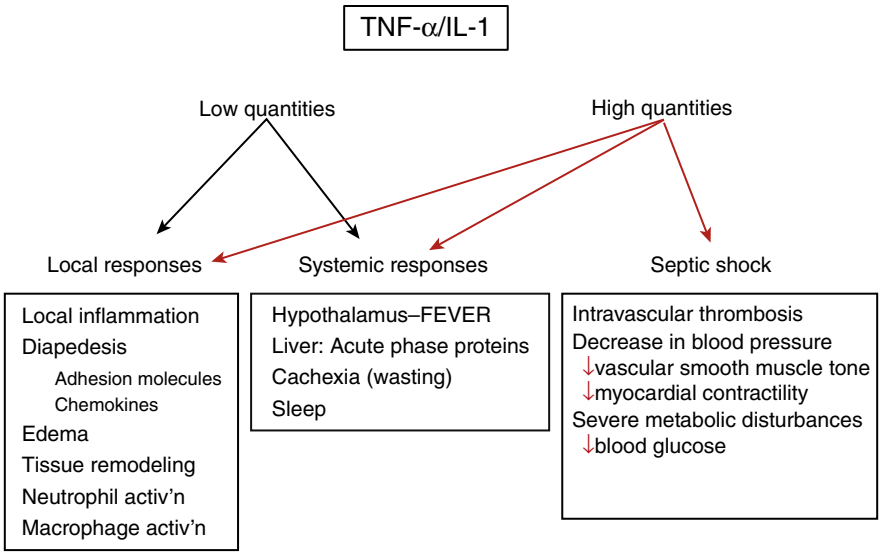

Fig. 8.8 Good, bad, and ugly effects of tumor necrosis factor *(TNF)*-α and interleukin *(IL)*-1. Low concentrations activate local inflammation (promote movement of fluid, proteins, and cells from the blood to the site of infection) and supportive responses. High concentrations activate systemic inflammation and shock.

Normal Flora–Associated Responses

The skin and mucosa-associated lymphoid tissue (MALT) of the nares, oral region, and urogenital and gastrointestinal tracts are constantly monitoring and being stimulated by the adjacent normal flora (see Fig. 7.5). DCs continuously probe the intestine and sense the LPS, LTA, flagella, and other components of the bacteria within the lumen. M2 macrophages, DCs, ILCs, and T cells regulate the response to the flora by instructing the epithelial cells to produce mucus and appropriate antimicrobial peptides and by preventing excess inflammation. An equilibrium is maintained between inflammatory and immune regulatory responses to the microbial stimuli. Disruption of the equilibrium can result in gastroenteritis, inflammatory bowel disease, or autoimmune diseases.

Inflammation

PROINFLAMMATORY CYTOKINES

The proinflammatory cytokines, sometimes referred to as *acute-phase cytokines,* are IL-1, TNF-α, and IL-6 (Fig. 8.8 and Table 8.4). These cytokines are produced by activated macrophages and other cells. IL-1 and TNF-α share properties. Both of these cytokines are **endogenous pyrogens** capable of stimulating fever, promoting local inflammatory reactions and synthesis of acute-phase proteins.

TNF-α is the ultimate mediator of inflammation and the systemic effects of infection. TNF-α stimulates endothelial cells to express adhesion molecules and chemokines to attract leukocytes to the site of infection, loosens the epithelial tight junctions to allow diapedesis, activates mast cells lining the vasculature to release histamine to promote seepage of fluid, activates neutrophils and macrophages, and promotes apoptosis of certain cell types. Systemically, TNF acts on the hypothalamus to induce fever; causes systemic metabolic changes, weight loss (cachexia), and loss of appetite; enhances production of IL-1, IL-6, and chemokines; and promotes acute-phase protein synthesis by the liver. At high concentrations, TNF-α elicits all of the functions leading to septic shock.

There are two types of **IL-1, IL-1α and IL-1β.** IL-1 is produced mainly by activated macrophages but also by neutrophils, epithelial cells, and endothelial cells. IL-1β must be cleaved by the inflammasome to become activated. IL-1 shares many of the activities of TNF-α to promote local and systemic inflammatory responses. Unlike TNF-α, IL-1 is a growth factor, cannot induce apoptosis, and will enhance but is not sufficient to cause septic shock.

IL-6 is produced by many cell types. It promotes the synthesis of acute-phase proteins in the liver, production of neutrophils in bone marrow, and activation of T and B lymphocytes.

IL-23 and **IL-12** *are cytokines that bridge the innate and immune responses.* Both cytokines have a p40 subunit, but IL-12 has a p35 subunit and IL-23 has a p19 subunit. IL-23 promotes TH17 responses from memory T cells, which enhance neutrophil action. IL-12 promotes NK-cell function and is required to promote a TH1 immune response, which enhances macrophages and other myeloid cell functions. These cytokines will be discussed in Chapter 9 regarding their actions on T cells. **IL-18** must be cleaved by the inflammasome to an active form, and it promotes NK- and T-cell function.

ACUTE INFLAMMATION

Acute local inflammation is an early defense mechanism to contain the infection, prevent its spread from the initial focus, and activate subsequent immune responses. Initially, inflammation can be triggered by the response to danger signals resulting from infection and tissue damage. Mast cells respond by releasing histamines, TNF-α, and prostaglandins, which can trigger

TABLE 8.4 Cytokines of Innate Immunity (STAT)[a,b]

Cytokine	Source	Trigger	Action	Target
TNF-α	Macrophages, T cells	PAMP, inflammation	Acute-phase responses, promotes inflammation, fever, symptoms of sepsis, cachexia, vascular permeability, altered muscle tone, apoptosis (some cells)	Endothelial cells, neutrophils, macrophages, hypothalamus, liver, muscle, mast cells, other cells
IL-1 (α, β [cleaved])	Macrophages, keratinocytes, endothelial and some epithelial cells	PAMP, inflammation	Acute-phase responses, promotes inflammation, fever, supports symptoms of sepsis, synthesis of acute-phase proteins	Endothelial cells, hypothalamus, liver, and other cells
IL-6	Macrophages, endothelial cells, T cells	PAMP, inflammation	Acute-phase responses, reinforces acute-phase responses, stimulation of T and B cells	Macrophages, endothelial cells, T cells
Type 1 IFNs (α,β)	Most cells, plasmacytoid dendritic cells	Viral infection (especially RNA viruses)	Inhibit virus replication, activate NK cells, enhance immune response	Virus-infected cells, NK cells, T cells
Chemokines	Macrophages, dendritic cells, many other cells	PAMP, inflammation, C5a, TNF-α	Chemotaxis, targeting of cells to infection/inflammation	Leukocytes, lymphocytes, endothelial cells, and other cells
IL-12	Dendritic cells, macrophages	PAMP	Promotes TH1 immune response, activates NK cell	NK cells, T cells
IL-23	Dendritic cells, macrophages	PAMP	Promotes TH17 response	T cells
IL-18 (cleaved)	Macrophages, epithelial and other cells	PAMP, inflammation	Promotes IFN-γ production and T-cell activation	NK cells, T cells
Type II IFN (γ)	NK cells, T cells	IL-18, IL-12 (TH1 responses)	Activates antimicrobial activity, production of inducible nitric oxide synthetase, other	Macrophages, dendritic cells, T and B cells, and so forth

[a]STAT: acronym for essential information for each cytokine: *s*ource, *t*rigger, *a*ction, *t*arget.
[b]Table is not all inclusive for cell sources, stimuli, activities, or targets.
IFN, Interferon; *IL,* interleukin; *NK,* natural killer; *PAMP,* pathogen-associated molecular pattern; *TH,* T helper (cell); *TNF,* tumor necrosis factor.

increases in permeability of capillaries. With chemokines, IL-1, and complement, these agents can promote acute inflammation.

The three major events in local acute inflammation are (1) expansion of capillaries to increase blood flow (causing redness or a rash and releasing heat); (2) increase in permeability of the microvasculature structure to allow escape of fluid, plasma proteins, and leukocytes from the circulation (swelling or edema); and (3) recruitment of neutrophils and their accumulation and response to infection at the site of injury. Inflammatory responses are beneficial but are associated with pain, redness, heat, and swelling and can cause tissue damage. The mediators of inflammation are listed in Table 8.5.

Tissue damage is caused to some extent by complement and macrophages but mostly by neutrophils and their products. Dead neutrophils are a major component of **pus.** Kinins and clotting factors induced by tissue damage (e.g., factor XII [Hageman factor], bradykinin, fibrinopeptides) are also involved in inflammation. These factors increase vascular permeability and are chemotactic for leukocytes. **Prostaglandins** and **leukotrienes** can mediate essentially every aspect of acute inflammation. These molecules are generated by cyclooxygenase-2 (COX-2) and 5-lipooxygenase, respectively, from arachidonic acid, The course of inflammation can be followed by rapid increases in acute-phase proteins, especially C-reactive protein (which can increase 1000-fold within 24 to 48 hours) and serum amyloid A.

TABLE 8.5 Mediators of Acute and Chronic Inflammation

Action	Mediators
ACUTE INFLAMMATION	
Increased vascular permeability	Histamine, bradykinin, C3a, C5a, leukotrienes, PAF, substance P, TNF-α
Vasodilation	Histamine, prostaglandins, PAF, NO
Pain	Bradykinin, prostaglandins
Leukocyte adhesion	Leukotriene B4, IL-1, TNF-α, C5a
Leukocyte chemotaxis	C5a, C3a, IL-8, chemokines, PAF, leukotriene B4
Acute-phase response	IL-1, IL-6, TNF-α
Tissue damage	Proteases, free radicals, NO, neutrophil granule contents
Fever	IL-1, TNF, IFN-α, IFN-β, prostaglandins
CHRONIC INFLAMMATION	
Activation of T cells and macrophages, and acute-phase processes	From T cells (TNF, IL-17, IFN-γ); from macrophages (IL-1, TNF-α, IL-23, IL-12)

IFN-γ, Interferon-γ; *IL,* interleukin; *NO,* nitric oxide; *PAF,* platelet-activating factor; *TNF,* tumor necrosis factor.
From Novak, R. 2006. Crash Course Immunology. Mosby, Philadelphia, PA.

BOX 8.5 Inflammatory Diseases of the Skin

Acne, atopic dermatitis, and eczema are initiated and maintained by innate keratinocyte and epithelial cell responses after entry of normal flora of the skin surface. Acne is the result of responses to *Propionibacterium acnes,* whereas staphylococci can drive atopic dermatitis and eczema. *P. acnes* grows in the anaerobic environment of the hair follicles and can promote keratinocyte growth and sebum production. It also activates TLR2 and TLR4 to initiate inflammatory cytokine (IL-1, IL-6, TNF-α) and chemokine responses from keratinocytes and Langerhans cells to recruit neutrophils and produce squalene, which is a lipid that is often used in vaccine adjuvants that increases IL-1α levels and activates the 5-lipoxygenase enzyme to produce LTB4. *P. acnes* also activate local ILCs and T cells to promote inflammation. These and other actions can stimulate whitehead and blackhead production, inflammation, and scarring.

Atopic dermatitis can result when the epidermal barrier function of the skin is continuously compromised to allow penetration of *Staphylococcus aureus* or other skin flora into the epidermis and dermis in which keratinocytes respond with IL-1, IL-8, IL-18, and chemokines; mast cells get activated and produce histamine; and macrophages are activated to trigger inflammation. Later, antigen-specific CD4 Th2 cells establish residence in the dermis, produce IL-4, and activate mast cells and inflammation. During the chronic phase of disease, CD4 Th17 and Th1 cells will arrive and activate neutrophils and macrophages, respectively, to exacerbate the inflammation.

CD, Cluster differentiation; *IL,* interleukin; *ILC,* innate lymphoid cell; *LTB4,* leukotriene B4; *TLR,* Toll-like receptor; *TNF,* tumor necrosis factor.

Innate inflammatory responses to bacteria are the primary cause of acne and atopic dermatitis (Box 8.5). *Propionibacterium acne* and the response to the bacteria lead to excess keratinocyte growth, sebum production, and inflammation to cause acne. A compromised skin barrier allows *S. aureus* entry into the epidermis and dermis in which inflammatory responses and a predilection toward allergies can cause chronic atopic dermatitis.

ACUTE-PHASE RESPONSE

The **acute-phase response** is triggered by infection, tissue injury, prostaglandin E_2, IFNs associated with viral infection, acute-phase cytokines (IL-1, IL-6, and TNF-α), and inflammation (Box 8.6). The acute-phase response promotes changes that support host defenses and include fever, anorexia, sleepiness, metabolic changes, and production of proteins. Acute-phase proteins that are produced and released into the serum include C-reactive protein, complement components, coagulation proteins, LPS-binding proteins, transport proteins, protease inhibitors, and adherence proteins. **C-reactive protein** binds to the polysaccharides of numerous bacteria and fungi and activates the complement pathway, facilitating removal of these organisms from the body by enhancing phagocytosis. **Hepcidin** inhibits iron uptake by the gut and macrophages, and this reduces availability to microbes. The acute-phase proteins reinforce the innate defenses against infection, but their excessive production during sepsis (induced by endotoxin or bacteremia) can cause serious problems such as shock.

BOX 8.6 Acute-Phase Proteins

α_1-Antitrypsin
α_1-Glycoprotein
Amyloids A and P
Antithrombin III
C-reactive protein
C1 esterase inhibitor
Complement C2, C3, C4, C5, C9
Ceruloplasmin
Fibrinogen
Haptoglobin
Orosomucoid
Plasminogen
Transferrin
Lipopolysaccharide-binding protein
Mannose-binding protein

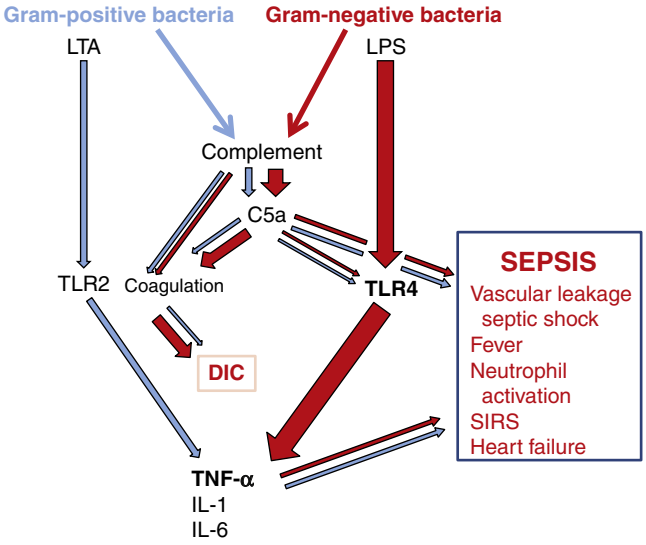

Fig. 8.9 Gram-positive and gram-negative bacteria induce sepsis by shared and separate pathways. Lipopolysaccharides *(LPSs)* activate complement, producing C5a, which promotes inflammation and activates coagulation. LPS, lipoteichoic acid *(LTA),* and other pathogen-associated molecular patterns (PAMPs) interact with Toll-like receptors *(TLRs)* and other PAMP receptors to activate inflammation and proinflammatory cytokine production. These can add up to cause sepsis. The thickness of the arrow indicates the strength of the response. Red is for gram-negative bacteria and blue is for gram-positive bacteria. *DIC,* Disseminated intravascular coagulation; *IL,* interleukin; *SIRS,* systemic inflammatory response syndrome; *TNF-α,* tumor necrosis factor-α. (Modified from Rittirsch, D., Flierl, M.A., Ward, P.A. 2008. Harmful molecular mechanisms in sepsis. Nat. Rev. Immunol. 8, 776–787.)

SEPSIS AND CYTOKINE STORMS

Cytokine storms are generated by an overwhelming release of cytokines in response to bacterial cell wall components, toxic shock toxins, and certain viral infections. Strong innate responses are triggered by the presence of microbes in the blood during bacteremia and viremia. During bacteremia, large amounts of complement C5a and cytokines are produced and distributed throughout the body (Fig. 8.9). C5a and TNF-α promote vascular leakage, neutrophil activation, and activation of the coagulation pathway. **Endotoxin** from LPS or LOS is an especially potent activator of cells and

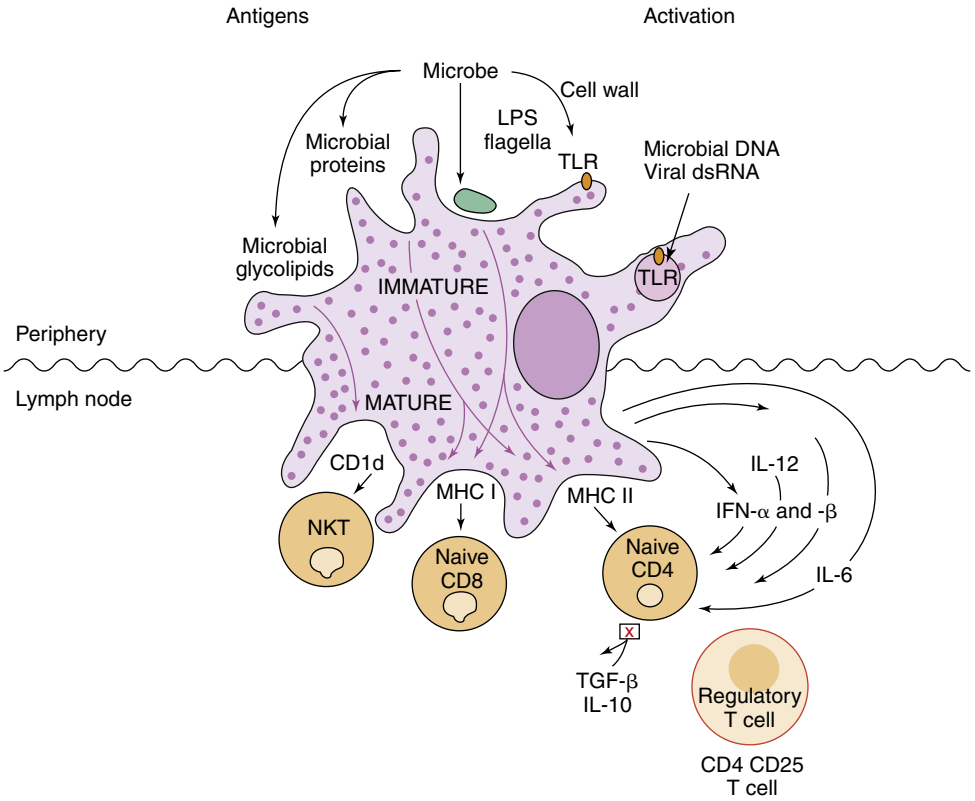

Fig. 8.10 Dendritic cells (DCs) initiate and direct immune responses. Immature DCs constantly internalize and process proteins, debris, and microbes. Binding of microbial components to Toll-like receptors *(TLRs)* activates the maturation of the DC so that it ceases to internalize any new material; moves to the lymph node and upregulates major histocompatibility complex *(MHC)* II for antigen presentation; coreceptors B7 and B7-1 and cytokines to activate T cells. The cell-surface interactions and cytokines activate the T cells and direct the nature of the subsequent response. *IFN,* Interferon; *LPS,* lipopolysaccharide.

inducer of cytokine production and sepsis (see Fig. 14.4). During viremia, large amounts of IFN-α and other cytokines are produced by plasmacytoid DCs and T cells. Plasmacytoid DCs respond to viral and bacterial PAMPs, especially DNA and RNA.

Cytokine storms can also occur following the abnormal stimulation of T cells and antigen-presenting cells (DCs, macrophages, and B cells) by superantigens produced by *S. aureus* or *S. pyogenes* (see Fig. 14.3).

Although beneficial on a limited and local basis, excess cytokines in the blood induce life-threatening inflammatory trauma throughout the entire body. Most significantly, increases in vascular permeability can result in leakage of fluids from the bloodstream into tissue and cause shock. **Septic shock** is a consequence of a cytokine storm and can be attributed to the systemic action of large quantities of C5a and TNF-α.

Bridge to Antigen-Specific Immune Responses

The innate response is often sufficient to control an infection, but it also initiates antigen-specific immunity. DCs (and Langerhans cells if in the skin) provide the bridge between the innate and immune responses. They become activated at the site of infection, deliver and process antigenic proteins to the T cells in the draining lymph node, and make appropriate cytokines to elicit the necessary T-cell response (Fig. 8.10; Animation 4).

DCs and Langerhans cells in the skin are constantly acquiring antigenic material by macropinocytosis, pinocytosis, or phagocytosis of apoptotic cells; debris; and proteins in normal tissue and at the site of infection or tumor. On activation by a combination of damage and pathogen-associated signals, acute-phase cytokines (IL-1, IL-6, and TNF-α) are released and the DC matures and its role changes. The DC loses its ability to phagocytize, preventing it from acquiring irrelevant antigenic material other than the ingested microbial debris, and it progresses to the lymph node. *By analogy, the DC is like a clam, constantly surveying its environment by filter feeding the cellular and microbial debris (if present), but when triggered by a PAMPR signal, indicating that microbes are present, it releases a local cytokine alarm, closes its shell, and moves to the lymph node to trigger a response to the challenge. Having experienced the challenge, the DC directs the appropriate response in the T cells.* The mature DC moves to T-cell areas of lymph nodes and upregulates its cell-surface molecules for optimal antigen presentation (class II MHC and B7-1 and B7-2 [co-stimulatory] molecules). Microbe-activated mature DCs release cytokines (e.g., IL-12, IL-23), which activate responses to reinforce local host defenses (TH1, TH17 responses). DCs present antigenic material attached to MHC class I and CD1 molecules to CD8 T cells and NKT cells, and on MHC class II molecules to CD4 T cells. DCs are so effective at presenting antigen that 10 DCs loaded

with antigen are sufficient to initiate protective immunity to a lethal bacterial challenge in a mouse. The subsequent T-cell responses will be described in the next chapter.

Questions

1. What are the innate soluble factors that act on microbial infections, and what are their functions?

2. What are the contributions of neutrophils, M1 and M2 macrophages, Langerhans cells, and DCs to antimicrobial responses?

3. A 65-year-old woman has fever and chills. A gram-negative, oxidase-negative bacillus is isolated from her blood. What triggered her symptoms, and what is causing her symptoms?

4. A 45-year-old man has a boil on his hand. A gram-positive, catalase-positive, and coagulase-positive coccus was isolated from the pus of the lesion. What innate responses are active in this infection?

Animation 1 Pathways of complement activation.

Animation 4 Capture and presentation of protein antigens by dendritic cells.

9 Antigen-Specific Immune Responses

Animations for this chapter are available on StudentConsult.com.

Antigen-specific immune responses provided by T and B cells and antibody expand the host protections provided by innate responses. The antigen-specific immune system is a randomly generated, coordinately regulated, inducible, and activatable system that ignores self-proteins and cells but specifically responds to and protects against infection. When not working properly, the immune response can be unregulated, overstimulated, uncontrolled, reactive to self-proteins, unresponsive or poorly responsive to infections, and become the cause of pathogenesis and disease. Once specifically activated by exposure to a new antigen, the immune response rapidly expands in strength, cell number, and specificity. For proteins, immune memory develops to allow more rapid recall on rechallenge.

Antibody, surface antibody and the antibody-like **T-cell receptor (TCR)** molecules recognize antigens and act as receptors to activate the growth and functions of those cells that can elicit the antigen-specific response. The soluble forms of antibody in the blood, body fluids, or secreted across membranes protect the body by inactivating and promoting the elimination of toxins and microbes, especially when they are in the blood (bacteremia, viremia). T cells are important for activating and regulating innate and immune responses and for direct killing of cells expressing inappropriate intracellular proteins (e.g., virus infections).

Although some molecules elicit only a limited antibody response (carbohydrates and lipids), proteins and protein-conjugated molecules (including carbohydrates) elicit a more complete immune response that includes T cells. Activation of a complete immune response must be closely regulated because it uses a large amount of energy and, once initiated, it develops memory and remains for most of a lifetime.

Development of an antigen-specific immune response progresses from the innate responses through ***d***endritic cells (DCs), which ***d***irect the ***T*** cells to ***t***ell other T cells, B cells, and other cells to grow and perform the necessary responses. Cell-receptor and cytokine-receptor interactions provide the necessary signals to activate cell growth and respond to the challenge. ***T*** cells ***t***ell the B cell which type of antibody to produce (immunoglobulin [Ig]G, IgE, IgA) and promote memory cell development. T cells continuously regulate the entire system, maintaining a balance that normally minimizes inflammation but still allows protection from normal and pathogenic microbes.

Immunogens, Antigens, and Epitopes

Almost all proteins and carbohydrates associated with an infectious agent, whether a bacterium, fungus, virus, or parasite, are considered foreign to the human host and have the potential to induce an immune response. A protein or carbohydrate that is recognized and sufficient to initiate an immune response is called an **immunogen** (Box 9.1). Immunogens may contain more than one antigen (e.g., bacteria). An **antigen** is a molecule that is recognized by specific antibodies or the TCR on T cells. An **epitope (antigenic determinant)** is the actual molecular structure that interacts with a single antibody molecule or TCR. Within a protein, an epitope may be formed by a specific sequence **(linear epitope)** or a three-dimensional structure **(conformational epitope).** *The TCR can recognize only linear peptide epitopes*. Antigens and immunogens usually contain several epitopes, each capable of binding to a different antibody molecule or TCR. As described later in this chapter, a **monoclonal antibody** recognizes a single epitope.

Not all molecules are immunogens. In general, *proteins are the best immunogens, carbohydrates are weaker immunogens, and lipids and nucleic acids are poor immunogens*. **Haptens (incomplete immunogens)** can be small molecules and too small to immunize (i.e., initiate a response) an individual but can be recognized by antibody. Haptens can be made immunogenic by attachment to a **carrier molecule,** such as a protein. For example, conjugation of penicillin to serum albumin converts it to an immunogen.

During artificial immunization (e.g., vaccines), an adjuvant is often used to enhance the response to an antigen. **Adjuvants** usually prolong the presence of antigen in the tissue; promote uptake of the immunogen; or activate DCs, macrophages, and lymphocytes. Some adjuvants mimic the activators of innate responses (e.g., microbial ligands for Toll-like receptors) present in a natural immunization.

Some molecules may not elicit an immune response in an individual. The body develops **central immune tolerance** toward self-antigens and any foreign antigens that may be introduced to the fetus or neonate, before maturation of the immune system (Animation 2). Later in life, **peripheral tolerance** develops to other proteins to prevent uncontrolled or autoimmune responses. For example, our immune response is tolerant of our normal flora and the food we eat; alternatively, eating steak would induce an antimuscle reponse.

The type of immune response initiated by an immunogen depends on its molecular structure. A primitive but rapid

BOX 9.1 Definitions

Adjuvant: substance that promotes immune response to immunogen
Antigen: substance recognized by immune response
Carrier: protein modified by hapten to elicit response
Epitope: minimal molecular structure recognized by immune response
Hapten: incomplete immunogen that cannot initiate response but can be recognized by antibody
Immunogen: substance capable of eliciting an immune response
T-dependent antigens: antigens that must be presented to T and B cells for antibody production
T-independent antigens: antigens with large, repetitive structures (e.g., bacteria, flagellin, lipopolysaccharide, polysaccharide)

antibody response can be initiated toward *bacterial polysaccharides (capsule), peptidoglycan, or flagellin*. Termed **T-independent antigens,** these molecules have a large repetitive structure that is sufficient to bind many surface antibody molecules and activate B cells directly without the participation of T-cell help. In these cases, the response is limited to production of **IgM** antibody and plasma cells but memory cells are not generated and **anamnestic (booster) responses** cannot occur. The transition from an IgM response to an IgG, IgE, or IgA response results from a big change in the B cell and is equivalent to differentiation of the cell. This requires help provided by T-cell interactions and cytokines. Portions of the antigen (likely to be different) must be recognized by both the T and B cells. **T-dependent antigens** are proteins; they generate all five classes of immunoglobulins and can elicit memory and an anamnestic response.

The structure of the antigen, the amount of antigens, the route of administration, and other factors influence the type of immune response, including the types of antibody produced. For example, oral or nasal administration of a vaccine across mucosal membranes promotes production of a secretory form of **IgA** (sIgA), which would not be produced on intramuscular administration.

T Cells

The thymus is essential for T-cell production. Bone marrow cells mature into T cells and are selected in the thymus. T cells are distinguished by their surface proteins, which include (1) the **TCR;** (2) the CD4 and CD8 coreceptors; (3) CD3 and accessory proteins that promote recognition, regulation, and activation; (4) cytokine receptors; and (5) adhesion proteins. T cells can be distinguished by the type of T-cell antigen receptor, either consisting of **γ** and **δ** chains or **α** and **β** chains, and for most **α/β** T cells, the presence of CD4 or CD8 coreceptors. T cells can be further distinguished by their functions, expression of characteristic transcription factors, and the cytokines that they produce (Box 9.2).

CD4 T cells are considered helper cells because their primary role is to activate and control immune and inflammatory responses by specific cell-to-cell interactions and by releasing cytokines. Helper T cells interact with peptide antigens presented on class II major histocompatibility complex (MHC) molecules expressed on antigen-presenting cells (APCs) (DCs, macrophages, and B cells). The transcription factor and repertoire of cytokines secreted by a specific CD4 T cell in response to antigenic challenge defines the type of CD4 T cell. CD4 T cells also can kill target cells with their Fas ligand surface protein.

BOX 9.2 T Cells

γ/δ T Cells

γ/δ TCR reactive to microbial metabolites
Local responses: resident in blood and tissue
Quicker responses than **α/β** T cells
Provide early cytokine support to *anti**microbial*** responses

α/β T Cells

CD4: α/β TCR reactive with peptides on MHC II on antigen-presenting cell
Cytokines activate and direct immune response (TH1, TH2, TH17, etc.)
Also, cytotoxic through Fas–Fas ligand interactions
CD4 CD25 Treg and TR1 cells: control and limit expansion of immune response; promote tolerance and memory cell development
CD8: α/β TCR reactive with peptides presented on MHC I
Cytotoxic through perforin and granzymes and Fas–Fas ligand induction of apoptosis
Also, produce similar cytokines as CD4 cells
NKT cells: α/β TCR binds glycolipids (mycobacteria) on CD1d molecules
Kill tumor and viral-infected cells, similar to NK cells
Provide early cytokine support to antimicrobial responses
MAITcells: α/β TCR binds vitamin B_2 derivatives from bacteria on MR-1 molecules
Provides rapid response to normal flora and infection
Provide early cytokine support to antimicrobial responses

MHC, Major histocompatibility complex; *NKT,* natural killer T cell; *TCR,* T-cell receptor; *TH,* T helper (cell).

CD8 T cells are categorized as cytolytic T cells but can make cytokines similar to CD4 T cells. Activated CD8 T cells "patrol" the body for virus-infected or tumor cells, which are identified by antigenic peptides presented by class I MHC molecules. Class I MHC molecules are found on all nucleated cells.

Natural killer T cells (NKT), mucosal-associated invariant T cells (MAIT) and **γδ** T cells are part of the innate response (see Chapters 8 and 10).

Cell-Surface Receptors of T Cells

The **TCR complex** is a combination of the antigen recognition structure (TCR) and cell-activation machinery **(CD3)** (Fig. 9.1). T cells expressing the **γ/δ TCR** are present primarily in mucosal epithelium; other tissue locations and blood and are important for stimulating innate and mucosal immunity. These cells make up 5% of circulating lymphocytes but expand to between 20% and 60% of T cells during certain bacterial and other types of infections. The **γ/δ** TCR senses unusual microbial metabolites and initiates cytokine-mediated immune responses.

The **α/β TCR** is expressed on most T cells, and these cells are primarily responsible for antigen-activated immune responses. NKT cells and MAIT cells also express **α/β** TCRs but their TCRs have very defined specificities. Classical T cells with the **α/β** TCR are distinguished further by expression of either a CD4 or a CD8 molecule.

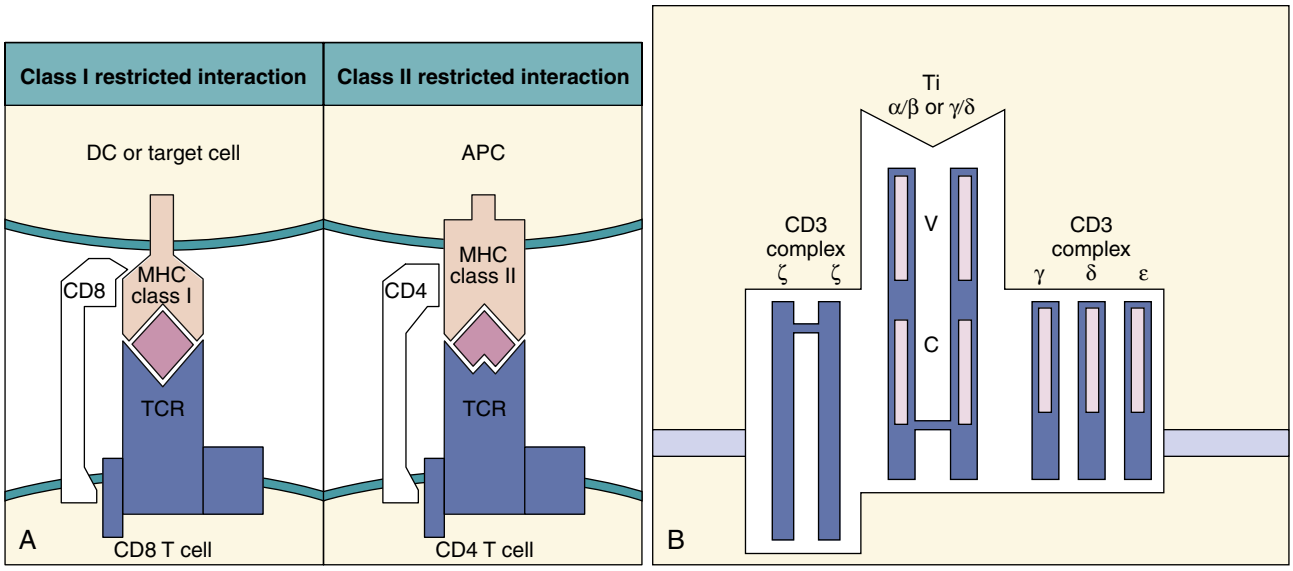

Fig. 9.1 Major histocompatibility complex *(MHC)* restriction and antigen presentation to T cells. (A) *Left*, Antigenic peptides bound to class I MHC molecules are presented to the T-cell receptor *(TCR)* on CD8 T-killer/suppressor cells. *Right*, Antigenic peptides bound to class II MHC molecules on the antigen-presenting cell *(APC)* (B cell, dendritic cell *[DC]*, or macrophage) are presented to CD4 T-helper cells. (B), T-cell receptor. The TCR consists of different subunits. Antigen recognition occurs through the **α/β** or **γ/δ** subunits. The CD3 complex of **γ**, **δ**, **ε**, and **ζ** subunits promotes T-cell activation. *C*, Constant region; *V*, variable region.

The specificity of the TCR determines the antigenic response of the T cell. Each TCR molecule is made up of two different polypeptide chains. As with antibody, each TCR chain has a constant region and a variable region. The repertoire of TCRs is very large and can identify an enormous number of antigenic specificities (estimated to be able to recognize 10^{15} separate epitopes). The genetic mechanisms for the development of this diversity are similar to those for antibody (Fig. 9.2). The TCR gene is made up of multiple V ($V_1V_2V_3 \ldots V_n$), D, and J segments. In the early stages of T-cell development, a particular V segment genetically recombines with one or more D segments, deleting intervening V and D segments, and then recombines with a J segment to form a unique TCR gene. Similar to antibody, random insertion of nucleotides at the recombination junctions increases the potential for diversity and the possibility of producing inactive TCRs. Unlike antibody, somatic mutation does not occur for TCR genes. Only cells with functional TCRs will survive their passage through the thymus. Each T cell and its progeny express a unique TCR.

Unlike antibody molecules, most TCRs can only recognize a linear peptide epitope held within a cleft on the surface of either the MHC I or MHC II molecules (see Fig. 9.1). Presentation of the antigenic peptide requires specialized proteolytic processing of the protein (see later) and presentation on MHC II molecules by an APC or on MHC I molecules by all nucleated cells.

The **CD3 complex** is found on all T cells and consists of the **γ**-, **δ**-, **ε**-, and **ζ**-polypeptide chains. The CD3 complex is the **signal transduction unit** for the TCR. **Tyrosine protein kinases** (ZAP-70, Lck) associate with the CD3 complex when antigen is bound to the TCR complex, promote a cascade of protein phosphorylations, activation of phospholipase C (PLC), and other events. The products of cleavage of inositol triphosphate by PLC cause the release of calcium and activate protein kinase C and **calcineurin,** which is a protein phosphatase. Calcineurin is a target for the immunosuppressive drugs cyclosporine and tacrolimus. Activation of membrane G-proteins, such as Ras, and the consequences of the previously described cascades result in the activation of specific transcription factors in the nucleus, activation of the T cell, and production of interleukin (IL)-2 and its receptor, IL-2R. These steps are depicted in Fig. 9.3.

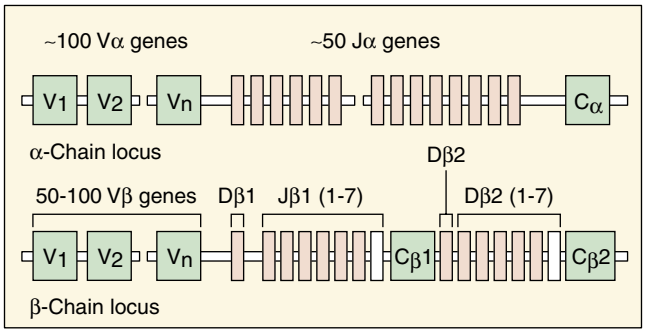

Fig. 9.2 Structure of the embryonic T-cell receptor gene. Note the similarity in structure to the immunoglobulin genes. Recombination of these segments also generates a diverse recognition repertoire. *C*, Connecting sequences; *J* and *D*, segments; *V*, variable segments.

The **CD4 and CD8 proteins** are coreceptors for the TCR (see Fig. 9.1) because they facilitate the interaction of the TCR with the antigen-presenting MHC molecule and can enhance the activation response. CD4 binds to class II MHC molecules on the surface of APCs. CD8 binds to class I MHC molecules on the surface of nucleated cells, including APCs (see more on MHC later in this chapter). The cytoplasmic tails of CD4 and CD8 associate with a protein tyrosine kinase (Lck), which enhances the TCR-induced activation of the cell on binding to the APC or target cell. CD4 or CD8 is found on **α/β** T cells but not on **γ/δ** T cells.

Accessory molecules expressed on the T-cell surface include several protein receptors that interact with their protein ligands on APCs and target cells leading to activation of the T cell, promotion of tighter interactions between

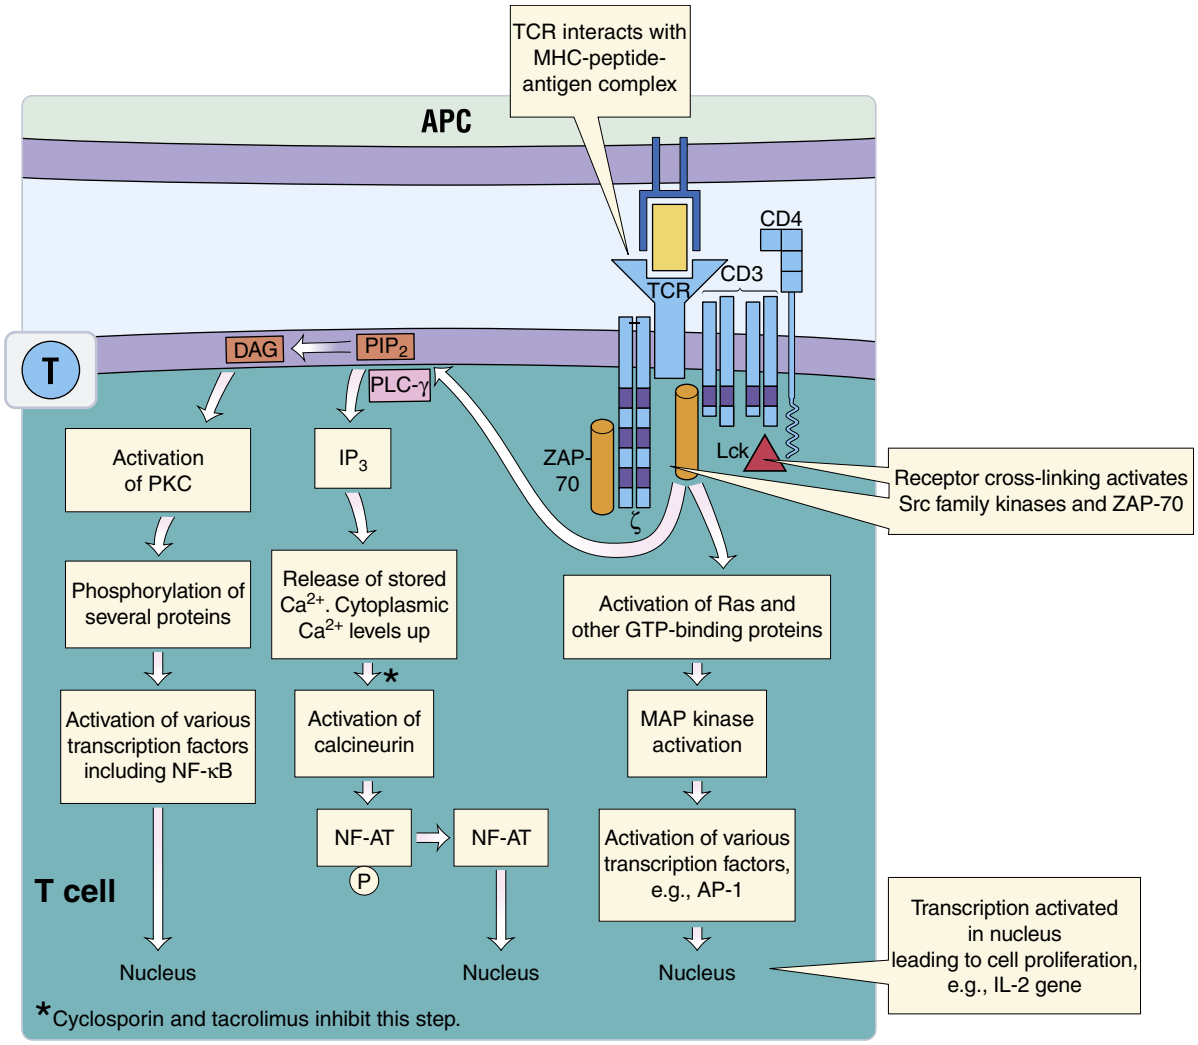

Fig. 9.3 Activation pathways for T cells. Binding of major histocompatibility complex *(MHC)* II-peptide to CD4 and the T-cell receptor *(TCR)* activate kinase cascades and phospholipase C to activate the nuclear factor of activated T cells *(NF-AT),* nuclear factor-kappa B *(NF-κβ),* activation protein 1 *(AP-1),* and other transcription factors. *APC,* Antigen-presenting cell; *DAG,* diacylglycerol; *GTP,* guanosine triphosphate; *IL-2,* interleukin-2; *IP_3,* inositol 1,4,5-triphosphate; *Lck,* lymphocyte-specific tyrosine protein kinase; *MAP kinase,* mitogen-activated protein kinase; *PIP_2,* phosphatidylinositol 4,5-bisphosphate; *PKC,* protein kinase C; *PLC-γ,* phospholipase C-γ; *ZAP,* ζ-associated protein. (Modified from Helbert, M. 2017. Immunology for Medical Students, third ed. Elsevier, Philadelphia, PA.)

the cells, or facilitation of the killing of the target cell. These accessory molecules are as follows:

1. **CD45RA (native T cells)** or **CD45RO (memory T cells):** a transmembrane protein tyrosine phosphatase (PTP).
2. **CD28:** cytotoxic T-lymphocyte–associated protein 4 **(CTLA-4), PD-1, and ICOS-1** (inducible T-cell co-stimulator) bind to proteins of the **B7** (B7-1, B7-2, PD-L1, PD-L2, L-ICOS) **check point regulator** family of proteins to deliver a co-stimulation or inhibitory signal to the T cell.
3. **CD154 (CD40L):** this is present on activated T cells and binds to CD40 on DCs, macrophages, and B cells to promote their activation.
4. **FasL:** this initiates apoptosis in a target cell that expresses **Fas** on its cell surface.

Adhesion molecules tighten the interaction of the T cell with the APC or target cell and also may promote activation. Adhesion molecules include **leukocyte function–associated antigen-1 (LFA-1),** which interacts with the **intercellular adhesion molecules (ICAM-1, ICAM-2, and ICAM-3)** on the target cell. **CD2** was originally identified by its ability to bind to sheep red blood cells and promote sheep red blood cell rosettes around T cells. CD2 binds to LFA-3 on the target cell and promotes cell-to-cell adhesion and T-cell activation. **Very late antigens (VLA-4 and VLA-5)** are expressed on activated cells later in the response and bind to fibronectin on target cells to enhance the interaction.

T cells express receptors for many cytokines that activate and regulate T-cell function (Table 9.1). Binding of the cytokine to the **cytokine receptor** activates protein kinase and other activation cascades that deliver their signal to the nucleus. **IL-2R** is composed of three subunits. The **β/γ** subunits are on most T cells (also natural killer [NK] cells) and have intermediate affinity for IL-2. The **α** subunit **(CD25)** is induced by cell activation to form a high-affinity **α/β/γ** IL-2R. Binding of IL-2 to the IL-2R initiates a growth-stimulating

TABLE 9.1 Inducers and Cytokines of T-Cell Responses

Type of Response	Acute Phase[a]	TH1	TH17	TH2	Treg/Sup
Inducers	PAMPs	IL-12	IL-6 + TGF-β	IL-6	??
	—	—	IL-23[b]	—	—
Mediators	IL-1 TNF-α IL-6	IL-2 LT (TNF-β) IFN-γ	IL-17 TNF-α IL-22	IL-4 IL-5 IL-10	IL-10 TGF-β —
	IFN-α, IFN-β	—	—	—	—
	IL-12, IL-23	—	—	—	—

[a]Acute-phase responses influence but are not T-cell responses.
[b]IL-23 activates memory TH17 responses.
IFN, Interferon; *IL,* interleukin; *LT,* lymphotoxin; *PAMPs,* pathogen-associated molecular patterns; *TGF-β,* transforming growth factor-β; *TH,* T helper (cell).

signal to the T cell, which also promotes the production of more IL-2 and IL-2R. CD25 is expressed on activated, growing cells, including the T regulator cells (Treg) subset of CD4 T cells ($CD4^+CD25^+$). **Chemokine receptors** distinguish the different T cells and guide the cell to where it will reside in the body.

Development of T Cells

T-cell precursors are continuously developing into T cells in the thymus (Fig. 9.4; Animation 3). Contact with the thymic epithelium and hormones such as thymosin, thymulin, and thymopoietin II in the thymus promote extensive proliferation and differentiation of the individual's T-cell population during fetal development. Individuals who congenitally lack a thymus (DiGeorge syndrome) lack T cells. While in the thymus, each T cell precursor, undergoes recombination of sequences within its TCR genes to generate a TCR unique to that cell. The thymic medullary epithelial cells express the autoimmune regulator (AIRE) transcription factor, which gives them the unique capacity to express most of the body's proteins. These proteins are processed and presented on MHC molecules to the TCR on the T cells. Strong binding promotes either apoptosis or the expression of the transcription factor FoxP3 and development of **Tregs**. T cells without TCRs, bearing nonfunctional TCRs, or those with TCRs that cannot, or interact poorly with MHC molecules, are forced into committing suicide (apoptosis). Only the cells that bind just right (Goldilocks levels) will differentiate into the CD4 or CD8 subpopulations of T cells. These T cells then enter the blood and travel to lymph nodes, spleen, and other sites.

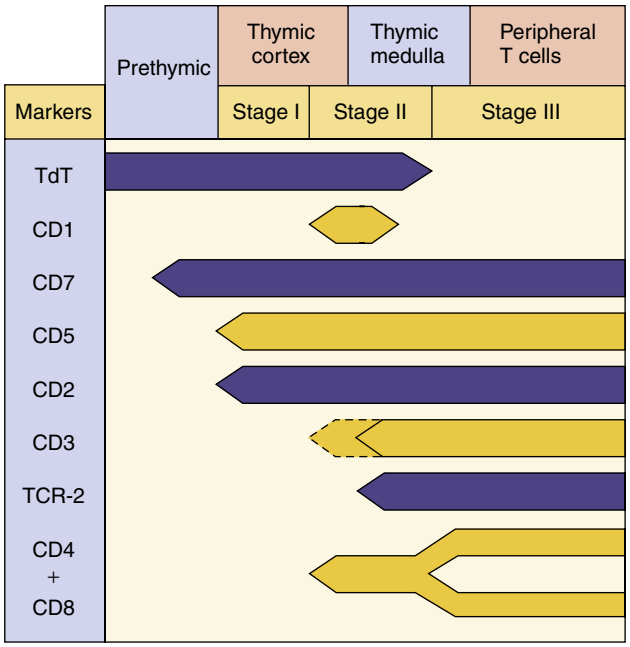

Fig. 9.4 Human T-cell development. T-cell markers are useful for the identification of the differentiation stages of the T cell and for characterizing T-cell leukemias and lymphomas. *TCR,* T-cell receptor; *TdT,* cytoplasmic terminal deoxynucleotidyl transferase.

BOX 9.3 Activation of T-Cell Responses

Only a DC can initiate a response from a naive CD4 or CD8 T cell.

CD4

Antigen-presenting cells present 11 to 13 amino acid peptides on MHC II.
Coreceptor (B7.1 or B7.2) interacts with CD28 to activate or CTLA4 to suppress response.
Cytokines activate and determine the nature of the response.
CD40L expression and binding to CD40 on APC is necessary for APC activation.
Activation of cell changes chemokine receptors and adhesion proteins, and it enters blood and cycles through skin, tissue, and B-cell zones of lymph node.

CD8

DC activates CD8 T cell with help from CD4 T cell.
CD8 T cell enters blood and cycles through skin and tissue.
Target cell presents 8 to 9 amino acid peptides on MHC I.
Adhesion proteins create immune synapse.
Perforin and granzyme are secreted into immune synapse.
Target cell commits apoptosis.

APC, Antigen-presenting cell; *CTLA4,* cytotoxic T-lymphocyte–associated protein 4; *DC,* dendritic cell; *MHC,* major histocompatability complex.

Initiation of T-Cell Responses

ANTIGEN PRESENTATION TO T CELLS

Activation of an antigen-specific T-cell response requires a combination of cytokine and cell-to-cell receptor interactions (Box 9.3) initiated by the interaction of the **α/β** TCR with MHC-bearing antigenic peptides. **Class I** and **II MHC** molecules provide a molecular cradle for the peptide. As such, these T cells only respond to protein epitopes. The **CD8** molecule on T cells binds to and promotes the interaction with class I MHC molecules on target cells (see Fig. 9.1A). The **CD4** molecule on T cells binds to and promotes interactions with class II MHC molecules on APCs. The MHC molecules are encoded within the MHC gene locus (Fig. 9.5). The MHC contains a cluster of genes important to the immune response.

Class I MHC molecules are found on all nucleated cells and are the major determinant of "self." The class I

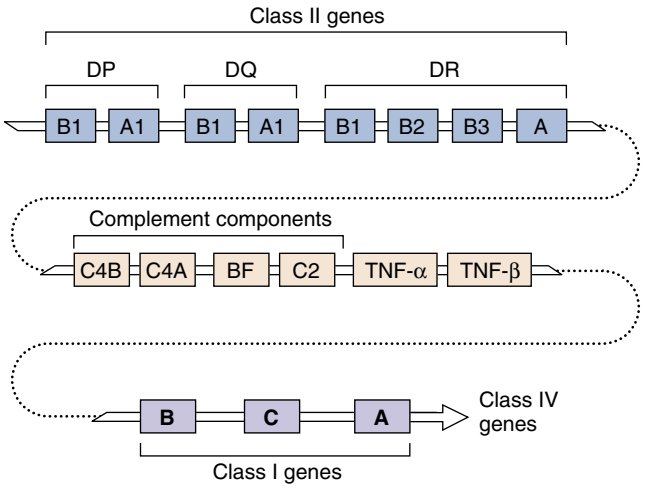

Fig. 9.5 Genetic map of the major histocompatibility complex (MHC). Genes for class I and class II molecules, as well as complement components and tumor necrosis factor *(TNF),* are within the MHC gene complex.

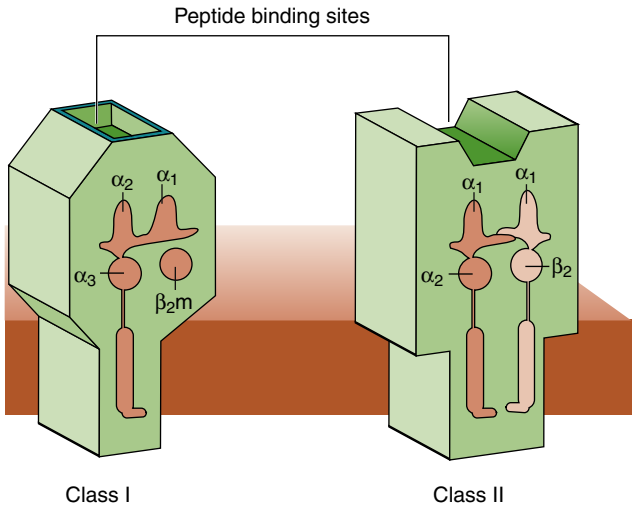

Fig. 9.6 Structure of class I and class II major histocompatibility complex (MHC) molecules. The class I MHC molecules consist of two subunits, the heavy chain, and β_2-microglobulin. The binding pocket is closed at each end and can only hold peptides of 8 to 9 amino acids. Class II MHC molecules consist of two subunits, **α** and **β**, are open at the ends, and hold peptides of 11 or more amino acids.

MHC molecule, also known as **HLA** for human and H-2 for mouse, consists of two chains, a **variable heavy chain** and a **light chain (β_2-microglobulin)** (Fig. 9.6). Differences in the heavy chain of the HLA molecule between individuals *(allotypic differences)* are responsible for the T-cell response that prevents graft (tissue) transplantation. There are three major HLA genes **(HLA-A, HLA-B,** and **HLA-C)** and other minor HLA genes. Each cell expresses a pair of different HLA-A, HLA-B, and HLA-C proteins, one from each parent, providing six different clefts to capture a repertoire of antigenic peptides. *The heavy chain of the class I MHC molecule forms a closed-ended cleft, similar to a pita bread pocket, which holds a peptide of eight to nine amino acids.* The class I MHC molecule presents antigenic peptides, most of which are from within the cell **(endogenous)**, to CD8-expressing T cells. Upregulation of class I MHC molecules makes the cell a better target for T-cell action. Some cells (brain) and some virus infections (herpes simplex virus, cytomegalovirus) downregulate the expression of MHC I molecules to reduce their potential as targets for T cells.

Class II MHC molecules are normally expressed on APCs, which are the cells that interact with CD4 T cells (e.g., macrophages, DCs, B cells). The class II MHC molecules are encoded by the **DP, DQ**, and **DR** loci and, similar to MHC I, also are co-dominantly expressed to produce six different molecules. The class II MHC molecules are a dimer of **α and β subunits** (see Fig. 9.6). *The chains of the class II MHC molecule form an open-ended peptide-binding cleft that resembles a hotdog bun and holds a peptide of 11 to 12 amino acids.* The class II MHC molecule presents ingested **(exogenous)** antigenic peptides to CD4-expressing T cells.

CD1 molecules resemble MHC I molecules and have a heavy chain and a light chain (β_2-microglobulin) but bind glycolipids instead of peptides. CD1 molecules are primarily expressed on DCs and present antigen to a specialized invariant TCR on NKT ($CD4^-CD8^-$) cells. CD1 molecules are especially important for defense against mycobacterial infections.

MR1 molecules also resemble MHC I molecules and have a heavy chain and a light chain (β_2-microglobulin) and bind vitamin B metabolites produced by bacteria. Specialized invariant TCRs for MR1 are present on MAIT cells. MAIT cells are important for regulating the normal flora of the intestines and provide an early response to infections.

PEPTIDE PRESENTATION BY CLASS I AND CLASS II MAJOR HISTOCOMPATABILITY COMPLEX MOLECULES

Unlike antibodies that also can recognize conformational epitopes, T-cell antigenic peptides must be linear epitopes. A T-cell antigen must be a peptide of 8 to 12 amino acids with a hydrophobic backbone that binds to the base of the molecular cleft of the class I or class II MHC molecule and displays a T-cell epitope on the other side to the TCR. Because of these constraints, there may be only one T-cell antigenic peptide in a protein. All nucleated cells proteolytically process intracellular proteins and display selected peptides to CD8 T cells **(endogenous route of antigen presentation)** to distinguish self, "nonself," inappropriate protein expression (tumor cell), or the presence of intracellular infections (virus), whereas APCs process and present peptides from ingested proteins to CD4 T cells **(exogenous route of antigen presentation)** (see Fig. 9.7; Animation 4). DCs can cross these routes **(cross-presentation)** to present exogenous antigen to CD8 T cells to initiate antiviral and antitumor responses.

Class I MHC molecules bind and present peptides that are degraded from cellular proteins by the **proteasome** (a protease machine) in the cytoplasm. These peptides are shuttled into the endoplasmic reticulum (ER) through the **transporter associated with antigen processing (TAP).** Most of these peptides come from misfolded or excess proteins (trash) marked for proteolysis by attachment of the **ubiquitin** protein. The antigenic peptide binds to the groove in the heavy chain of the class I MHC molecule. Then the MHC heavy chain can assemble properly with β_2-microglobulin, exit the ER, and proceed to the cell membrane.

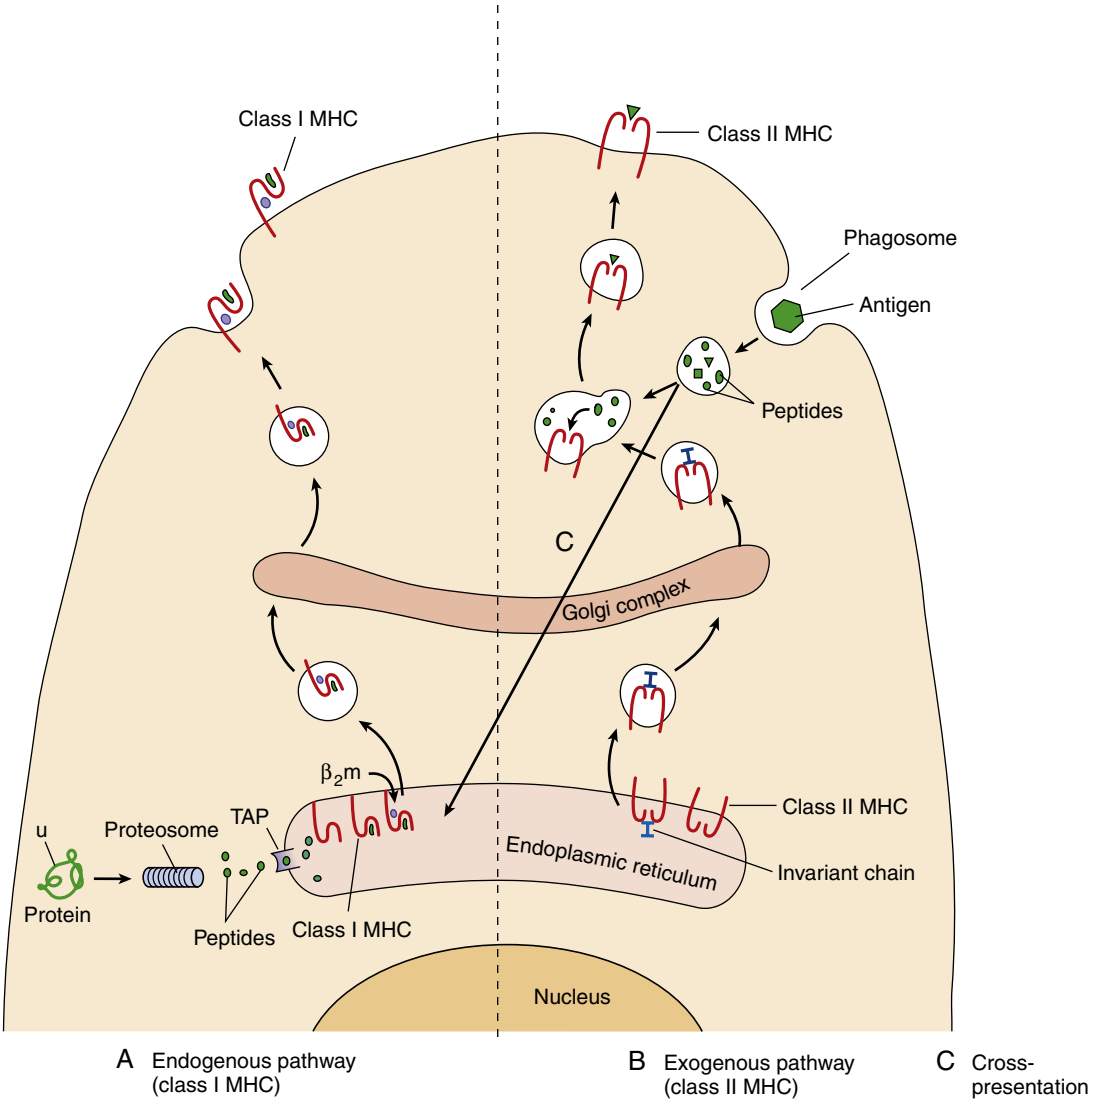

Fig. 9.7 Antigen presentation. (A) **Endogenous:** Endogenous antigen (produced by the cell and analogous to cell trash) is targeted by attachment of ubiquitin *(u)* for digestion in the proteasome. Peptides of eight to nine amino acids are transported through the transporter associated with antigen processing *(TAP)* into the endoplasmic reticulum (ER). The peptide binds to a groove in the heavy chain of the class I major histocompatibility complex *(MHC)* molecule, and the β_2-microglobulin *(β_2m)* binds to the heavy chain. The complex is processed through the Golgi apparatus and delivered to the cell surface for presentation to CD8 T cells. (B) **Exogenous:** Class II MHC molecules assemble in the ER with an invariant chain protein to prevent acquisition of a peptide in the ER. They are transported in a vesicle through the Golgi apparatus. Exogenous antigen (phagocytosed) is degraded in lysosomes, which then fuse with a vesicle containing the class II MHC molecules. The invariant chain is degraded and displaced by peptides of 11 to 13 amino acids, which bind to the class II MHC molecule. The complex is then delivered to the cell surface for presentation to CD4 T cells. (C) **Cross-presentation:** Exogenous antigenic peptides transit from the phagosome to the ER of dendritic cells and is presented on MHC I molecules to CD8 T cells.

During a **viral infection,** large quantities of viral proteins are produced and degraded into peptides and become the predominant source of peptides occupying the class I MHC molecules to be presented to CD8 T cells. **Transplanted cells (grafts)** express peptides on their MHC molecules, which differ from those of the host and therefore may be recognized as foreign. **Tumor cells** often express peptides derived from abnormal or embryonic proteins, which may elicit responses in the adult because the adult was not tolerized to these proteins. *Expression of these "foreign" peptides on MHC I at the cell surface allows the T cell to "see" what is going on within the cell.*

Class II MHC molecules present peptides from exogenous proteins that were acquired by macropinocytosis, pinocytosis, or phagocytosis and then degraded in lysosomes by APCs. The class II MHC protein also is synthesized in the ER, but unlike MHC I, the invariant chain associates with MHC II to block the peptide-binding cleft and prevent acquisition of a peptide. MHC II acquires its antigenic peptide as a result of a merging of the vesicular transport pathway (carrying newly synthesized class II MHC molecules) and the lysosomal degradation pathway (carrying phagocytosed and proteolyzed proteins). The invariant chain is cleaved and antigenic peptides displace it and associate with the cleft formed in the class II MHC protein; the complex is then delivered to the cell surface.

Cross-presentation of antigen is used mostly by DCs to present antigen to naive CD8 T cells to initiate the response to viruses and tumor cells. After picking up antigen (including debris from apoptotic cells) in the periphery, the protein is degraded in lysosomes, and its peptides enter

the cytoplasm and are then shuttled through the TAP into the ER to bind to MHC I molecules.

The following analogy might aid in the understanding of antigen presentation: All cells degrade their protein "trash" and then display it on the cell surface on class I MHC trash cans. CD8 T cells "policing" the neighborhood are not alarmed by the normal, everyday peptide trash. A viral intruder would produce large amounts of viral peptide trash (e.g., beer cans, pizza boxes) displayed on class I MHC molecular garbage cans, which would alert specific CD8 T cells that were previously activated by DCs. APCs (DCs, macrophages, and B cells) are similar to garbage collectors or sewage workers; they gobble up the neighborhood trash or lymphatic sewage, degrade it, display it on class II MHC molecules, and then move to a lymph node to present the antigenic peptides to the CD4 T cells in the "police station." Foreign antigens would alert the CD4 T cells to release cytokines and activate an immune response.

Activation of CD4 T Cells and Their Response to Antigen

Activation of naive T-cell responses is initiated by DCs and then expanded by other APCs (Animation 5). Activated DCs have octopus-like arms with large surface area (dendrites), produce cytokines, and have an MHC-rich cell surface to present antigen to T cells. Macrophages and B cells can present antigen to T cells but cannot activate a naive T cell to initiate a new immune response. CD4 helper T cells require at least two signals to become activated. The first signal is provided by interaction of the TCR with antigenic peptide presented by class II MHC molecules on the APC (Fig. 9.8A). The interaction is strengthened by the binding of CD4 to the class II MHC molecule and the linkage of adhesion proteins on the T cell and the APC. The second signal, a **co-stimulatory or checkpoint signal,** is mediated by binding of B7 molecules on the macrophage, DC, or B-cell APC to **CD28** molecules on the T cell and is a fail-safe mechanism to ensure legitimate activation. B7 also interacts with **CTLA4**, which delivers an inhibitory signal. Activated APCs express sufficient B7 to fill up all the CTLA4 and then bind to the CD28 to provide the "go" signal. Cytokine signals (e.g., IL-1, IL-2, IL-6) also are required to initiate growth and overcome regulatory suppression of the cell. Proper activation of the helper T cell promotes production of IL-2 and increases expression of IL-2Rs on the cell surface, enhancing the cell's own ability to bind and maintain activation by IL-2 (Fig. 9.9). Once activated, the IL-2 sustains the growth of the cell, and other cytokines influence the subsequent helper T-cell response (see the following section). Effector and **memory T cells** are generated as the T cells divide (see Fig. 9.9B).

Partial activation of a CD4 T cell occurs when the TCR interacts with the peptide:MHC complex without co-stimulation from CD28 and leads to **anergy** (unresponsiveness) or apoptotic death (cell suicide). This is also a mechanism for (1) eliminating self-reactive T cells in the thymus and (2) promoting the development of **tolerance** to self-proteins.

The activated, growing CD4 T cells express different adhesion proteins and new chemokine receptors, exit the T-cell sites of the lymph node, and enter the blood or move to B-cell zones of the lymph nodes and spleen. Many of the activated T cells cycle through the skin and mucoepithelium. APCs that present antigen recognized by the TCR initiate close interactions between the T cell that allow the CD28 molecules on the T cell to bind B7 molecules on the APC. These interactions then stimulate the expression of CD40L on the T cell, which interacts with the CD40 molecule on the APC, resulting in mutual activation of the T cell and the APC (see Fig. 9.8B). This interaction and the cytokines produced by the T cell will activate and determine the function of the macrophages and DCs and which immunoglobulin the B cell will produce.

CD4 T-HELPER CELL FUNCTIONS

The CD4 T cells promote expansion of the immune response with cell growth–promoting cytokines and define the nature of the immune response with other cytokines. The different types of T-helper cells are defined by characteristic transcription factors and the cytokines they produce and thus the responses they induce (Fig. 9.10 and Box 9.4; also see Table 9.1).

TH0 cells are uncommitted to a specific response and their activation initiates a generic response by producing cytokines that promote lymphocyte growth and activate DCs, including IL-2, interferon (IFN)-**γ**, and IL-4. **IL-2** promotes T, B, and innate lymphoid (including NK cells) cell growth to expand the immune response.

Initial antibacterial and antifungal responses are mediated by the **TH17** cells. These are CD4 T-helper cells stimulated by IL-6 plus transforming growth factor (TGF)-**β** or, for memory T cells, IL23. IL-23 is in the IL-12 family of cytokines. IL-23 and IL-12 both have a p40 subunit, but IL-12 has a p35, whereas IL-23 has a p19 subunit. TH17 cells express the RORγt transcription factor and make cytokines (e.g., **IL-17**, **IL-22**, IL-6, tumor necrosis factor [TNF]-**α**) and proinflammatory chemokines, which activate epithelial cells and neutrophils and promote inflammatory responses. TH17 responses provide protection in immunoprivileged sites such as the eye, in which there is an abundance of TGF-**β**. TH17 responses are associated with the keratinocyte growth in psoriasis and cell-mediated autoimmune inflammatory diseases such as rheumatoid arthritis.

The **TH1 response** activates both cellular and antibody responses (Animation 6). Activation of **TH1** responses requires **IL-12** produced by DCs and macrophages. TH1 cells are characterized by expression of the T-bet transcription factor and secretion of **IL-2, IFN-γ,** and **TNF-β (lymphotoxin [LT])**. **IFN-γ,** also known as **macrophage activation factor,** reinforces TH1 responses by promoting more IL-12 production by macrophages and DCs, creating a self-sustaining cycle. IFN-**γ** also promotes production of IgG and inhibits TH2 responses. **TNF-β** can activate neutrophils. TH1 cells are inhibited by IL-4 and IL-10, which is produced by TH2 cells. Activated TH1 cells express the **FasL** ligand, which can interact with the **Fas** protein on target cells to promote apoptosis (killing) of the target cell, and the **CCR5 chemokine receptor** that promotes relocation to sites of infection. Human immunodeficiency virus (HIV) uses the CCR5 chemokine receptor as a coreceptor with CD4 to initiate infection of an individual.

The TH1 responses amplify local inflammatory reactions and delayed-type hypersensitivity (DTH) reactions by

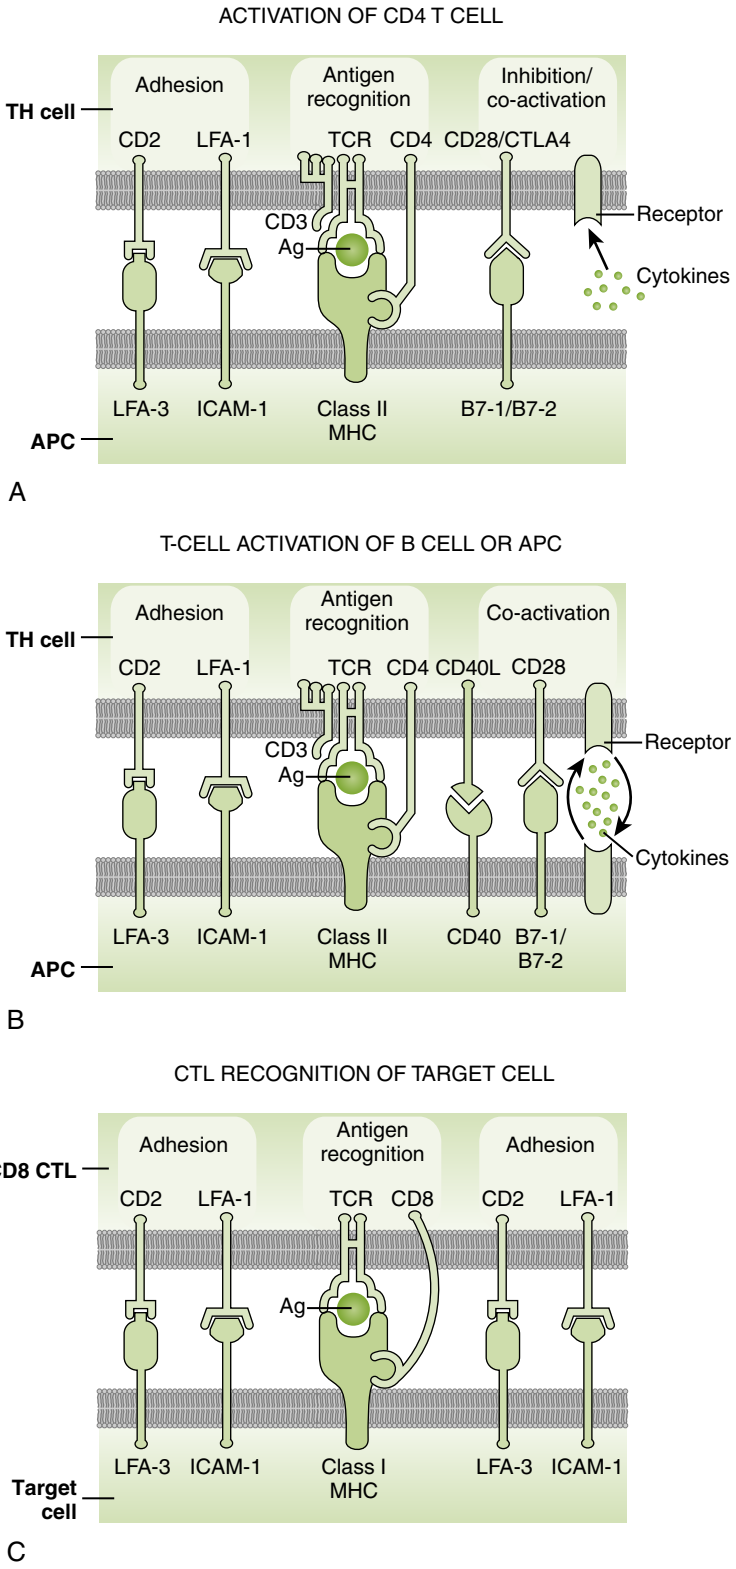

Fig. 9.8 Molecules involved in the interaction between T cells and antigen-presenting cells *(APCs).* (A) Initiation of a T-cell response. CD4 T cells interact with major histocompatibility complex *(MHC)* II and its peptide and co-stimulatory/inhibitory ligands on dendritic cells (DCs). Initiation of a CD8 T-cell response is similar, but CD8 and the T-cell receptor *(TCR)* interact with peptide MHC I and the peptide it holds. (B) CD4 T-cell helper activation of a B cell, DC, or macrophage. CD40L–CD40 interaction activates the APC. (C) CD8 T-cell binding to target cell creates an immunosynapse into which perforin and granzymes are secreted. Cell-surface receptor-ligand interactions and cytokines are indicated with the direction of their action. *Ag,* Antigen; *APC,* antigen-presenting cell; *CTLA4,* cytotoxic T lymphocyte A4; *ICAM-1,* intercellular adhesion molecule-1; *LFA-1,* leukocyte function–associated antigen-1 TH, T helper. (From Rosenthal, K.S., Tan, M., 2010. Rapid Reviews in Microbiology and Immunology, third ed. Elsevier, Philadelphia, PA.)

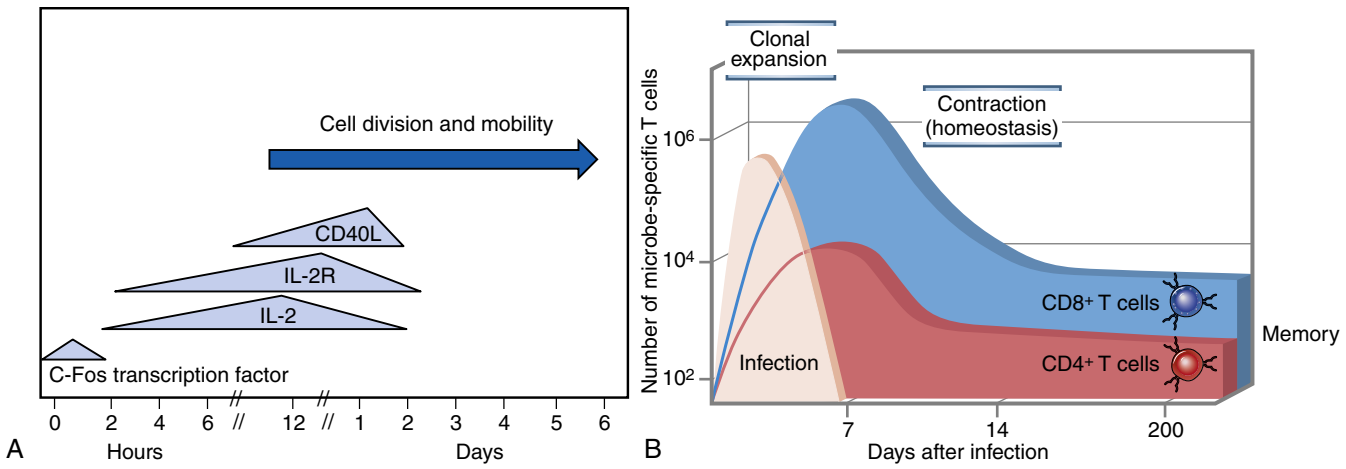

Fig. 9.9 Progression of naive T-cell activation and response. (A) Interaction with antigen and coreceptors from the antigen-presenting cell (APC) activates expression of new transcription factors *(c-Fos)*, interleukin *(IL)*-2, and the IL-2R to promote growth and CD40L to activate the APC. (B) CD4 or CD8 T-cell numbers rise rapidly in response to infection, after which the activated effector T cells will apoptose, leaving memory T cells. Subsequent activation of memory T-cell responses is quicker. (B, Modified from Abbas, A.K., Lichtman, A.H., Pillai, S., et al., 2015. Cellular and Molecular Immunology, eighth ed. Elsevier, Philadelphia, PA.)

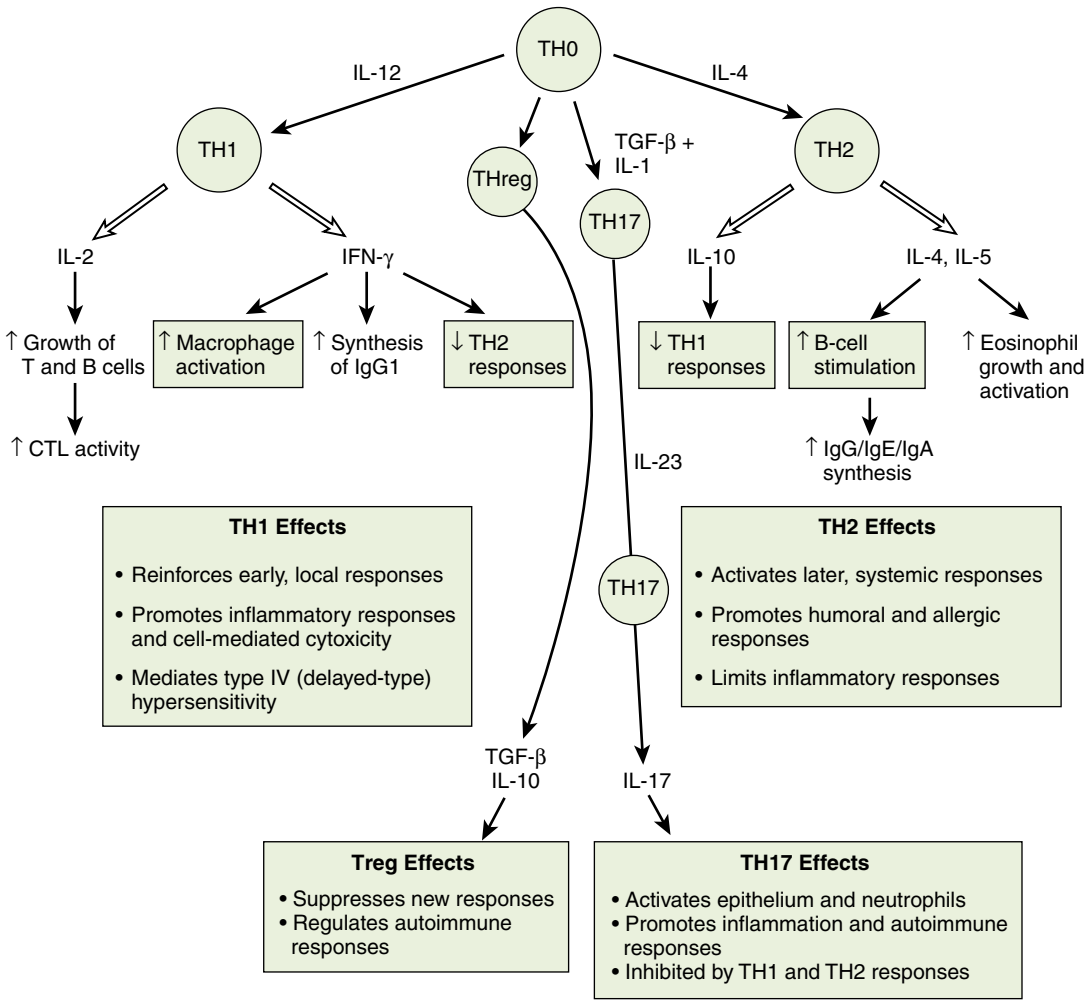

Fig. 9.10 T-cell responses are determined by cytokines. Dendritic cells initiate and determine the type of CD4 T-cell responses by the cytokines they produce. Similarly, T cells use other cytokines to tell other cells what to do. The response-defining cytokines are indicated. ↑, Increase; ↓, decrease; *CTL,* cytotoxic T lymphocyte; *IFN-γ,* interferon-γ; *IgG/IgE/IgA,* immunoglobulin G/E/A; *IL,* interleukin; *TGF-β,* transforming growth factor-β; *TH,* T helper (cell); Treg, T regulator cells. BOX 9.4 T-Helper Responses and Their Cytokines

Activated TH cells express CD40L to activate B cells, macrophages, and DCs.
TH cells produce growth-stimulating and response-defining cytokines.
Growth-stimulating cytokines: GM-CSF, IL-3
TH1: requires induction with IL-12, T-bet transcription factor
- *IFN-γ:* activates CD8 T cells, M1 (inflammatory) macrophages; promotes B-cell production of IgG; inhibits TH2
- *IL-2:* promotes T-, B-, and NK-cell growth
- *TNF-α and TNF-β:* promote inflammation and cytotoxicity

TH2: induced by IL-4, GATA-3 transcription factor
- *IL-4:* T-cell growth factor, stimulates immunoglobulin class switch (IgG, IgE), activation of mast cells, M2 (alternative) macrophage
- *IL-5:* B-cell and eosinophil growth factor, stimulates immunoglobulin class switch (IgG, IgA)
- *IL-10:* B-cell growth factor and inhibitor of TH1 and inflammatory responses

TH17: induced by TGF-β + IL-6; memory T cells by IL-23, ROR-γt transcription factor
- *IL-17:* activates neutrophils, monocytes
- *IL-22:* stimulates epithelium to grow and produce antimicrobial peptides

TFH: influenced by TH1 or TH2 cytokines
- *IL-21:* germinal center development, plasma cell and memory B-cell development
- *IFN-γ or IL-4:* see previous mention

Treg: requires IL-2, FoxP3 transcription factor
- *TGF-β:* inhibits naïve T-cell and other T-cell activation, inhibits inflammation
- *IL-10:* see previous mention

DCs, Dendritic cells; *GM-CSF,* granulocyte-macrophage colony-stimulating factor; *IFN,* interferon; *Ig,* immunoglobulin; *IL,* interleukin; *TFH,* follicular helper T cell; *TGF,* transforming growth factor; *TH,* T helper; *TNF,* tumor necrosis factor; *Treg,* T regulator cell.

activating macrophages, NK cells, and CD8 cytotoxic T cells and expanding the immune response by stimulating growth of B and T cells with IL-2. These responses are important for eliminating intracellular infections (e.g., viruses, bacteria, parasites) and fungi and for antitumor responses; they also are associated with cell-mediated autoimmune inflammatory diseases (e.g., multiple sclerosis, Crohn disease).

The **TH2 response** is the default T-helper cell response. It occurs later in response to infection and acts systemically through antibody-mediated responses. The TH2 response promotes antibody production to antigenic debris presented on MHC II in the lymphatic system, which occurs in the absence of an IL-12/IFN-γ signal from innate responses. TH2 cells express the GATA-3 transcription factor and release **IL-4, IL-5, IL-6, IL10, and IL-13** cytokines that promote humoral (systemic) responses. These cytokines stimulate the B cell to undergo recombination events within the immunoglobulin gene to switch from production of IgM and IgD to production of specific types and subtypes of IgG, IgE, or IgA. TH2 responses are associated with production of IgE and activation of mast cells, which are useful for antihelminthic responses but mediates allergies. TH2 responses can exacerbate an intracellular infection (e.g., *Mycobacterium leprae, Leishmania*) by prematurely shutting off protective TH1 responses. TH2 cell development is inhibited by IFN-γ.

Follicular helper T cells (TFH) reside in the follicles of the lymph node, which are the B-cell zones of the lymph node. They relay the cytokine responses, whether TH1 or TH2, to the B cells to promote production of the appropriate antibody. They also promote development of germinal centers, which are foci of specific memory cell, plasma cell, and antibody production.

Regulatory T cells include Treg and Tr1 cells, which are antigen-specific suppressor cells. **Treg cells** express the FoxP3 transcription factor and the **CD25** IL2 receptor and are generated in the thymus. **Tr1 cells** are regulatory cells that are generated by and produce suppressive cytokines in the tissue. These cells prevent development of autoimmune and overzealous responses by producing **TGF-β and IL-10.** They help to keep T-cell responses under control and promote memory cell development. Regulatory T cells are especially important to regulate responses to normal flora on the skin and in the gastrointestinal tract. Tr1 cells can be derived from Th17 cells in the tissue and revert back to reinforce the necessary immune response. Other TH responses (e.g., TH9 and TH22) have been described, and their names refer to the primary cytokine they produce or the functions promoted by the cytokine.

CD8 T Cells

CD8 T cells include cytotoxic T lymphocytes **(CTLs),** but they also can produce cytokines and influence immune responses. CTLs are part of the TH1 response and are important for eliminating virally infected cells and tumor cells. They kill by releasing proteins that convince the target cell to commit apoptosis.

The CTL response is initiated when naive CD8 T cells in the lymph node are activated by antigen-presenting DCs and cytokines produced by TH1 CD4 T cells, including IL-2 and IFN-γ. The DC may have acquired the antigen as a result of a viral infection or by cross-presentation of antigens of internalized cells, viruses or proteins. The activated CD8 T cells divide and differentiate into mature CTLs, which disseminate through the blood. During a viral challenge, the numbers of specific CTLs will increase up to 100,000 times. When the activated CTL finds a target cell, it binds tightly through interactions of the TCR with antigen-bearing class I MHC proteins and adhesion molecules on both cells (similar to the closing of a zipper) (see Fig. 9.8C). **Granules** containing toxic molecules, **granzymes (esterases),** and a pore-forming protein **(perforin)** move to the site of interaction and release their contents into the pocket **(immune synapse)** formed between the T cell and target cell. **Perforin** generates holes in the target cell membrane to allow the granule contents to enter and induce **apoptosis (programmed cell death)** in the target cell. CD8 T cells also can initiate apoptosis in target cells through the interaction of the **FasL on the T cell with the Fas protein on the target cell surface.** FasL is a member of the TNF family of proteins, and Fas is a member of the TNF receptor family of proteins. Apoptosis is characterized by degradation of the target cell deoxyribonucleic acid (DNA) into discrete fragments of approximately 200 base pairs and disruption of internal membranes. The cells shrink into apoptotic bodies, which are readily phagocytosed by macrophages and DCs. Apoptosis is a clean method of cell death and can promote

tolerance, whereas necrosis signals neutrophil action and further tissue damage. TH1 CD4 T cells and NK cells also express FasL and can initiate apoptosis in target cells.

Suppressor T cells provide antigen-specific regulation of helper T-cell function through inhibitory cytokines and other means. Similar to CTLs, suppressor T cells interact with class I MHC molecules.

INNATE T Cells

NKT cells are like a hybrid between NK cells and T cells. They express NK cell markers such as NK1.1 (an NK immunoglobulin-like receptor [KIR]), and an **α/β** TCR. Unlike other T cells, the TCR repertoire is very limited. They may express CD4, but most lack CD4 and CD8 molecules ($CD4^-CD8^-$). The TCR of most NKT cells reacts with CD1 molecules, which present microbial and host glycolipids and glycopeptides. On activation, NKT cells release large amounts of IL-4 and IFN-**γ**. NKT cells help in the initial responses to infection and are very important for defense against mycobacterial infections.

MAIT cells express an invariant **αβ** TCR that recognizes the MR1 receptor for vitamin B derivatives produced by most bacteria. They are present in the lungs, liver, joints, blood, and mucosal tissues. On activation, these MAIT cells produce TNF-**α**, IFN-**γ**, and IL-17 to enhance neutrophil and macrophage action. They also produce perforin and granzyme for direct cytotoxicity toward bacteria and other cells.

γβ T cells comprise at least 35% of the T cells in the gastrointestinal (GI) tract. These cells express the invariant **γδ** TCR instead of one of many different **αβ** TCRs. The **γδ** T cells are activated by small molecules, including cellular stress molecules, from a wide array of bacteria, parasites, and even stressed human cells including alkylamines, bisphosphonates, and organic phosphoantigens, such as hydroxy-methyl-butyl-pyrophosphate, which is a microbial metabolite from the isoprenoid pathway. The **γδ** T cells can generate different cytokine or even cytotoxic responses depending on the nature of the stimuli. These cells rapidly respond to infections and produce cytokines, including IL17, IFN-**γ** and TNF-**α**, and chemokines. **γδ** T cells also can promote regulatory functions to maintain the status quo within the intestine.

B Cells and Humoral Immunity

The primary molecular component of the humoral immune response is antibody produced by B cells and plasma cells. Antibodies provide protection from rechallenge by an infectious agent, block spread of the agent in the blood, neutralize virulence factors, and facilitate elimination of the infectious agent. To accomplish these tasks, an incredibly large repertoire of antibody molecules must be available to recognize the tremendous number of infectious agents and molecules that challenge our bodies. In addition to interacting specifically with foreign structures, the antibody molecules also must interact with host systems and cells (e.g., complement, macrophages) to promote clearance of antigen and activation of subsequent immune responses (Box 9.5). Antibody molecules also serve as the cell-surface receptors that stimulate the appropriate B-cell antibody factories to grow and produce more antibody in response to antigenic challenge.

BOX 9.5 Antimicrobial Actions of Antibodies

Opsonize: promote ingestion and killing by phagocytic cells (IgG)
Neutralize: block attachment of bacteria bacteria, toxins, and viruses
Agglutinate bacteria: aids in clearing
Render motile organisms nonmotile
Combine with antigens on the microbial surface and activate the complement cascade, thus inducing an inflammatory response, bringing fresh phagocytes and serum antibodies into the site
Combine with antigens on the microbial surface, activate the complement cascade, and anchor the membrane attack complex

Ig, Immunoglobulin.

B cells

Most B cells are derived from and mature in the bone marrow. These cells have the potential to produce any of the immunoglobulin classes with T-cell help and can mature into memory cells or plasma cells. **B-1 cells** are a more primitive B lymphocyte derived from fetal liver and continuously produce natural antibody (IgM or IgA of low affinity) against bacterial polysaccharides, ABO blood groups, and even self-antigens without T-cell help. These cells are stimulated by pathogen-associated molecular patterns (PAMPs) to divide and produce more antibody. **Marginal zone B cells** produce IgM and are found in the spleen. B-1 cells and marginal zone B cells are especially important for generating antibody against the capsular polysaccharides of bacteria and fungi.

Immunoglobulin Types and Structures

Immunoglobulins are composed of at least two heavy chains and two light chains, which is a dimer of dimers. They are subdivided into classes and subclasses based on the structure and antigenic distinction of their heavy chains. IgG, IgM, and IgA are the major antibody forms, whereas IgD and IgE make up less than 1% of the total immunoglobulins. The IgA and IgG classes of immunoglobulin are divided further into subclasses based on differences in the Fc portion. There are four subclasses of IgG, designated as IgG1 through IgG4, and two IgA subclasses (IgA1 and IgA2) (Fig. 9.11).

Antibody molecules are Y-shaped molecules with two major structural regions that mediate the two major functions of the molecule (Table 9.2; also see Fig. 9.11). The **variable-region/antigen-combining site** must be able to identify and specifically interact with an epitope on an antigen. A large number of different antibody molecules, each with a different variable region, are produced in every individual to recognize the seemingly infinite number of different antigens in nature. The **Fc portion** (stem of the antibody Y) interacts with host systems and cells to promote clearance of

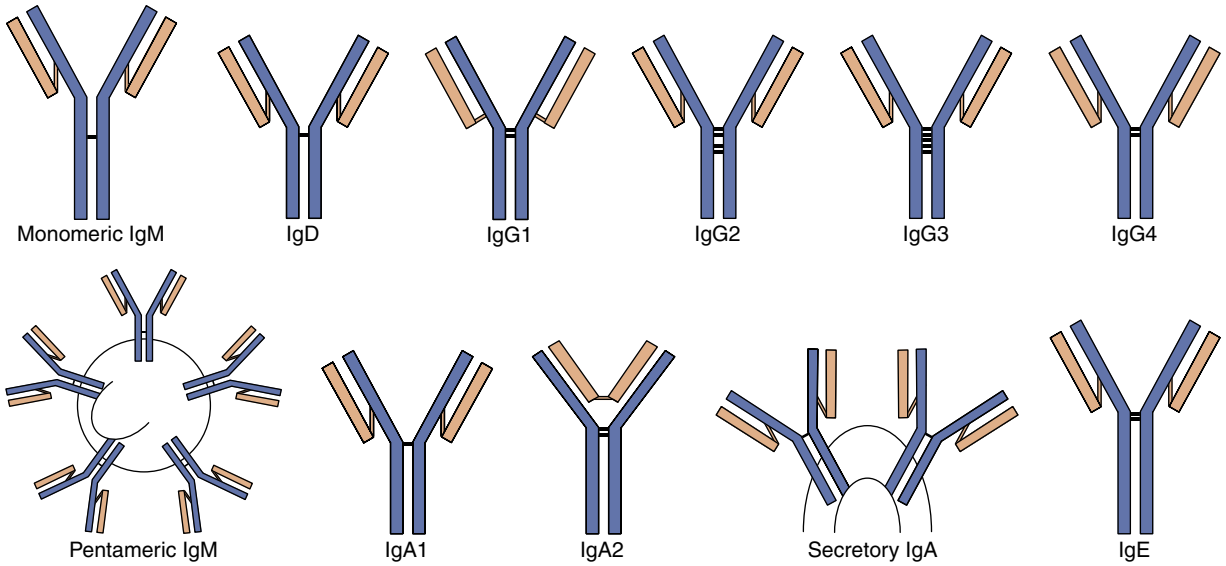

Fig. 9.11 Comparative structures of the immunoglobulin *(Ig)* classes and subclasses in humans. IgA and IgM are held together in multimers by the J chain. IgA can acquire the secretory component for the traversal of epithelial cells.

TABLE 9.2 Properties and Functions of Immunoglobulins

Properties and Functions	IgM	IgD	IgG	IgE	IgA
Heavy-chain gene	μ	δ	γ	ε	α
Subclasses	—	—	$\gamma_1, \gamma_2, \gamma_3, \gamma_4$		α_1, α_2
Molecular weight (kDa)	900	185	154	190	160
% Serum immunoglobulin	5-10	<1	75-85	<1	5-15
Half-life (days)	5	2-3	23	2-3	6
T-cell requirement	Independent	Independent	Dependent	Dependent	Dependent

antigen and activation of subsequent immune responses. The Fc portion is responsible for fixation of complement and binding of the molecule to cell-surface immunoglobulin receptors **(FcR)** on macrophages, NK cells, T cells, and other cells. For IgG and IgA, the Fc portion interacts with other proteins to promote transfer across the placenta and the mucosa, respectively (Table 9.3). In addition, each of the different types of antibody can be synthesized with a **membrane-spanning portion** to make it a B-cell surface antigen receptor.

IgG and IgA have a flexible **hinge region** rich in proline and susceptible to cleavage by proteolytic enzymes. Digestion of IgG molecules with **papain** yields two **Fab** fragments and one **Fc** fragment (Fig. 9.12). Each Fab fragment has one antigen-binding site. **Pepsin** cleaves the molecule, producing an **$F(ab')_2$** fragment with two antigen-binding sites and a **pFc′** fragment.

The different types and parts of immunoglobulin also can be distinguished using antibodies directed against different portions of the molecule. **Isotypes (IgM, IgD, IgG, IgA, and IgE)** are determined by antibodies directed against the Fc portion of the molecule (*iso-*, meaning the same for all people.) **Allotypic** differences occur for antibody molecules with the same isotype but contain protein sequences that differ from one person to another (in addition to the antigen-binding region). *(All ["allo"] of us have differences.)* The **idiotype** refers to the protein sequences in the variable region that comprise the large number of antigen-binding regions. *(There are many different idiots in the world.)*

On a molecular basis, each antibody molecule is made up of heavy and light chains encoded by separate genes. The basic immunoglobulin unit consists of **two heavy (H)** and **two light (L) chains.** IgM and IgA consist of multimers of this basic structure. The heavy and light chains of immunoglobulin are fastened together by **interchain disulfide bonds.** Two types of light chains, **κ** and **λ,** are present in all five immunoglobulin classes, although only one type is present in an individual molecule. There are **five types of heavy chains,** one for each isotype of antibody **(IgM, μ; IgG, γ; IgD, δ; IgA, α; and IgE, ε)**. **Intrachain disulfide bonds** define molecular domains within each chain. Light chains have a variable and a constant domain. The heavy chains have a variable and three (IgG, IgA) or four (IgM, IgE) constant domains (see Fig. 9.12). The heavy chain of the different antibody molecules also can be synthesized with a membrane-spanning region to make the antibody an antigen-specific cell-surface receptor for the B cell.

TABLE 9.3 Fc Interactions with Immune Components

Immune Component	Interaction	Function
Fc receptor	Macrophages	Opsonization
	Polymorphonuclear neutrophils	Opsonization
	T cells	Check point regulation
	Natural killer cells (antibody-dependent cellular cytotoxicity)	Killing
	Mast cells for IgE	Allergic reactions, antiparasitic
	Neonatal IgG receptor	Transport across capillary membranes
Complement	Complement system	Opsonization, killing (especially bacteria), activation of inflammation

Ig, Immunoglobulin.

IMMUNOGLOBULIN D

IgD, which has a molecular mass of 185 kDa, accounts for 0.25% of serum immunoglobulins. IgD exists primarily as membrane IgD, which serves with IgM as an antigen receptor on early B-cell membranes to help initiate antibody responses by activating B-cell growth. IgD and IgM are the only isotypes that can be expressed together by the same cell.

IMMUNOGLOBULIN M

IgM is the first antibody produced in response to antigenic challenge and can be produced in a T-cell–independent manner. Monomeric IgM is found with IgD on the B-cell surface, in which it serves as the receptor for antigen. IgM makes up 5% to 10% of the total serum immunoglobulins in adults and has a half-life of 5 days. It is a **pentameric molecule** with five immunoglobulin units joined by the **J chain,** with a total molecular mass of 900 kDa. Theoretically, this immunoglobulin has 10 antigen-binding sites. IgM is the most efficient immunoglobulin for fixing (binding) complement. A single IgM pentamer can activate the classical complement pathway. Because IgM is relatively large, it remains in the blood and spreads inefficiently from the blood into tissue. IgM is particularly important for immunity against polysaccharide antigens on the exterior of pathogenic microorganisms. It also promotes phagocytosis and promotes bacteriolysis by activating complement through its Fc portion. IgM is also a major component of rheumatoid factors (autoantibodies).

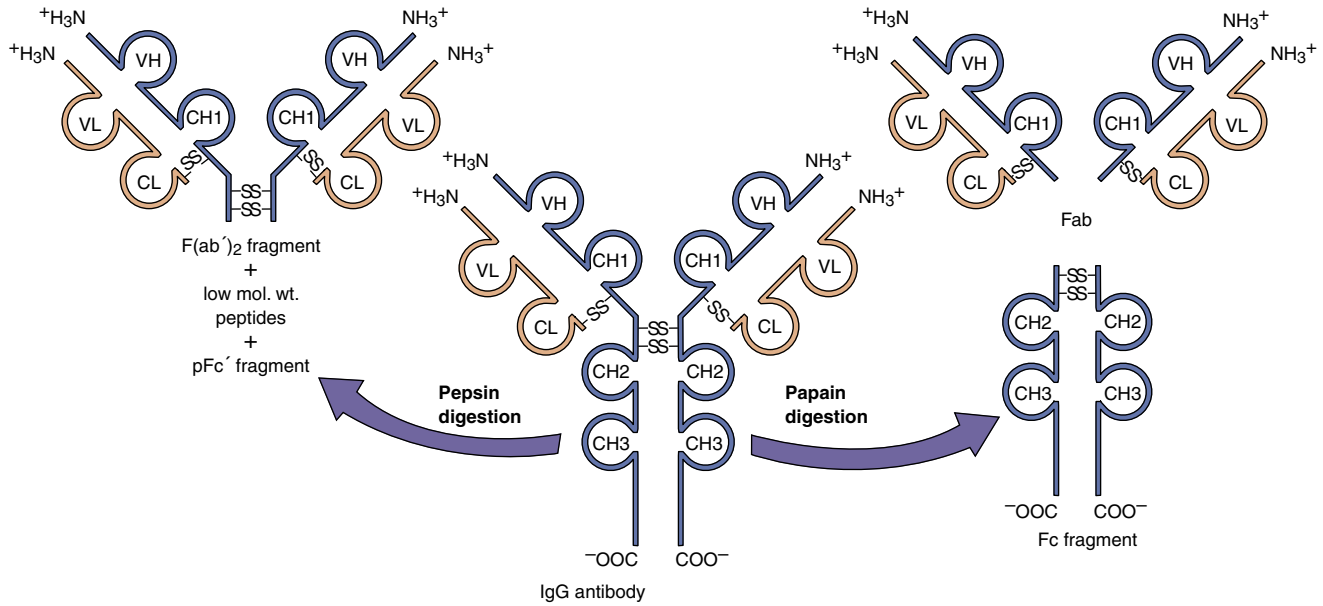

Fig. 9.12 Proteolytic digestion of immunoglobulin *(Ig)*G. Pepsin treatment produces a dimeric $F(ab')_2$ fragment. Papain treatment produces monovalent Fab fragments and an Fc fragment. The $F(ab')_2$ and the Fab fragments bind antigen but lack a functional Fc region. The heavy chain is depicted in *blue;* the light chain in *orange. mol. wt.,* Molecular weight.

IMMUNOGLOBULIN G

IgG comprises approximately 85% of the immunoglobulins in adults. It has a molecular mass of 154 kDa, based on two L chains of 22,000 Da each and two H chains of 55,000 Da each. The four subclasses of IgG differ in structure (see Fig. 9.11), relative concentration, and function. Production of IgG requires T-cell help. IgG, as a class of antibody molecules, has the longest half-life (23 days) of the five immunoglobulin classes, binds the neonatal Fc receptor and is transported across the placenta and certain other membranes, and is the principal antibody in the **anamnestic (booster) response.** IgG shows high avidity (binding capacity) for antigens, fixes complement, stimulates chemotaxis, and acts as an opsonin to facilitate phagocytosis.

IMMUNOGLOBULIN A

IgA comprises 5% to 15% of the serum immunoglobulins and has a half-life of 6 days. It has a molecular mass of 160 kDa. It can occur as monomers, dimers, trimers, and multimers combined by the J chain (similar to IgM). In addition to serum IgA, a **secretory IgA** is released by mucosal epithelial cells. IgA production requires specialized T-cell help and mucosal stimulation. The J chain of IgA binds to a **poly-Ig receptor** on epithelial cells for transport across the cell. The poly-Ig receptor remains bound to IgA and is then cleaved to become the **secretory component** when secretory IgA is secreted from the cell. An adult secretes approximately 2 g of IgA per day. Secretory IgA appears in colostrum, intestinal and respiratory secretions, saliva, tears, stool, and other secretions. IgA deficiency is relatively common (0.1% to 1% of the population) and these individuals have an increased incidence of respiratory tract infections.

IMMUNOGLOBULIN E

IgE accounts for less than 1% of the total immunoglobulins and has a half-life of approximately 2.5 days. Most IgE is bound to Fc receptors on **mast cells,** on which it serves as a receptor for activating the cell to allergens and parasite antigens. When sufficient antigen binds to the IgE on the mast cell, the mast cell releases histamine, prostaglandin, platelet-activating factor, and cytokines. IgE is important for protection against parasitic infection and is responsible for **anaphylactic hypersensitivity** (type 1) (rapid allergic reactions).

Immunogenetics

The antibody response can recognize at least 10^8 structures but can still specifically amplify and focus a response directed to a specific challenge. The mechanisms for generating this antibody repertoire and the different immunoglobulin subclasses are tied to random genetic events that accompany the development (differentiation) of the B cell (Fig. 9.13).

Production of the antibody gene in the pre–B cell occurs in the bone marrow. Human chromosomes 2, 22, and 14 contain immunoglobulin genes for **κ**, **λ**, and H chains, respectively. Genetic recombination at the DNA level and posttranscriptional processing at the ribonucleic acid (RNA) level assemble the immunoglobulin gene and produce the functional messenger RNA (mRNA) (see Fig. 9.13). The **germline** forms of these genes consist of different and separate sets of genetic building blocks for the light **(V and J gene segments)** and heavy chains **(V, D, and J gene segments),** which are genetically recombined to produce the immunoglobulin variable regions. These variable regions are then connected to the constant-region C gene segments. For the **κ** light chain, there are ~35 V gene segments, 5 J gene segments, and only one C gene segment. For the **λ** gene there are ~30 V and one J segment but 4 C gene segments. For the heavy chain, there are ~45 V genes, 23 D genes, and 6 (heavy chain) J genes with 9 C genes (one for each class and subclass of antibody **[μ; δ; γ_3, γ_1, γ_2, and γ_4; ε; α_1 and α_2]**). In addition, gene segments for membrane-spanning peptides can be attached to the heavy-chain genes to allow the antibody molecule to insert into the B-cell membrane as an antigen-activation receptor.

Each of the V, D, and J segments is surrounded by DNA sequences that promote **directional recombination and loss of the intervening DNA sequences.** The enzyme produced by the **RAG gene** is essential for recombination of these segments. Randomly inserted nucleotides at the junction sites connect the two strands, which can enhance the diversity of sequences or inactivate the gene if it disrupts the reading frame for the subsequent mRNA. The light-chain gene segment is produced by the juxtaposition of randomly chosen **κ** or **λ** V and J gene segments, and the variable region of the heavy-chain segment is produced by the juxtaposition of a V, D, and J gene.

The complete heavy-chain gene is produced by attachment of the variable-region sequences (VDJ) to the μ; **δ**; **γ**, γ_1, γ_2, or γ_4; **ε**; or α_1 or α_2 sequences of the constant region (C) gene segments. Pre–B and B cells co-express IgM and IgD and mRNAs are produced that contain the variable-region gene segments connected to the contiguous μ and **δ** C gene sequences. Processing of the mRNA removes either the μ or **δ**, as if it were an intron, to produce the final immunoglobulin mRNA. The pre–B cell expresses cytoplasmic IgM, whereas the B cell expresses cytoplasmic and cell-surface IgM and cell-surface IgD. IgM and IgD are the only pair of isotypes that can be expressed on the same cell.

Class switching (IgM to IgG, IgE, or IgA) occurs in mature B cells in response to different cytokines produced by TH1 or TH2 CD4 helper T cells (Fig. 9.14). Each of the C gene segments, except **δ**, is preceded by a DNA sequence called the **switch site.** After the appropriate cytokine signal, the switch in front of the μ sequence recombines with the switch in front of the γ_3, γ_1, γ_2, or γ_4; **ε**; or α_1 or α_2 sequences, creating a DNA loop containing the intervening constant region gene that is subsequently removed. Processing of the RNA transcript yields the final mRNA for the immunoglobulin heavy-chain protein. For example, IgG1 production would result from excision of DNA containing the C gene segments C_μ, C**δ**, and Cγ_3 to attach the

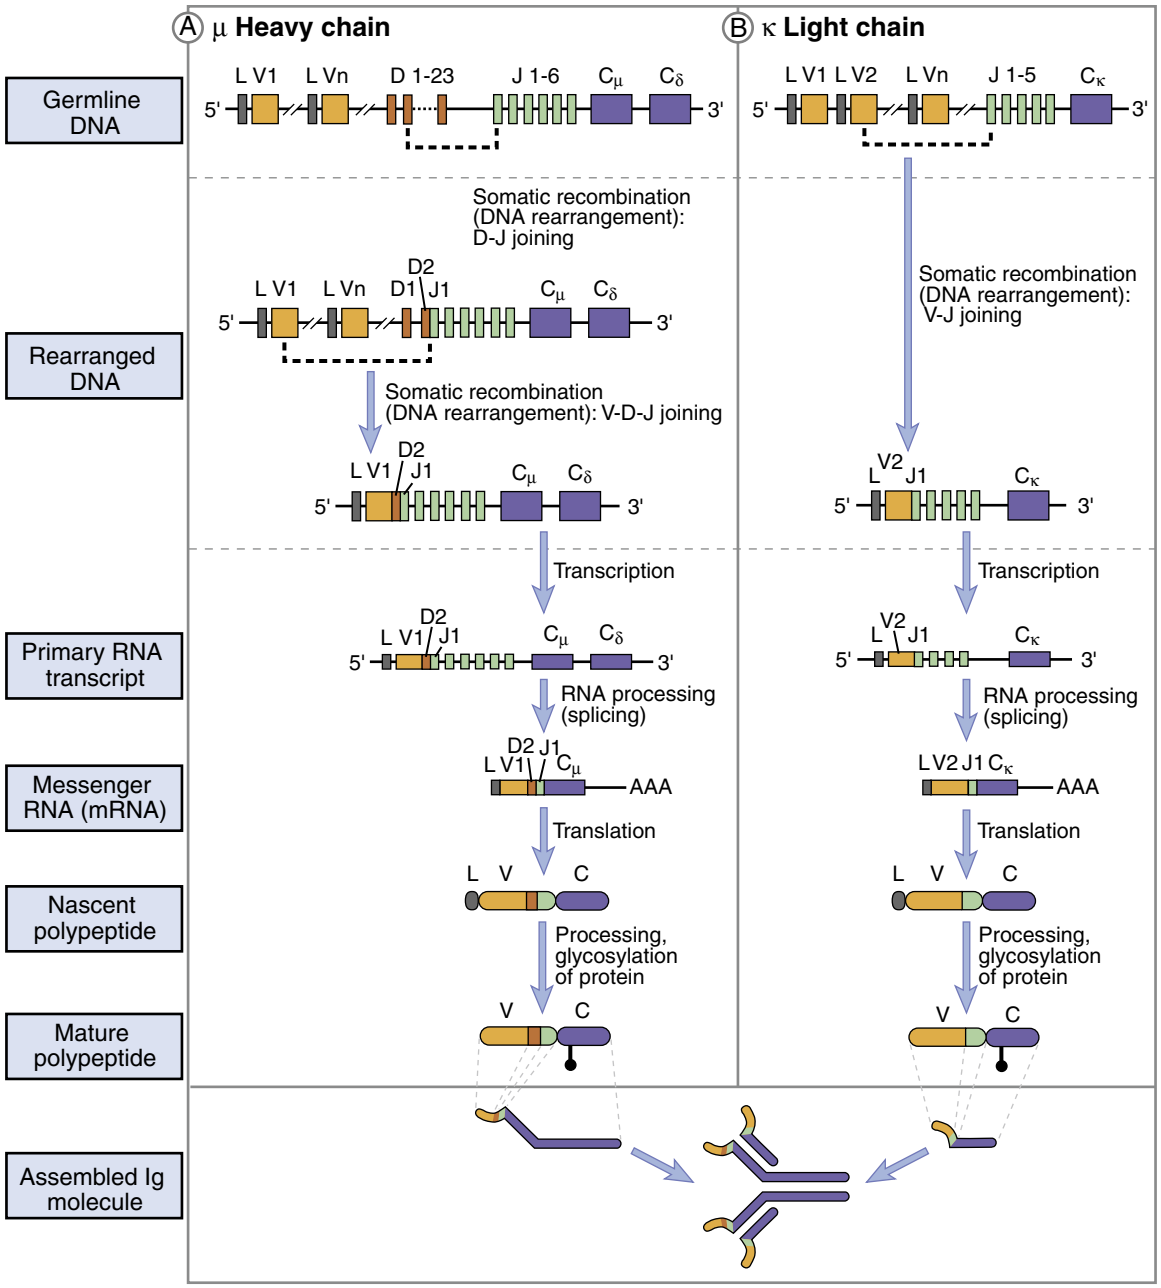

Fig. 9.13 Immunoglobulin *(Ig)* gene rearrangement to produce IgM and IgD (A) heavy-chain sequences and (B) light-chain sequences. The germline immunoglobulin gene contains multiple V, D, and J genes that recombine and delete intervening sequences and juxtaposes the new variable region sequences to the μ-δ heavy-chain sequences during the development of the B cell in the bone marrow. This produces a messenger RNA (mRNA) that can be processed into mRNA for either IgM or IgD. Protein synthesis and assembly of the subsequent heavy- and light-chain proteins produces the immunoglobulins.

variable region to the γ_1 C gene segment. **Class switching changes the function of the antibody molecule (Fc region) but does not change its specificity (variable region).**

The final steps in B-cell differentiation to memory cells or plasma cells do not change the antibody gene. **Memory cells** are long-lived, antigen-responsive B cells expressing the CD45RO surface marker. Memory cells can be activated in response to antigen later in life to divide and then produce its specific antibody. **Plasma cells** are terminally differentiated B cells with a small nucleus but a large cytoplasm filled with ER. Plasma cells are antibody factories with a long but finite lifetime.

Antibody Response

T-independent antigens, such as flagellin and capsular polysaccharide, have repetitive structures that can cross-link sufficient numbers of surface antibody to stimulate growth of the antigen-specific B-1 lymphocytes

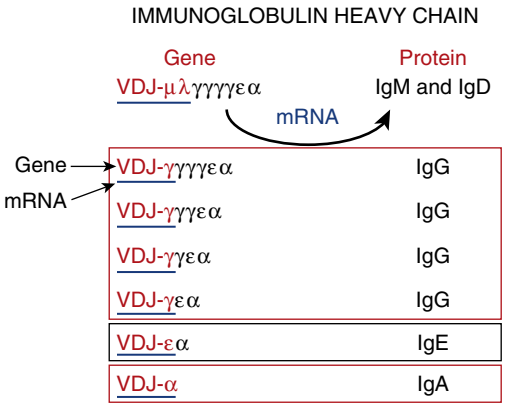

Fig. 9.14 Immunoglobulin class switching. T-cell help induces differentiation of the B cell and promotes genetic recombination, somatic mutation, and immunoglobulin class switching. Switch regions in front of the constant-region genes (including IgG and IgA subclasses) allow attachment of the preformed VDJ region to other heavy-chain constant-region genes, genetically removing the μ, δ, and other intervening genes. This produces an immunoglobulin gene with the same VDJ region (except for somatic mutation) and the desired antigen specificity but with different Fc-determined functions.

and IgM- and IgD-producing B cells by cross-linking surface immunoglobulin. The B cells use membrane bound antibody as an antigen receptor to trigger activation of the B cell through its immunoglobulin-associated signal transduction receptors, Ig-**α** (CD79a) and Ig-**β** (CD79b). The surface antibody has the same antigen specificity as the secreted antibody of that cell. A cascade of protein tyrosine kinases, PLC, and calcium fluxes activate transcription and cell growth to mediate the activation signal. Other surface molecules, including the CR2 (CD21) complement (C3d) receptor, amplify the activation signal.

T-dependent antibodies are generated with the help provided by CD4 T cells (Fig. 9.15). Antigen bound to surface immunoglobulin on the B cell is internalized and processed into peptides, and these peptides are then presented on MHC II molecules to those CD4 T cells that have the appropriate TCR. This activates the T cell to produce cytokines and express CD40L, which then binds to CD40 on the B cell. The combination of these signals stimulates the activation and growth of the B cell (Animation 8).

The B cells that best recognize the different epitopes of the antigen are selected to increase in number by **somatic mutation, affinity maturation,** and **clonal expansion.** These processes, isotype switching, and memory and plasma cell generation occur primarily within the germinal centers of the lymph nodes (Fig. 9.16). Germinal centers develop several days after an antigen challenge. Activated B cells enter the dark zone of the germinal center and while they proliferate they express enzymes that promote isotype switching and mutation within the immunoglobulin gene that cause somatic mutations. Mutations trigger mechanisms within most cells that promote apoptosis. The B cells proceed to the light zone of the germinal center in which they encounter **follicular DCs and Tfh.** The follicular DCs act like bulletin boards to display multiple units of the antigen to the surface antibody, and those B cells that bind efficiently to the displayed antigen receive a survival signal from the Tfh, whereas the other B cells die by apoptosis (Animation 7). The surviving B cells may recycle through the dark zone to repeat the cycle or receive signals for differentiation into memory cells or plasma cells and leave the lymph node.

With an increase in the number of plasma cell antibody factories making the relevant antibody, the strength and specificity of the antibody response is thus increased. During an immune response, antibodies are made against different epitopes of the foreign object, protein, or infectious agent. *Specific antibody is a mixture of many different immunoglobulin molecules made by many different B cells* **(polyclonal antibody),** with each immunoglobulin molecule differing in the epitope it recognizes and the strength of the interaction. Antibody molecules that recognize the same antigen may bind with different strengths (**affinity,** monovalent binding to an epitope; **avidity,** multivalent binding of antibody to antigen).

Monoclonal antibodies are identical antibodies produced by a single clone of cells or by myelomas (cancers of plasma cells) or hybridomas. Hybridomas are cloned, laboratory-derived cells obtained by the fusion of antibody-producing cells and a myeloma cell. In 1975, Kohler and Millstein developed the technique for producing monoclonal antibodies from B-cell hybridomas. The hybridoma is immortal and produces a single (monoclonal) antibody. This technique has revolutionized the study of immunology because it allows selection (cloning) of individual antibody-producing cells and their development into cellular factories for production of large quantities of that antibody. Genetic approaches also are used to generate monoclonal antibodies. Monoclonal antibodies are produced commercially as diagnostic reagents and for therapeutic purposes.

TIME COURSE OF THE ANTIBODY RESPONSE

The primary antibody response is characterized by the initial production of IgM. IgM antibodies appear in the blood within 3 days to 2 weeks after exposure to a novel immunogen. This is the only type of antibody elicited toward carbohydrates (bacterial capsule). Production of IgG, IgA, or IgE to protein containing antigens requires development of a sufficient helper T-cell response to promote the class switch and requires approximately 8 days. The predominant serum antibody will be IgG (Fig. 9.17). The first antibodies produced react with residual antigen and therefore are rapidly cleared. After the initial lag phase, however, the antibody titer increases logarithmically to reach a plateau. IgG has a half-life in blood of 23 days, and long-lived plasma cells may continue to produce the antibody for years, depending on the strength and nature of the challenge.

Reexposure to an immunogen, which is a **secondary response,** induces a heightened antibody response (also termed **anamnestic response**). Activation of preformed memory cells yields a much more rapid production of antibody, which lasts longer and reaches a higher titer. The antibodies in a secondary response are principally of the IgG class.

For questions see StudentConsult.com.

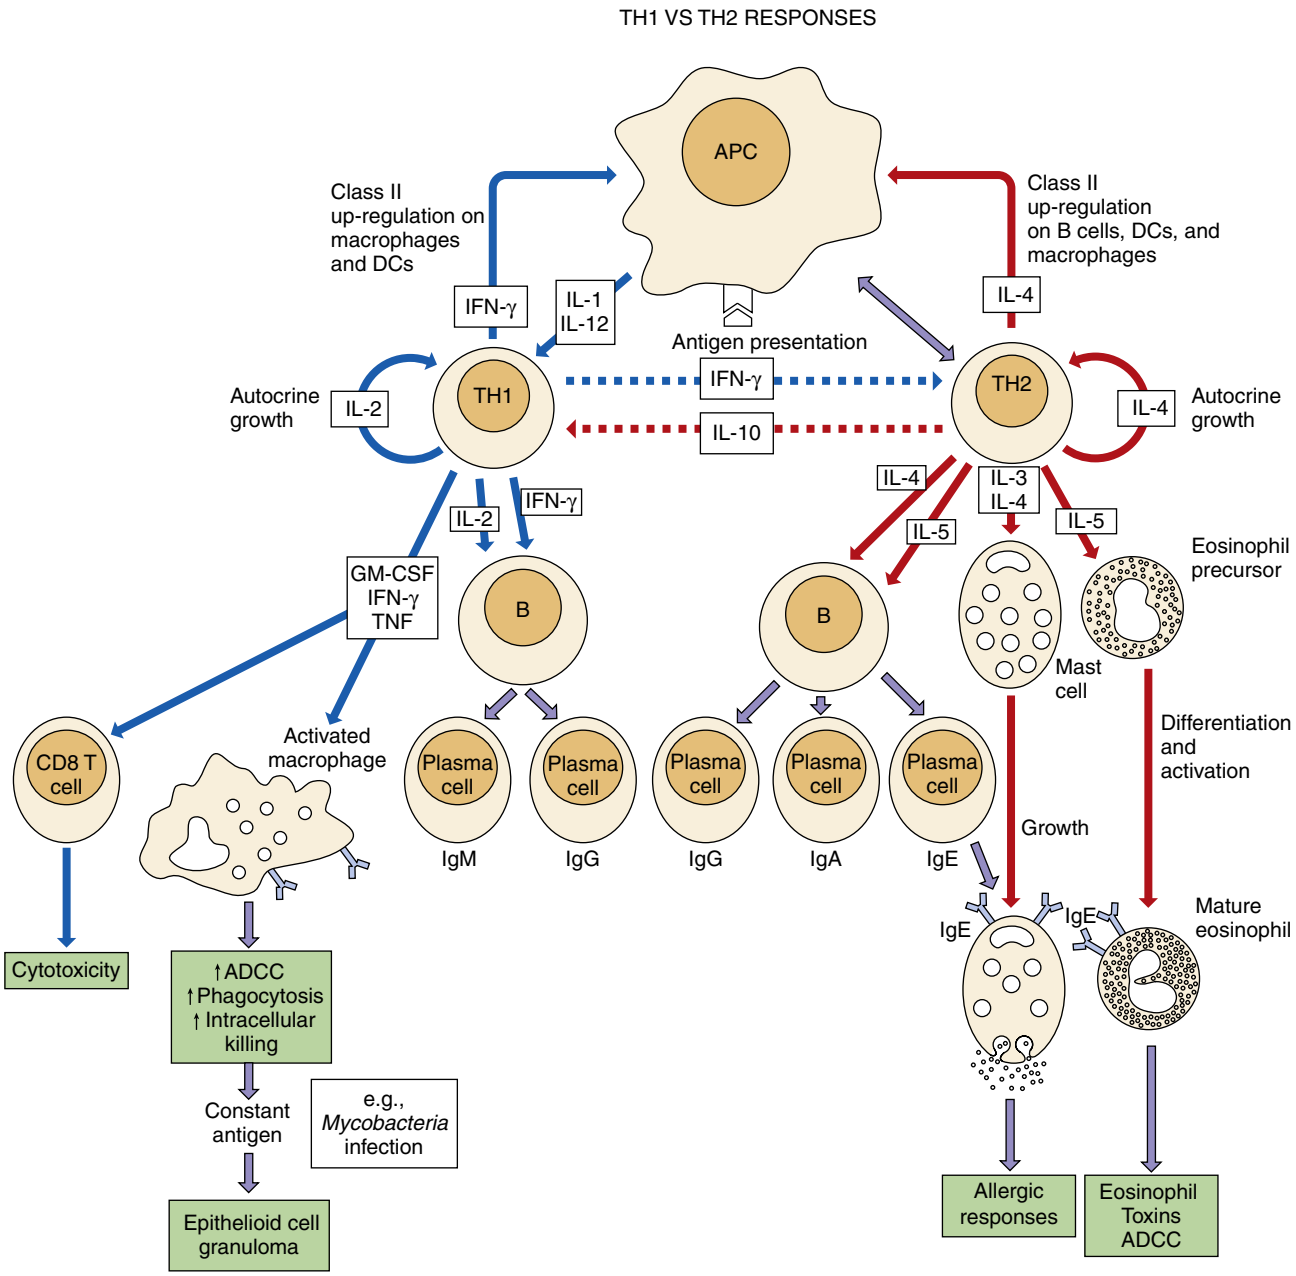

Fig. 9.15 T-cell help determines the nature of the immune response. Receptor-ligand interactions between T cells and B cells and cytokines associated with TH1 or TH2 determine the subsequent response. TH1 responses are initiated by interleukin *(IL)*-12 and delivered by interferon-γ *(IFN-γ)* and IL-2 to promote cell-mediated and immunoglobulin *(Ig)*G production *(solid blue lines)* and inhibit TH2 responses *(dotted blue lines)*. IL-4 and IL-5 from TH2 cells promote humoral responses *(solid red lines)*, and IL-4 and IL-10 inhibit TH1 responses *(dotted red lines)*. Mucosal epithelium promotes secretory IgA production. Colored boxes denote end results. ↑, Increase; ↓, decrease; *ADCC*, antibody-dependent cellular cytotoxicity; *APC*, antigen-presenting cell; *CTL*, cytotoxic T lymphocyte; *DCs*, dendritic cells; *DTH*, delayed type hypersensitivity; *GM-CSF*, granulocyte-macrophage colony-stimulating factor; *TNF*, tumor necrosis factor.

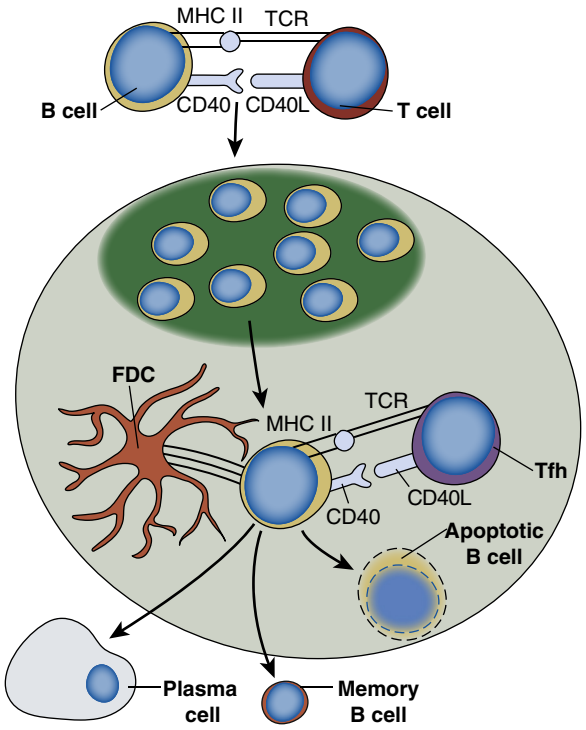

Fig. 9.16 Somatic mutation and clonal selection in the germinal centers of lymph nodes. B cells activated by CD4 T cells enter the dark zone of the germinal center, proliferate, and undergo mutation of the immunoglobulin genes and isotope switching. The mutations trigger apoptosis. The B cells proceed to the light zone of the germinal center in which follicular dendritic cells *(FDC)* act like bulletin boards to display multiple units of the antigen to surface antibody on B cells. B cells with surface immunoglobulin that bind tightly to antigen and present peptides recognized by follicular helper cells *(Tfh)* receive a survival signal from the Tfh while the other B cells die by apoptosis. The surviving B cells may recycle through the dark zone to repeat the cycle or receive signals for differentiation into memory cells or plasma cells and leave the lymph node. *MHC,* Major histocompatibility complex; *TCR,* T-cell receptor.

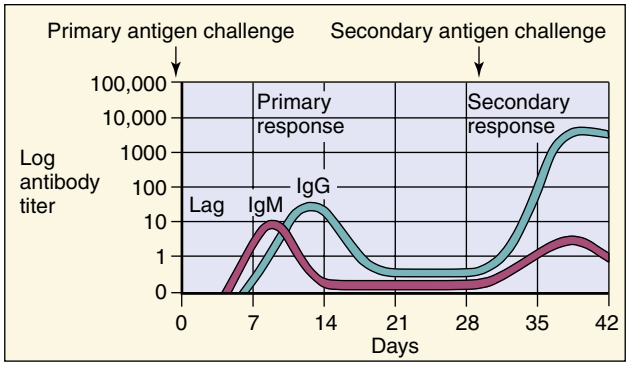

Fig. 9.17 Time course of immune responses. The primary response occurs after a lag period. The immunoglobulin *(Ig)*M response is the earliest response. The secondary immune response (anamnestic response) progresses faster, reaches a higher titer, lasts longer, and consists predominantly of IgG.

Questions

What is wrong with each of the following statements, and why?

1. The laboratory tested a baby for IgM maternal antibodies.

2. An investigator attempted to use fluorescent-labeled $F(ab')_2$ fragments to locate class II MHC molecules on the cell surface of APCs but did not want to activate the cells or promote the "capping" that would occur with cross-linking (binding two molecules together) of these cell-surface molecules.

3. A patient is diagnosed as having been infected with a new and specific strain of influenza A (A/Bangkok/1/79/H3N2) on the basis of the presence of antiinfluenza IgG in serum taken from the patient at the initial visit (within 2 days of symptoms).

4. A patient was considered to be at higher risk of bacterial infection because of the inability to activate the complement system because of a T-cell deficiency that precluded the ability to promote class switching of B cells.

5. Analysis of immunoglobulin genes from B cells taken from the patient described in question 4 did not contain recombined VDJ variable-region gene sequences.

6. A patient was considered to have a B-cell deficiency because serum levels of IgE and IgD were undetectable despite proper concentrations of IgG and IgM.

10 Immune Responses to Infectious Agents

Animations for this chapter are available on Student Consult.com.

The previous chapters in this section introduced the different immunologic actors and their characteristics. This chapter describes the different roles they play in host protection from infection, their interactions, and the immunopathogenic consequences that may arise as a result of the response (Box 10.1).

Most infections are controlled by innate responses before immune responses can be initiated, but immune responses are necessary to resolve the more troublesome infections. Innate and immune responses are also important for regulating the constituents and restricting normal flora to their niche in the body and restricting virulent species. The importance of each of the components of the host response differs for different types of infectious agents (Table 10.1), and their importance becomes obvious when it is genetically deficient or diminished by chemotherapy, disease, or infection (e.g., acquired immunodeficiency syndrome [AIDS]).

Human beings have four basic lines of protection against inappropriate microbial infection:

1. **Natural barriers** such as skin, mucus, ciliated epithelium, gastric acid, and bile restrict entry of the agent.
2. **Competition** with normal flora.
3. **Innate antigen-nonspecific immune defenses** such as fever, antimicrobial peptides, interferon, complement, neutrophils, macrophages, dendritic cells (DCs), innate lymphoid cells (including natural killer [NK] cells), and innate T cells (mucosal-associated invariant T cell [MAIT], NK T cell [NKT], **γδ** T cells) and B-1 B cells provide continuous or rapid local responses at body surfaces and at the infection site to restrict the growth and spread of the agent.
4. **Adaptive antigen-specific immune responses** such as antibody and T cells reinforce the innate protections; specifically they target, attack, and eliminate the invaders that succeed in passing the first two defenses, as well as the infected cells; and they remember the pathogen for future challenges.

Symptoms and disease occur when barrier functions and innate responses are insufficient to keep normal flora within its niche or control other infections. Infections can grow, spread, and cause damage during the time period required to initiate a new antigen-specific immune response. *The extent of the disease is determined by a combination of the microbial and immunopathogenesis initiated by the infection.* The more extensive and established the infection, the more immunopathogenesis will occur. Immune memory elicited by prior infection or vaccination can be activated quickly enough to control most infections before symptoms occur.

Antibacterial Responses

Fig. 10.1 illustrates the progression of protective responses to a bacterial challenge. Protection is initiated by activation of local innate and inflammatory responses and progresses to system-wide acute-phase and antigen-specific responses. *The most important antibacterial host responses are the barrier functions, antimicrobial peptides, phagocytic killing by neutrophils and macrophages, and antitoxin and opsonizing antibodies.* Complement and antibody facilitate the uptake of microbes (opsonization) by phagocytes, and TH17 and TH1 CD4 T-cell responses enhance their function. A summary of antibacterial responses is presented in Box 10.2.

INITIATION OF THE RESPONSE

Many different responses act together during the early stages of a bacterial infection triggered by the surface structures and metabolites of the bacteria and the stress and damage occurring to the tissue. During infection of skin or mucous membranes, the epithelial cells, Langerhans cells (skin), or immature DCs (iDCs) and tissue macrophages respond to the small molecules (e.g., adenosine triphosphate [ATP], nuclear proteins, cytosolic proteins) released by cell damage with **damage-associated molecular pattern (DAMP) receptors**. Bacterial cell wall molecules (teichoic acid, lipoteichoic acid, and peptidoglycan fragments of gram-positive bacteria and lipid A of lipopolysaccharide [LPS] of gram-negative bacteria) bind and activate **pathogen-associated molecular pattern (PAMP) receptors** (see Table 8.2 and Fig. 8.4). **Lipid A (endotoxin)** binds to TLR4 and other PAMP receptors and is a very strong activator of DCs, macrophages, B cells, and selected other cells (e.g., epithelial and endothelial cells). Innate lymphoid cells and natural T cells (NKT cells, MAIT and **γ δ** T cells) residing in tissue also respond, produce cytokines, and reinforce antimicrobial peptide production and cellular responses by producing interleukin (IL)-17, IL-22, and interferon (IFN)-**γ**. **γ δ T cells** in tissue sense phosphorylated amine metabolites from most bacteria. **NKT** cells respond to bacterial glycolipids presented on CD1 molecules by DCs, and **MAIT** cells respond to vitamin B derivatives produced by many bacteria. The natural T cells also respond to PAMPs.

B-1 B cells are also activated by the binding of the repetitive surface structures of bacteria to PAMP receptors and to their surface immunoglobulin. The cells proliferate and produce immunoglobulin (Ig)M. This response is especially important for capsular polysaccharides.

Antimicrobial peptides, including defensins, are released by activated epithelial cells, neutrophils, and other cells to protect skin and mucoepithelial surfaces. Their release is reinforced by IL-17 and IL-22 produced by natural T cells

BOX 10.1 Summary of the Immune Response

The innate and adaptive immune systems foster maintenance and repair; provide garbage collection, border protection, and policing; and have military-like responses to microbial invasion of the human body. The immunologic personnel can be distinguished by their outer structures, their uniforms, and tool belts, which also define their roles in the immune response. The borders of the body, especially the GI tract, are maintained and defended by teams of epithelial cells, neutrophils, monocyte-macrophage lineage cells, iDCs, and DCs; ILCs (including NK cells); natural T (NKT, MAIT, and γδ T) and B-1 lymphocytes; the T and B lymphocytes of the antigen-specific response; and other cells. These cells rebuild and provide surveillance and policing of the barriers. They communicate with each other with cytokines and by direct contact to promote the health of the epithelial barrier, and with production of antimicrobial peptides to control the adjacent microbial population while preventing unnecessary inflammatory responses. Tissue resident macrophages provide garbage service by eating up, degrading, and recycling dead cells, degraded proteins, and other materials. They also produce cytokines that support growth, angiogenesis, and healing, when needed. ILCs, NKT, MAIT, γδ T and B-1 cells, and iDCs are sentries within the tissue using PAMPR sensors to become activated by microbial infections and then release early warning system cytokines (e.g., IL-1, TNF-α, IL-6) and chemokines to maintain protections or initiate rapid responses. Soluble sensors of the complement system become activated by microbial surfaces and immune complexes to release the "a" fragments (C3a, C4a, and C5a) to attract more neutrophils and monocytes to the site of infection. Monocytes mature into M1-activated macrophages in response to the IFN-γ produced by ILCs and T cells. Neutrophils and the activated M1 macrophages act directly to kill bacteria and fungi. In response to viruses, most cells, and especially pDCs, release a type I interferon warning system that limits virus replication, activates NK cells, and facilitates the development of subsequent T-cell responses.

After tasting the local environment by pinocytosis and phagocytosis and on activation, iDCs mature and progress to the lymph node to recruit antigen-specific military assistance. The DC is the only APC that can command a naive T cell to initiate a new immune response. The mature DCs display stimulatory receptors and antigenic peptides from the microbe on MHC molecules on its surface and releases cytokines to initiate the appropriate T-cell response. A regiment of TH17 or TH1 cells may be generated to mobilize and reinforce local-site inflammatory responses or TH2 helper/support may be activated to promote systemic humoral responses. The T-cell responses are defined by the cytokines that they produce. Regulation and control is provided by Treg and Tr1 cells. Macrophages, DCs, and B cells refine and strengthen the direction of the response as APCs. The antibody produced by B cells and plasma cells block pathogenic microbial functions and facilitate their clearance. B cells are also powerful specialists in presentation of the epitopes from a single antigen to reinforce antigen-specific CD4 T cell commands. These targeted weapons are necessary for microbes that evade or overpower the innate protections but oftentimes cause peripheral damage and disruption termed disease.

As the response matures, T cells and B cells increase in number and terminally differentiate into effector and plasma cells to deliver antigen-specific cellular and antibody immune responses or maintain a low profile and become memory cells. Memory cells can mobilize a response more quickly and efficiently to a future challenge. Once the challenge has been controlled, the excess troops of B and T cells die off and the status quo is renewed.

APC, Antigen-presenting cell; *DC,* dendritic cell; *GI,* gastrointestinal; *iDC,* immature dendritic cells; *IFN,* interferon; *IL,* interleukin; *ILC,* innate lymphoid cells; *MAIT,* mucosal-associated invariant T cell; *MHC,* major histocompatibility complex; *NK,* natural killer (cell); *NKT,* natural killer T (cell); *PAMPR,* pathogen-associated molecular pattern receptor; *TH,* T helper (cell); *TNF,* tumor necrosis factor; *Treg,* regulatory T cells.

and TH17 responses. Antimicrobial peptides are very important for regulating the species of bacteria in the gastrointestinal tract. In addition, chelating peptides are released as part of the inflammatory response to sequester essential metal ions, such as iron and zinc, to limit microbial growth.

In addition, the bacterial cell surfaces activate the alternative or lectin pathways of complement that are present in interstitial fluids and serum. The **complement system** (see Chapter 8; Animation 1) is a very early and important antibacterial defense. The **alternative complement pathway (properdin)** is activated by cleavage and binding of C3 to bacterial surfaces. Binding of the **mannose-binding protein** to polysaccharides activates the **lectin complement pathway.** Later, when IgM or IgG is present, the **classical**

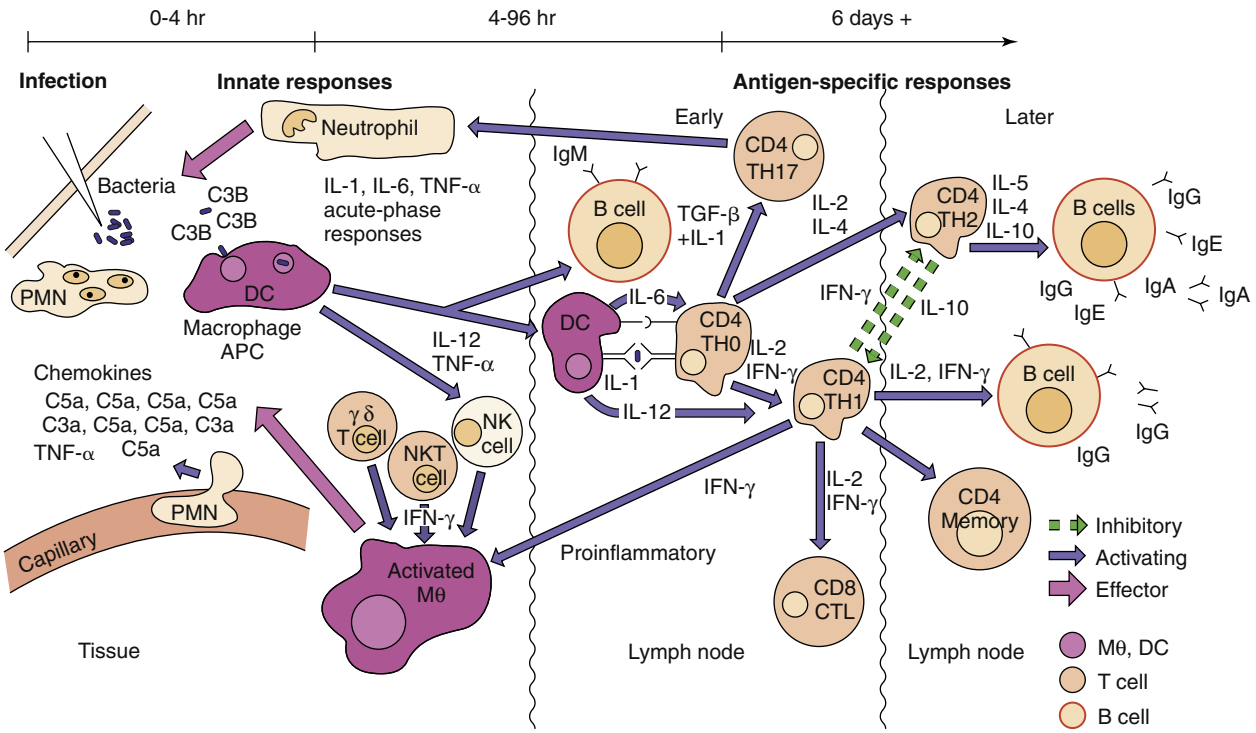

Fig. 10.1 Antibacterial responses to a splinter. The time course proceeds from local *(left)* to lymph node *(right)* and then returns as indicated at the top of the figure. First, innate antigen-nonspecific responses attract and promote polymorphonuclear neutrophil *(PMN)* and macrophage *(Mθ)* responses. Epithelial cells and other cells produce antimicrobial peptides (not shown). Dendritic cells *(DCs)* mature taking antigen to the lymph node to activate early immune responses *(TH17, TH1, IgM,* and *IgG)*. TH1 and TH17 cells mobilize to the site of infection to provide cytokine help. Later, when antigen reaches the lymph node through lymphatics, TH2 systemic antibody responses are developed. *APC,* Antigen-presenting cell; *CTL,* cytotoxic T lymphocyte; *Ig,* immunoglobulin; *IFN-γ,* interferon-γ; *IL,* interleukin; *TGF-β,* transforming growth factor-β; *TH,* T helper (cell); *TNF-α,* tumor necrosis factor-α.

complement pathway is activated. All three pathways converge to cleave C3 into C3a, C3b, and C3d and generate the C5 convertase to produce C5a. The membrane attack complex (MAC) can directly kill gram-negative bacteria and, to a much lesser extent, gram-positive bacteria (the thick peptidoglycan of gram-positive bacteria shields them from the components). *Neisseria* are especially sensitive to complement lysis because of the truncated structure of lipooligosaccharide in the outer membrane. Complement facilitates elimination of all bacteria by producing:

1. **Chemotactic factors (C3a and C5a)** to attract neutrophils and macrophages to the site of infection;
2. **Anaphylatoxins (C5a, C3a, and to a lesser extent, C4a)** to stimulate mast cell release of histamine, increasing vascular permeability and allowing access to the infection site;
3. **Opsonins (C3b),** which bind to bacteria and promote their phagocytosis; and
4. **B-cell activator (C3d)** to enhance antibody production.

Binding of PAMPs to their receptors leads to activation of the inflammasome in epithelial and other cells to promote cytokine production (including the **acute-phase cytokines IL-1, IL-6, and tumor necrosis factor [TNF]-α**), protective responses, and maturation of DCs. The inflammasome promotes the cleavage and activation of precursors of IL-1β and IL-18 to initiate local inflammation (see Fig. 8.5).

IL-1 and TNF-α elicit a local inflammatory response by stimulating changes in the tissue, activating mast cells to produce histamine, and promoting fluid leakage by facilitating the attraction and diapedesis of neutrophils and macrophages to the site, activating these cells, and also activating systemic responses.

IL-1 and TNF-α are endogenous pyrogens, which induce fever and the **acute-phase response.** The acute-phase response can also be triggered by inflammation, tissue injury, prostaglandin E_2, and interferons generated during infection. The acute-phase response promotes changes that support host defenses and include fever, anorexia, sleepiness, metabolic changes, and production of proteins. Acute-phase proteins that are produced and released into the serum include C-reactive protein, complement components, coagulation proteins, LPS-binding proteins, transport proteins, protease inhibitors, and adherence proteins. The **C-reactive protein** complexes with phosphocholine on the surface of numerous bacteria and fungi and activates the complement pathway, facilitating removal of these organisms from the body through greater phagocytosis. The acute-phase proteins reinforce the innate defenses against infection.

These actions initiate **local acute inflammation**. Expansion of capillaries and increased blood flow brings more antimicrobial agents to the site. Increase in permeability and alteration of surface molecules of the microvasculature structure attracts and facilitates leukocyte entry and provides access for fluid and plasma proteins into the site of infection. Kinins and clotting factors induced by tissue damage (e.g., factor XII [Hageman factor], bradykinin, fibrinopeptides) also are involved in inflammation. These factors increase vascular permeability and are chemotactic for leukocytes. Products of arachidonic acid metabolism

BOX 10.2 Summary of Antibacterial Responses

Antimicrobial Peptides and Proteins

Defensins and other peptides disrupt membranes
Transferrin, lactoferrin, and other proteins sequester iron and other essential ions

Complement

Production of chemotactic and anaphylatoxin proteins (C3a, C5a)
Opsonization of bacteria (C3b)
Promotion of killing of gram-negative bacteria
Activation of B cells (C3d)

Neutrophils

Important antibacterial phagocytic cells
Killing by oxygen-dependent and oxygen-independent mechanisms

Activated Macrophages (M1)

Important antibacterial phagocytic cells
Killing by oxygen-dependent and oxygen-independent mechanisms
Production of TNF-α, IL-1, IL-6, IL-23, IL-12
Activation of acute-phase and inflammatory responses
Presentation of antigen to CD4 T cell

Dendritic Cells

Production of acute phase cytokines (TNF-α, IL-6, IL-1); IL-23; IL-12; IFN-α
Presentation of antigen to CD4 and CD8 T cells
Initiation of immune responses in naive T cells

T Cells

γ/δ T-cell and MAIT cell response to bacterial metabolites
NKT cell response to CD1 presentation of mycobacterial glycolipids
TH17 CD4 response activates neutrophils and epithelial cells
TH1 CD4 responses important for bacterial, especially intracellular, infections
TH2 CD4 response important for antibody protections

Antibody

Binding to surface structures of bacteria (fimbriae, lipoteichoic acid, capsule)
Blocking of attachment
Opsonization of bacteria for phagocytosis
Promotion of complement action
Promotion of clearance of bacteria
Neutralization of toxins and toxic enzymes

IFN-α, Interferon-α; *IL,* interleukin; *MAIT,* mucosal-associated invariant T cell; *NKT,* natural killer T (cell); *TH,* T helper (cell); *TNF-α,* tumor necrosis factor-α.

also affect inflammation. Cyclooxygenase-2 (COX-2) and 5-lipooxygenase convert arachidonic acid to **prostaglandins and leukotrienes,** respectively, which can mediate essentially every aspect of acute inflammation. The course of inflammation can be followed by rapid increases in serum levels of acute-phase proteins, especially C-reactive protein (which can increase 1000-fold within 24 to 48 hours) and serum amyloid A. Although these processes are beneficial, inflammation also causes **pain, redness, heat, and swelling and promotes tissue damage.** Inflammatory damage is caused to some extent by complement and macrophages but mostly by neutrophils.

The iDCs, macrophages, and other cells of the macrophage lineage also respond to PAMPs by producing acute-phase cytokines, IL-23 and IL-12. IL-23 and IL-12 provide the bridge to antigen-specific T-cell responses and activate memory TH17 cells and TH1 responses, respectively.

PHAGOCYTIC RESPONSES

C3a, C5a, bacterial products (e.g., formyl-methionyl-leucyl-phenylalanine [f-met-leu-phe]), and chemokines produced by epithelial cells, Langerhans cells, and other cells in skin and mucous epithelium are powerful chemoattractants for neutrophils, macrophages, and later in the response, lymphocytes. The chemokines and **TNF-α** cause the endothelial cells lining the capillaries (near the inflammation) and the leukocytes passing by to express complementary adhesion molecules (molecular "Velcro") to promote diapedesis (see Fig. 8.6; Animation 9). Polymorphonuclear neutrophils (PMNs) are the first cells to arrive at the site in response to infection; they are followed later by monocytes and macrophages. High demand causes recruitment of immature band forms of neutrophils from the bone marrow during infection. This is indicated by a "left shift" in the complete blood cell count. Neutrophils are recruited and activated by ILC3 cells and the TH17 response and macrophages, and DCs are activated by IFN-γ produced by ILC1 and NKT cells and the TH1 response.

Bacteria bind directly to the neutrophils and macrophages through receptors for bacterial carbohydrates (**lectins** [specific sugar-binding proteins]); fibronectin receptors (especially for *Staphylococcus aureus*); and via **receptors for opsonins** such as complement (C3b), C-reactive protein, mannose-binding protein, and the Fc portion of antibody (Animation 9). The microbes are internalized in a **phagocytic vacuole** that fuses with **primary lysosomes** (macrophages) or **granules** (PMNs) to allow inactivation and digestion of the vacuole contents (see Fig. 8.7 and Box 8.4).

The neutrophil kills the phagocytosed microbes by **oxygen-dependent killing** with hydrogen peroxide, superoxide ion, and hypochlorous ions and with **oxygen-independent killing** on fusion of the phagosome with azurophilic granules containing cationic proteins (e.g., cathepsin G) and specific granules containing lysozyme and lactoferrin. These proteins kill gram-negative bacteria by disrupting their cell membrane integrity, but they are far less effective against gram-positive bacteria, which are killed principally through the oxygen-dependent mechanism. **Nitric oxide** produced by neutrophils and activated macrophages has antimicrobial activity and is also a major second messenger molecule that enhances the inflammatory and other responses.

Neutrophils contribute to the inflammation in several ways. Prostaglandins and leukotrienes are released and increase vascular permeability, cause swelling (edema), and stimulate pain receptors. During phagocytosis, the granules may leak their contents to cause tissue damage. The neutrophils have short lives, and on death, neutrophils release a sticky deoxyribonucleic acid (DNA) **neutrophil extracellular trap (NET**) and become **pus.**

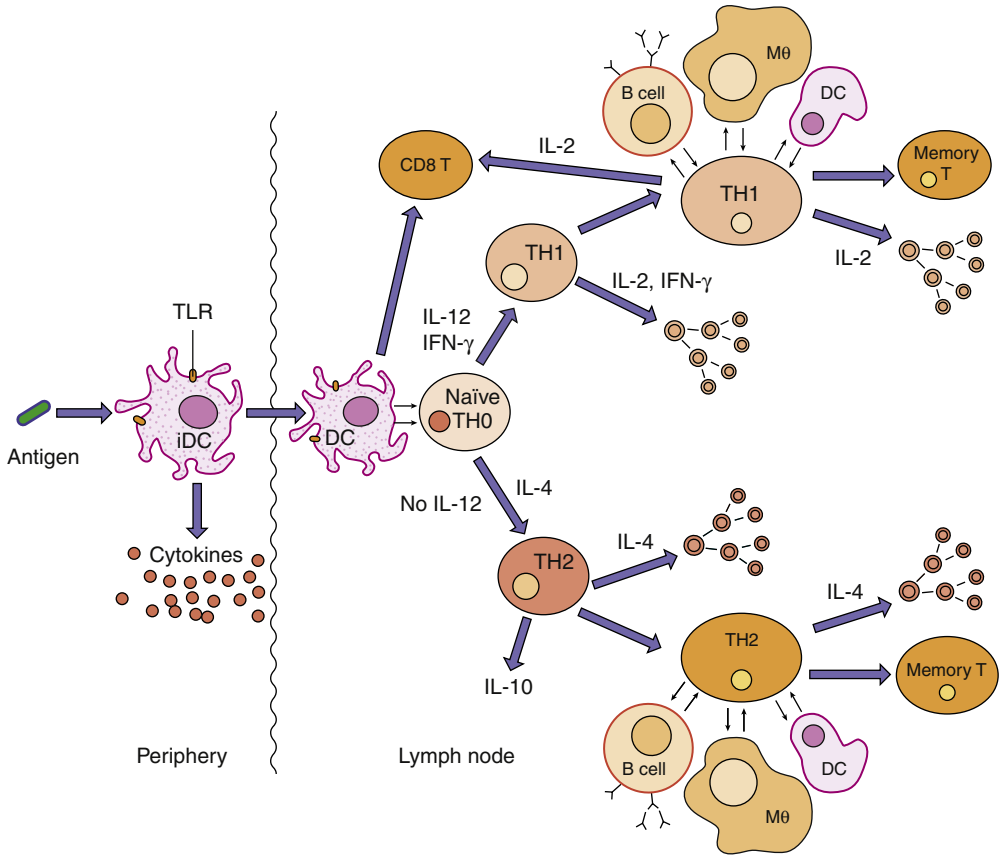

Fig. 10.2 Initiation and expansion of specific immune responses. Immature dendritic cells *(iDCs)* at the site of infection acquire microbial debris and become activated by Toll-like receptors *(TLRs)* and other pathogen pattern receptors binding their ligands. DCs produce cytokines, mature, and move to the lymph node. DCs present peptide antigen to naive T cells to initiate the antigen-specific and cytokine-directed response. During a secondary or memory response, B cells, macrophages, and DCs can present antigen to initiate the response. *IFN-γ,* Interferon-γ; *IL,* interleukin; *Mθ,* macrophage; *TH,* T helper (cell).

In contrast to neutrophils, macrophages have long lives, but the cells must be activated (*made angry*) and converted into M1 macrophages with IFN-**γ** to kill phagocytized microbes. Granulocyte-macrophage colony-stimulating factor (GM-CSF), TNF-**α**, and lymphotoxin (TNF-**β**) maintain the antimicrobial action (*keep them aggravated*). **Splenic macrophages** are important for clearing bacteria, especially encapsulated bacteria, from blood. Asplenic (congenitally or surgically) individuals are highly susceptible to pneumonia, meningitis, and other manifestations of *Streptococcus pneumoniae, Neisseria meningitidis,* and other encapsulated bacteria and yeast.

ANTIGEN-SPECIFIC RESPONSE TO BACTERIAL CHALLENGE

On ingestion of bacteria and after stimulation of Toll-like receptors (TLRs) by bacterial components, Langerhans cells and iDCs become mature, cease to phagocytize, and move to the lymph nodes to process and deliver their internalized antigen for presentation to T cells (Fig. 10.2). Movement of the DC to the lymph node may take 1 to 3 days. DCs also insert dendrites into the lumen of the intestine to "check" the normal flora. Antigenic peptides (with >11 amino acids) produced from phagocytosed proteins (exogenous route) are bound to class II major histocompatibility complex (MHC) molecules and are presented by these antigen-presenting cells (APCs) to naive **CD4 TH0 T cells.** TH0 provides the first stage, which is a generic expansion of the immune cells needed to respond to the infection. The CD4 T cells are activated by a combination of (1) antigenic peptide in the cleft of the MHC II molecule with the T-cell antigen receptor (TCR) and with CD4, (2) co-stimulatory signals provided by sufficient numbers of interactions of B7 molecules on the DC with CD28 molecules on the T cells to override inhibitory CTLA4 signals, and (3) IL-6 and other cytokines produced by the DCs. The TH0 cells produce IL-2, IFN-**γ**, and IL-4. Simultaneously, bacterial molecules with repetitive structures (e.g., capsular polysaccharide) interact with B cells expressing surface IgM and IgD specific for the antigen and activate the cell to grow and produce IgM. LPS and also the C3d component of complement activate B cells and promote the specific IgM antibody responses. Swollen lymph nodes are an indication of lymphocyte growth in response to antigenic challenge.

The conversion of TH0 cells to TH17 and TH1 cells initiates expansion of the host response. IL-6 together with the omnipresent transforming growth factor (TGF)-**β** promote the development of **CD4 TH17 T cells** (see Animation 5). *The IL-6, an acute phase cytokine, provides a cry for help despite the calming influence of TGF-β to elicit a quick inflammatory cytokine yell by the CD4 TH17 T*

cells to the epithelial cells and neutrophils to activate inflammatory responses. IL23 activates memory TH17 cells and maintains the response. TH17 cells produce IL-17, IL22 and TNF-**α** to activate epithelial cells and neutrophils and also promote production of antimicrobial peptides. *TH17 responses are especially important for early antibacterial responses and antimycobacterial responses.* A balance of TH17 and regulatory T cells (Treg) responses are also important to regulate the populations of intestinal flora.

DCs producing IL-12 promote TH1 responses. **CD4 TH1 T cells** (1) promote and reinforce inflammatory responses (e.g., IFN-**γ** activation of macrophage) and growth of T and B cells (IL-2) to expand the immune response and (2) promote B cells to produce complement-binding antibodies (IgM and then IgG on class switching) and mature into plasma cells and memory cells. These responses are important for the early phases of an antibacterial defense. TH1 responses are also essential for combating intracellular bacterial infections, including mycobacteria, which are hidden from antibody. During intracellular bacterial or fungal infections, macrophages will continuously present antigen to CD4 TH1 T cells, which will produce IFN-**γ** and TNF-**α** and cause transformation of other macrophages into epithelioid cells and giant cells, which surround the infection and produce a **granuloma**. Granulomas wall off intracellular infections arising either because the microbe can evade antimicrobial responses (e.g., *Mycobacterium tuberculosis*), the macrophages are not activated and cannot kill them (normal alveolar macrophages), or a genetic defect prevents generation of antimicrobial reactive oxygen substances, as in chronic granulomatous disease. *CD8 T cells facilitate clearance of intracellular infections by producing cytokines but are not essential for antibacterial immunity*.

CD4 TH2 T-cell responses are the default T-cell response to antigen. These responses are also initiated by DCs and are sustained by the B-cell presentation of antigen. TH2 responses can occur at the same time as TH17 and TH1 responses when antigen is delivered in lymph fluid to lymph nodes other than the draining lymph node. The DCs act as sewage inspectors who promote a response to clear out excess and damaged protein. This is the same type of response that occurs to injection of a bolus of antigen for an inactivated vaccine. Binding of antigen to the cell-surface antibody on B cells activates the B cells and also promotes uptake, processing of the antigen, and presentation of antigenic peptides on class II MHC molecules to the CD4 TH2 cell. The TH2 cell produces IL-4, IL-5, IL-6, IL-10, and IL-13, which enhance IgG production and, depending on other factors, the production of IgE or IgA. **CD4TFH** cells are a conduit for the TH1 or TH2 responses to promote somatic mutation, class switching, memory cell production, and terminal differentiation of B cells to plasma cell antibody factories in germinal centers.

$CD4^+CD25^+$ Tregs are generated in the thymus and prevent spurious activation of naive T cells, curtail both TH1 and TH2 responses, and promote development of some of the antigen-specific cells into memory T cells. Only DCs can override the Treg block to activate naive T cells. **Tr1 regulatory cells** are generated in the tissue, especially at mucosal surfaces, to control excessive and inflammatory local responses.

Antibodies are the primary protection against extracellular bacteria and toxins and promote the clearance and prevent the spread of bacteria in the blood (bacteremia). Antibody promotes complement activation, opsonizes bacteria for phagocytosis, blocks bacterial adhesion, and neutralizes (inactivates) exotoxins (e.g., tetanospasmin, botulinum toxin) and other cytotoxic proteins produced by bacteria (e.g., degradative enzymes). Vaccine immunization with inactivated exotoxins (toxoids) is the primary means of protection against the potentially lethal effects of exotoxins.

IgM antibodies are produced early in the antibacterial response. IgM bound to bacteria activates the classical complement cascade, promoting both the direct killing of gram-negative bacteria and the inflammatory responses. IgM is usually the only antibody produced against capsular polysaccharides and promotes opsonization of the bacteria with complement. Splenic macrophages depend on IgM bound to capsular polysaccharides to activate complement and opsonize the encapsulated bacteria so they can be recognized, phagocytized, and eliminated. The large size and limited transport mechanisms for IgM limits its ability to spread into tissue. IgM produced in response to polysaccharide vaccines (as for *S. pneumoniae*) can prevent bacteremia but not infection of the interstitium of the lung.

Approximately a week after IgM production is initiated, T-cell help promotes differentiation of the B cell and immunoglobulin class switching to produce IgG. **IgG** antibodies are the predominant serum antibody, especially on rechallenge. IgG antibodies fix complement and promote phagocytic uptake of the bacteria through Fc receptors on macrophages. **IgA** is the primary secretory antibody and is important for protecting mucosal membranes. Large amounts of secretory IgA are released to regulate the normal flora population, prevent adhesion of bacteria, and neutralize toxins at epithelial cell surfaces.

A primary antigen-specific response to bacterial infection takes at least 5 to 7 days, which allows considerable progression of a bacterial infection. On rechallenge to infection, long-lived plasma cells may still be producing antibody. Memory T cells can respond quickly to antigen presentation by DCs, macrophages, or B cells, not just DCs; memory B cells are present to respond quickly to antigen, and the secondary antibody response occurs within 2 to 3 days.

SKIN, INTESTINAL, AND MUCOSAL IMMUNITY

The skin, intestine, and mucous membranes are populated with bacteria on traversing the birth canal and soon thereafter. The immune response matures, and a balance develops between regulatory and inflammatory cells in response to this normal flora.

The intestinal flora is constantly interacting with and being regulated by the innate and immune systems of the gut-associated lymphoid tissue (see Fig. 7.5). Similarly, the immune response is shaped by its interaction with intestinal flora because regulatory cells limit the development of autoimmune responses and inflammation. A resident squad of immune cells works together within and adjacent to the epithelium of the intestine and in organized structures of the lymphoid follicles and Peyer patches. DCs, innate lymphoid cells, Treg, TH17, TH1, and other T and B cells work

together with the epithelial cells to monitor and control the bacteria within the gut. These cells produce antimicrobial peptides, and plasma cells secrete IgA into the gut to maintain a healthy mixture of bacteria. At the same time, Treg and Tr1 regulatory cells prevent the development of detrimental or excessive immune responses to the contents of the gut. Alterations in the microbial flora and its interaction with the innate and immune cells can disrupt the system and result in inflammatory bowel diseases. For example, absence or a mutation in the IL-23 receptor or NOD2 receptor for peptidoglycan enhances chances for certain types of Crohn disease.

In the skin, Langerhans cells are sentinel iDCs responsive to trauma and infection. Memory CD4 and CD8 T cells constantly cycle into the skin from the blood. In the respiratory tract, mucus traps, and cilia move the mucus and bacteria out of the lungs and antimicrobial peptides and secreted IgA control bacteria. Inflammatory responses are controlled by alveolar macrophages (M2 macrophages) to prevent tissue damage to normal flora. Similar to the gastrointestinal tract, DCs monitor the epithelium for normal and abnormal microbes.

BACTERIAL IMMUNOPATHOGENESIS

Activation of the inflammatory and acute-phase responses can initiate significant tissue and systemic damage and symptoms. Activation of macrophages and DCs in the liver, spleen, and blood by endotoxin can promote release of acute-phase cytokines into the blood, causing many of the symptoms of **sepsis,** including hemodynamic failure, shock, and death (see Cytokine Storm section in this chapter). Although IL-1, IL-6, and TNF-**α** promote protective responses to a local infection, these same responses can be life-threatening when activated by bloodstream or systemic infection. Increased blood flow and fluid leakage can lead to shock when it occurs throughout the body. Antibodies produced against bacterial antigens that share determinants with human proteins can initiate autoimmune tissue destruction (e.g., antibodies produced in poststreptococcal rheumatic fever). Nonspecific activation of CD4 T cells by **superantigens** (e.g., toxic shock syndrome toxin of *S. aureus*) promotes production of large amounts of cytokines and, eventually, the death of large numbers of T cells. The sudden massive release of cytokines ("cytokine storm") can cause shock and severe tissue damage (e.g., toxic shock syndrome) (see Cytokine Storm section in this chapter and Chapter 14).

BACTERIAL EVASION OF PROTECTIVE RESPONSES

The mechanisms used by bacteria to evade host-protective responses are discussed in Chapter 14 as virulence factors. These mechanisms include (1) inhibition of phagocytosis and intracellular killing in the phagocyte, (2) inactivation of complement function, (3) binding of the Fc portion of IgG and cleavage of IgA, (4) intracellular growth (avoidance of antibody), and (5) change in bacterial antigenic appearance. Some microorganisms, including but not limited to mycobacteria (also *Listeria* and *Brucella* species), survive and multiply within macrophages and use the macrophages as a protective reservoir or transport system to help spread the organisms throughout the body. However, cytokine-activated M1 macrophages can often kill the intracellular pathogens.

Antiviral Responses

HOST DEFENSES AGAINST VIRAL INFECTION

The immune response is the best and, in most cases, the only means of controlling a viral infection (Fig. 10.3 and Box 10.3). Unfortunately, it is also the source of pathogenesis for many viral diseases. Both humoral and cellular immune responses are important for antiviral immunity. **The ultimate goal of the immune response in a viral infection is to eliminate both the virus and the host cells harboring or replicating the virus.** Failure to resolve the infection may lead to persistent or chronic infection or death.

The course of the immune response and the nature of the immunopathogenesis of bacterial and viral infections are different. For bacteria, complement and the recruitment of neutrophils and macrophages are the initial response, and they rapidly drive the disease-associated inflammation. Antibody can control extracellular bacteria and their toxins. Interferons, NK cells, CD4 TH1 responses, and CD8 cytotoxic killer T cells are more important for viral infections than for bacterial infections. Complement and neutrophils have limited roles in antiviral defense.

For viruses, type I interferons and other cytokines initiate the response and cause **prodrome symptoms** followed by antigen-specific immunity, tissue-specific disease, and resolution. As a result, the time course and nature of bacterial and viral disease are very different.

INNATE DEFENSES

The innate defenses are oftentimes sufficient to control a viral infection, preventing the occurrence of symptoms. Body temperature, fever, interferons, other cytokines, the mononuclear phagocyte system, and NK cells provide a local rapid response to viral infection and also activate the specific immune defenses.

Body temperature and fever can limit replication or destabilize some viruses. Many viruses are less stable (e.g., herpes simplex virus) or cannot replicate (rhinoviruses) at 37° C or higher. The live influenza vaccine (LAIV) is attenuated because it cannot replicate above 25° C.

Viral infection can induce the release of cytokines (e.g., TNF, IL-1) and type 1 and 3 interferon from infected cells, macrophages, and especially plasmacytoid DCs (pDCs). Viral ribonucleic acid (RNA) (especially double-stranded [ds] RNA), DNA, and some viral glycoproteins are potent activators of TLRs and other pathogen pattern receptors to initiate these interferon and cytokine responses. Interferons and other cytokines trigger early local and systemic responses. Induction of fever and stimulation of the immune system are two of these systemic effects.

Cells of the **dendritic and mononuclear phagocyte system** phagocytose the viral and cell debris from virally infected cells. Macrophages in the liver (Kupffer cells) and

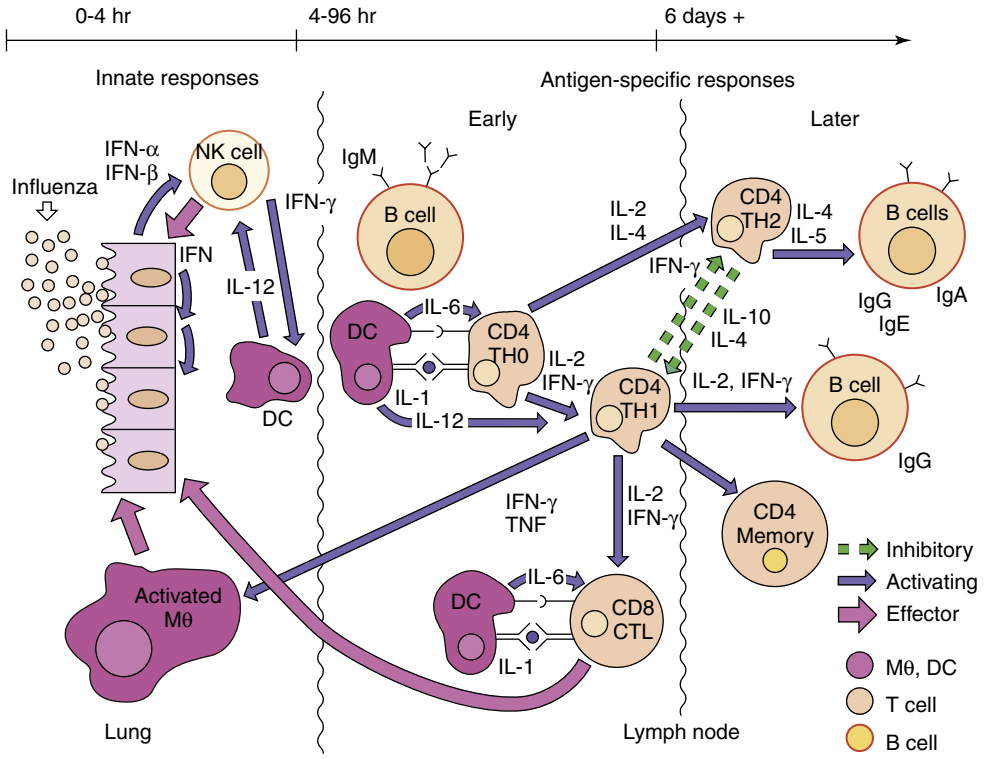

Fig. 10.3 Antiviral responses. The time course proceeds from local *(left)* to lymph node *(right)* and then returns to the infected site. The response to a virus (e.g., influenza virus) initiates with type 1 interferon production and action and natural killer *(NK)* cells. Dendritic cell *(DC)* initiation of CD4 and CD8 T cells is followed by activation of antigen-specific immunity similar to the antibacterial response, except that CD8 cytotoxic T lymphocytes *(CTLs)* are important antiviral responses. *IFN,* Interferon; *Ig,* immunoglobulin; *IL,* interleukin; *Mθ,* macrophage; *TH,* T helper (cell); *TNF,* tumor necrosis factor.

spleen rapidly filter many viruses from the blood. Antibody and complement bound to a virus facilitate its uptake and clearance by macrophages (opsonization). DCs and macrophages also present antigen to T cells and release IL-1, IL-12, and IFN-**α** to expand the innate and initiate the antigen-specific immune responses. The pDCs in the blood produce large amounts of IFN-**α** and other cytokines in response to a viremia.

NK cells are activated by IFN-**α**, IFN-**β**, and IL-12 to kill virally infected cells. Viral infection may reduce the expression of MHC antigens to remove inhibitory signals or may alter the carbohydrates on cell-surface proteins to provide cytolytic signals to the NK cell.

INTERFERON

Interferon was first described by Isaacs and Lindemann as a very potent factor that "interferes with" the replication of many different viruses. Interferon is the body's first active defense against a viral infection and acts like an "early warning system." In addition to activating a target cell antiviral defense to block viral replication, interferons activate the immune response and enhance T-cell recognition of the infected cell. Interferon is a very important defense against infection, but it also triggers systemic symptoms associated with many viral infections, such as malaise, myalgia, chills, and fever (nonspecific flulike symptoms), especially during viremia. Type I interferon is also a factor in causing systemic lupus erythematosus.

Interferons comprise a family of proteins that can be subdivided according to several properties, including size, stability, cell of origin, and mode of action (Table 10.2). **IFN-α** and **IFN-β** are type I interferons that share many properties, including structural homology and mode of action. B cells, epithelial cells, monocytes, macrophages, and iDCs make **IFN-α.** The pDCs in blood produce large amounts in response to viremia. Fibroblasts and other cells make **IFN-β** in response to viral infection and other stimuli. **IFN-λ** is a type III interferon with activity similar to **IFN-α** and is especially important for antiinfluenza responses. IFN-lambda (gr) is produced at epithelial and endothelial Barriers and promotes antiviral action and healing. **IFN-γ** is a type II interferon, which is a cytokine produced by activated T and ILC1 cells that occurs later in the infection. Although IFN-**γ** inhibits viral replication, its structure and mode of action differ from those of the other interferons. IFN-**γ** is also known as the **macrophage activation factor** and is the defining component of the TH1 response.

*The best inducer of IFN-**α** and IFN-**β** production is* **dsRNA,** *produced as the replicative intermediates of RNA viruses* or from the interaction of sense/antisense messenger RNAs (mRNAs) for some DNA viruses (Box 10.4). One dsRNA molecule per cell is sufficient to induce production of interferon. IFN-**α**, IFN-**β**, and IFN-**λ** can be induced and released within hours of infection (Fig. 10.4). Interaction of some enveloped viruses (e.g., herpes simplex virus and human immunodeficiency virus [HIV]) with pDCs can promote production of IFN-**α**. Alternatively, inhibition of protein synthesis in a virally infected cell can decrease production of a repressor protein of the interferon gene, allowing production of interferon. Nonviral interferon inducers include:

1. Intracellular microorganisms (e.g., mycobacteria, fungi, protozoa)

BOX 10.3 Summary of Antiviral Responses

Interferon

Induced by double-stranded RNA, inhibition of cellular protein synthesis, or enveloped virus
Initiates the antiviral state in surrounding cells
Antiviral state blocks viral replication on infection
Activates NK cells and systemic antiviral responses

NK Cells

Activated by IFN-α and IL-12
Produce IFN-γ, which activates macrophages and DCs
Target and kill virus-infected cells (especially enveloped viruses)

Macrophages and DCs

Macrophages filter viral particles from blood
Macrophages inactivate opsonized virus particles
Immature and plasmacytoid DCs produce IFN-α and other cytokines
DCs initiate and determine the nature of the CD4 and CD8 T-cell response
DCs and macrophages present antigen to CD4 and CD8 T cells

T Cells

Essential for controlling enveloped and noncytolytic viral infections
Recognize viral peptides presented by MHC molecules on cell surfaces
Antigenic viral peptides (linear epitopes) can come from any viral protein (e.g., glycoproteins, nucleoproteins)
CD4 T cells promote and regulate antiviral responses
CD8 cytotoxic T cells respond to viral peptide: class I MHC protein complexes on the infected cell surface

Antibody

Neutralizes extracellular virus:
  It blocks viral attachment proteins (e.g., glycoproteins, capsid proteins)
  It destabilizes viral structure
Opsonizes virus for phagocytosis
Promotes killing of target cell by the complement cascade and antibody-dependent cellular cytotoxicity
Resolves lytic viral infections
Blocks viremic spread to target tissue
IgM is an indicator of recent or current infection
IgG is a more effective antiviral than IgM
Secretory IgA is important for protecting mucosal surfaces
Resolution requires elimination of free virus (antibody) and the virus-producing cell (viral or immune cell–mediated lysis)

DC, Dendritic cell; *IFN,* interferon; *Ig,* immunoglobulin; *IL,* interleukin; *MHC,* major histocompatibility complex; *NK,* natural killer; *RNA,* ribonucleic acid.

TABLE 10.2 Basic Properties of Human Interferons

Property	IFN-α	IFN-β	IFN-γ
Previous designations	Leukocyte IFN type I	Fibroblast IFN type I	Immune IFN type II
Genes	>20	1	1
Molecular mass (Da)[a]	16,000-23,000	23,000	20,000-25,000
Acid stability	Stable[b]	Stable	Labile
Primary activator	Viruses	Viruses	Immune response
Principal source	Epithelium, leukocytes	Fibroblast	NK or T cell
Homology with human IFN-α	100%	30%-50%	<10%

[a]Molecular mass of monomeric form.
[b]Most subtypes but not all.
Da, Dalton; *IFN,* interferon; *NK,* natural killer (cell).
Data from White, D.O., 1984. Antiviral Chemotherapy, Interferons and Vaccines. Karger, Basel; Samuel, C.E., 1991. Antiviral actions of interferon. Interferon-regulated cellular proteins and their surprisingly selective antiviral activities. Virology 183, 1–11.

BOX 10.4 Type I Interferons

Induction

Double-stranded ribonucleic acid (during virus replication)
Viral inhibition of cellular protein synthesis
Enveloped virus interaction with plasmacytoid dendritic cell

Mechanism of Action

1. Initial infected cell or plasmacytoid dendritic cell releases interferon
2. Interferon binds to a specific cell-surface receptor on another cell
3. Interferon induces the "antiviral state":
   Synthesis of protein kinase R, 2′,5′-oligoadenylate synthetase, and ribonuclease L
4. Viral infection of the cell activates these enzymes
5. Protein synthesis is inhibited to block viral replication
   Degradation of mRNA (2′,5′-oligoadenylate synthase and RNAase L)
   Inhibition of ribosome assembly (protein kinase R)
6. Activation of innate and immune antiviral responses

Induction of flulike symptoms

2. Activators of certain TLRs or mitogens (e.g., endotoxins, phytohemagglutinin)
3. Double-stranded polynucleotides (e.g., poly I:C, poly dA:dT)
4. Synthetic polyanion polymers (e.g., polysulfates, polyphosphates, pyran)
5. Antibiotics (e.g., kanamycin, cycloheximide)
6. Low-molecular-weight synthetic compounds (e.g., tilorone, acridine dyes)

The interferon binds to specific receptors on the neighboring cells and induces the production of antiviral proteins and **the antiviral state.** However, these antiviral proteins are not activated until they bind dsRNA. The major antiviral effects of interferon are produced by two enzymes, **2′,5′-oligoadenylate synthetase** (an unusual polymerase) and **protein kinase R (PKR)** (Fig. 10.5), and for influenza, the **mx protein** is also important. Viral infection of the cell and production of dsRNA activate these enzymes and trigger a cascade of biochemical events that leads to (1) the inhibition of protein synthesis by PKR phosphorylation of an important ribosomal initiation factor (elongation initiation factor 2-α [eIF-2α]) and (2) the degradation of mRNA (preferentially, viral mRNA) by ribonuclease L, activated by 2′,5′-oligoadenosine. PKR and ribonuclease L become activated by multimerizing after binding to dsRNA or 2′,5′-oligoadenosine,

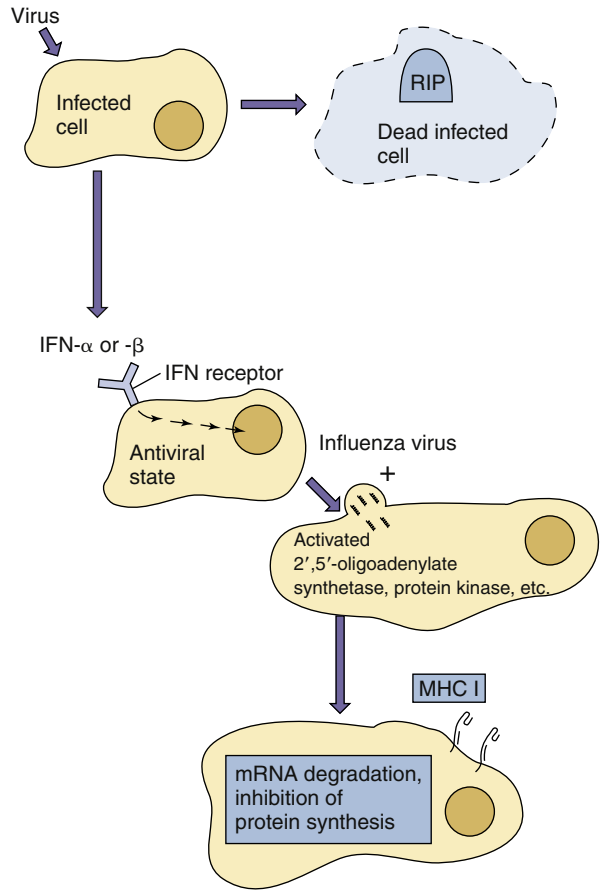

Fig. 10.4 Induction of the antiviral state by interferon *(IFN)*-**α** or IFN-**β**. Interferon is produced in response to viral infection but does not protect the initially infected cell. The interferon binds to a cell-surface receptor on other cells and induces production of antiviral enzymes (antiviral state). Viral infection and production of double-stranded RNA activates the antiviral activity, which results in protein synthesis inhibition. *MHC I,* Major histocompatibility antigen type I.

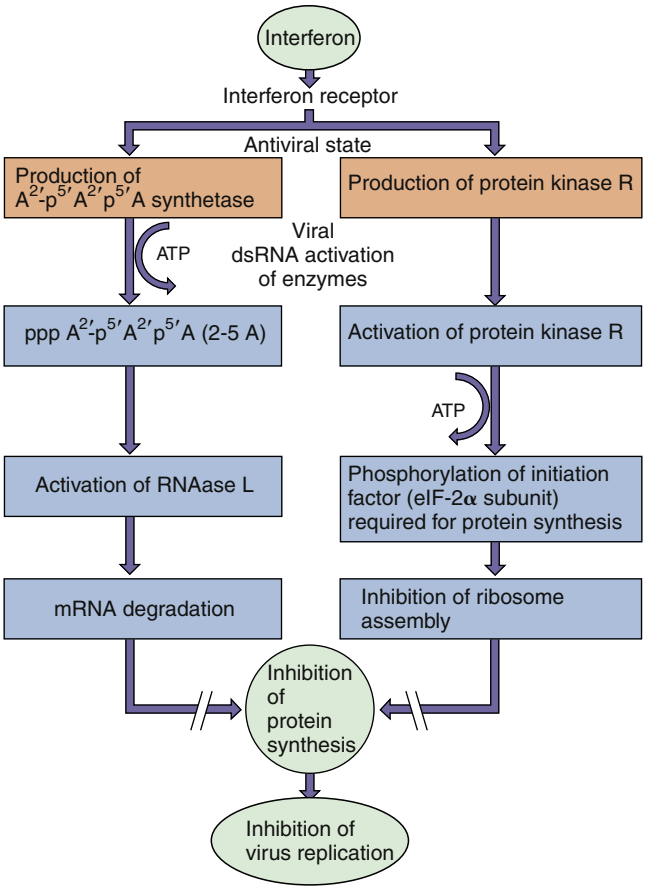

Fig. 10.5 Two major routes for interferon inhibition of viral protein synthesis. One mechanism involves induction of an unusual polymerase (2′,5′-oligoadenylate synthetase [2-5 A]) that is activated by double-stranded RNA *(dsRNA)*. The activated enzyme synthesizes an unusual adenine chain with a 2′,5′-phosphodiester linkage. The oligomer activates RNAase L, which degrades messenger RNA *(mRNA)*. The other mechanism involves induction of protein kinase R (PKR), which prevents assembly of the ribosome by phosphorylation of the elongation initiation factor *(eIF-2α)* to prevent initiation of protein synthesis from capped mRNAs. *ATP,* Adenosine triphosphate.

respectively, like beads on a string. *This process essentially puts the cellular protein synthesis factory "on strike" and prevents viral replication.* It must be stressed that interferon does not directly block viral replication. The antiviral state lasts for 2 to 3 days, which may be sufficient for the cell to degrade and eliminate the virus without being killed. Many viruses have mechanisms to evade or inhibit the interferon response.

Interferons stimulate cell-mediated immunity by activating effector cells and enhancing recognition of the virally infected target cell. Type I interferons activate NK cells and assist in activation of CD8 T cells. *IFN and activated NK cells provide an early, local, natural defense against viral infection.* IFN-**α** and IFN-**β** increase the expression of class I MHC antigens, enhancing the cell's ability to present antigen and making the cell a better target for cytotoxic T cells (CTLs).

Activation of macrophages by IFN-**γ** promotes production of more IFN-**α** and IFN-**β**, secretion of other biologic response modifiers, phagocytosis, production of reactive oxygen and nitrogen species, recruitment, and inflammatory responses. IFN-**γ** increases expression of class II MHC antigens on the macrophage to help promote antigen presentation to T cells.

Interferon also has widespread regulatory effects on cell growth, protein synthesis, and the immune response. All three interferon types block cell proliferation at appropriate doses.

Genetically engineered recombinant interferon is being used as an antiviral therapy for some viral infections (e.g., human papilloma and hepatitis C viruses). Effective treatment requires the use of the correct interferon subtype(s) and its prompt delivery at the appropriate concentration. IFN-**β** is used for treatment of multiple sclerosis. Interferons have also been used in clinical trials for the treatment of certain cancers. However, *interferon treatment causes flulike side effects such as chills, fever, and fatigue.*

ANTIGEN-SPECIFIC IMMUNITY

The goal of antigen-specific immunity is to eliminate free virus and virus-producing cells, but sometimes it can only control a chronic infection. Humoral immunity and cell-mediated immunity play different roles in resolving viral infections (i.e., eliminating the virus from the body). Humoral immunity (antibody) acts mainly on extracellular

virions, whereas cell-mediated immunity (T cells) is directed at the virus-producing cell.

HUMORAL IMMUNITY

Practically all viral proteins are foreign to the host and are immunogenic (i.e., capable of eliciting an antibody response). However, not all immunogens elicit protective immunity.

Antibody blocks the progression of disease through the **neutralization and opsonization** of cell-free virus. Protective antibody responses are generated toward the viral capsid proteins of naked viruses and the glycoproteins of enveloped viruses that interact with cell-surface receptors (viral attachment proteins). These antibodies can neutralize the virus by preventing viral interaction with target cells or by destabilizing the virus, initiating its degradation. Binding of antibody to these proteins also opsonizes the virus, promoting its uptake and clearance by macrophages. Antibody recognition of infected cells can also promote antibody-dependent cellular cytotoxicity (ADCC) by NK cells. Antibodies to other viral antigens may be useful for serologic analysis of the viral infection.

The major antiviral role of antibody is to prevent the spread of extracellular virus to other cells. Antibody is especially important in limiting the spread of the virus by **viremia,** preventing the virus from reaching the target tissue for disease production. *Antibody is most effective at resolving cytolytic infections.* For cytolytic infections, resolution occurs because the virus kills the cell factory and the antibody eliminates the extracellular virus.

T-CELL IMMUNITY

T-cell–mediated immunity promotes antibody and inflammatory responses (CD4 helper T cells) and kills infected cells (CTLs [primarily CD8 T cells]). The **CD4 TH1** response is generally more important than TH2 responses for controlling a viral infection, especially noncytolytic and enveloped viruses. **CD8** killer T cells promote apoptosis in infected cells after their TCR binds to a viral peptide presented by a class I MHC protein. The peptides expressed on class I MHC antigens are obtained from viral proteins synthesized within the infected cell (endogenous route). *The viral protein from which these peptides are derived may not elicit protective antibody* (e.g., intracellular or internal virion proteins, nuclear proteins, improperly folded or processed proteins [cell trash]). For example, the matrix and nucleoproteins (cytoplasmic) of the influenza virus and the infected cell protein 4 (ICP4) (nuclear) of herpes simplex virus are targets for CTLs but do not elicit protective antibody. An **immune synapse** formed by interactions of the TCR and MHC I and adhesion molecules creates a space into which **perforin,** a complement-like membrane pore former, and granzymes (degradative enzymes) are released to induce apoptosis in the target cell. Interaction of the Fas ligand protein on CD4 or CD8 T cells with the Fas protein on the target cell can also promote apoptosis. *CTLs kill infected cells and, as a result, eliminate the source of new virus.*

The CD8 T-cell response probably evolved as a defense against viral infection. Cell-mediated immunity is especially important for resolving infections by syncytia-forming viruses (e.g., measles, herpes simplex virus, varicella-zoster virus, HIV), which can spread from cell to cell without exposure to antibody, and by noncytolytic viruses (e.g., hepatitis A and measles viruses). CD8 T cells also interact with neurons to control, without killing, the recurrence of latent viruses (herpes simplex virus, varicella-zoster virus, and JC papillomaviruses).

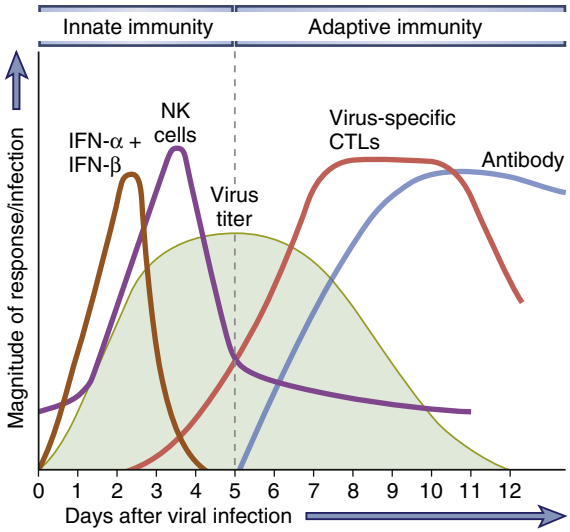

Fig. 10.6 Time course of antiviral immune responses. *CTL,* Cytotoxic T lymphocyte; *IFN-γ,* interferon-**γ.** (Modified from Abbas, A.K., Lichtman, A.H., Pillai, S., et al., 2015. Cellular and Molecular Immunology, eighth ed. Elsevier, Philadelphia, PA.)

IMMUNE RESPONSE TO VIRAL CHALLENGE

Primary Viral Challenge

The innate host responses are the earliest responses to viral challenge and are often sufficient to limit viral spread (Fig. 10.6; also see Fig. 10.3). The **type I interferons** produced in response to most viral infections initiate the protection of adjacent cells, enhance antigen presentation by increasing the expression of MHC antigens, and initiate the clearance of infected cells by activating NK cells and antigen-specific responses. Virus and viral components released from the infected cells are phagocytosed by and activate **iDCs** to produce cytokines, mature, and then move to the lymph nodes. Macrophages in the liver and spleen are especially important for clearing virus from the bloodstream (filters). These phagocytic cells degrade and process the viral antigens. DCs present the appropriate peptide fragments bound to class II MHC antigens to CD4 T cells and can also cross-present these antigens on MHC I molecules to CD8 T cells to initiate the response. The APCs also release IL-1, IL-6, and TNF-**α** and, with IL-12, promote activation of helper T cells and specific cytokine production (TH1 response). The type I interferons and these cytokines induce the prodromal flulike symptoms of many viral infections. The activated T cells move to the site of infection and also B-cell areas of the lymph node, in which macrophages and B cells present antigen and become stimulated by the T cells.

Antiviral immune responses require up to 8 days to develop after the virus has had time to spread. **IgM** is produced first, and its production indicates a primary infection. Activated **CD4** and **CD8** T cells are present 7 to 10

days after infection, which is approximately the same time as serum IgG. During infection, the number of CD8 T cells specific for antigen may increase 100,000-fold. The antigen-specific CD8 T cells move to the site of infection and kill virally infected cells. Recognition and binding to class I MHC viral-peptide complexes promotes apoptotic killing of the target cells, either through the release of perforin and granzymes (to disrupt the cell membrane) or through the binding of the Fas ligand with Fas on the target cell. **IgG** and **IgA** are produced after 7 to 10 days. Secretory IgA is made in response to a viral challenge of mucosal surfaces at the natural openings of the body (i.e., eyes, mouth, and respiratory and gastrointestinal systems). Resolution of the infection occurs later, when sufficient antibody is available to neutralize all virus progeny or when cellular immunity has been able to reach and eliminate the infected cells. *For the resolution of most enveloped and noncytolytic viral infections, TH1-mediated responses are required to kill the viral factory in addition to antibody neutralization of free virus.*

Viral infections of the brain and the eye can cause serious damage because these tissues cannot repair tissue damage and are **immunologically privileged sites** of the body. TH1 responses are normally suppressed to prevent the serious tissue destruction that accompanies extended inflammation. TH17 responses and special neutrophils are initiated against herpes simplex virus and other virus infections of the eye.

For many viral infections, the virus infection expands, spreads through the body, and infects the target tissue (e.g., brain, encephalitis; liver, hepatitis) before T-cell and antibody responses are generated. As a result, resolution of the expanded infection requires a larger and more intense immune response, which often includes the immunopathogenesis and tissue damage that cause disease symptoms.

Secondary Viral Challenge

In any war, it is easier to eliminate an enemy if its identity and origin are known and if establishment of its foothold can be prevented. Similarly in the human body, prior immunity established by prior infection or vaccination allows rapid, specific mobilization of defenses to prevent disease symptoms, promote rapid clearance of the virus, and block viremic spread from the primary site of infection to the target tissue to prevent disease. As a result, a viral challenge of an immunized individual is usually asymptomatic. Antibody and memory B and T cells are present in an immune host to generate a more rapid and extensive anamnestic (booster) response to the virus. Secretory antiviral IgA is produced quickly to provide an important defense to reinfection through the natural openings of the body, but it is produced only transiently.

Host, viral, and other factors determine the outcome of the immune response to a viral infection. Host factors include genetic background, immune status, age, and the general health of the individual. Viral factors include viral strain, infectious dose, and route of entry. The time required to initiate immune protection, the extent of the response, the level of control of the infection, and the potential for immunopathology (see Chapter 37) resulting from the infection differ after a primary infection and a rechallenge.

VIRAL MECHANISMS FOR ESCAPING THE HOST PROTECTIVE RESPONSES

A major factor in the virulence of a virus is its ability to escape immune resolution. Viruses may escape immune resolution by evading detection, preventing activation, or blocking delivery of the immune response. Specific examples are presented in Table 10.3. Many viruses encode special proteins that suppress innate and immune responses.

VIRAL IMMUNOPATHOGENESIS

The symptoms of many viral diseases are the consequence of cytokine action or overzealous immune responses. The flulike symptoms of influenza and any virus that establishes a viremia (e.g., arboviruses) occurring during the disease prodrome are a result of the interferon and other cytokine responses induced by the virus. Antibody interactions with large amounts of viral antigen in blood, such as occurs with hepatitis B virus infection, can lead to immune complex diseases. The measles rash, the extensive tissue damage to the brain associated with herpes simplex virus encephalitis (*-itis* means "inflammation"), and the tissue damage and symptoms of hepatitis are a result of cell-mediated immune and inflammatory responses. The more aggressive NK-cell and T-cell responses of adults exacerbate some diseases that are benign in children, such as varicella zoster virus, Epstein-Barr virus infectious mononucleosis, and hepatitis B infection. Yet, the lack of such a response in children makes them prone to chronic hepatitis B infection because the response is insufficient to kill the infected cells and resolve the infection.

Viral infections may provide the initial activation trigger that allows the immune system to respond to self-antigens and or express proteins that mimic host proteins to cause autoimmune diseases. A cytokine storm produced in response to an influenza or other virus infection may override peripheral tolerance mediated by Treg cells and allow initiation of an antiself CD4 T cell, antibody, or CD8 T-cell response in a person who is genetically predisposed to an autoimmune disease (MHC type).

Specific Immune Responses to Fungi

The primary protective responses to fungal infection are initiated by fungal cell wall carbohydrates binding to TLRs and the dectin-1 lectin and are provided by **neutrophils, macrophages, and antimicrobial peptides** (Box 10.5). CD4 T-cell **TH17 and TH1 responses** stimulate the neutrophil and macrophage responses. Patients deficient in neutrophils or these CD4 T-cell–mediated responses (e.g., patients with AIDS) are most susceptible to fungal (opportunistic) infections. Fungal infections can be held in check, undetectable for decades, by effective T-cell–induced immune

TABLE 10.3 Examples of Viral Evasion of Immune Responses

Mechanism	Viral Examples	Action
HUMORAL RESPONSE		
Hidden from antibody	Herpesviruses, retroviruses Herpes simplex virus, varicella zoster virus, paramyxoviruses, HIV	Latent infection Cell-to-cell infection (syncytia formation)
Antigenic variation	Lentiviruses (HIV) Influenza virus	Genetic change after infection Annual genetic changes (drift) Pandemic changes (shift)
Secretion of blocking antigen	Hepatitis B virus	Hepatitis B surface antigen
INTERFERON		
Block production	Hepatitis B virus Epstein-Barr virus	Inhibition of IFN transcription IL-10 analog (BCRF-1) blocks IFN-γ production
Block action	Adenovirus Herpes simplex virus	Inhibits upregulation of MHC expression; VA1 blocks double-stranded RNA activation of interferon-induced PKR Inactivates PKR and activates phosphatase (PP1) to reverse inactivation of initiation factor for protein synthesis
IMMUNE CELL FUNCTION		
Impairment of DC function	Measles, hepatitis C	Induction of IFN-β, which limits DC function
Impairment of lymphocyte function	Herpes simplex virus HIV Measles virus	Prevention of CD8 T-cell killing Kills CD4 T cells and alters macrophages Suppression of NK, T, and B cells
Immunosuppressive factors	Epstein-Barr virus	BCRF-1 (similar to IL-10) suppression of CD4 TH1 helper T-cell responses
DECREASED ANTIGEN PRESENTATION		
Reduced class I MHC expression	Adenovirus 12 Cytomegalovirus Herpes simplex virus	Inhibition of class I MHC transcription; 19-kDa protein (E3 gene) binds class I MHC heavy chain, blocking translocation to surface H301 protein blocks surface expression of β_2-microglobulin and class I MHC molecules ICP47 blocks TAP, preventing peptide entry into ER and binding to class I MHC molecules
INHIBITION OF INFLAMMATION		
	Poxvirus, adenovirus	Blocking of action of IL-1 or tumor necrosis factor

DC, Dendritic cell; *ER,* endoplasmic reticulum; *HIV,* human immunodeficiency virus; *ICP47,* infected cell protein 47; *IFN,* interferon; *IL,* interleukin; *kDa,* kilodalton; *MHC I,* major histocompatibility complex, antigen type 1; *NK,* natural killer; *PKR,* protein kinase R; *RNA,* ribonucleic acid; *TAP,* transporter associated with antigen production; *TH,* T helper (cell).

and neutrophil responses, only to awaken on neutrophil or T-cell deficiency and become lethal. Defensins and other cationic peptides may be important for some fungal infections (e.g., mucormycosis, aspergillosis), and nitric oxide may be important against *Cryptococcus* and other fungi. Respiratory infection with *Histoplasma* causes intracellular infection of macrophages eliciting granulomatous immune responses similar to *M. tuberculosis.* Antibody, as an opsonin, may facilitate clearance of the fungi but may also elicit disease-causing hypersensitivity reactions. Fungi and fungal spores are a common allergen and inducer of asthma and allergic alveolitis.

Specific Immune Responses to Parasites

It is difficult to generalize about the mechanisms of antiparasitic immunity because there are many different parasites that have different forms and reside in different tissue locations during their life cycles (Box 10.6 and Table 10.4). Stimulation of CD4 TH1, TH17, CD8 T-cell, and macrophage responses are important for intracellular infections, and neutrophils, macrophages, and TH2 antibody responses are important for extracellular parasites in blood and fluids. **IgE, eosinophil,** and **mast cell** action are triggered by and are especially important for eliminating worm (cestode and nematode) infections. The efficiency of control of the infection may depend on which response is initiated in the host. Dominance of a TH2 response against *Leishmania* infections results in the inhibition of TH1 activation of macrophages, inability to clear intracellular parasites, and a poor outcome. This observation provided the basis for the discovery that TH1 and TH2 responses are separate and antagonistic. Parasites have developed sophisticated mechanisms for avoiding immune clearance and often establish chronic infections.

BOX 10.5 Summary of Antifungal Responses

Antimicrobial peptides produced by epithelial cells, neutrophils, macrophages, and other cells are a primary defense.
Neutrophils are very important. They release reactive oxygen species and antifungal compounds and phagocytize fungi.
Macrophages are also important.
TH17 responses reinforce antifungal neutrophil and epithelial cell function and antimicrobial peptide production but promote inflammation.
TH1 responses reinforce macrophage functions but promote inflammation. Granuloma formation is important for intracellular infections *(Histoplasma)*.
TH2 responses, through IgG and IgA, can block attachment of fungi and toxin action, but IgE can promote allergy and asthma.

Ig, Immunoglobulin; *TH,* T helper (cell).

BOX 10.6 Summary of Antiparasitic Responses

Different immune responses are necessary depending on the nature of the parasite and the replicative stage.
Many parasites have multiple tricks to evade immune responses.
TH2 responses, through IgG and IgA, are important for preventing parasite binding to tissue, to block binding and entry into cells, to activate complement, and as an opsonin.
IgE bound to mast cells and eosinophils binds parasite and parasite antigen, and releases histamine and toxic substances to promote expulsion.
TH2 responses activate mucus secretion into colon to promote expulsion.
TH1 responses are especially important for intracellular infections *(Leishmania)* but promote inflammation.
Granuloma formation is important for intracellular infections *(Schistosoma)*.
TH17 responses reinforce epithelial and neutrophil action for extracellular parasites.

Ig, Immunoglobulin; *TH,* T helper (cell).

Extracellular parasites such as *Trypanosoma cruzi, Toxoplasma gondii,* and *Leishmania* species are phagocytosed by **macrophage. Antibody** may facilitate the uptake of (opsonize) the parasites. The parasites may replicate in the macrophage and hide from subsequent immune detection unless the macrophage is activated by TH1 responses. Killing of the parasites follows activation of the macrophage by IFN-γ or TNF-α and the induction of **oxygen-dependent killing mechanisms** (peroxide, superoxide, and nitric oxide).

TH1 production of IFN-γ and activation of macrophages are also essential for defense against intracellular protozoa and for the development of **granulomas** around *Schistosoma mansoni* eggs and worms in the liver. The granuloma protects the liver from toxins produced by the eggs. However, the granuloma also causes fibrosis that can interrupt the venous blood supply to portions of the liver, leading to hypertension and cirrhosis.

Neutrophils phagocytize and kill extracellular parasites through both oxygen-dependent and oxygen-independent mechanisms. **Eosinophils** localize near parasites, bind to IgG or IgE on the surface of larvae or worms (e.g., helminths, *S. mansoni,* and *Trichinella spiralis*), degranulate by fusing their intracellular granules with the plasma membrane, and release the **major basic protein** into the intercellular space. The major basic protein is toxic to the parasite.

For parasitic worm infections, IL-4 and other cytokines produced by epithelial cells, ILC2, and CD4 TH2 T cells are very important for stimulating production of IgE and activating mast cells (Fig. 10.7). IgE bound to Fc receptors on mast cells targets the cells to antigens of the infecting parasite. In the lumen of the intestine, antigen binding and cross-linking of the IgE on the mast cell surface stimulate the release of histamine and substances toxic to the parasite. TH2 responses also promote mucus secretion to coat and promote expulsion of the worm.

IgG antibody also plays an important role in antiparasitic immunity as an opsonin and by activating complement on the surface of the parasite.

TABLE 10.4 Examples of Antiparasitic Immune Responses

Parasite	Habitat	Main Host Effector Mechanism[a]	Method of Avoidance
Trypanosoma brucei	Bloodstream	Antibody + complement	Antigenic variation
Plasmodium species	Hepatocyte, erythrocyte	Antibody, cytokines, TH1 for hepatocyte	Intracellular growth, erythrocyte infection, antigenic variation
Toxoplasma gondii	Macrophage	O_2 metabolites, NO, lysosomal enzymes (TH1)	Inhibition of fusion with lysosomes
T. cruzi	Many cells	O_2 metabolites, NO, lysosomal enzymes (TH1)	Escape into cytoplasm, thus avoiding digestion in lysosome
Leishmania species	Macrophage	O_2 metabolites, NO, lysosomal enzymes, TH1 not TH2 response	Impairment of O_2 burst and scavenging of products; avoidance of digestion
Trichinella spiralis	Gut, blood, muscle	Myeloid cells, antibody + complement (TH2)	Encystment in muscle
Schistosoma mansoni	Skin, blood, lungs, portal vein	Myeloid cells, antibody + complement (TH2)	Acquisition of host antigens as camouflage: soluble antigens and immune complexes; antioxidants
Wuchereria bancrofti	Lymphatic system	Myeloid cells, antibody + complement (TH2)	Thick, extracellular cuticle; antioxidants
Helminths	Gut	IgE	Extracellular cuticle

[a]Antibody is most important for extracellular pathogens. Cell-mediated immunity (TH1 response) is most important for intracellular pathogens.
IgE, Immunoglobulin E; *NO,* nitric oxide; *TH,* T helper (cell).

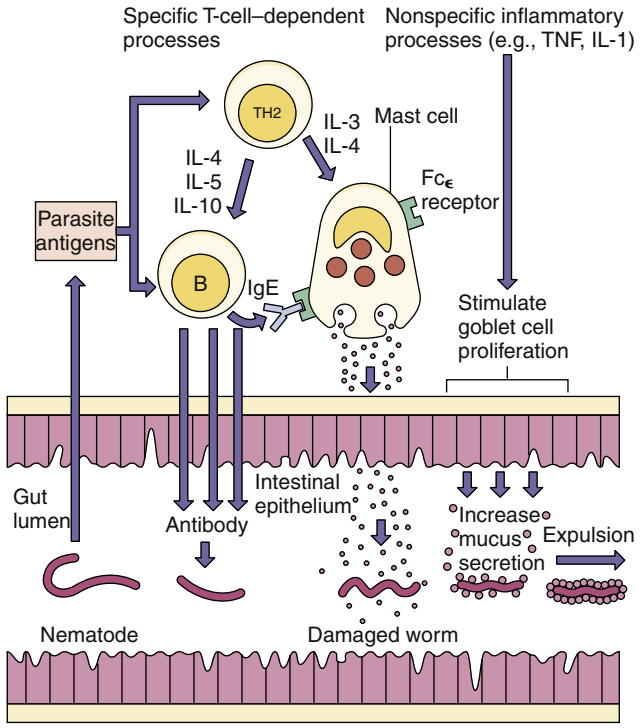

Fig. 10.7 Elimination of nematodes from the gut. TH2 responses are important for stimulating the production of antibody. Antibody can damage the worm. Antigen binding to immunoglobulin E *(IgE)* bound to mast cells triggers release of histamine and toxic substances. Increased mucus secretion also promotes expulsion. *IL,* Interleukin; *TH,* T helper (cell); *TNF,* tumor necrosis factor. (From Roitt, I., Brostoff, J., Male, D., et al., 1996. Immunology, fourth ed. Mosby, St Louis, MO.)

Malaria poses an interesting challenge for the immune response. Protective antibodies are made toward attachment and other surface proteins, but these differ for each of the stages of the parasite's development. TH1 responses and CTLs may be important during liver phases of infection. While in the erythrocyte, the parasite is hidden from antibody, unrecognizable by CTLs, but it can stimulate NK- and NKT-cell responses. Cytokines, especially TNF-α, produced by these cells promote protection but also immunopathogenesis. Immune complexes containing malarial components and cell debris released on erythrocyte lysis can clog small capillaries and activate type II hypersensitivity reactions (see later) and promote inflammatory tissue damage.

EVASION OF IMMUNE MECHANISMS BY PARASITES

Animal parasites have developed remarkable mechanisms for establishing chronic infections in the vertebrate host (see Table 10.4). These mechanisms include intracellular growth, inactivation of phagocytic killing, release of blocking antigen (e.g., *T. brucei, Plasmodium falciparum*), changing of antigenic appearance and development of cysts (e.g., protozoa, *Entamoeba histolytica;* helminths, *T. spiralis*) to limit access by the immune response. The African trypanosomes can reengineer the genes for their surface antigen (variable surface glycoprotein), which changes their antigenic appearance. Schistosomes can coat themselves with host antigens, including MHC molecules.

Other Immune Responses

Antitumor responses and **rejection of tissue transplants** are primarily mediated by the TH1 immune response (Animation 10). CD8 cytolytic T cells recognize and kill tumors expressing peptides from embryologic proteins, mutated proteins, or other proteins on class I MHC molecules (endogenous route of peptide presentation). These proteins may be expressed inappropriately by the tumor cell, and the host immune response may not be tolerized to them. Antitumor responses are suppressed by overexpression of checkpoint inhibitory molecules on the tumor cell, such as PD-L1 and PD-L2 that bind to PD-1, which prevent killing by cytolytic T cells. Wound healing immunosuppressive responses (tissue remodeling and angiogenesis) from M2 macrophages are also stimulated by tumors.

T-cell rejection of **allografts** used for tissue transplants is triggered by recognition of graft protein peptides and the graft MHC I antigen. Antibody to foreign antigens can also cause rejection by activating complement and ADCC killing of the graft. In addition to host rejection of the transplanted tissue, cells from the donor of a blood transfusion or a tissue transplant can initiate a response or react against the new host in a **graft-versus-host (GVH) response.** An in vitro test of T-cell activation and growth in a GVH-like response is the **mixed lymphocyte reaction.**

Immunopathogenesis

HYPERSENSITIVITY RESPONSES

Once activated, the immune response is sometimes difficult to control and causes tissue damage. Hypersensitivity reactions are responsible for many of the symptoms associated with microbial infections. Hypersensitivity reactions occur to people with an established immunity to the antigen. *The mediator and the time course* primarily distinguish the four types of hypersensitivity responses (Table 10.5). Types I to III are antibody driven and type IV is cell-mediated responses.

Type I hypersensitivity is caused by **IgE** and is associated with **allergic, atopic,** and **anaphylactic reactions** (Fig. 10.8; Animation 11). IgE allergic reactions are rapid-onset reactions. IgE binds to Fc receptors on mast cells and becomes the cell-surface receptor for antigens **(allergens).** Cross-linking of several cell-surface IgE molecules by an allergen (e.g., pollen) triggers degranulation, releasing **chemoattractants** (chemokines, leukotrienes) to attract eosinophils, neutrophils, and mononuclear cells; **activators** (histamine, platelet-activating factor, tryptase, kininogenase, and cytokines) to promote vasodilation and edema; and **spasmogens** (histamine, prostaglandin D_2, and leukotrienes) to directly affect bronchial smooth muscle and promote mucus secretion. After 8 to 12 hours, a late-phase reaction develops because of the infiltration of eosinophils and CD4 T cells and cytokine reinforcement of inflammation. Desensitization (allergy shots) produces IgG to bind the allergen and prevent allergen binding to IgE.

Type II hypersensitivity is caused by **antibody binding to cell-surface molecules.** The antibody may

TABLE 10.5 Hypersensitivity Reactions

Reaction Type	Onset Time	Key Features	Beneficial Effects	Pathologic Effects
Type I	<30 min	Soluble antigen-triggered, IgE-dependent release of vasoactive mediators followed by late-phase reaction	Antiparasitic responses and toxin neutralization	Localized allergies (e.g., hay fever, asthma) Systemic anaphylaxis
Type II	<8 hr	Cell-bound antibody promoting C′-mediated cytotoxicity; antibody binding and modulation of receptor function	Direct lysis and phagocytosis of extracellular bacteria and other susceptible microbes	Destruction of red blood cells (e.g., transfusion reactions, Rh disease) Organ-specific tissue damage in some autoimmune diseases (e.g., Goodpasture syndrome)
Type III	<8 hr	Soluble antigen-antibody complexes activate C′	Acute inflammatory reaction at site of extracellular microbes and their clearance	Arthus reaction (localized) Serum sickness and drug reactions (generalized) Systemic autoimmune diseases
Type IV	24-72 hr (acute); >1 week (chronic)	Phagocytized protein antigen presented to CD4 T cells activates macrophages and inflammation	Protection against infection by fungi, intracellular bacteria, and viruses	Acute: contact dermatitis, tuberculosis skin test Chronic: granuloma formation

Ig, Immunoglobulin.

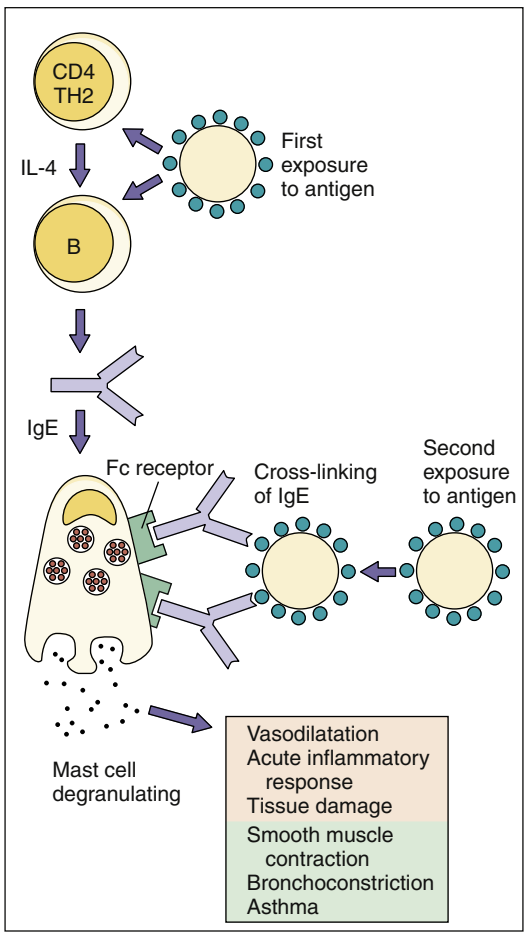

Fig. 10.8 Type I hypersensitivity: immunoglobulin E *(IgE)*–mediated atopic and anaphylactic reactions. IgE produced in response to the initial challenge binds to Fc receptors on mast cells and basophils. Allergen binding and cross-linking of the cell-surface IgE promotes release of histamine and prostaglandins from granules to produce symptoms. Examples are hay fever, asthma, penicillin allergy, and reaction to bee stings. *IL,* Interleukin; *TH,* T helper (cell).

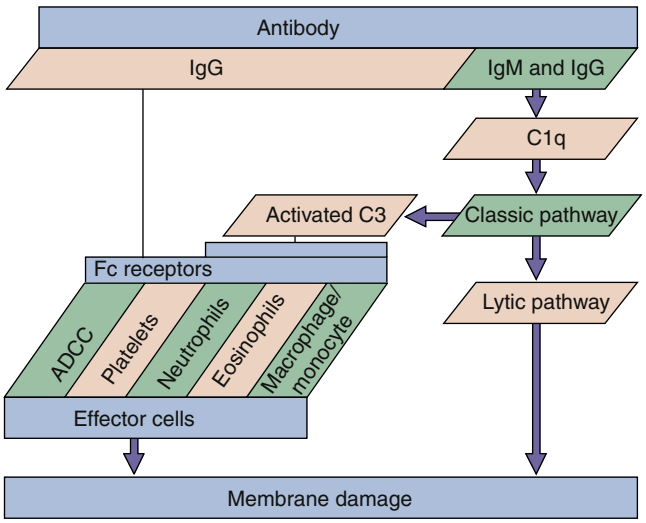

Fig. 10.9 Type II hypersensitivity: mediated by cell-bound antibody and complement. Complement activation promotes direct cell damage through the complement cascade and by the activation of effector cells. Examples are Goodpasture syndrome, the response to Rh factor in newborns, and autoimmune endocrinopathies. *ADCC,* Antibody-dependent cellular cytotoxicity; *Ig,* immunoglobulin.

promote cytolytic responses by the **classic complement cascade** or ADCC (Fig. 10.9). These reactions occur as early as 8 hours after a tissue or blood transplant or as part of a chronic disease. Examples of these reactions are autoimmune hemolytic anemia and Goodpasture syndrome (lung and kidney basement membrane damage). Another example is hemolytic disease of newborns (blue babies), which results when maternal IgG antibody, generated during the first pregnancy to an incompatible Rh protein factor on fetal erythrocytes, crosses the placenta and harms a second baby (Rh incompatibility).

Antireceptor antibody activation or inhibition of effector functions is also considered a type II response. Myasthenia gravis is caused by antibodies to acetylcholine receptors on

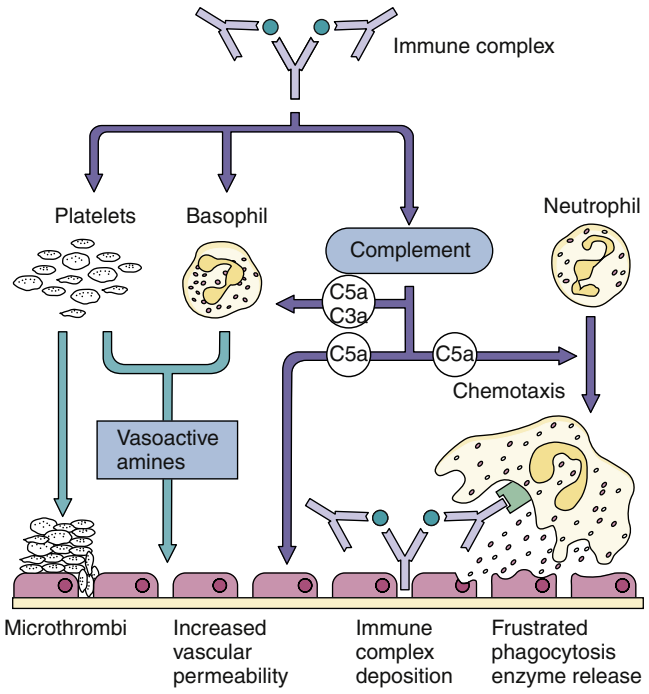

Fig. 10.10 Type III hypersensitivity: immune complex mediated. Immune complexes can be trapped in the kidney and elsewhere in the body and can activate complement to promote inflammation. Examples are serum sickness, nephritis associated with chronic hepatitis B infection, and Arthus reaction.

neurons, Graves disease results from antibody stimulation of the thyroid-stimulating hormone (TSH) receptor, and some forms of diabetes can result from antibodies blocking the insulin receptor.

Type III hypersensitivity responses result from activation of **complement** by **immune complexes** (Fig. 10.10). In the presence of an abundance of soluble antigen in the bloodstream, large antigen-antibody complexes form, become trapped in capillaries (especially in the kidney), and then initiate the classical complement cascade. Activation of the complement cascade initiates inflammatory reactions. Immune complex disease may be caused by infections (e.g., hepatitis B, malaria, staphylococcal infective endocarditis, group A streptococcal–associated glomerulonephritis, viral antigen (e.g., hepatitis B surface antigen induced polyarteritis nodosa), autoimmunity (e.g., rheumatoid arthritis, systemic lupus erythematosus), or persistent inhalation of antigen (e.g., mold, plant, or animal antigens). For example, farmer's lung, a pneumonitis, is caused by preformed IgG binding to mold spores within the alveolae that were inhaled from hay. Type III hypersensitivity reactions can be induced in presensitized people by the intradermal injection of antigen to cause an **Arthus reaction,** which is a skin reaction characterized by redness and swelling. Annual booster immunizations to influenza often elicits an Arthus reaction at the site of the immunization because of the presence of antibody from the previous year's immunization. Serum sickness, extrinsic allergic alveolitis (a reaction to inhaled fungal antigen), and glomerulonephritis result from type III hypersensitivity reactions. Serum sickness can result after receiving animal immunoglobulin (e.g., antisnake venom) on multiple occasions.

Type IV hypersensitivity responses **(delayed-type hypersensitivity [DTH] reactions)** are **T-cell–mediated** inflammatory responses (Fig. 10.11 and Table 10.6). It usually takes 24 to 48 hours for antigen to be presented to **circulating T cells,** for them to move to the site, and then for them to **activate neutrophils and macrophages** to induce inflammation. DTH is responsible for **contact dermatitis** (e.g., cosmetics, nickel) and the response to poison ivy. Intradermal injection of **tuberculin antigen** (purified protein derivative) elicits firm swelling that is maximal 48 to 72 hours after injection and indicative of prior exposure to *M. tuberculosis* (Fig. 10.12). Granulomatous hypersensitivity occurs with tuberculosis, leprosy, schistosomiasis, sarcoidosis, and Crohn disease. **Granulomas** form in response to continued stimulation by the intracellular growth of *M. tuberculosis*. These structures consist of epithelioid cells created from chronically activated macrophages, fused epithelioid cells (multinucleated giant cells) surrounded by lymphocytes, and fibrosis caused by the deposition of collagen from fibroblasts. The granulomas restrict the spread of *M. tuberculosis* as long as CD4 T cells can provide IFN-γ.

CYTOKINE STORM

Sepsis, toxin-mediated shock syndrome (e.g., induced by *Staphylococcus* toxic shock syndrome toxin), some viral infections (e.g., severe acute respiratory syndrome [SARS]) and influenza, and GVH disease induce an overwhelming stimulation of innate and/or immune responses, producing excessive amounts of cytokines that disrupt the physiology of the body. The consequences are multisystem dysregulation, rash, fever, and shock. **Superantigens** clamp together TCRs with the MHC II molecules on APCs to activate up to 20% of CD4 T cells. This triggers uncontrolled release of excess T-cell–produced and macrophage-produced cytokines until the T cell dies of apoptosis. Bacteria, endotoxin, or viruses in blood can promote production of large amounts of acute-phase cytokines and type I interferons by pDCs, and certain viruses are very potent activators of interferon and cytokine production. Large amounts of TNF-α are produced during cytokine storms. TNF-α can promote inflammatory processes such as enhanced vascular leakage and activation of neutrophils that can be beneficial on a local level, but on a systemic level they will lead to fever, chills, aches, stimulation of coagulation pathways, elevated liver enzymes, loss of appetite, enhanced metabolism, weight loss, increased vascular permeability, and potentially shock.

Autoimmune Responses

Normally a person is tolerized to self-antigens during the development of T cells and B cells and by Treg cells. Autoimmunity can be induced by any or all of the following: overriding Treg-induced tolerance by excessive cytokine production (e.g., cytokine storm, systemic lupus erythematosus), cross-reactivity with microbial antigens (e.g.,

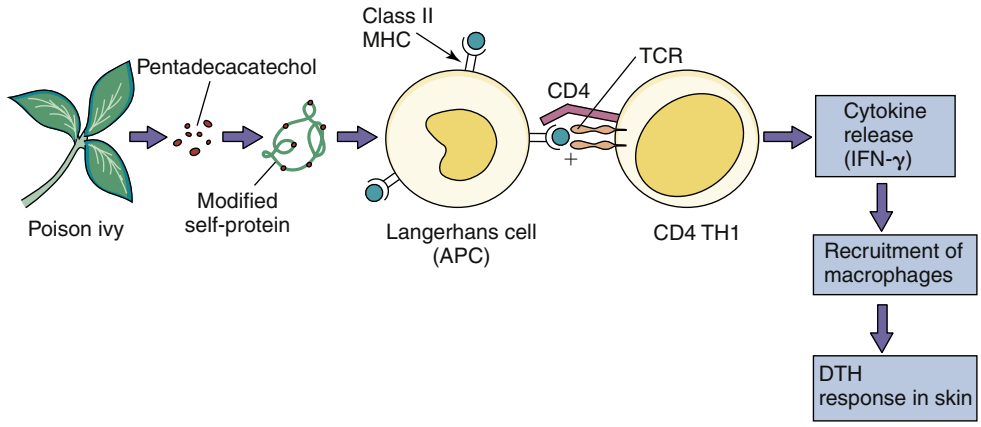

Fig. 10.11 Type IV hypersensitivity: delayed-type hypersensitivity *(DTH)* mediated by CD4 T cells *(TH1)*. In this case, chemically modified self-proteins are processed, and peptides are presented on antigen-presenting cells *(APCs)* to CD4 memory T cells cycling through the skin, which become activated and release cytokines (including interferon-γ *[IFN-γ]*) that promote inflammation. Other examples of DTH are the tuberculin response (purified protein derivative test) and reaction to metals such as nickel. *TCR,* T-cell receptor; *TH,* T helper (cell).

TABLE 10.6 Important Characteristics of Four Types of Delayed-Type Hypersensitivity Reactions

Type	Reaction Time	Clinical Appearance	Histologic Appearance	Antigen
Jones-Mote	24-48 hr	Skin swelling	Basophils, lymphocytes, mononuclear cells	Intradermal antigen: reaction to PPD or other protein antigen
Tuberculin	48 hr	Local induration and swelling with or without fever	Mononuclear cells, lymphocytes and monocytes, reduced macrophages	Dermal: tuberculin (PPD), mycobacterial, leishmanial
Contact	48 hr	Eczema	Mononuclear cells, edema, raised epidermis	Epidermal: nickel, rubber, poison ivy
Granulomatous	4 wk	Skin induration	Epithelioid cell granuloma, giant cells, macrophages, fibrosis with or without necrosis	Persistent antigen or antigen-antibody complexes in macrophages or "nonimmunologic" (e.g., talcum powder)

PPD, Purified protein derivative.

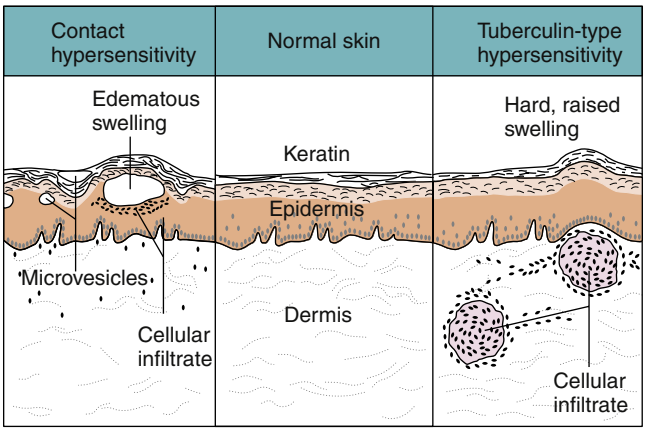

Fig. 10.12 Contact and tuberculin hypersensitivity responses. These type IV responses are cell mediated but differ in the site of cell infiltration and in the symptoms. Contact hypersensitivity occurs in the epidermis and leads to the formation of blisters; tuberculin-type hypersensitivity occurs in the dermis and is characterized by swelling.

group A streptococcal infection, rheumatic fever), polyclonal activation of lymphocytes induced by tumors or infection (e.g., malaria, Epstein-Barr virus infection), a genetic predisposition toward presentation of self-antigenic peptides on MHC molecules, or lack of tolerization to specific antigens.

Autoimmune diseases result from the hypersensitivity reactions initiated by autoantibodies and self-reactive T cells. People with certain MHC antigens are at higher risk for autoimmune responses (e.g., HLA-B27: juvenile rheumatoid arthritis, ankylosing spondylitis) because of its ability to bind and present self-peptides. Once initiated, a cycle is established between APCs, especially B cells, and T cells, which produce cytokines to promote inflammation and tissue damage and more self-antigen. TH17 and TH1 responses are responsible for rheumatoid arthritis and other diseases.

Immunodeficiency

Immunodeficiency may result from genetic deficiencies, starvation, drug-induced immunosuppression (e.g., steroid treatment, cancer chemotherapy, chemotherapeutic suppression of tissue graft rejection), cancer (especially of immune cells), or disease (e.g., AIDS) and naturally occurs in neonates and pregnant women. Deficiencies in specific protective responses put a patient at high risk for serious disease caused by infectious agents that should be controlled by that response (Table 10.7). These "natural experiments" illustrate the importance of specific responses in controlling specific infections.

TABLE 10.7 Infections Associated with Defects in Immune Responses

Defect	Pathogen
Induction by physical means (e.g., burns, trauma)	*Pseudomonas aeruginosa* *Staphylococcus aureus* *S. epidermidis* *Streptococcus pyogenes* *Aspergillus* species *Candida* species
Splenectomy	Encapsulated bacteria and fungi
Granulocyte and monocyte defects in movement, phagocytosis, or killing or decreased number of cells (neutropenia)	*S. aureus* *S. pyogenes* *S. pneumoniae* *Haemophilus influenzae* *Escherichia coli* *Klebsiella* species *P. aeruginosa* *Nocardia* species *Aspergillus* species *Candida* species
Individual components of complement system	*S. aureus* *S. pneumoniae* *Pseudomonas* species *Proteus* species *Neisseria* species
T cells	Herpes viruses (HSV, EBV, CMV, HHV6, HHV7, HHV8) Polyoma viruses (JC, BK) *Listeria monocytogenes* *Mycobacterium* species *Nocardia* species *Aspergillus* species *Candida* species *Cryptococcus neoformans* *Histoplasma capsulatum* *Pneumocystis jiroveci* *Toxoplasma* *Strongyloides stercoralis*
B cells	Enteroviruses *S. aureus* *Streptococcus* species *H. influenzae* *Neisseria meningitidis* *E. coli* *Giardia lamblia* *P. jiroveci*
Combined immunodeficiency	See pathogens listed for T cells and B cells

CMV, Cytomegalovirus; *EBV,* Epstein-Barr virus; *HHV,* human herpesvirus; *HSV,* herpes simplex virus.

IMMUNOSUPPRESSION

Immunosuppressive therapy is important for reducing excessive inflammatory or immune responses or for preventing the rejection of tissue transplants by T cells. Aspirin and nonsteroidal antiinflammatory drugs (NSAIDs) target the cyclooxygenases that generate inflammatory prostaglandins (e.g., PGD_2) and pain. Other antiinflammatory treatments target the production and action of cytokines. Corticosteroids prevent their production by macrophages and may be toxic to T cells. Soluble forms of the TNF-**α** receptor and antibody to TNF-**α** can be used to block the binding of TNF-**α** and prevent its action. Antibodies to IL-12, IL-23, IL-1, and other cytokines and adhesion proteins on T cells or APCs, can block T-cell activation of inflammatory and other responses.

Immunosuppressive therapy for transplantation generally inhibits the action or causes the lysis of T cells. Cyclosporine, tacrolimus (FK-506), and rapamycin prevent the activation of T cells (see Fig. 9.3). Anti-CD40 ligand and anti–IL-2 prevent activation of T cells, whereas anti-CD3 promotes complement lysis of T cells to suppress T-cell responses. Anti–TNF-**α** and other ablative therapies increase risk of *M. tuberculosis* disease and anti-**α**4 integrin cell adhesion molecule increases the risk of JC virus reactivation disease (progressive multifocal leukoencephalopathy).

HEREDITARY COMPLEMENT DEFICIENCIES AND MICROBIAL INFECTION

Inherited **deficiencies of C1q, C1r, C1s, C4,** and **C2** components are associated with defects in activation of the classic complement pathway that lead to greater susceptibility to pyogenic (pus-producing) staphylococcal and streptococcal infections (Fig. 10.13). A **deficiency of C3** leads to a defect in activation of all pathways, which also results in a higher incidence of pyogenic infections. **Defects of the properdin factors** impair activation of the alternative pathway, which also results in an increased susceptibility to pyogenic infections. Finally, **deficiencies of C5 through C9** are associated with defective cell killing, which raises the susceptibility to disseminated infections by *Neisseria* species.

DEFECTS IN PHAGOCYTE ACTION

People with defective phagocytes are more susceptible to bacterial infections but not to viral or protozoal infections (Fig. 10.14). The clinical relevance of oxygen-dependent killing is illustrated by **chronic granulomatous disease** in children who lack the enzymes (e.g., nicotinamide adenine dinucleotide phosphate [NADPH] oxidase) to produce superoxide anions. Although phagocytosis is normal, these children have an impaired ability to oxidize NADPH and destroy bacteria or fungi through the oxidative pathway. In patients with **Chédiak-Higashi syndrome,** the neutrophil granules fuse when the cells are immature in the bone marrow. Thus neutrophils from these patients can phagocytose bacteria but have greatly diminished ability to kill them. Granulomas are formed around the infected phagocyte to control the infection. **Asplenic individuals** are at risk for infection with encapsulated organisms because such people lack the filtration mechanism of spleen macrophages. Other deficiencies are shown in Fig. 10.14.

DEFICIENCIES IN ANTIGEN-SPECIFIC IMMUNE RESPONSES

People deficient in **T-cell function** are susceptible to **opportunistic infections** by (1) viruses, especially enveloped and noncytolytic viruses and recurrences of viruses that establish latent infections; (2) intracellular bacteria; (3) fungi; and (4) some parasites. T-cell deficiencies can also prevent the maturation of B-cell antibody responses. T-cell deficiencies can arise from genetic disorders (e.g., X-linked immunodeficiency syndrome, Duncan disease, DiGeorge syndrome) (Table 10.8), infection (e.g., HIV and AIDS),

cancer chemotherapy, or immunosuppressive therapy for tissue transplantation.

The T-cell response of **neonates** is deficient but supplemented by maternal IgG. Insufficient TH1 responses and the resulting deficiency in IFN-γ puts them at high risk to infections by herpesviruses. Similarly, the less pronounced cell-mediated immune and inflammatory responses of **children** decrease the severity (compared with adults) of herpes (e.g., infectious mononucleosis, chickenpox) and hepatitis B infections but increase the potential for the establishment of a chronic hepatitis B virus infection because of incomplete resolution. Pregnancy also induces immunosuppressive measures to prevent rejection of the fetus (a foreign tissue).

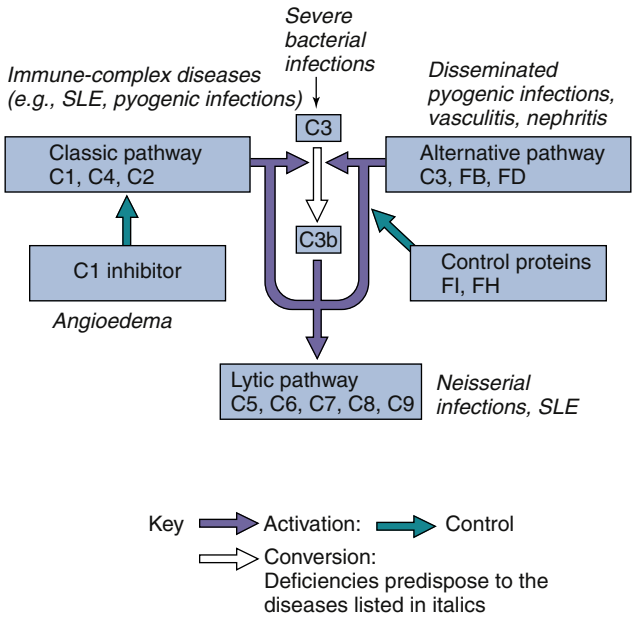

Fig. 10.13 Consequences of deficiencies in the complement pathways. A deficiency in the activation or control of complement can lead to disease. Inability to generate C3 or C5 fragments compromises recruitment of neutrophils and macrophages, opsonization and clearance of bacteria and proteins, and activation of B cells. Lack of inhibitors allows spurious activation and inflammation. *SLE,* Systemic lupus erythematosus.

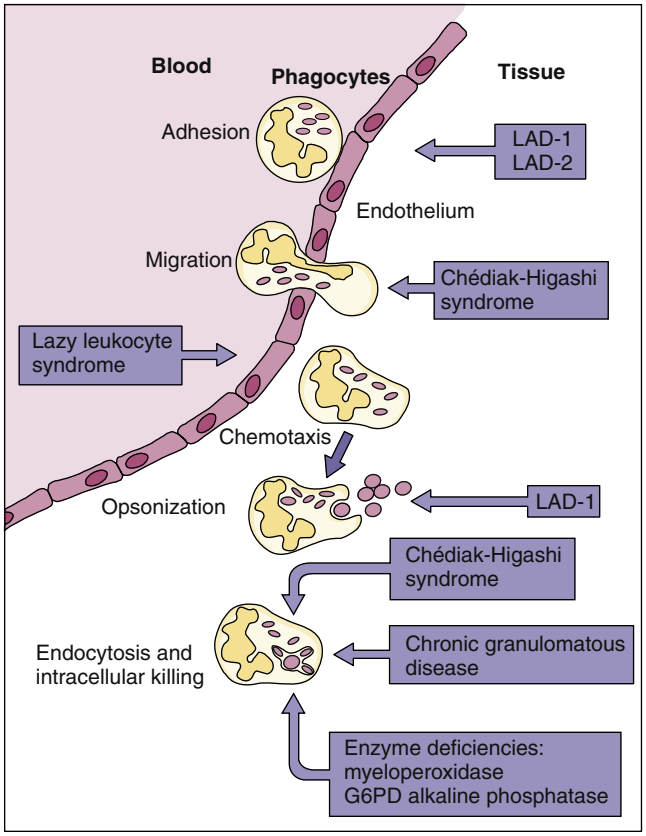

Fig. 10.14 Consequences of phagocyte dysfunction. Inability to sense or access an infection or to bind, internalize, or kill internalized bacteria increases susceptibility to serious bacterial and fungal disease. *G6PD,* Glucose-6-phosphate dehydrogenase; *LAD-1,* leukocyte adhesion deficiency-1.

TABLE 10.8 Immunodeficiencies of Lymphocytes

Condition	T Cell No.	T-Cell Function	B Cell No.	Serum Antibodies	Incidence[a]
XLA, Bruton syndrome	✓	✓	⇊	↓	Rare
RAG1 or RAG2 deficiency	⇊	⇊	⇊	None	Rare
X-SCID	⇊	↓	✓	↓	Rare
XLP, Duncan syndrome	✓	↓	✓	✓ or ↓	Rare
X-hyper IgM (CD40 or CD40L mutation)	✓	↓	✓	IgM↑↑ No IgG, IgE, or IgA	Rare
Wiskott-Aldrich syndrome	✓	↓	✓	↓	Rare

Ataxia telangiectasia	↓	↓	✓	IgE↓, IgA↓, IgG2↓	Uncommon
DiGeorge syndrome	⇊	↓	✓	IgG↓, IgE↓, IgA↓	Very rare
IgA deficiency	✓	✓	✓	IgA↓	Common

[a]Approximate incidence: very rare = $<10^{-6}$; rare = 10^{-5} to 10^{-6}; common = 10^{-2} to 10^{-3}.

✓, Normal; ↑, increased; ↓, decreased or defective; *ADA,* adenosine deaminase; *Ag,* antigen; *HLA,* human leukocyte antigen; *Ig,* immunoglobulin; *PNP,* purine nucleoside phosphorylase; *RAG,* recombination-activating gene; *XLA,* X-linked agammaglobulinemia; *XLP,* X-linked lymphoproliferative (syndrome); *X-SCID,* X-linked severe, combined immunodeficiency disease.

Modified from Brostoff, J., Male, D.K., 1994. Clinical Immunology: An Illustrated Outline. Mosby, St Louis, MO.

B-cell deficiencies may result in a complete lack of antibody production (hypogammaglobulinemia), inability to undergo class switching, or inability to produce specific subclasses of antibody. People deficient in antibody production are very susceptible to **bacterial infection. IgA deficiency,** which occurs in 1 of 700 whites, results in a greater susceptibility to respiratory infections.

Questions

1. Describe the types of immune responses that would be generated to the following different types of vaccines. Consider the route of processing and presentation of the antigens and the cells and cytokines involved in generating each response.
   a. Tetanus toxoid: intramuscular injection of a bolus of formalin-fixed, heat-inactivated tetanus toxin protein
   b. *S. pneumoniae* 23 valent capsular vaccine: intramuscular injection of 23 types of capsular polysaccharide (no protein)
   c. Live, attenuated measles vaccine: intramuscular injection of virus that replicates in cells and expresses antigen in cells and on cell surfaces

2. Fill in the appropriate columns:

IMMUNODEFICIENCY DISEASE	IMMUNE DEFECT	SUSCEPTIBILITY TO SPECIFIC INFECTIONS
Chédiak-Higashi syndrome		
Chronic granulomatous disease		
Complement C5 deficiency		
Complement C3 deficiency		
Complement C1 deficiency		
Complement C6, C7, C8, or C9 deficiency		
IgA deficiency		
X-linked agammaglobulinemia		
X-linked T-cell deficiency		
AIDS		
DiGeorge syndrome		

11 Antimicrobial Vaccines

Immunity, whether generated in reaction to infection or immunization or administered as therapy, can prevent or lessen the serious symptoms of disease. The memory immune responses activated on challenge of an immunized individual are faster and stronger than for an unimmunized individual. The immunization of a population, such as personal immunity, stops the spread of the infectious agent by reducing the number of susceptible hosts **(herd immunity).** Protection of newborns and infants who are too young for vaccination depend on herd immunity. Immunization programs on national and international levels have achieved the following goals:

1. Protection of population groups from the symptoms of pertussis, diphtheria, tetanus, and rabies
2. Protection and control of the spread of measles, mumps, rubella, varicella zoster virus, influenza, rotavirus, and *Haemophilus influenzae* type B (Hib)
3. Elimination of wild-type poliomyelitis in most of the world and smallpox worldwide
4. Reduction in cancer risk caused by high-risk human papillomavirus (HPV) or chronic hepatitis B virus (HBV) infections

In conjunction with immunization programs, measures can be taken to prevent disease by limiting the exposure of healthy people to infected people **(quarantine)** and by eliminating the source (e.g., water purification) or means of spread (e.g., mosquito eradication) of the infectious agent. As of 1977, natural smallpox was eliminated through a successful World Health Organization (WHO) program that combined vaccination and quarantine. Polio and measles have also been targeted for elimination.

Vaccine-preventable diseases still occur, however, where immunization is unavailable or too expensive (developing countries) or misinformation, personal beliefs, or complacency deter use. For example, measles outbreaks, which cause 2 million deaths annually worldwide, have increased in Europe and the United States for all of these reasons. Further discussion of each of the vaccines is presented in later chapters with the disease they prevent.

Types of Immunizations

The injection of purified antibody, antibody-containing serum, or immune cells to provide rapid temporary protection or treatment of a person is termed **passive immunization.** Newborns receive natural passive immunity from maternal immunoglobulin that crosses the placenta or is present in the mother's milk. Therapeutic antibodies that block autoimmune responses and personalized T-cell or dendritic cell (DC) antitumor therapy are also forms of passive immunity.

Active immunization occurs when an immune response is stimulated because of challenge with an immunogen, such as exposure to an infectious agent **(natural immunization)** or through exposure to microbes or their antigens in **vaccines.** On subsequent challenge with the virulent agent, a secondary immune response is activated that is faster and more effective at protecting the individual, or antibody is present to block the spread or virulence of the agent.

PASSIVE IMMUNIZATION

Passive immunization may be used

1. To prevent disease after a known exposure (e.g., needlestick injury with blood that is contaminated with HBV),
2. To ameliorate the symptoms of an ongoing disease,
3. To protect immunodeficient individuals, and
4. To block the action of bacterial toxins or venoms and prevent the diseases they cause (i.e., as therapy).

Immune serum globulin preparations derived from seropositive humans or animals (e.g., horses) are available as prophylaxis for several bacterial and viral diseases (Table 11.1). Human serum globulin is prepared from pooled plasma and contains the normal repertoire of antibodies for an adult. Special high-titer immune globulin preparations are available for HBV (HBIg), varicella zoster virus (VZIg), rabies (RIg), and tetanus (TIg). Human immunoglobulin is preferable to animal immunoglobulin because there is little risk of a hypersensitivity reaction (serum sickness).

Monoclonal antibody preparations are being developed for protection against various agents and diseases. Many of these antibodies are genetically engineered from human immunoglobulin genes or "humanized" to minimize rejection reactions. In addition to infectious diseases, monoclonal antibodies are being used as therapy to block the overzealous cytokine and cellular responses in autoimmune diseases, to initiate antitumor responses, and for other therapies.

ACTIVE IMMUNIZATION

The term *vaccine* is derived from vaccinia virus, which is a less virulent member of the poxvirus family that is used to immunize people against smallpox. Classical vaccines can be subdivided into two groups on the basis of whether they elicit an immune response on infection (**live vaccines** such as vaccinia) or not **(inactivated–subunit-killed vaccines)** (Fig. 11.1). Newer approaches simulate infection by injecting **deoxyribonucleic acid (DNA) or ribonucleic acid (RNA) vaccines,** which elicit immune responses to an encoded microbial or other protein (described later).

TABLE 11.1 Immune Globulins for Passive Immunity[a]

Disease	Source
Hepatitis A	Human
Hepatitis B	Human
Measles	Human
Rabies	Human[b]
Chickenpox, varicella zoster	Human[b]
Cytomegalovirus	Human
Tetanus	Human[b], equine
Botulism	Equine
Diphtheria	Equine
Respiratory syncytial virus	Monoclonal

[a]Immunoglobulins to other agents may also be available.
[b]Specific high-titer antibody is available and is the preferred therapy.

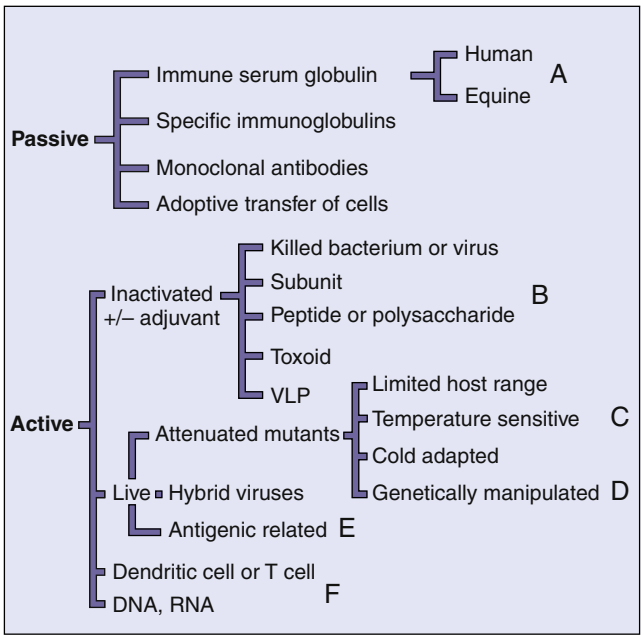

Fig. 11.1 Types of immunizations. Antibodies (passive immunization) can be provided to block the action of an infectious agent, or an immune response can be elicited (active immunization) by natural infection or vaccination. The different forms of passive and active immunization are indicated. (A) Equine antibodies can be used if human or genetically engineered antibody is not available. (B) Vaccine can consist of components purified from the infectious agent or can be developed through genetic engineering (virus-like particle *[VLP]*). (C) Vaccine selected by passage at low or high temperature in animals, embryonated eggs, or tissue culture cells. (D) Deletion, insertion, reassortment, and other laboratory-derived mutants. (E) Vaccine composed of a virus from a different species that has a common antigen with the human virus. (F) Newer and experimental vaccine approaches. *RNA,* Ribonucleic acid.

Inactivated Vaccines

Inactivated vaccines use a large amount of antigen to produce a protective antibody response but without the risk of infection by the agent. Inactivated vaccines can be produced by chemical (e.g., formalin), irradiation, or heat inactivation of bacteria, bacterial toxins, or viruses, or by purification or synthesis of the components or subunits of the infectious agents. Inactivated vaccines usually generate antibody (TH2 responses) instead of cell-mediated immune responses.

TABLE 11.2 Advantages and Disadvantages of Live versus Inactivated Vaccines

Property	Live	Inactivated
Route of administration	Natural[a] or injection	Injection
Dose of antigen	Low	High
Number of doses, amount	Single,[b] low	Multiple, high
Need for adjuvant	No	Yes
Duration of immunity	Long term	Short term
Antibody response	IgG, IgA[c]	IgM, IgG
Cell-mediated immune response	Good	Poor
Potential lability	Yes	More stable
Side effects	Occasional mild symptoms	Occasional sore arm
Reversion to virulence	Rarely	None

[a]Oral or respiratory, in certain cases.
[b]Boosters may be required (yellow fever, measles, rubella) after 6 to 10 years.
[c]IgA if delivered via the oral or respiratory route.
Ig, Immunoglobulin.
Adapted from White, D.O., Fenner, F.J., 1986. Medical Virology, third ed. Academic, New York.

These vaccines are usually administered with an **adjuvant** that boosts their immunogenicity by enhancing uptake by or stimulating DCs and macrophages. Aluminum hydroxide or aluminum phosphate **(alum)** is the most common and approved adjuvant. Many protein vaccines are precipitated onto alum to form particles large enough to promote their uptake by DCs and macrophages. Other adjuvants may stimulate Toll-like receptors or activate the inflammasome in these antigen-presenting cells to elicit responses that more closely resemble natural immunization. Experimental adjuvants include emulsions, virus-like particles (VLPs), liposomes (defined lipid complexes), bacterial cell wall components, molecular cages for antigen, polymeric surfactants, and attenuated forms of cholera toxin and *Escherichia coli* lymphotoxin. These latter molecules are potent adjuvants for secretory antibody (immunoglobulin [Ig]A) after intranasal or oral immunization. MF59 (squalene microfluidized in an oil and water emulsion) is used in the Fluad influenza vaccine and $AS01_b$, monophosphoryl lipid A (MPL) mixed with saponin in a liposome, is used for the Shingrix zoster vaccine. Use of the adjuvant promotes cell-mediated responses and allows reduction in the amount of antigen required to elicit protective immunity.

Inactivated, rather than live, vaccines are used to confer protection against toxins, most bacteria, and viruses that cannot be attenuated; they may cause recurrent infection, or have oncogenic potential. Inactivated vaccines are generally safe except in people who have allergic reactions to vaccine components. The disadvantages of inactivated vaccines are listed next and compared with live vaccines in Table 11.2:

1. Immunity is not usually lifelong.
2. Immunity may be only humoral (TH2) and not cell mediated.

TABLE 11.3 Bacterial Vaccines[a,b]

Bacteria (Disease)	Vaccine Components	Who Should Receive Vaccinations
Corynebacterium diphtheriae (diphtheria)	Toxoid	Children and adults
Clostridium tetani (tetanus)	Toxoid	Children and adults
Bordetella pertussis (pertussis)	Acellular	Children and teens
Haemophilus influenzae B (Hib)	Capsule polysaccharide-protein conjugate	Children
Neisseria meningitidis A, C, Y, W135 (meningococcal disease) *N. meningitidis* B	Capsule polysaccharide-protein conjugate, capsule polysaccharide Outer membrane proteins	People at high risk (e.g., those with asplenia), travelers to epidemic areas (e.g., military personnel), children
Streptococcus pneumoniae (pneumococcal disease; meningitis)	Capsule polysaccharides; capsule polysaccharide-protein conjugate	Children, people at high risk (e.g., those with asplenia), the elderly
Vibrio cholerae (cholera)	Killed cell	Travelers at risk to exposure
Salmonella typhi (typhoid)	Killed cell; polysaccharide	Travelers at risk to exposure, household contacts, sewage workers
Bacillus anthracis (anthrax)	Killed cell	Handlers of imported fur, military personnel
Yersinia pestis (plague)	Killed cell	Veterinarians, animal handlers
Francisella tularensis (tularemia)	Live attenuated	Animal handlers in endemic areas
Coxiella burnetii (Q fever)	Inactivated	Sheep handlers, laboratory personnel working with *C. burnetii*
Mycobacterium tuberculosis (tuberculosis)	Live attenuated bacillus Calmette-Guérin *M. bovis*	Not recommended in United States

[a]Listed in order of frequency of use.
[b]A more complete list can be found at www.fda.gov/BiologicsBloodVaccines/Vaccines/ApprovedProducts/ucm093833.htm (accessed September 18, 2019).

3. The vaccine does not elicit a local IgA response.
4. Booster shots are required.
5. Larger doses must be used.

There are three major types of inactivated bacterial vaccines: **toxoid** (inactivated toxins), **inactivated (killed)** bacteria, and surface components of the bacteria, such as **capsule or protein subunits.** The bacterial vaccines currently available are listed in Table 11.3. Most antibacterial vaccines protect against the pathogenic action of toxins.

Inactivated viral vaccines are available for **polio, hepatitis A, influenza, and rabies,** among other viruses. The Salk polio vaccine **(inactivated poliomyelitis vaccine [IPV])** is prepared through formaldehyde inactivation of virions. A rabies vaccine is prepared through the chemical inactivation of virions grown in human diploid tissue culture cells. Because of the slow course of rabies, the vaccine can be administered immediately after a person is exposed to the virus and still elicit a protective antibody response.

A **subunit vaccine** consists of the bacterial or viral components that elicit a protective immune response. Surface structures of bacteria and the viral attachment proteins (capsid or glycoproteins) elicit protective antibodies. T-cell antigens may also be included in a subunit vaccine. The immunogenic component can be isolated from the bacterium, virus, or virally infected cells by biochemical means, or the vaccine can be prepared through genetic engineering by the expression of cloned viral genes in bacteria or eukaryotic cells. For example, the HBV subunit vaccine was initially prepared from surface antigen obtained from human sera of chronic carriers of the virus. Today HBV vaccine is obtained from yeast bearing the HBsAg gene. The antigen is purified, chemically treated, and absorbed onto alum to be used as a vaccine. The subunit proteins used in the HBV and the HPV vaccines form **VLPs,** which are more immunogenic than individual proteins. Similarly, a vaccine to prevent recurrence of varicella zoster virus (VZV) (shingles) consists of the $AS101_b$ adjuvanted liposome formulation of VZV glycoprotein E.

Most of the inactivated annual influenza vaccines consist of a mixture of the hemagglutinin and neuraminidase proteins purified from embryonated eggs or tissue culture cells infected with different strains of influenza A and B or from genetically engineered protein. The vaccine mixture is formulated annually to elicit protection from the virus strains predicted to threaten the population in the coming year.

Vaccines against *H. influenzae* B, *Neisseria meningitidis* types, *Salmonella typhi,* and *Streptococcus pneumoniae* (23 strains) are prepared from capsular polysaccharides. Unfortunately, polysaccharides are generally poor immunogens (T-independent antigens). The meningococcal vaccine contains the polysaccharides of four major serotypes (A, C, Y, and W-135 but not B). The pneumococcal vaccine contains polysaccharides from 23 serotypes. The immunogenicity of a polysaccharide can be enhanced by making it into a T-dependent antigen by chemical linkage to a protein carrier **(conjugate vaccine)** (e.g., diphtheria toxoid or *N. meningitidis* outer membrane protein) (Fig. 11.2). The Hib polysaccharide-diphtheria toxoid complex is approved for administration to infants and children. An *S. pneumoniae* "pneumococcal" conjugate vaccine has been developed in which polysaccharide from the 13 most prevalent strains in the United States is attached to a nontoxic form of the diphtheria toxoid. This vaccine is available for use in infants and young children. The other polysaccharide vaccines are

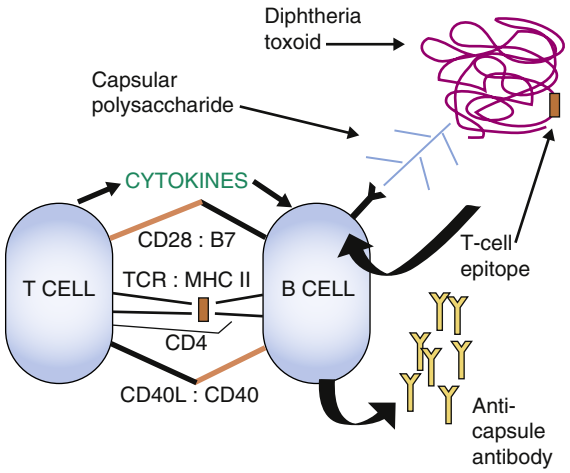

Fig. 11.2 Capsular polysaccharide conjugate vaccines. Capsular polysaccharides are poor immunogens, do not elicit T-cell help, and only elicit immunoglobulin (Ig)M without memory. Capsule polysaccharide conjugated to a protein (e.g., diphtheria toxoid) binds to surface anti-polysaccharide IgM on the B cell, the complex is internalized and processed, and then a peptide is presented on major histocompatibility complex II *(MHC II)* to CD4 T cells. The T cells become activated, produce cytokines, and promote immunoglobulin class switching for the polysaccharide-specific B cell. The B cell can become activated and make IgG, and memory cells will develop. *TCR,* T-cell receptor.

less immunogenic and are administered to individuals older than 2 years.

Live Vaccines

Live vaccines are prepared with microbes limited in their ability to cause disease (e.g., **avirulent** or **attenuated** microbes). Live vaccines are especially useful for protection against infections caused by enveloped viruses, which require T-cell immune responses for resolution of the infection. Immunization with a live vaccine resembles the natural infection in that the immune response progresses through the natural innate and antigen-specific immune responses so that humoral, cellular, and memory immune responses are developed. Immunity is generally long-lived and, depending on the route of administration, can mimic the normal immune response to the infecting agent. However, the following list includes three problems with live vaccines:

1. The vaccine virus may still be dangerous for immunosuppressed people or pregnant women who do not have the immunologic resources to resolve even a weakened virus infection.
2. The vaccine may revert to a virulent viral form.
3. The viability of the vaccine must be maintained.

Live bacterial vaccines are especially important for eliciting protection against intracellularly growing bacteria that require a combination of antibody and cell-mediated immune responses. These vaccines include the orally administered live, attenuated *S. typhi* strain (Ty2la) vaccine for typhoid; the bacillus Calmette-Guérin (BCG) vaccine for tuberculosis, which consists of an attenuated strain of *Mycobacterium bovis;* and an attenuated tularemia vaccine. The BCG vaccine is not used in the United States because immunization is not always protective and people vaccinated with it show a false-positive skin reaction to the purified protein derivative (PPD) test, which is the screening test used to control tuberculosis in the United States.

Live virus vaccines consist of less virulent mutants **(attenuated)** of the wild-type virus, viruses from other species that share antigenic determinants (vaccinia for smallpox, bovine rotavirus), or genetically engineered viruses lacking virulence properties (see Fig. 11.1). Wild-type viruses are attenuated by growth in animals or embryonated eggs or tissue culture cells at nonphysiologic temperatures (25° C to 34° C) and away from the selective pressures of the host immune response. These conditions **select** for or allow the growth of viral strains (mutants) that (1) are less virulent because they grow poorly at 37° C (**temperature-sensitive strains** [e.g., measles vaccine] and cold-adapted strains [influenza vaccine]); (2) do not replicate well in any human cell **(host-range mutants);** (3) cannot escape immune control; or (4) can replicate at a benign site but do not disseminate, bind, or replicate in the target tissue characteristically affected by the disease (e.g., polio vaccine replicates in the gastrointestinal tract but does not reach or infect neurons). Table 11.4 lists examples of attenuated live virus vaccines currently in use.

The smallpox vaccine was conceived after Edward Jenner noted that cowpox (vaccinia), a virulent virus from another species that shares antigenic determinants with smallpox, caused benign infections in humans but conferred protective immunity against smallpox. Similarly, a mixture of genetic reassortant human and bovine rotaviruses are the basis for one of the current vaccines administered to protect infants against human rotavirus.

Albert Sabin developed the first live **oral polio vaccine (OPV)** in the 1950s. The attenuated virus vaccine was obtained by multiple passages of the three types of poliovirus through monkey kidney tissue culture cells. At least 57 mutations accumulated in the polio type 1 vaccine strain. When this vaccine is administered orally, IgA is secreted in the gut and IgG in the serum, providing protection along the normal route of infection by the wild-type virus. This vaccine is inexpensive, easy to administer, and relatively stable and can spread to contacts of the immunized individual. Effective immunization programs have led to the elimination of wild-type polio in most of the world. The IPV is now used in most of the world for routine well-baby immunizations because of the risk of vaccine-virus–induced polio disease by the OPV (see Table 11.2 and Fig. 46.10). Although the immune response elicited by the IPV can prevent spread of the virus to the central nervous system and muscles to protect the individual from disease, immunization does not prevent production of virus in the gastrointestinal tract and transmission to others in stool, as does the OPV.

The HBV and HPV vaccines are genetically engineered and grown in yeast cells. The viral attachment proteins from HBV (HBsAg) and high-risk HPV strains (L protein) form VLPs that are better immunogens than individual proteins. By limiting the spread of these viruses, these vaccines are also preventing their associated cancers (cervical carcinoma: HPV; primary hepatocellular carcinoma: HBV).

Live vaccines for measles, mumps, and rubella (administered together as the MMR vaccine), **varicella zoster,** and **influenza** elicit potent cellular immune responses and immune memory necessary for protection from these viruses. To elicit a mature T-cell response, the vaccine must

TABLE 11.4 Viral Vaccines[a,b]

Virus	Vaccine Components	Who Should Receive Vaccinations
Polio, inactivated	Trivalent (Salk vaccine)	Children
Attenuated polio	Live (oral polio vaccine, Sabin vaccine)	Children in epidemic areas
Measles	Attenuated	Children
Mumps	Attenuated	Children
Rubella	Attenuated	Children
Varicella zoster Zoster	Attenuated Larger dose Adjuvanted gpE	Children Adults (>60) years
Rotavirus	Human-bovine hybrids Attenuated	Infants
Human papillomavirus	VLP	Girls and boys ages 9-26 yr
Influenza	Inactivated or recombinant HA High dose or adjuvanted Attenuated (nasal spray)	Children, adults, especially medical personnel and the elderly Ages >65 Ages 2-50 yr
Hepatitis B	Subunit (VLP)	Newborns, health care workers, high-risk groups (e.g., sexually promiscuous, intravenous drug users)
Hepatitis A	Inactivated	Children, child care workers, travelers to endemic areas, Native Americans, and Alaskans
Adenovirus	Attenuated	Military personnel
Yellow fever	Attenuated	Travelers at risk to exposure, military personnel
Rabies	Inactivated	Anyone exposed to virus Preexposure: veterinarians, animal handlers
Smallpox	Live vaccinia virus	People seeking protection from bioterrorism, military
Japanese encephalitis	Inactivated	Travelers at risk to exposure

gpE, Varicella zoster virus glycoprotein E; *VLP*, virus-like particle.

be administered after 1 year of age, when there will be no interference by maternal antibodies and cell-mediated immunity is sufficiently mature. A killed measles vaccine proved to be a failure because it conferred an incomplete immunity that induced more serious symptoms (atypical measles) on challenge with wild-type measles virus than the symptoms associated with the natural infection.

The initial live measles vaccine consisted of the Edmonston B strain, which was developed by Enders and colleagues. This virus underwent extensive passage at 35° C through primary human kidney cells, human amnion cells, and chicken embryo cells. The currently used Moraten (United States) and Schwarz (other countries) vaccine strains of measles were obtained by further passage of the Edmonston B strain in chick embryos at 32° C.

The mumps vaccine (Jeryl Lynn strain) and rubella vaccine (Wistar RA 27/3) viruses were also attenuated by extensive passage of the virus in cell culture. The varicella zoster vaccine uses the Oka strain, which is an attenuated virus. The varicella zoster vaccine is administered along with the MMR vaccine, or a stronger version is administered to adults to prevent zoster (shingles).

The live trivalent and tetravalent live attenuated influenza vaccines (LAIVs) are administered nasally within a mist or as drops and is cold adapted to 25° C. Unlike the inactivated vaccine, T- and B-cell responses and mucosal immunity are elicited by this vaccine. This vaccine can only be administered to individuals between ages 2 and 49 years.

FUTURE DIRECTIONS FOR VACCINATION

Molecular biology techniques are being used to develop new vaccines. New live vaccines can be created by genetic engineering mutations that inactivate or delete a virulence gene instead of through random attenuation of the virus by passage through tissue culture. Genes from infectious agents that cannot be properly attenuated can be inserted into safe viruses (e.g., vaccinia, canarypox, attenuated adenovirus) to form **hybrid virus vaccines.** This approach holds the promise of allowing the development of a polyvalent vaccine to many agents in a single, safe, inexpensive, and relatively stable vector. On infection, the hybrid virus vaccine need not complete a replication cycle; it simply promotes expression of the inserted gene to initiate an immune response to the antigens. A canarypox human immunodeficiency virus (HIV) vaccine followed by two booster immunizations with recombinant HIV gp120 protein showed modest but promising results. A vaccinia-based vaccine is used to immunize forest animals against rabies. Other viruses have also been considered as vectors.

Genetically engineered **subunit vaccines** are being developed through cloning of genes that encode immunogenic proteins into bacterial and eukaryotic vectors. The greatest difficulties in the development of such vaccines are (1) identifying the appropriate subunit or peptide immunogen that can elicit protective antibody and, ideally, T-cell responses, and (2) presenting the antigen in the correct conformation. Once identified, the gene can be isolated, cloned, and expressed in bacteria or yeast cells, and then large quantities of these proteins can be produced. The envelope protein gp120 of HIV, the hemagglutinin and neuraminidase of influenza, the G antigen of rabies, and the glycoprotein D of herpes simplex virus have been cloned, and their proteins have been generated in bacteria or eukaryotic cells for use (or potential use) as subunit vaccines.

Peptide subunit vaccines contain *specific epitopes* of microbial proteins that elicit neutralizing antibody or desired T-cell responses. To generate such a response, the peptide must contain sequences that bind to major histocompatibility (MHC) class I or MHC class II proteins on DCs for presentation and recognition by T cells to initiate an immune response. The immunogenicity of the peptide can be enhanced by its covalent attachment to a carrier protein (e.g., tetanus or diphtheria toxoid or keyhole limpet hemocyanin [KLH]), which is a ligand for a Toll-like receptor (e.g., flagellin) or an immunologic peptide that can specifically present the epitope to the appropriate immune response. Better vaccines are being developed as the mechanisms of antigen presentation and T-cell receptor–specific antigens are better understood.

Adjuvants in addition to alum are being developed to enhance the immunogenicity and direct the response of vaccines to a TH1-type or TH2-type response. These include activators of Toll-like receptors, such as oligodeoxynucleotides of CpG, derivatives of lipid A from lipopolysaccharide, cytokines, liposomes, nanoparticles, and others.

DNA and RNA vaccines offer great potential for immunization against infectious agents and for tumor immunotherapy that require T-cell responses. For these vaccines, the gene for a protein that elicits protective responses is cloned into a plasmid that allows the protein to be expressed in eukaryotic cells. For DNA vaccines, naked DNA is delivered into the muscle or skin of the vaccine recipient, in which the DNA is taken up by cells, the gene is expressed, and the protein is produced. It also is presented to and activates T-cell responses. DNA vaccines usually require a boost with antigenic protein to produce antibody. RNA vaccines resemble noninfectious RNA viruses in which the gene for the immunogen is combined with sequences that promote its expression or replication in the cell, and the RNA is expressed and purified and may be administered in a viral envelope-like liposome. The potency of these vaccines can be enhanced by including genes for immunoenhancing cytokines.

Autologous activated DCs loaded with tumor antigens and activated antitumor T cells can be prepared in the laboratory from the patient's own cells and injected back into the cancer patient as immunotherapy. These approaches also have potential for antiviral and other antimicrobial infections requiring cell-mediated immune control.

Reverse vaccinology was used to develop a vaccine for *N. meningitidis* B. Based on protein properties predicted from the gene sequence, thousands of proteins were tested for their ability to confer protection against infection to identify protein candidates. Similarly, antibody from survivors of infections with significant pathogens can be used to identify appropriate immunogens. With the advent of this and other new technology, it should be possible to develop vaccines against infectious agents such as *S. mutans* (to prevent tooth decay), the herpesviruses, HIV, and parasites such as *Plasmodium falciparum* (malaria) and *Leishmania*. In fact, it should be possible to produce a vaccine for almost any infectious agent once the appropriate protective immunogen is identified and its gene isolated.

Immunization Programs

An effective vaccine program can save millions of dollars in health care costs. Such a program not only protects each vaccinated person against infection and disease but also reduces the number of susceptible people in the population, preventing the spread of the infectious agent within the population. Although immunization may be the best means of protecting people against infection, vaccines cannot be developed for all infectious agents because it is very time-consuming and costly to develop vaccines. Box 11.1 lists the considerations that are weighed in the choice of a candidate for a vaccine program.

Natural smallpox was eliminated by means of an effective vaccine program because it was a good candidate for such a program; the virus existed in only one serotype, symptoms were always present in infected people, and the vaccine was relatively benign and stable. However, its elimination came about only as the result of a concerted cooperative effort on the part of the WHO and local health agencies worldwide. Rhinovirus is an example of a poor candidate for vaccine development because the viral disease is not serious and there are too many serotypes for vaccination to be successful. Practical aspects of and problems with vaccine development are listed in Box 11.2.

From the standpoint of the individual, the ideal vaccine should elicit dependable lifelong immunity to infection, without serious side effects. Factors that influence the success of an immunization program include not only the composition of the vaccine but also the timing, site, conditions of its administration, and the age and gender of the recipients.

Recommended schedules of vaccinations for children are given in Fig. 11.3. Tables of recommended schedules for vaccination of children, teens, adults, and special cases are

BOX 11.1 Properties of Ideal Candidate for Vaccine Development

Microbe causes significant illness
Microbe exists as only one serotype
Microbe only infects humans
Antibody blocks infection or systemic spread
Vaccine is heat stable so that it can be transported to endemic areas
Immunization protects recipient and population

BOX 11.2 Problems with Vaccines

Live vaccine can occasionally revert to virulent forms.
Vaccinating an immunocompromised person with a live vaccine can be life-threatening.
Side effects to vaccination can occur; these include hypersensitivity and allergic reactions to the antigen, to nonmicrobial material in the vaccine, and to contaminants (e.g., eggs).
Vaccine development is high risk and very expensive.
Misinformation about safety causes underutilization of important vaccines.
Microbes with many serotypes are difficult to control with vaccination.

provided annually by the Advisory Committee on Immunization Practices (ACIP) of the Centers for Disease Control and Prevention. **Booster immunizations** of inactivated vaccines and the live measles vaccine are required later in life. Men and women younger than age 26 should receive the HPV vaccine, and college students should receive the meningococcal vaccine or a booster. Adults should be immunized with vaccines for *S. pneumoniae* (pneumococcus), influenza, rabies, varicella zoster, HBV, and other diseases, depending on their age, jobs, the type of traveling they do, and other risk factors that may make them particularly susceptible to specific infectious agents.

Despite the incredible progress that has been made to protect the population from serious disease with vaccines, complacency and misinformation regarding safety issues with vaccines have deterred some individuals and their children from being vaccinated. This puts the individual at risk for disease and can prevent the establishment of herd immunity, which can result in outbreaks and put infants at increased risk for these diseases. For example, unless 95% of the population is immunized, measles will cause an outbreak. In 2018, an outbreak of measles reached epidemic proportions in Europe with over 60,000 cases and more than 50 deaths caused by poor vaccine compliance.

Questions

1. Why is an inactivated rather than a live vaccine used for the following immunizations: rabies, influenza, tetanus, HBV, Hib, diphtheria, polio, and pertussis?

2. Tetanus is treated with passive immunization and prevented by active immunization. Compare the nature and function of each of these therapies.

3. The inactivated polio vaccine is administered intramuscularly, whereas the live polio vaccine is administered as an oral vaccine. How do the course of the immune response and the immunoglobulins produced in response to each vaccine differ? What step in the poliovirus infection is blocked in a person vaccinated by each vaccine?

4. Why have large-scale vaccine programs not been developed for rhinovirus, herpes simplex virus, and respiratory syncytial virus?

5. Describe the public or personal health benefits that justify development of the following major vaccine programs: measles, mumps, rubella, polio, smallpox, tetanus, and pertussis.

6. Immunization with the capsular polysaccharide and the conjugated polysaccharide vaccines for *S. pneumoniae* elicit different types of immunity and are indicated for different people. Who are the recipients of these vaccines? What are the advantages and disadvantages of each?

SECTION 4

Bacteriology

SECTION OUTLINE

12 Bacterial Classification, Structure, and Replication

The structural differences between bacteria and eukaryotes trigger host protections in humans and provide the basis for much of the antimicrobial therapy. Designation of bacteria as gram-positive, gram-negative or acid-fast staining indicates the basis for differences in means of transmission, disease presentation, and antibiotic sensitivities. The outer structures of bacteria provide structure and transport functions, the means for interaction with each other and the host as virulence factors, and comprise pathogen-associated molecular patterns (PAMP) that trigger innate and immune responses.

The smallest bacteria *(Chlamydia* and *Rickettsia)* are just 0.1 to 0.2 μm in diameter, whereas larger bacteria may be many microns in length. A newly described species is hundreds of times larger than the average bacterial cell and is visible to the naked eye. Most species, however, are approximately 1 μm in diameter and are therefore visible with the use of the light microscope, which has a resolution of 0.2 μm. In comparison, animal and plant cells are much larger, ranging from 7 μm (the diameter of a red blood cell) to several feet (the length of certain nerve cells).

Differences between Eukaryotes and Prokaryotes

Cells from animals, plants, and fungi are **eukaryotes** (Greek for "true nucleus"), whereas bacteria, archae, and blue-green algae belong to the **prokaryotes** (Greek for "primitive nucleus"). The **archae** (archaebacteria) resemble bacteria in most ways but represent a domain unique from bacteria and eukaryotes.

Prokaryotes differ from eukaryotes in several ways (Table 12.1 and Fig. 12.1). Bacteria lack a nucleus and other organelles. The chromosome of a typical bacterium, such as *Escherichia coli,* is a single, double-stranded, circular molecule of deoxyribonucleic acid (DNA) containing approximately 5 million base pairs, with an approximate length of 1.3 mm (i.e., nearly 1000 times the diameter of the cell). The smallest bacterial chromosomes (from mycoplasmas) are approximately one-fourth of this size. In comparison, humans have two copies of 23 chromosomes, which represent 2.9×10^9 base pairs, 990 mm in length. Bacteria use a smaller ribosome, the 70S ribosome, and in most bacteria, a unique meshlike peptidoglycan cell wall surrounds the membranes to protect them against the environment. Bacteria can survive and, in some cases, grow in hostile environments in which the osmotic pressure outside the cell is so low that most eukaryotic cells would lyse, at temperature extremes (both hot and cold), with dryness, and with very dilute and diverse energy sources. Bacteria have evolved their structures and functions to adapt to these conditions. Several of these distinctions provide the basis for antimicrobial action.

Bacterial Classification

Bacteria can be classified by their macroscopic and microscopic appearance, by characteristic growth and metabolic properties, by their antigenicity, and finally by their genotype.

MACROSCOPIC AND MICROSCOPIC DISTINCTION

The initial distinction between bacteria can be made by growth characteristics on different nutrient and selective media. Bacteria grow in colonies; each colony is like a city of as many as a million or more organisms. The sum of their characteristics provides the colony with distinguishing characteristics such as color, size, shape, and smell. The bacteria's ability to resist certain antibiotics, ferment specific sugars (e.g., lactose, to distinguish *E. coli* from *Salmonella*), to lyse erythrocytes (streptococcal hemolytic properties), or to hydrolyze lipids (e.g., clostridial lipase) can be determined using the appropriate growth media.

The microscopic appearance, including size, shape, and configuration of the organisms (cocci, rods, curved, or spiral), and their ability to retain the Gram stain (gram positive or gram negative) are the primary means for distinguishing bacteria (a library of images are available at http://studentconsult.inkling.com/). A spherical bacterium such as *Staphylococcus* is a coccus, a rod-shaped bacterium such as *E. coli* is a bacillus, and the snakelike treponeme is a spirillum. In addition, *Nocardia* and *Actinomyces* species have branched filamentous appearances similar to those of fungi. Some bacteria form aggregates, such as the grapelike clusters of *Staphylococcus aureus* or chains, like *Streptococcus pyogenes*, or diplococcus (two cells together) as for *S. pneumoniae and Neisseria* species.

Gram stain is a rapid, powerful, easy test that allows clinicians to distinguish between the two major classes of bacteria, develop an initial diagnosis, and initiate therapy based on inherent differences in the bacteria (Fig. 12.2). Bacteria are heat fixed or otherwise dried onto a slide; stained with **crystal violet** (Fig. 12.3), which is a stain that is precipitated with **iodine;** and then the unbound and excess stain is removed by washing with the acetone-based **decolorizer** and water. A red counterstain, **safranin,** is added to stain any decolorized cells. This process takes less than 10 minutes.

For **gram-positive bacteria,** which turn **purple,** the stain gets trapped in a thick, cross-linked, meshlike structure (the peptidoglycan layer), which surrounds the cell. **Gram-negative bacteria** have a thin peptidoglycan layer that does not retain the crystal violet stain, so the cells must be counterstained with safranin and turned red (Fig. 12.3). A mnemonic device that may help is **"P-PURPLE-POSITIVE."**

Gram staining loses dependability for bacteria that are starved (e.g., old or stationary-phase cultures) or treated

Table 12.1 Major Characteristics of Eukaryotes and Prokaryotes

Characteristic	Eukaryote	Prokaryote
Major groups	Algae, fungi, protozoa, plants, animals	Bacteria
Size (approximate)	>5 μm	0.5-3.0 μm
NUCLEAR STRUCTURES		
Nucleus	Classic membrane	No nuclear membrane
Chromosomes	Strands of DNA diploid genome	Single, circular DNA haploid genome
CYTOPLASMIC STRUCTURES		
Mitochondria	Present	Absent
Golgi bodies	Present	Absent
Endoplasmic reticulum	Present	Absent
Ribosomes (sedimentation coefficient)	80S (60S + 40S)	70S (50S + 30S)
Cytoplasmic membrane	Contains sterols	Does not contain sterols (except mycoplasma)
Cell wall	Present for fungi; otherwise absent	Complex structure containing protein and peptidoglycan. May contain polysaccharides, teichoic acid, lipopolysaccharide
Reproduction	Sexual and asexual	Asexual (binary fission)
Movement	Complex flagellum, if present	Simple flagellum, if present
Electron transport (ATP production)	Mitochondria	Cytoplasmic membrane

ATP, Adenosine triphosphate.

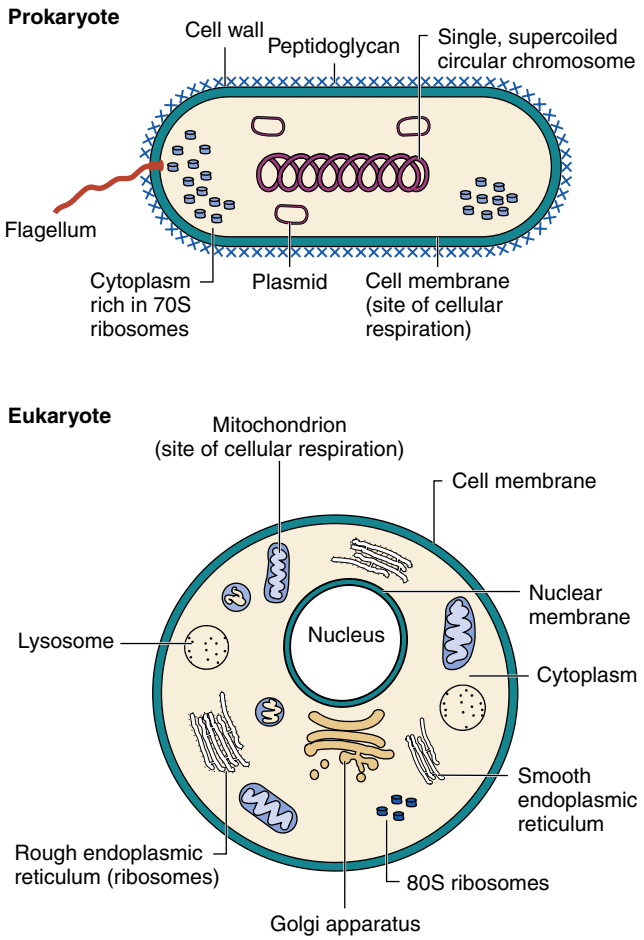

Fig. 12.1 Major features of prokaryotes and eukaryotes.

with antibiotics because of degradation of the peptidoglycan. Bacteria that cannot be classified by Gram staining include mycobacteria, which have a waxy outer shell and are distinguished with the acid-fast stain, and mycoplasmas, which have no peptidoglycan.

METABOLIC, ANTIGENIC, AND GENETIC DISTINCTION

The next level of classification is based on the structural and metabolic signature of the bacteria, including susceptibility to detergents (e.g., bile acids), requirement for anaerobic or aerobic environments, requirement for specific nutrients (e.g., ability to ferment specific carbohydrates or use different compounds as a source of carbon for growth), and production of characteristic metabolic products (acid, alcohols) and specific enzymes (e.g., staphylococcal catalase). Automated procedures for distinguishing enteric and other bacteria have been developed; they analyze the growth in different media and their microbial products and provide a numerical biotype for each of the bacteria.

A particular strain of bacteria can be distinguished using antibodies to detect characteristic antigens on the bacteria **(serotyping).** These serologic tests also can be used to identify organisms that are difficult (e.g., *Treponema pallidum,* the organism responsible for syphilis) or too dangerous (e.g., *Francisella,* the organism that causes tularemia), do not grow in the laboratory, are associated with specific disease syndromes (e.g., *E. coli* serotype O157:H7, responsible for hemorrhagic colitis), or need to be identified rapidly (e.g., *S. pyogenes,* responsible for streptococcal pharyngitis). Serotyping also is used to subdivide bacteria below the species level for epidemiologic purposes.

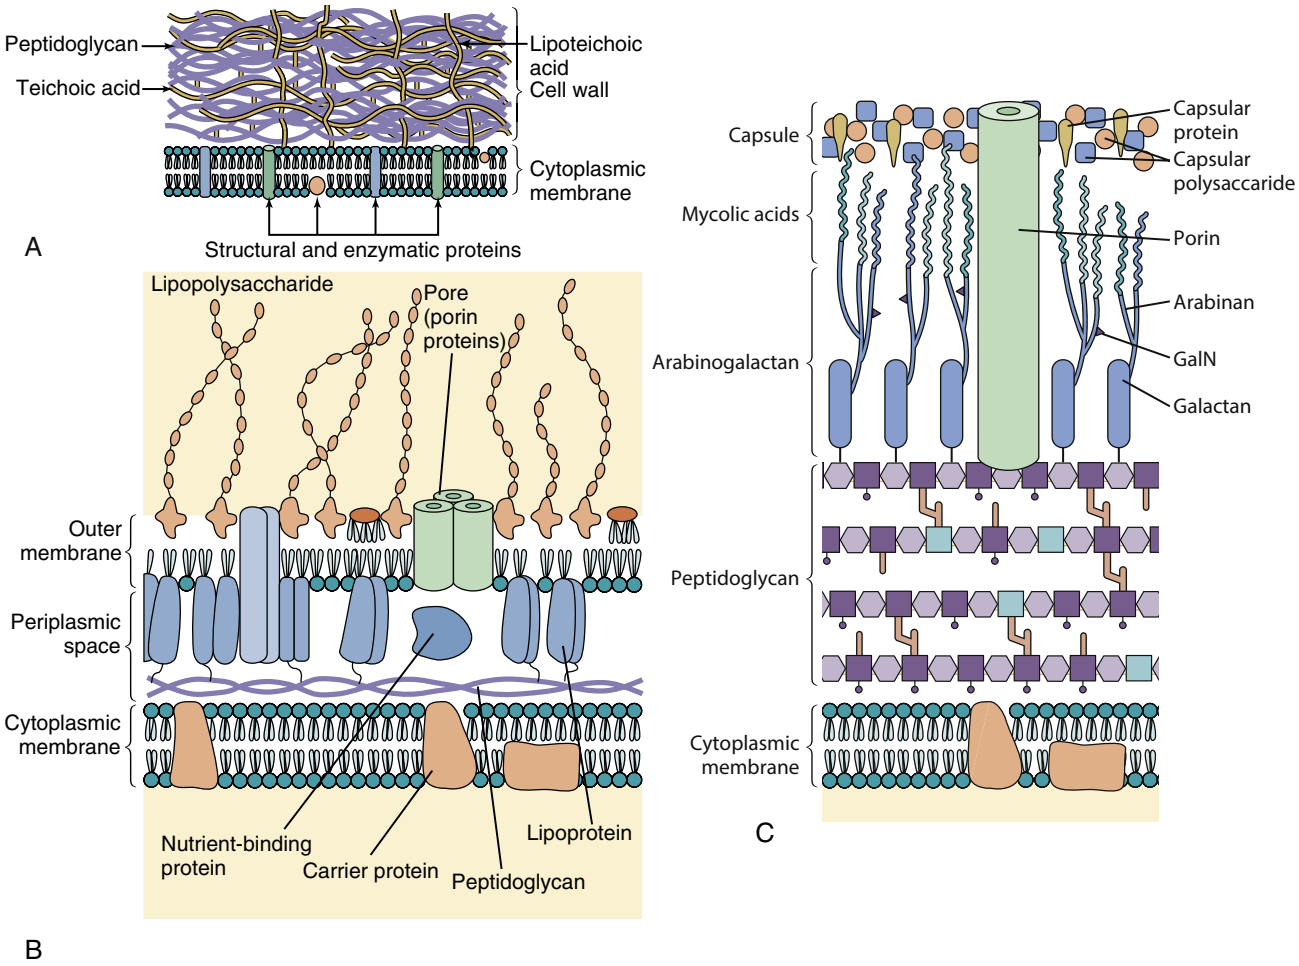

Fig. 12.2 Comparison of gram-positive, gram-negative, and mycobacterial cell walls. (A) A gram-positive bacterium has a thick peptidoglycan layer that contains teichoic and lipoteichoic acids. (B) A gram-negative bacterium has a thin peptidoglycan layer and an outer membrane that contains lipopolysaccharide, phospholipids, and proteins. The periplasmic space between the cytoplasmic and outer membranes contains transport, degradative, and cell wall synthetic proteins. The outer membrane is joined to the cytoplasmic membrane at adhesion points and is attached to the peptidoglycan by lipoprotein links. (C) Mycobacterial cell walls confer acid-fast staining to the bacteria. They have a complex structure with a lipid rich waxy outer layer of mycolic acids with porins that permeate that layer.

The most precise method for classifying bacteria is by analysis of their genetic material or proteins. Specific characteristic DNA sequences can be detected by **DNA hybridization, polymerase chain reaction (PCR) amplification, DNA sequencing,** and related techniques described in Chapter 5. Characteristic protein profiles of bacteria also can be rapidly analyzed by mass spectrometry (MALDI-TOF). These techniques do not require living or growing bacteria and can be used for rapid detection and identification of slow-growing organisms (e.g., mycobacteria, fungi) or analysis of pathology samples of even very virulent bacteria. Ribosomal DNA sequences can be determined to identify a family or genus and distinguish a species or subspecies. In recent years the technical aspects of these methods have been simplified and have become sufficiently cost effective so that most clinical laboratories use variations of these methods in their day-to-day practice.

Bacterial Structure

The cytoplasm of bacteria is encased by a cytoplasmic membrane, which is surrounded by a cell wall consisting of peptidoglycan that is thick for gram-positive and thin for gram-negative bacteria. A periplasmic space and an outer membrane surround the peptidoglycan of gram-negative bacteria. For some bacteria, a capsule surrounds the entire bacteria.

CYTOPLASMIC STRUCTURES

The cytoplasm of the bacterial cell contains the DNA chromosome, messenger ribonucleic acid (mRNA), ribosomes, proteins, and metabolites (Fig. 12.4). Unlike eukaryotes, most **bacterial chromosomes** are a single, double-stranded circle that is contained not in a nucleus but in a discrete area known as the **nucleoid.** Some bacteria may have two or three circular chromosomes or even a single linear chromosome. Histones are not present to maintain the conformation of the DNA, and the DNA does not form nucleosomes. **Plasmids,** which are smaller, circular, extrachromosomal DNAs, also may be present. Plasmids, although not usually essential for cellular survival, often provide a selective advantage; many of them confer resistance to one or more antibiotics.

The lack of a nuclear membrane simplifies the requirements and control mechanisms for the synthesis of proteins.

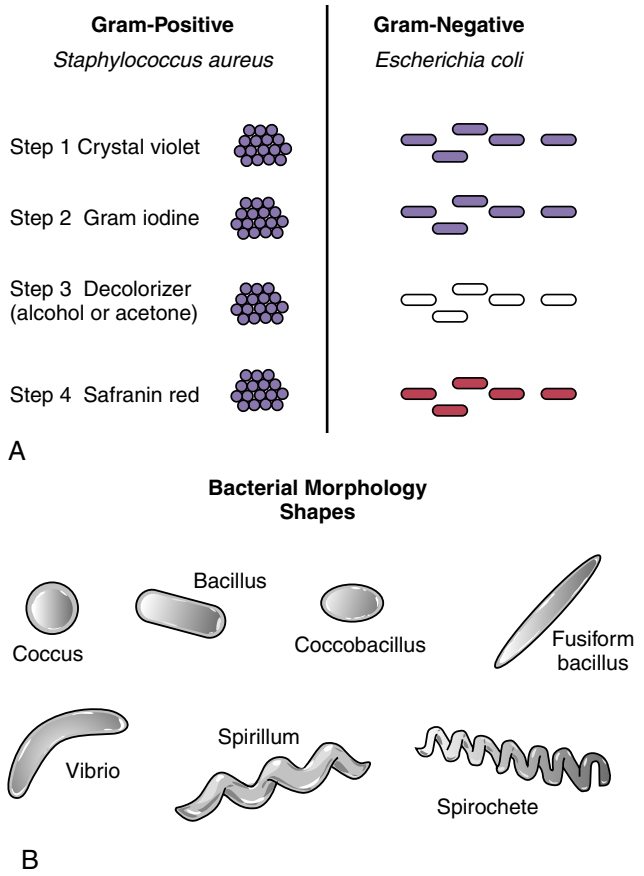

Fig. 12.3 Gram-stain morphology of bacteria. (A) The crystal violet of the Gram stain is precipitated by Gram iodine and is trapped in the thick peptidoglycan layer in gram-positive bacteria. The decolorizer disperses the gram-negative outer membrane and washes the crystal violet from the thin layer of peptidoglycan. Gram-negative bacteria are visualized by the red counterstain. (B) Bacterial morphologies.

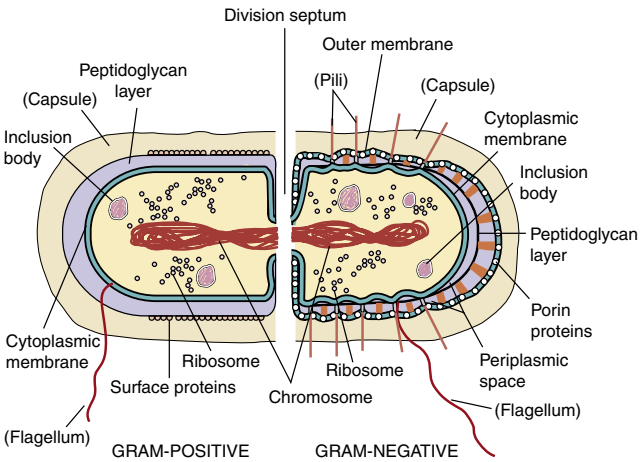

Fig. 12.4 Gram-positive and gram-negative bacteria. A gram-positive bacterium has a thick layer of peptidoglycan (filling the purple space) *(left)*. A gram-negative bacterium has a thin peptidoglycan layer *(single black line)* and an outer membrane *(right)*. Structures in parentheses are not found in all bacteria. On cell division, the membrane and peptidoglycan grow toward each other to form a division septum to separate the daughter cells.

Without a nuclear membrane, transcription and translation are coupled; in other words, ribosomes can bind to the mRNA, and protein can be made as the mRNA is being synthesized and still attached to the DNA.

The **bacterial ribosome** consists of 30S + 50S subunits, forming a **70S ribosome**. This is unlike the eukaryotic 80S (40S + 60S) ribosome. The proteins and RNA of the bacterial ribosome are significantly different from those of eukaryotic ribosomes and are major targets for antibacterial drugs.

The **cytoplasmic membrane** has a lipid bilayer structure similar to the structure of the eukaryotic membranes, but it contains no steroids (e.g., cholesterol); mycoplasmas are the exception to this rule. The cytoplasmic membrane is responsible for many of the functions attributable to organelles in eukaryotes. These tasks include electron transport and energy production, which are normally achieved in the mitochondria. In addition, the membrane contains transport proteins that allow uptake of metabolites and release of other substances, ion pumps to maintain a membrane potential, and enzymes. The inside of the membrane is lined with actin-like protein filaments that help determine the shape of the bacteria and the site of septum formation for cell division. These filaments determine the spiral shape of treponemes.

CELL WALL

The structure (Table 12.2), components, and functions (Table 12.3) of the cell wall distinguish gram-positive from gram-negative bacteria. Cell wall components also are unique to bacteria, and their repetitive structures bind to pathogen pattern receptors on human cells to elicit innate protective responses. The important differences in cell wall for gram-positive and gram-negative bacteria are outlined in Table 12.4.

Rigid **peptidoglycan (murein)** layers surround the cytoplasmic membranes of most prokaryotes. The exceptions are *Archaea* organisms (which contain pseudoglycans or pseudomureins related to peptidoglycan) and mycoplasmas (which have no peptidoglycan). Because the peptidoglycan provides rigidity, it also helps determine the shape of the particular bacterial cell. Proteins and other molecules may be attached to the peptidoglycan.

GRAM-POSITIVE BACTERIA

A gram-positive bacterium has a *thick, multilayered cell wall consisting mainly of peptidoglycan* (150 to 500 Å) surrounding the cytoplasmic membrane (Fig. 12.2 and 12.4). The peptidoglycan is a meshlike exoskeleton similar in function to the exoskeleton of an insect. Unlike the exoskeleton of the insect, however, the peptidoglycan of the cell is sufficiently porous to allow diffusion of metabolites to the plasma membrane. The glycan chains extend out from the plasma membrane like bristles that are cross-linked with short peptide chains. The **peptidoglycan is essential** for structure, replication, and survival in the normally hostile conditions in which bacteria grow.

The peptidoglycan can be degraded by **lysozyme.** Lysozyme is an enzyme in human tears and mucus, but it also is produced by bacteria and other organisms. Lysozyme cleaves the glycan backbone of the peptidoglycan. Without the peptidoglycan, the bacteria succumb to the large

Table 12.2 Bacterial Membrane Structures

Structure	Chemical Constituents	Functions
Plasma membrane	Phospholipids, proteins, and enzymes	Containment, generation of energy, membrane potential, and transport
CELL WALL		
Gram-Positive Bacteria		
Peptidoglycan	Multiple layers of glycan chains of GlcNAc and MurNAc cross-linked by peptide bridge	Cell shape and structure; protection from environment and complement killing
Teichoic acid	Polyribitol phosphate or glycerol phosphate cross-linked to peptidoglycan	Strengthens cell wall; calcium ion sequestration
Lipoteichoic acid	Lipid-linked teichoic acid	Activator of innate host protections
Proteins	Bound to peptidoglycan or teichoic acid	Immune evasion, adhesion, etc.
Gram-Negative Bacteria		
Peptidoglycan	Thinner version of that found in gram-positive bacteria	Cell shape and structure
Periplasmic space	transport proteins, enzymes	Enzymes involved in transport, degradation, and synthesis
Outer membrane	Phospholipids, LPS, proteins, enzymes	Cell structure; protection from host environment
Proteins	Porin channel	Permeation of small hydrophilic molecules; restricts some antibiotics
	Secretory devices (types I–V)	Penetrates and delivers proteins across membranes, including virulence factors
	Lipoprotein	Outer membrane link to peptidoglycan
LPS	Lipid A, core polysaccharide, O antigen	Outer membrane structure; barrier protection, potent activator of innate host responses
Phospholipids	With saturated fatty acids	Structure
OTHER STRUCTURES		
Capsule	Polysaccharides or polypeptides (anthrax)	Antiphagocytic
Biofilm	Polysaccharides	Protection of colony from environment, antimicrobials, and host response
Pili	Pilin, adhesins	Adherence, sex pili
Flagellum	Motor proteins, flagellin	Movement, chemotaxis
Proteins	M protein of streptococci (for example)	Immune evasion, adhesion, enzymes, etc.

GlcNAc, N-Acetylglucosamine; *LPS,* lipopolysaccharide; *MurNAc, N*-acetylmuramic acid.

osmotic pressure differences across the cytoplasmic membrane and lyse. Removal of the cell wall produces a **protoplast** that lyses unless it is osmotically stabilized.

The gram-positive cell wall also may include other components such as proteins, teichoic and lipoteichoic acids, and complex polysaccharides (usually called **C polysaccharides**). Virulence proteins, such as the M protein of streptococci and protein A of *S. aureus,* are covalently bound to the peptidoglycan as are proteins that promote adherence to human cells. **Teichoic acids** are water-soluble anionic polymers of polyol phosphates that are covalently linked to the peptidoglycan and essential to cell viability. **Lipoteichoic acids** have a fatty acid and are anchored in the cytoplasmic membrane. These molecules are common surface antigens that distinguish bacterial serotypes and promote attachment to other bacteria and to specific receptors on mammalian cell surfaces (adherence). Teichoic acids are important factors in virulence. Lipoteichoic acids are shed into the media and the host and, although weaker, they bind to pathogen pattern receptors and initiate innate protective host responses similar to endotoxin.

GRAM-NEGATIVE BACTERIA

Gram-negative cell walls are more complex than gram-positive cell walls, both structurally and chemically (see Fig. 12.2 and 12. 4). Immediately external to the cytoplasmic membrane is a *thin peptidoglycan layer* that accounts for only 5% to 10% of the gram-negative cell wall by weight. There are *no teichoic or lipoteichoic acids* in the gram-negative cell wall. External to the peptidoglycan layer is the **outer membrane,** which is unique to gram-negative bacteria. The area between the external surface of the cytoplasmic membrane and the internal surface of the outer membrane is referred to as the **periplasmic space.** This space is actually a compartment containing components of transport systems for iron, proteins, sugars and other metabolites, and a variety of hydrolytic enzymes that are important to the cell for the breakdown of large macromolecules for metabolism. These enzymes typically include proteases, phosphatases, lipases, nucleases, and carbohydrate-degrading enzymes. In the case of pathogenic gram-negative species, many of the virulence factors, such as

Table 12.3 Functions of the Bacterial Envelope

Function	Component
STRUCTURE	
Rigidity	All
Packaging of internal contents	All
BACTERIAL FUNCTIONS	
Permeability barrier	Outer membrane and plasma membrane
Metabolite uptake	Membranes and periplasmic transport proteins, porins, permeases
Energy production	Plasma membrane
Motility	Flagella
Mating	Pili
HOST INTERACTION	
Adhesion to host cells	Pili, proteins, teichoic acid
Immune recognition by host	All outer structures and peptidoglycan
Escape from host immune protections	
Antibody	Protein A, capsule
Phagocytosis	Capsule, M protein
Complement	Gram-positive peptidoglycan
MEDICAL RELEVANCE	
Antibiotic targets	Peptidoglycan synthesis
Antibiotic resistance	Outer membrane barrier

Table 12.4 Comparison of Gram-Positive and Gram-Negative Bacteria

Characteristic	Gram-Positive	Gram-Negative
Outer membrane	–	+
Peptidoglycan	Thick	Thin
Lipopolysaccharide	–	+
Endotoxin	–	+
Teichoic acid	Often present	–
Sporulation	Some bacteria	–
Capsule	Sometimes present	Sometimes present
Lysozyme	Sensitive	Resistant
Antibacterial activity of penicillin	More susceptible	More resistant
Susceptibility to drying and physical disruption	less	more
Exotoxin production	Some strains	Some strains

collagenases, hyaluronidases, proteases, and β-lactamase, are in the periplasmic space.

The gram-negative cell wall also is traversed by different transport systems that provide mechanisms for the uptake and release of different metabolites and other compounds. The membranes also are transversed by **type I to V secretion devices.** Production of the secretion devices may be induced during infection and contribute to the virulence of the microbe by transporting molecules that facilitate bacterial adhesion or intracellular growth. **The type III secretion device** is a major virulence factor for some bacteria, with a complex structure that traverses both the inner and outer membranes and looks and acts like a syringe to inject proteins into other cells, bacterial and human (see Fig. 14-2).

As mentioned previously, outer membranes (see Fig. 12.2) are unique to gram-negative bacteria. The outer membrane is like a stiff canvas sack around the bacteria. *The outer membrane maintains the bacterial structure and is a permeability barrier to large molecules* (e.g., proteins such as lysozyme) *and hydrophobic molecules* (e.g., some antimicrobials). It also provides protection from adverse environmental conditions, such as the digestive system of the host (important for Enterobacteriaceae organisms). The outer membrane has an asymmetric bilayer structure that differs from any other biologic membrane. The inner leaflet contains phospholipids normally found in bacterial membranes; however, the outer leaflet is composed primarily of **lipopolysaccharide (LPS).** Except for those LPS molecules in the process of synthesis, the outer leaflet of the outer membrane is the only location in which LPS molecules are found.

LPS also is called **endotoxin,** which is a powerful stimulator of innate and immune responses. LPS is shed from the bacteria into the host. LPS binds to pathogen pattern receptors and activates B cells and induces macrophage, dendritic, and other cells to release interleukin (IL)-1, IL-6, tumor necrosis factor (TNF), and other factors. LPS can induce fever and shock. The **Shwartzman reaction** (disseminated intravascular coagulation) follows the release of large amounts of endotoxin into the bloodstream. *Neisseria* bacteria shed large amounts of a related truncated molecule **(lipooligosaccharide [LOS]),** resulting in fever and severe symptoms.

The variety of proteins found in gram-negative outer membranes is limited, but several of the proteins are present in high concentration, resulting in a higher total protein content than that of the cytoplasmic membrane. Many of the proteins traverse the entire lipid bilayer and are thus transmembrane proteins. A group of these proteins is known as **porins** because they form pores **that allow diffusion of hydrophilic molecules less than 700 Da in mass through the membrane.** *The porin channel restricts entry of large and hydrophobic molecules including many antimicrobials.* The outer membrane also contains structural proteins, receptor molecules for bacteriophages, and other ligands and components of transport and secretory systems.

The outer membrane is connected to the cytoplasmic membrane at adhesion sites and is tied to the peptidoglycan by **lipoprotein.** The lipoprotein is covalently attached to the peptidoglycan and is anchored in the outer membrane. The adhesion sites provide a membranous route for the delivery of newly synthesized outer membrane components to the outer membrane.

The outer membrane is held together by divalent cation (Mg^{2+} and Ca^{2+}) linkages between phosphates on LPS molecules and hydrophobic interactions between the LPS and proteins. These interactions produce a stiff, strong membrane that can be disrupted by antibiotics (e.g., polymyxin) or by the removal of Mg and Ca ions (chelation with ethylenediaminetetraacetic acid [EDTA] or tetracycline). Disruption of the outer membrane weakens the bacteria and allows the permeability of large or hydrophobic molecules.

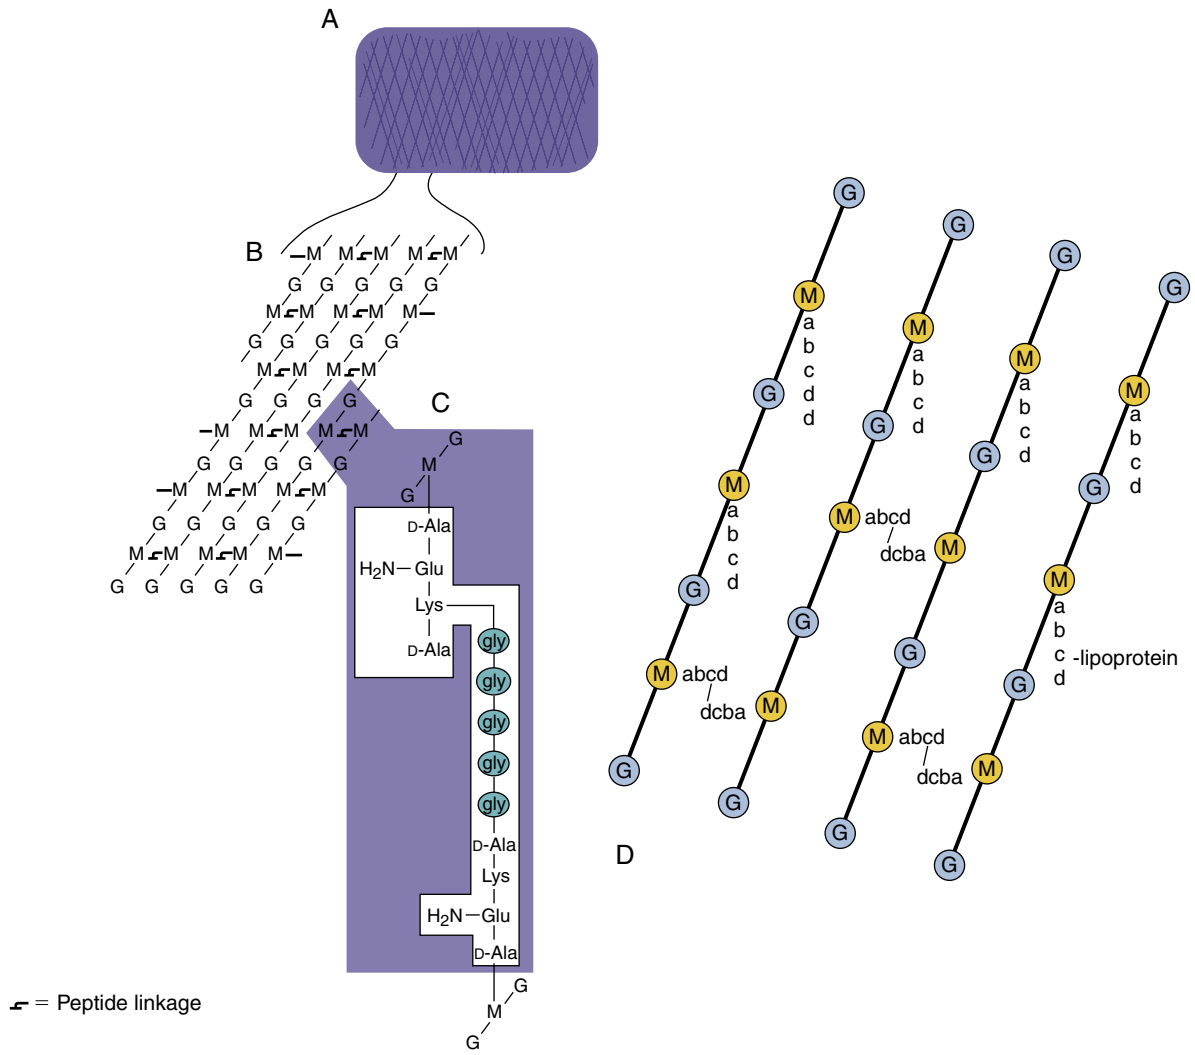

Fig. 12.5 General structure of the peptidoglycan component of the cell wall. (A) The peptidoglycan forms a meshlike layer around the cell. (B) The peptidoglycan mesh consists of a polysaccharide polymer that is cross-linked by peptide bonds. (C) Peptides are cross-linked through a peptide bond between the terminal D-alanine *(D-Ala)* from one chain and a lysine *(Lys)* (or another diamino amino acid) from the other chain. A pentaglycine bridge (gly_5) expands the cross-link in *Staphylococcus aureus* (as shown). (D) Representation of the *Escherichia coli* peptidoglycan structure. Diaminopimelic acid, the diamino amino acid in the third position of the peptide, is *directly linked* to the terminal alanine of another chain to cross-link the peptidoglycan. Lipoprotein anchors the outer membrane to the peptidoglycan. *G, N*-Acetylglucosamine; *Glu,* D-glutamic acid; *gly,* glycine; *M, N*-acetylmuramic acid. (A to C, Modified from Talaro, K., Talaro, A., 1996. Foundations in Microbiology, second ed. William C. Brown, Dubuque, IA. D, Modified from Joklik, W.K., Willett, H.P., Amos, D.B., et al., 1988. Zinsser Microbiology. Appleton & Lange, Norwalk, CT.)

Disruption of the outer membrane can provide entry of lysozyme to produce **spheroplasts,** which, like protoplasts, are osmotically sensitive.

EXTERNAL STRUCTURES

Some bacteria (gram-positive or gram-negative) are closely surrounded by loose polysaccharide or protein layers called **capsules** that are sometimes referred to as a **slime layer** or a **glycocalyx.** *Bacillus anthracis,* the exception to this rule, produces a polypeptide capsule. The capsule is hard to see in a microscope, but its space can be visualized by the exclusion of India ink particles.

Capsules are unnecessary for the growth of bacteria, but they are very important for survival in the host. *The capsule is poorly antigenic and antiphagocytic and is a major virulence factor* (e.g., *S. pneumoniae*). The capsule also can act as a barrier to toxic hydrophobic molecules, such as detergents, and can promote **adherence** to other bacteria or host tissue surfaces. Bacterial strains lacking a capsule may arise during growth under laboratory conditions, away from the selective pressures of the host; therefore they are less virulent. Some bacteria (e.g., *Pseudomonas aeruginosa, S. aureus*) will produce a polysaccharide **biofilm** when sufficient numbers (quorum) are present and under conditions that support growth. The biofilm contains and protects the bacterial community from antibiotics and host defenses. For *S. mutans*, the dextran and levan biofilm promotes adhesion to the tooth enamel and forms tooth plaque.

Flagella are ropelike propellers composed of helically coiled protein subunits **(flagellin)** that are anchored in the bacterial membranes through hook and basal body structures and are driven by membrane potential. Bacterial species may have one or several flagella on their surfaces, and they may be anchored at different parts of the cell. The membrane potential powers the protein motor,

which spins the whiplike propeller. Flagella provide motility for bacteria, allowing the cell to swim **(chemotaxis)** toward food and away from poisons. Bacteria approach food by swimming straight and then tumbling in a new direction. The swimming period becomes longer as the concentration of chemoattractant increases. The direction of flagellar spinning determines whether the bacteria swim or tumble. Flagella express antigenic and strain determinants and are a ligand for a pathogen pattern receptor to activate innate host protections.

Fimbriae (pili) (Latin for "fringe") are hairlike structures on the outside of bacteria, and they are composed of protein subunits **(pilin).** Fimbriae can be morphologically distinguished from flagella because they are smaller in diameter (3 to 8 nm versus 15 to 20 nm) and usually are not coiled in structure. In general, several hundred fimbriae are arranged peritrichously (uniformly) over the entire surface of the bacterial cell. They may be as long as 15 to 20 μm or many times the length of the cell.

Fimbriae promote adherence to other bacteria or to the host (alternative names are *adhesins, lectins, evasins,* and *aggressins*). The tips of the fimbriae may contain proteins (**lectins**) that bind to specific sugars (e.g., mannose). As an adherence factor **(adhesin),** fimbriae are an important virulence factor for colonization and infection of the urinary tract by *E. coli, Neisseria gonorrhoeae,* and other bacteria. **F pili (sex pili)** bind to other bacteria and are a tube for transfer of large segments of bacterial chromosomes between bacteria. These pili are encoded by a plasmid (F).

BACTERIA WITH ALTERNATIVE CELL WALL STRUCTURES

Mycobacteria have a peptidoglycan layer (slightly different structure) that is intertwined with and covalently attached to an arabinogalactan polymer and surrounded by a **waxlike lipid coat** of mycolic acid (large α-branched β-hydroxy fatty acids), cord factor (glycolipid of trehalose and two mycolic acids), wax D (glycolipid of 15 to 20 mycolic acids and sugar), and sulfolipids (see Fig. 12.2C). These bacteria are described as **staining acid-fast.** The coat is responsible for virulence and is antiphagocytic. *Corynebacterium* and *Nocardia* organisms also produce mycolic acid lipids. **Mycoplasmas** have no peptidoglycan cell wall and incorporate steroids from the host into their membranes.

Structure and Biosynthesis of the Major Components of the Bacterial Cell Wall

The cell wall components are large structures made up of polymers of subunits. This type of structure facilitates their synthesis. Like astronauts building a space station, bacteria face problems assembling their cell walls. Synthesis of the peptidoglycan, LPS, teichoic acid, and capsule occurs on the outside of the bacteria, away from the synthetic machinery and energy sources of the cytoplasm and in an inhospitable environment. For both the space station and the bacteria, prefabricated precursors and subunits of the final structure are assembled in a factory-like setting on the inside, attached to a structure similar to a conveyor belt, brought to the surface, and then attached to the preexisting structure. The prefabricated precursors must also be activated with high-energy bonds (e.g., phosphates) or other means to power the attachment reactions occurring outside the cell.

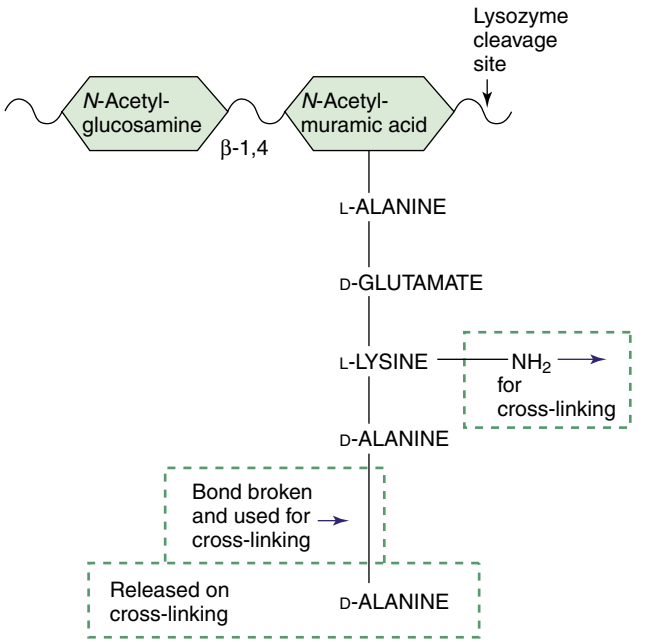

Fig. 12.6 Precursor of peptidoglycan. The peptidoglycan is built from prefabricated units that contain a pentapeptide attached to the *N*-acetylmuramic acid. The pentapeptide contains a terminal D-alanine-D-alanine unit. This dipeptide is required for cross-linking the peptidoglycan and is the basis for the action of β-lactam and vancomycin antibiotics. The β-1,4 disaccharide link cleaved by lysozyme is indicated.

PEPTIDOGLYCAN (MUCOPEPTIDE, MUREIN)

The peptidoglycan is a rigid mesh made up of fencepost-like linear polysaccharide chains cross-linked by peptides. The polysaccharide is made up of repeating disaccharides of ***N*-acetylglucosamine (GlcNAc, NAG, G)** and ***N*-acetylmuramic acid (MurNAc, NAM, M)** (Fig. 12.6; see Fig. 12.5).

A tetrapeptide is attached to the MurNAc. The peptide is unusual because it contains both D and L amino acids (D amino acids are not normally used in nature) and the peptide is produced enzymatically rather than by a ribosome. The first two amino acids attached to the MurNAc may vary for different organisms.

The diamino amino acids in the third position are essential for the cross-linking of the peptidoglycan chain. Examples of diamino amino acids include lysine and diaminopimelic and diaminobutyric acids. The peptide cross-link is formed between the free amine of the diamino amino acid and the D-alanine in the fourth position of another chain. *S. aureus* and other gram-positive bacteria use an amino acid bridge (e.g., a $glycine_5$ peptide) between these amino acids to lengthen the cross-link. The precursor form of the peptide has an extra D-alanine, which is released during the cross-linking step.

The peptidoglycan in gram-positive bacteria forms multiple layers and is often cross-linked in three dimensions,

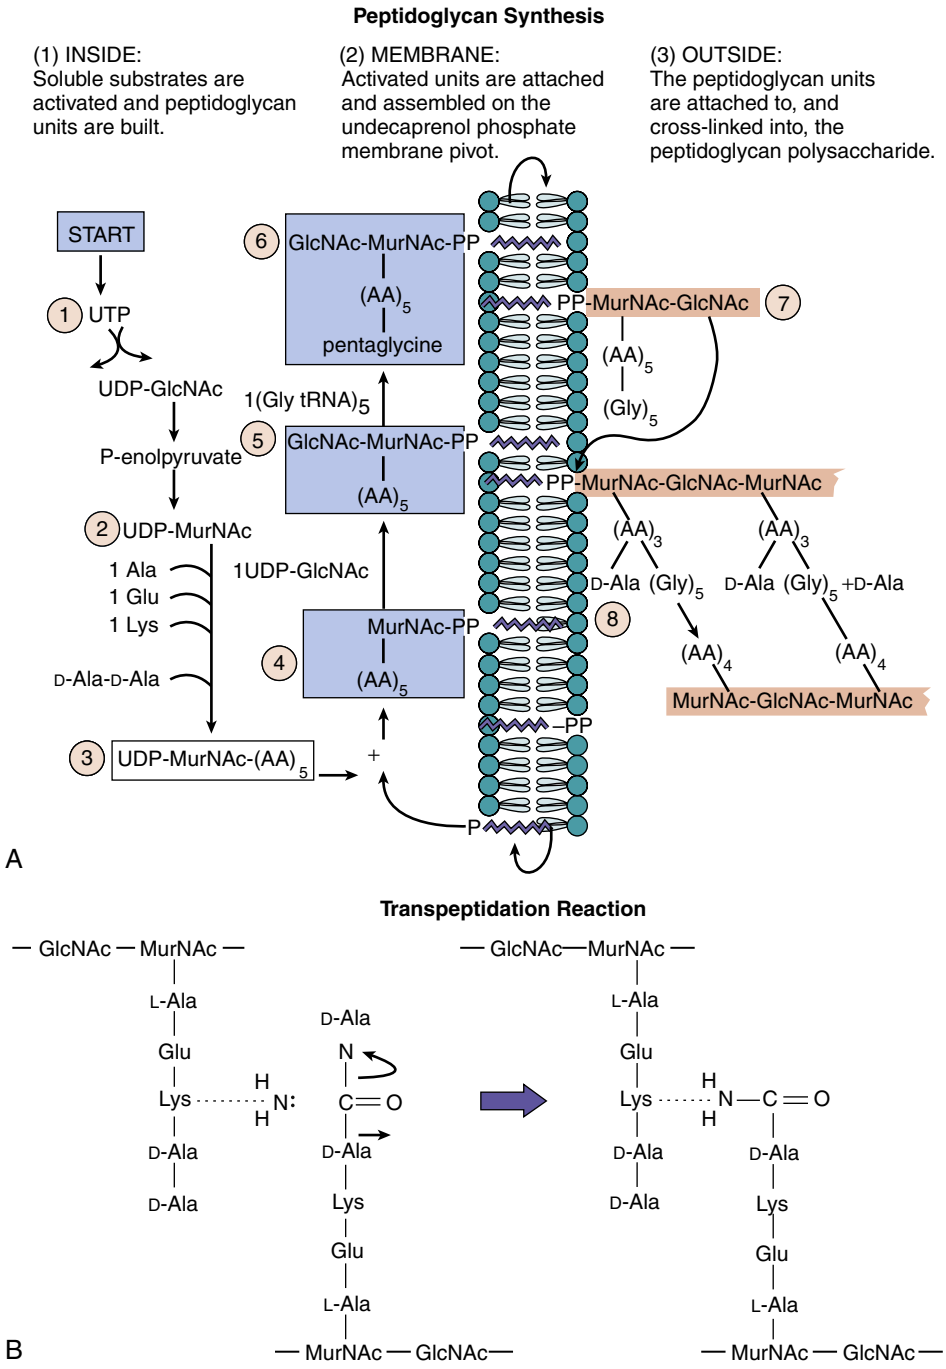

Fig. 12.7 Peptidoglycan synthesis. (A) Peptidoglycan synthesis occurs in the following four phases: (1) Peptidoglycan is synthesized from prefabricated units constructed and activated for assembly and transport inside the cell. (2) At the membrane the units are assembled onto the undecaprenol phosphate conveyor belt, and fabrication is completed. (3) The unit is translocated to the outside of the cell and (4) the unit is attached to the polysaccharide chain, and the peptide is cross-linked to finish the construction. *Staphylococcus aureus* uses a pentaglycine bridge in the cross-link. Such a construction can be compared with the assembly of a space station of prefabricated units. (B) The cross-linking reaction is a transpeptidation. *Escherichia coli* uses a direct cross-link between D-alanine and lysine. One peptide bond (produced inside the cell) is traded for another (outside the cell) with the release of D-alanine. The enzymes that catalyze these reactions are called *D-alanine, D-alanine transpeptidase, or carboxypeptidases*. These enzymes are the targets of β-lactam antibiotics and are called penicillin-binding proteins. *AA_3,* Tripeptide; *AA_4,* tetrapeptide with terminal D-alanine; *AA_5,* pentapeptide with D-alanine-D-alanine; *Glu,* glutamate; *Gly_5,* glycine pentapeptide; *Lys,* lysine; *MurNAc-PP, N*-acetylmuramic acid diphosphate; *tRNA,* transfer ribonucleic acid; *UDP-GlcNAc,* uridine diphosphate *N*-acetylglucosamine; *UDP-MurNAc,* uridine diphosphate-*N*-acetylmuramic acid; *UTP,* uridine triphosphate.

providing a very strong, rigid cell wall. In contrast, the peptidoglycan in gram-negative cell walls is usually only one molecule (layer) thick. The number of cross-links and the length of the cross-link determine the rigidity of the peptidoglycan mesh. **Lysozyme** disperses the peptidoglycan by cleaving the glycan, as shown in Fig. 12.6.

PEPTIDOGLYCAN SYNTHESIS

Peptidoglycan synthesis occurs in four phases (Fig. 12.7). First, the precursors are synthesized and activated inside the cell. Glucosamine is enzymatically converted into MurNAc and then energetically activated by a reaction with uridine

triphosphate (UTP) to produce uridine diphosphate-*N*-acetylmuramic acid (UDP-MurNAc). Next, the UDP-MurNAc-pentapeptide precursor is assembled in a series of enzymatic steps.

In the second phase, the UDP-MurNAc pentapeptide is attached to a molecular conveyor belt–like structure called **bactoprenol (undecaprenol [C_{55} isoprenoid])** in the cytoplasmic membrane through a pyrophosphate link, with the release of uridine monophosphate (UMP). GlcNAc is added to make the disaccharide building block of the peptidoglycan. Some bacteria (e.g., *S. aureus*) add a pentaglycine or another chain to the diamino amino acid at the third position of the peptide chain to lengthen the cross-link.

In the third phase, the bactoprenol molecule with its disaccharide:peptide precursor is translocated to the outside surface of the membrane by a flippase enzyme.

In the last phase, the peptidoglycan is extended at the outside surface of the plasma membrane. The GlcNAc-MurNAc disaccharide is attached to a peptidoglycan chain, using the pyrophosphate link between itself and the bactoprenol as energy to drive the reaction by enzymes called **transglycosylases.** The pyrophosphobactoprenol is converted back to a phosphobactoprenol and recycled. **Bacitracin** blocks the recycling. The peptide chains from adjacent glycan chains are cross-linked to each other by a peptide bond exchange **(transpeptidation)** between the free amine of the amino acid in the third position of the pentapeptide (e.g., lysine), or the N-terminus of the attached pentaglycine chain, and the D-alanine at the fourth position of the other peptide chain, releasing the terminal D-alanine of the precursor. This step requires no additional energy because peptide bonds are "traded."

The cross-linking reaction is catalyzed by membrane-bound **transpeptidases.** Related enzymes called **D-carboxypeptidases** remove unreacted terminal D-alanines to limit the extent of cross-linking. The transpeptidases and carboxypeptidases are called **penicillin-binding proteins (PBPs)** because they are targets for penicillin and other β-lactam antibiotics. *Penicillin* and related **β-lactam antibiotics** resemble the "transition state" conformation of the D-Ala-D-Ala substrate when bound to these enzymes. **Vancomycin** binds like a clamp to the D-Ala-D-Ala structure to block these reactions. Different PBPs are used for extending the peptidoglycan, creating a septum for cell division, and for curving the peptidoglycan mesh (cell shape). Peptidoglycan extension and cross-linking are necessary for cell growth and division.

The peptidoglycan is constantly being synthesized and degraded in a coordinated manner. **Autolysins,** such as lysozyme, are important for determining bacterial shape. Inhibition of synthesis or the cross-linking of the peptidoglycan does not stop the autolysins, and their continued action weakens the mesh and leads to cell lysis and death. New peptidoglycan synthesis does not occur during starvation, which leads to a weakening of the peptidoglycan and a loss in the dependability of the Gram stain.

An understanding of the biosynthesis of peptidoglycan is essential in medicine because these reactions are unique to bacterial cells; hence they can be inhibited with little or no adverse effect on host (human) cells. As indicated earlier, a number of antibacterials target one or more steps in this pathway (see Chapter 17).

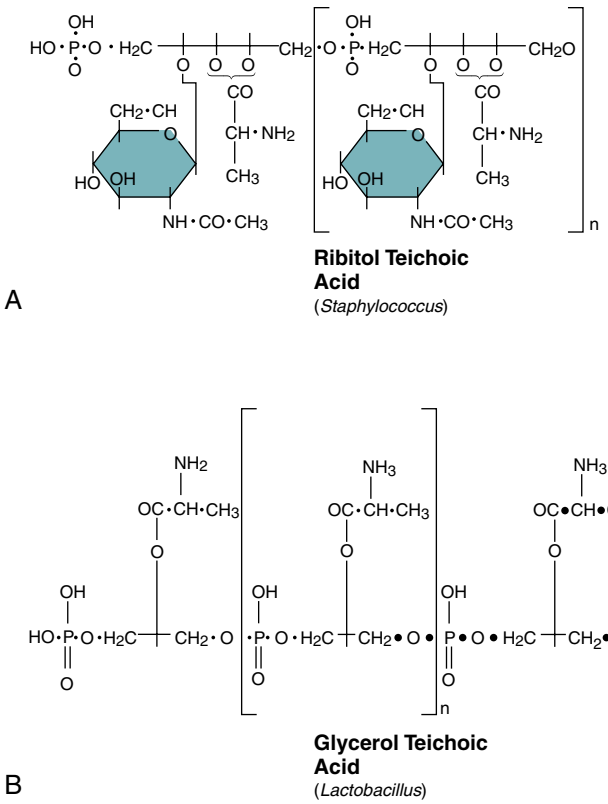

Fig. 12.8 Teichoic acid. Teichoic acid is a polymer of chemically modified ribitol (A) or glycerol phosphate (B). The nature of the modification (e.g., sugars, amino acids) can define the serotype of the bacteria. Teichoic acid is covalently attached to the peptidoglycan. Lipoteichoic acid is anchored in the cytoplasmic membrane by a covalently attached fatty acid.

TEICHOIC ACID

Teichoic and **lipoteichoic acids** are polymers of chemically modified ribose or glycerol connected by phosphates (Fig. 12.8). Sugars, choline, or D-alanine may be attached to the hydroxyls of the ribose or glycerol, providing antigenic determinants. These can be distinguished by antibodies and may determine the bacterial serotype. Lipoteichoic acid has a fatty acid and is anchored in the membrane. Lipoteichoic and teichoic acids are assembled from activated building blocks on the bactoprenol and then translocated to the outer surface in a manner similar to that of peptidoglycan. Teichoic acid is enzymatically attached to the N-terminus of the peptide of peptidoglycan and secreted from the cells.

LIPOPOLYSACCHARIDE

LPS consists of three structural sections: lipid A, core polysaccharide (rough core), and O antigen (Fig. 12.9). Lipid A is a basic component of LPS and is essential for bacterial viability. **Lipid A is responsible for the endotoxin activity of LPS**. It has a phosphorylated glucosamine disaccharide backbone with fatty acids attached to anchor the structure in the outer membrane. The phosphates connect LPS units into aggregates. One carbohydrate chain is attached to each disaccharide backbone and extends away from the bacteria. The core polysaccharide is a branched polysaccharide of 9 to 12 sugars. Most of the core region also is essential for LPS

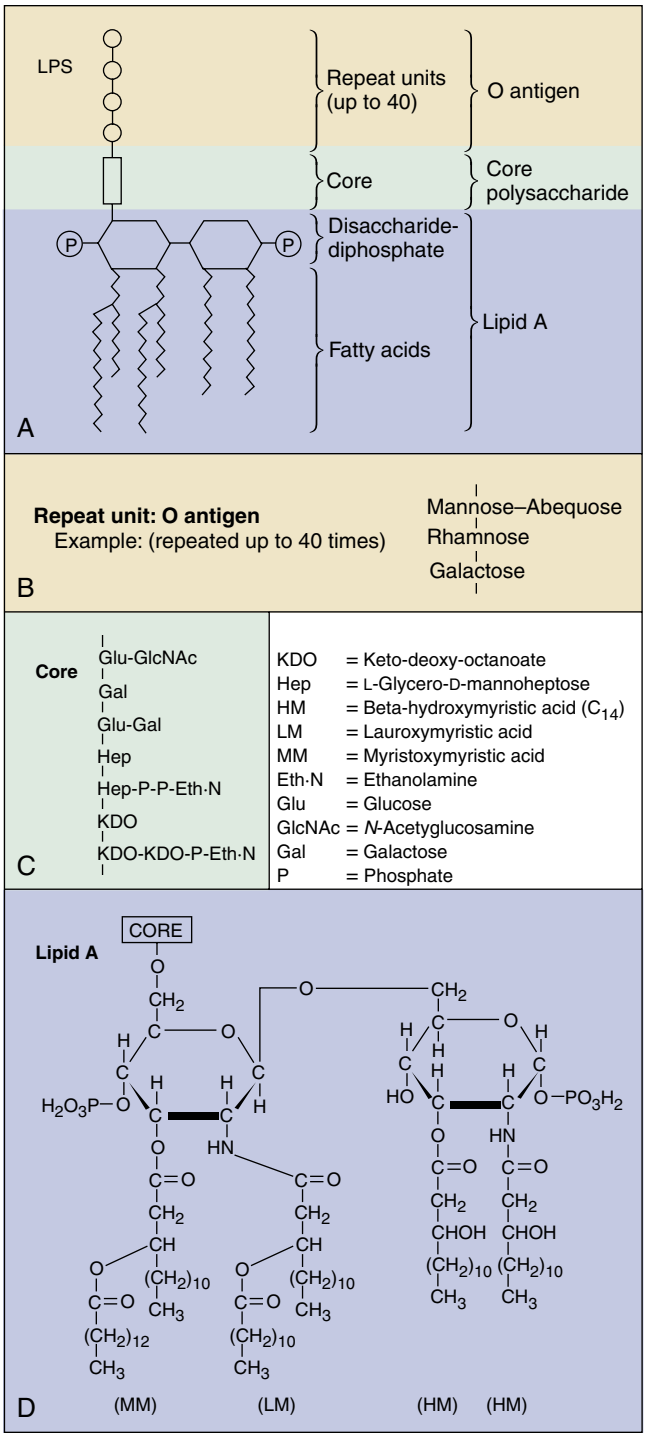

Fig. 12.9 Lipopolysaccharide *(LPS)* of the gram-negative cell envelope. (A) Segment of the molecule showing the arrangements of the major constituents. Each LPS molecule has one lipid A and one polysaccharide core unit but many repeats of the O antigen. (B) Typical O-antigen repeat unit *(Salmonella typhimurium).* (C) Polysaccharide core. (D) Structure of lipid A of *S. typhimurium.* (Modified from Brooks, G.F., Butel, J.S., Ornston, L.N., 1991. Jawetz, Melnick, and Aldenberg's Medical Microbiology, nineteenth ed. Appleton & Lange, Norwalk, CT.)

structure and bacterial viability. The core region contains an unusual sugar called 2-keto-3-deoxy-octanoate (KDO) and is phosphorylated. *Divalent cations link the phosphates within the core of the LPS to strengthen the outer membrane.* The O antigen is attached to the core and extends away from the bacteria. It is a long, linear polysaccharide consisting of 50 to 100 repeating saccharide units of 4 to 7 sugars per unit. **LOS,** which is present in *Neisseria* species, lacks the O-antigen portion of LPS. The shorter O antigen allows LOS aggregates to be shed and diminishes protection of the membrane, which makes *Neisseria* more susceptible to host-mediated complement lysis.

LPS structure is used to classify bacteria. The basic structure of lipid A is identical for related bacteria and is similar for all gram-negative Enterobacteriaceae. The core region is the same for a species of bacteria. The O antigen distinguishes serotypes (strains) of a bacterial species. For example, the O157:H7 (O antigen:flagellin) serotype identifies the *E. coli* agent of hemolytic-uremic syndrome.

The lipid A and core portions are enzymatically synthesized in a sequential manner on the inside surface of the cytoplasmic membrane and then translocated across the membrane. The units of the O antigen are attached to a bactoprenol molecule, translocated to the outside of the cytoplasmic membrane, and 50 to 100 of these units are sequentially attached to the growing O-antigen chain. The finished O-antigen chain is then transferred to the core lipid A structure. The entire LPS molecule is then translocated by a group of proteins that form a bucket-brigade–like escalator from the cytoplasmic membrane through the peptidoglycan, periplasmic space and outer membrane to its outer surface.

Cell Division

Replication of the bacterial chromosome also triggers initiation of cell division (Fig. 12.10). The production of two daughter bacteria requires growth and extension of the cell wall components, followed by production of a septum (cross wall) to divide the daughter bacteria into two cells. The septum consists of two membranes separated by two layers of peptidoglycan. Septum formation is initiated at midcell, at a site defined by protein complexes affixed to a protein filament ring that lines the inside of the cytoplasmic membrane. The septum grows from opposite sides toward the center of the cell, causing cleavage of the daughter cells. This process requires special transpeptidases (PBPs) and other enzymes. For streptococci, the growth zone is located 180 degrees from each other. In contrast, the growth zone of staphylococci is at 90 degrees. Incomplete cleavage of the septum can cause the bacteria to remain linked, forming chains (e.g., streptococci) or clusters (e.g., staphylococci).

Spores

Some gram-positive, but never gram-negative, bacteria, such as members of the genera *Bacillus* (e.g., *B. anthracis*) and *Clostridium* (e.g., *C. tetani* or *botulinum*) (soil bacteria), are spore formers. Under harsh environmental conditions, such as loss of a nutritional requirement, these bacteria can convert from a **vegetative state** to a **dormant state,** or **spore.** The location of the spore within a cell is a characteristic of the bacteria and can assist in identification of the bacterium.

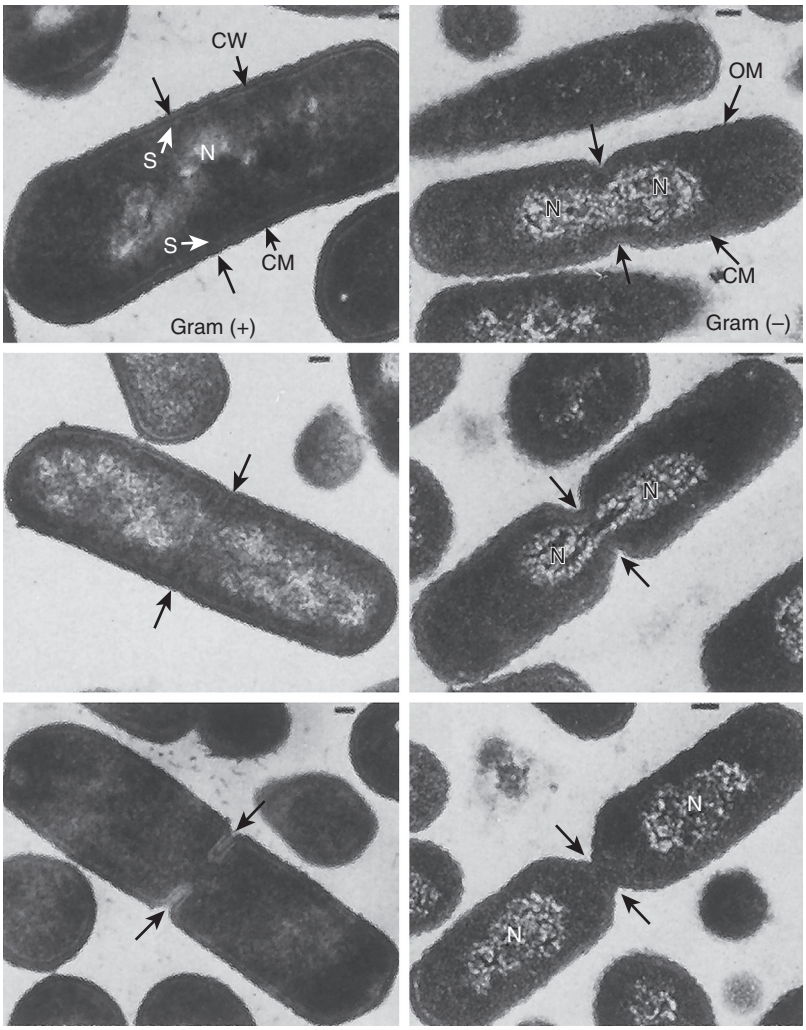

Fig. 12.10 Electron photomicrographs of gram-positive *(Bacillus subtilis)* cell division *(left)* and gram-negative *(Escherichia coli)* cell division *(right)*. Progression in cell division from top to bottom. *CM,* Cytoplasmic membrane; *CW,* cell wall; *N,* nucleoid; *OM,* outer membrane; *S,* septum. Bar = 0.2 μm. (From Slots, J., Taubman, M.A., 1992. Contemporary Oral Biology and Immunology. Mosby, St Louis, MO.)

The spore is a dehydrated multishelled structure that protects and allows the bacteria to exist in "suspended animation" (Fig. 12.11). It contains a complete copy of the chromosome, the bare minimum concentrations of essential proteins and ribosomes, and a high concentration of **calcium bound to dipicolinic acid.** The spore has an inner membrane, two peptidoglycan layers, and an outer keratin–like protein coat. The spore looks refractile (bright) in the microscope. The structure of the spore protects the genomic DNA from intense heat, radiation, and attack by most enzymes and chemical agents. In fact, bacterial spores are so resistant to environmental factors that they can exist for centuries as viable spores. Spores also are difficult to decontaminate with standard disinfectants or autoclaving conditions.

Depletion of specific nutrients (e.g., alanine) from the growth medium triggers a cascade of genetic events (comparable to differentiation) leading to the production of a spore. Spore mRNAs are transcribed, and other mRNAs are turned off. Dipicolinic acid is produced, and antibiotics and toxins are often excreted. After duplication of the chromosome, one copy of the DNA and cytoplasmic contents **(core)** are surrounded by the cytoplasmic membrane, the peptidoglycan, and the membrane of the septum. This wraps the DNA in the two layers of membrane and peptidoglycan that would normally divide the cell. These two layers are surrounded by the **cortex,** which is made up of a thin inner layer of tightly cross-linked peptidoglycan surrounding a membrane (which used to be the cytoplasmic membrane) and a loose outer peptidoglycan layer. The cortex is surrounded by the tough **keratin-like protein coat** that protects the spore. The process requires 6 to 8 hours for completion.

Germination of spores into the vegetative state is stimulated by disruption of the outer coat by mechanical stress, pH, heat, or another stressor and requires water and a triggering nutrient (e.g., alanine). The process takes approximately 90 minutes. After the germination process begins, the spore will take up water, swell, shed its coats, and produce one new vegetative cell identical to the original vegetative cell, completing the entire cycle. Once germination has begun and the spore coat has been compromised, the spore is weakened and vulnerable, and can be inactivated like other bacteria.

For questions see StudentConsult.com

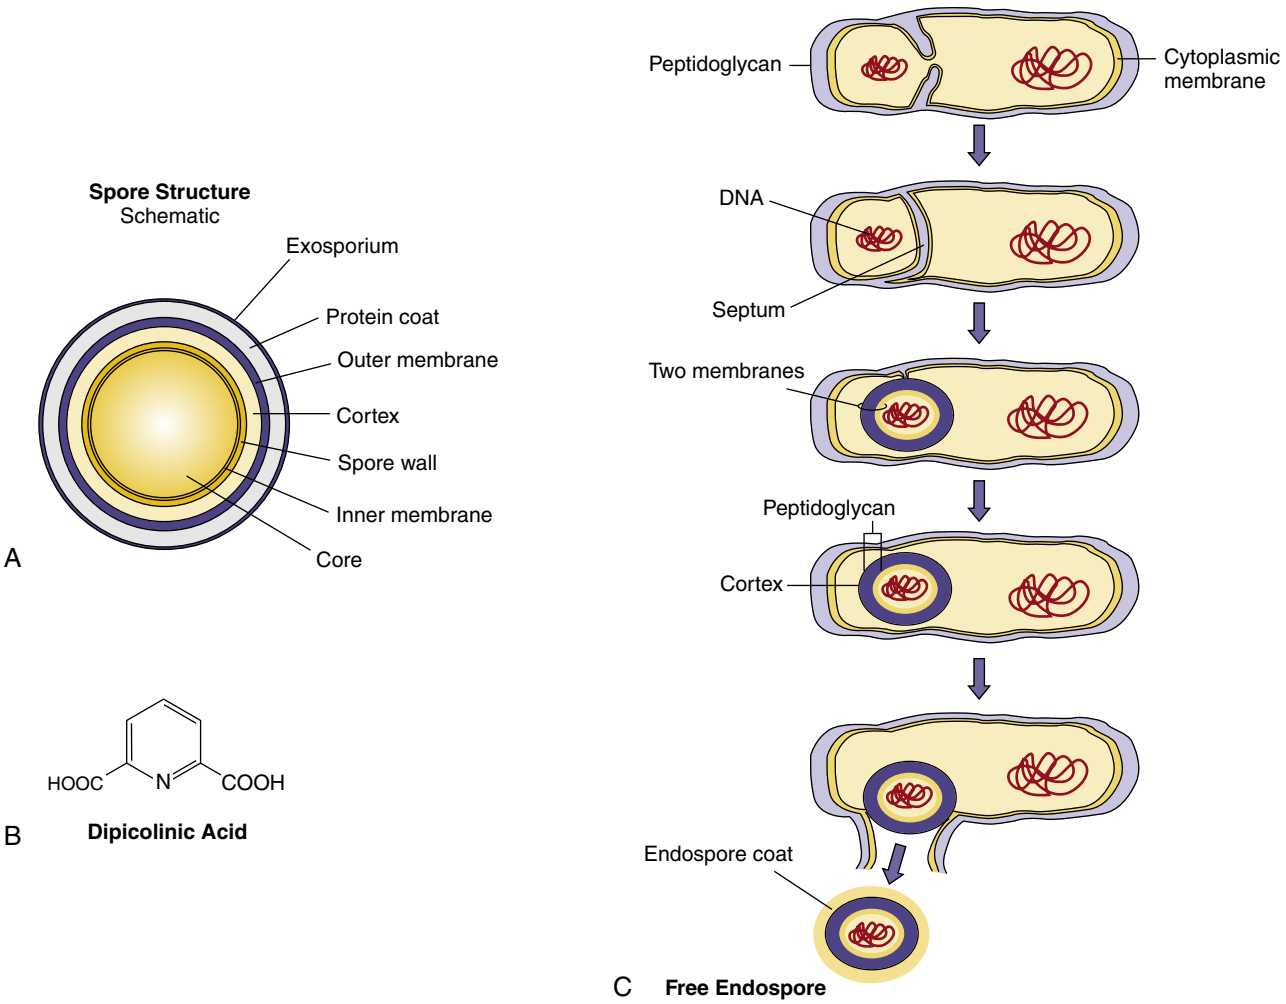

Fig. 12.11 (A) Structure of a spore. (B) High concentrations of dipicolinic acid in the spore bind calcium and stabilize the contents. (C) Sporogenesis, the process of endospore formation.

Questions

1. How do the differences between prokaryotes and eukaryotes (see Table 12.1) influence bacterial infection and treatment?

2. How do the differences between gram-positive and gram-negative cell walls (see Table 12.4) influence cells' clinical behavior, detection, and treatment?

3. List the cell wall components that contribute to virulence by protecting the bacteria from immune responses. List those that contribute to virulence by eliciting toxic responses in the human host.

4. When peptidoglycan synthesis is inhibited, what processes kill the bacteria? List the precursors that would build up within the bacteria if recycling of bactoprenol were inhibited by penicillin, vancomycin, or bacitracin.

5. Why are spores more resistant to environmental stresses?

6. The laboratory would like to selectively eliminate gram-positive bacteria from a mixture of gram-positive and gram-negative bacteria. Which of the following procedures would be more appropriate and why or why not?
   a. Treatment with EDTA (a divalent cation chelator)
   b. Treatment with mild detergent
   c. Treatment with lysozyme
   d. Treatment with transpeptidase
   e. Treatment with ampicillin (a hydrophilic β-lactam antibiotic)

13 Bacterial Metabolism and Genetics

Bacterial Metabolism

Bacteria have developed different approaches to obtain and use the raw materials necessary for growth and survival in the human body. The differences in metabolic requirements and their processes and products allow the distinction of bacteria, define their habitats within our bodies, and provide targets for antimicrobial drugs. Bacteria have developed sophisticated means to regulate their growth and to control protein and enzyme expression in response to their environment. These include mechanisms for expressing appropriate virulence factors within specific parts of the human body. They have also developed the means to share deoxyribonucleic acid (DNA) to acquire new selective advantages in challenging environments, including the presence of antibiotics.

METABOLIC REQUIREMENTS

Bacterial growth requires a source of energy and the raw materials to build the proteins, structures, and membranes that make up and power the cell. Bacteria must obtain or synthesize the amino acids, carbohydrates, and lipids used as building blocks of the cell.

The minimum requirements for growth are a source of carbon and nitrogen, an energy source, water, and various ions. The essential elements include the components of proteins, lipids, and nucleic acids (C, O, H, N, S, P), important ions (K, Na, Mg, Ca, Cl), and components of enzymes (Fe, Zn, Mn, Mo, Se, Co, Cu, Ni). **Iron** is so important that many bacteria secrete special proteins (siderophores) to concentrate iron from dilute solutions, and our bodies will sequester iron to reduce its availability as a means of protection.

Oxygen (O_2 gas), although essential for the human host, is actually a poison for many bacteria. Some organisms (e.g., *Clostridium perfringens*, which causes gas gangrene) cannot grow in the presence of oxygen. Such bacteria are referred to as **obligate anaerobes.** Other organisms (e.g., *Mycobacterium tuberculosis*, which causes tuberculosis) require the presence of molecular oxygen for metabolism and growth and are therefore referred to as **obligate aerobes.** Most bacteria, however, grow in either the presence or the absence of oxygen. These bacteria are referred to as **facultative anaerobes.** Aerobic bacteria produce superoxide dismutase and catalase enzymes, which can detoxify hydrogen peroxide and superoxide radicals that are the toxic by-products of aerobic metabolism and produced by neutrophils and macrophages to kill bacteria.

Growth requirements and metabolic by-products may be used as a convenient means of classifying different bacteria. Some bacteria, such as certain strains of *Escherichia coli* (a member of the intestinal flora), can synthesize all the amino acids, nucleotides, lipids, and carbohydrates necessary for growth and division, whereas the growth requirements of the causative agent of syphilis, *Treponema pallidum,* are so complex that a defined laboratory medium capable of supporting its growth has yet to be developed. Bacteria that can rely entirely on inorganic chemicals for their energy and source of carbon (carbon dioxide [CO_2]) are referred to as autotrophs (lithotrophs), whereas many bacteria and animal cells that require organic carbon sources are known as heterotrophs (organotrophs). Clinical microbiology laboratories distinguish bacteria by their ability to grow on specific carbon sources (e.g., lactose) and generation of the end products of metabolism (e.g., ethanol, lactic acid, succinic acid).

The metabolism of normal flora bacteria is optimized for the pH, ion concentration, and types of food present in their environment within the body. As in the rumen of a cow, the bacteria of the gastrointestinal (GI) tract break down complex carbohydrates into simpler compounds and produce short-chain fatty acids (SCFAs; e.g., butyrate, propionate, lactate, acetate) as by-products of **fermentation.** The lactic acid and SCFAs that are produced can decrease luminal pH, are absorbed and metabolized more readily, and modulate the immune response. Changes in diet, water, or health, antibiotics, and certain drugs can change the environment and influence the metabolism and composition of microbes in the GI tract. Bacteria, like lactobacillus species, that can improve the function of the normal GI flora are included in probiotic therapies (Box 13.1).

METABOLISM, ENERGY, AND BIOSYNTHESIS

All cells require a constant supply of energy to survive. This energy is derived from the controlled breakdown of various organic substrates (carbohydrates, lipids, and proteins). This process of substrate breakdown and conversion into usable energy is known as **catabolism.** The energy produced may then be used in the synthesis of cellular constituents (cell walls, proteins, fatty acids, nucleic acids), which is a process known as **anabolism.** Together, these two processes, which are interrelated and tightly integrated, are referred to as **intermediary metabolism.**

The metabolic process generally begins with hydrolysis of large macromolecules in the external cellular environment by specific enzymes (Fig. 13.1). The smaller molecules that are produced (e.g., monosaccharides, short peptides, fatty acids) are transported across the cell membranes into the cytoplasm by active or passive transport mechanisms specific for the metabolite. These mechanisms may use specific carrier or membrane transport proteins to help concentrate metabolites from the medium. The metabolites are converted via one or more pathways to one common universal intermediate, **pyruvic acid.** From pyruvic acid, the carbons may be channeled toward energy production or the synthesis of new carbohydrates, amino acids, lipids, and nucleic acids.

BOX 13.1 Metabolism of Probiotic and Gastrointestinal Microbes

Probiotic microbes are primarily gram-positive bacteria and include *Lactobacillus* spp., *Bifidobacterium* spp., and the yeast *Saccharomyces boulardii* (Stone, S., Edmonds, R., Rosenthal, K.S., 2013. Probiotics: helping out the normal flora. Infectious Diseases in Clinical Practice 21, 305–311; Saad, N., Delattre, C., Urdaci, M., et al., 2013. An overview of the last advances in probiotic and prebiotic field. Food Science Technology 50, 1–16). *Bifidobacterium infantis* is one of the bacteria acquired by newborns and then selected by the complex carbohydrates in mother's milk. Probiotics consist of microbes that can be ingested, facilitate the development and maintenance of a healthy gut flora, and influence the cells of the immune system. Many of these probiotic bacteria are present in yogurt and are capable of metabolizing complex carbohydrates, including those in milk. These bacteria break down complex carbohydrates into simpler compounds and produce short-chain fatty acids (e.g., butyrate, propionate, lactate, acetate) as by-products of **fermentation.** The lactic acid and short-chain fatty acids produced can decrease luminal pH and are absorbed and metabolized more readily. Acidification of the colon can select for and promote the growth of beneficial lactate-producing endogenous bacteria. Short-chain fatty acids are taken up by the bowel and metabolized more efficiently by the body, enhance cell growth, and improve barrier function of the epithelial cells lining the gastrointestinal tract, as well as support the growth of T-regulator cells to limit inflammatory and autoimmune responses (Smith, P.M., Howitt, M.R., Panikov, N., et al., 2013. The microbial metabolites, short-chain fatty acids, regulate colonic Treg cell homeostasis. Science 341, 569–573).

Some normal flora bacteria, such as *Bacteroidetes* and *Firmicutes,* are more efficient than others at breaking down complex carbohydrates, including plant cell wall compounds (cellulose, pectin, xylan) and mucins or chondroitin sulfates of the protective mucous layer of the intestine. Increases in the ratio of these bacteria in the gut microbiome can lead to obesity (Vijay-Kumar, M., Aitken, J.D., Carvalho, F.A., et al., 2010. Metabolic syndrome and altered gut microbiota in mice lacking Toll-like receptor 5. Science 328, 228–231.)

Instead of releasing all of glucose's energy as heat (as for burning), bacteria break down glucose in discrete steps and capture the energy in usable chemical and electrochemical forms. Chemical energy is typically in the form of a high-energy phosphate bond in **adenosine triphosphate (ATP)** or guanosine triphosphate (GTP), whereas electrochemical energy is stored by reduction (adding electrons to) of **nicotinamide adenine dinucleotide (NAD) to nicotinamide adenine dinucleotide hydride (NADH)** or flavin adenine dinucleotide (FAD) to $FADH_2$. **The NADH** can be converted by a series of oxidation-reduction reactions into chemical (pH) and **electrical potential gradients (Eh)** across the cytoplasmic membrane. The electrochemical energy can be used by **ATP synthase** to drive the phosphorylation of adenosine diphosphate (ADP) to ATP and to drive the spinning of flagella and the transport of molecules across the membrane.

Bacteria can produce energy from glucose by (in order of increasing efficiency) fermentation, anaerobic respiration (both of which occur in the absence of oxygen), or aerobic respiration. Aerobic respiration can completely convert the six carbons of glucose to CO_2 and water (H_2O) plus energy, whereas two- and three-carbon compounds are the end products of fermentation. For a more complete discussion of metabolism, please refer to a textbook on biochemistry.

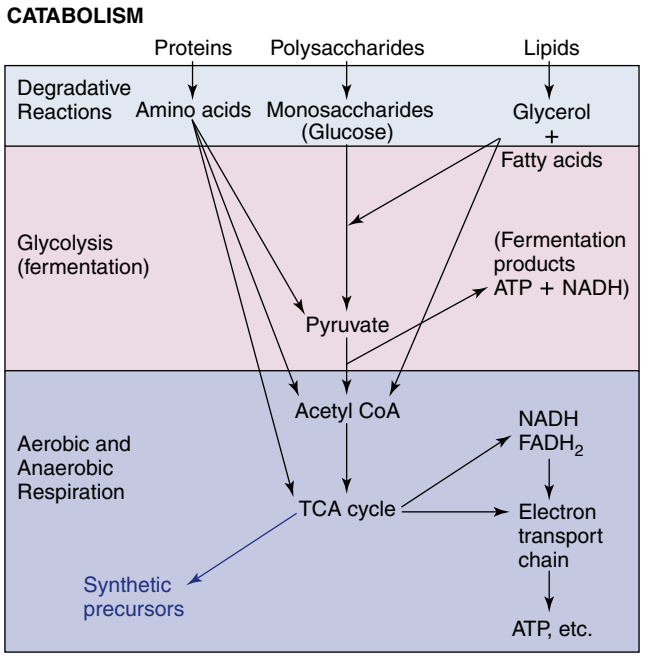

Fig. 13.1 Catabolism of proteins, polysaccharides, and lipids produces glucose, pyruvate, or intermediates of the tricarboxylic acid *(TCA)* cycle and, ultimately, energy in the form of adenosine triphosphate *(ATP)* or the reduced form of nicotinamide adenine dinucleotide *(NADH). CoA,* Coenzyme A.

Glycolysis and Fermentation

The most common glycolytic pathway, the Embden-Meyerhof-Parnas (EMP) pathway, occurs under both aerobic and anaerobic conditions. This pathway yields two ATP molecules per molecule of glucose, two molecules of reduced NADH and two pyruvate molecules.

Fermentation occurs without oxygen, and the pyruvic acid produced from glycolysis is converted to various end products, depending on the bacterial species. *Many bacteria are identified on the basis of their fermentative end products* (Fig. 13.2). These organic molecules, rather than oxygen, are used as electron acceptors to recycle the NADH to NAD. In yeast, fermentative metabolism results in the conversion of pyruvate to ethanol plus CO_2. Alcoholic fermentation is uncommon in bacteria, which most commonly uses the one-step conversion of pyruvic acid to lactic acid. This process is responsible for making milk into yogurt and cabbage into sauerkraut. Other bacteria use more complex fermentative pathways, producing various acids, alcohols, and often gases (many of which have vile odors). These products lend flavors to various cheeses and wines and odors to wound and other infections.

Aerobic Respiration

In the presence of oxygen, the pyruvic acid produced from glycolysis and from the metabolism of other substrates may be completely oxidized (controlled burning) to H_2O and CO_2 using the tricarboxylic acid (TCA) cycle, which results in production of additional energy. The process begins with production of acetyl coenzyme A (acetyl CoA) and release of CO_2. It also produces two NADH molecules from pyruvate.

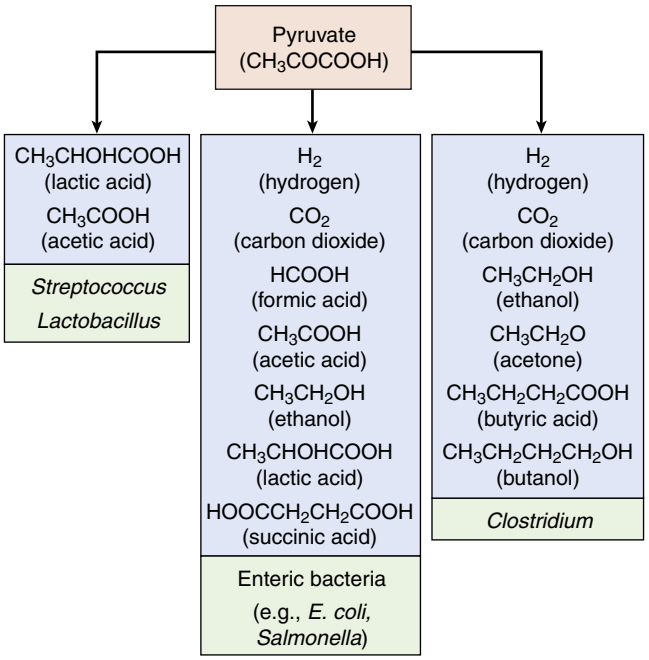

Fig. 13.2 Fermentation of pyruvate by different microorganisms results in different end products. The clinical laboratory uses these pathways and end products as a means of distinguishing different bacteria.

The two remaining carbons derived from pyruvate in the acetyl CoA then enter the TCA by attachment to oxaloacetate to form the six-carbon citrate molecule. In a stepwise series of oxidative reactions, the citrate is converted back to oxaloacetate (the cycle). The theoretical yield from each pyruvate is 2 moles of CO_2, 3 moles of NADH, 1 mole of $FADH_2$, and 1 mole of GTP.

The TCA cycle allows the organism to generate substantially more energy per mole of glucose than is possible from glycolysis alone. In addition to GTP (an ATP equivalent) produced by substrate-level phosphorylation, conversion of the NADH and $FADH_2$ back to NAD and FAD contributes electrons to the electron transport chain to produce ATP. In this chain the electrons are passed in a stepwise fashion through a series of donor-acceptor pairs (e.g., cytochromes) and ultimately to oxygen **(aerobic respiration)** to produce three ATP molecules for each NADH molecule and two ATP for each $FADH_2$. *Whereas fermentation produces only two ATP molecules per glucose, aerobic metabolism with electron transport and a complete TCA cycle can generate as much as 19 times more energy (38 ATP molecules) from the same starting material (and it is much less smelly).*

In addition to efficient generation of ATP from glucose (and other carbohydrates), the TCA cycle provides a means by which carbons derived from **lipids** (in the form of acetyl CoA) may be shunted toward either energy production or the generation of biosynthetic precursors. Similarly, the cycle includes several points at which **deaminated amino acids** may enter. For example, deamination of glutamic acid yields α-ketoglutarate, whereas deamination of aspartic acid yields oxaloacetate, both of which are TCA cycle intermediates. The TCA cycle therefore serves the following functions:

1. It is the most efficient mechanism for the generation of ATP.
2. It serves as the final common pathway for the complete oxidation of amino acids, fatty acids, and carbohydrates.
3. It supplies key intermediates (i.e., α-ketoglutarate, pyruvate, oxaloacetate) for the ultimate synthesis of amino acids, lipids, purines, and pyrimidines.

The last two functions make the TCA cycle a so-called **amphibolic cycle** (i.e., it may function to break down and synthesize molecules).

The electron transport chain resides in the plasma membrane of bacteria and consists of cytochromes, quinones, and iron-sulfur proteins. It uses electrons obtained from NADH and $FADH_2$ to produce a transmembrane proton electrochemical gradient that drives the ATP synthase and powers transport and flagella.

Anaerobic Respiration

During anaerobic respiration, other terminal electron acceptors are used instead of oxygen. Nitrate may be converted to NH_4, sulfate or molecular sulfur to H_2S, CO_2 to methane, ferric ion to ferrous ion, and fumarate to succinate. Less ATP is produced for each NADH than during aerobic respiration because the reduction-oxidation potential is less for these reactions. These reactions are used by facultative anaerobic bacteria in the GI tract and other anaerobic environments.

Pentose Phosphate Pathway

The final pathway of glucose metabolism considered here is known as the **pentose phosphate pathway,** or the **hexose monophosphate shunt.** The function of this pathway is to provide nucleic acid precursors and reducing power in the form of **NADPH** (reduced form) for use in biosynthesis.

Human Bacterial Metabolism

The normal flora of the body obtains its nutrients from our bodies, processes them, and then releases their products into or onto the body. In the gut, bacteria obtain much of their nutrients from our food, but they can also obtain proteins and carbohydrates from the mucus lining. They process complex carbohydrates and release SCFAs as products of fermentation. These molecules are easily absorbed and, in excess, are converted into fat. Some mixtures of intestinal flora are more efficient at this process than others and, can promote obesity. SCFAs also modulate the immune response and inflammation. The bacteria also metabolize bile and facilitate its reabsorption. Other metabolites have widespread influences on the brain, body, and drug metabolism and action. Skin bacteria catabolize the keratin, oils, and dead cells in the stratum corneum outer layer. Similarly, normal flora of other sites graze on the metabolites that are available.

Bacterial Genes and Expression

The bacterial genome is the total collection of genes carried by a bacterium, both on its chromosome and on its extrachromosomal genetic elements, if any. Bacteria usually have only one copy of their chromosomes (they are therefore **haploid**), whereas eukaryotes usually have two

distinct copies of each chromosome (they are therefore diploid). With only one chromosome, alteration of a bacterial gene (mutation) will have a more obvious effect on the cell. In addition, the structure of the bacterial chromosome is maintained by polyamines, such as spermine and spermidine, rather than by histones.

In addition to protein-structural genes (**cistrons,** which are coding genes), the bacterial chromosome contains genes for ribosomal and transfer ribonucleic acid (tRNA). Bacterial genes are often grouped into **operons** or islands (e.g., **pathogenicity islands**) that share function or coordinate their control. Operons with many structural genes are **polycistronic**.

Bacteria also may contain **extrachromosomal genetic elements** such as **plasmids** or **bacteriophages** (bacterial viruses). These elements are independent of the bacterial chromosome and in most cases can be transmitted from one cell to another.

TRANSCRIPTION

The information carried in the genetic memory of the DNA is transcribed (from one form of nucleic acid to another form) into a **messenger RNA (mRNA)** for subsequent translation (to a different substance) into protein. RNA synthesis is performed by a **DNA-dependent RNA polymerase.** The process begins when the **sigma factor** recognizes a particular sequence of nucleotides in the DNA (the **promoter**) and binds tightly to this site. **Promoter sequences** occur just before the start of the DNA that actually encodes a protein. **Sigma factors** bind to these promoters to provide a docking site for the RNA polymerase. Some bacteria encode several sigma factors to coordinate transcription of a group of genes under special conditions such as heat shock, starvation, special nitrogen metabolism, or sporulation.

Once the polymerase has bound to the appropriate site on the DNA, RNA synthesis proceeds with the sequential addition of ribonucleotides complementary to the sequence in the DNA. Once an entire gene or group of genes (operon) has been transcribed, the RNA polymerase dissociates from the DNA, which is a process mediated by signals within the DNA. The bacterial DNA-dependent RNA polymerase is inhibited by rifampin, which is an antibiotic often used in the treatment of tuberculosis.

TRANSLATION

Translation is the process by which the language of the **genetic code,** in the form of mRNA, is converted (translated) into a sequence of amino acids, which is the protein product. Each amino acid word and the punctuation of the genetic code is written as sets of three nucleotides known as **codons.** There are 64 different codon combinations encoding the 20 amino acids, plus start and termination codons. Some of the amino acids are encoded by more than one triplet codon. This feature is known as the *degeneracy of the genetic code* and may function in protecting the cell from the effects of minor mutations in the DNA or mRNA. Each tRNA molecule contains a three-nucleotide sequence complementary to one of the codon sequences. This tRNA sequence is known as the **anticodon;** it allows base pairing and binds to the codon sequence on the mRNA. Attached

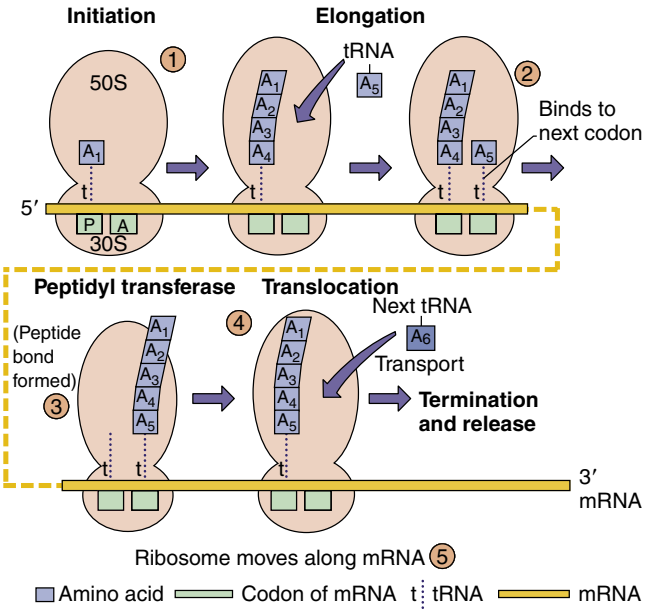

Fig. 13.3 Bacterial protein synthesis. *1,* Binding of the 30S subunit to the messenger RNA *(mRNA)* with the formyl methionine transfer RNA (fMet-tRNA) at the AUG start codon allows assembly of the 70S ribosome. The fMet-tRNA binds to the peptidyl site *(P). 2,* The next *tRNA* binds to its codon at the *A* site and "accepts" the growing peptide chain. *3* and *4,* Before translocation to the peptidyl site. *5,* The process is repeated until a stop codon and the protein are released.

to the opposite end of the tRNA is the amino acid that corresponds to the particular codon-anticodon pair.

Bacterial protein synthesis (Fig. 13.3) begins with the binding of the 30S ribosomal subunit and a special initiator tRNA for formyl methionine (fMet) at the methionine codon (AUG) start codon to form the **initiation complex.** The 50S ribosomal subunit binds to the complex to initiate mRNA synthesis. The ribosome contains two tRNA binding sites, the **A (aminoacyl) site** and the **P (peptidyl) site,** each of which allows base pairing between the bound tRNA and the codon sequence in the mRNA. The tRNA corresponding to the second codon occupies the A site. The amino group of the amino acid attached to the A site forms a peptide bond with the carboxyl group of the amino acid in the P site in a reaction known as **transpeptidation,** and the empty tRNA in the P site (uncharged tRNA) is released from the ribosome. The ribosome then moves down the mRNA exactly three nucleotides, transferring the tRNA with attached nascent peptide to the P site and bringing the next codon into the A site. The appropriate charged tRNA is brought into the A site, and the process is then repeated. Translation continues until the new codon in the A site is one of the three termination codons, for which there is no corresponding tRNA. At that point, the new protein is released to the cytoplasm and the translation complex may be disassembled, or the ribosome shuffles to the next start codon and initiates a new protein. The ability to shuffle along the mRNA to start a new protein is a characteristic of the 70S bacterial but not of the 80S eukaryotic ribosome. The eukaryotic constraint has implications for the synthesis of proteins for some viruses.

The process of protein synthesis by the 70S ribosome represents an important target of antimicrobial action. The

aminoglycosides (e.g., streptomycin and gentamicin) and the tetracyclines act by binding to the small ribosomal subunit and inhibiting normal ribosomal function. Similarly, the macrolide (e.g., erythromycin) and lincosamide (e.g., clindamycin) groups of antibiotics act by binding to the large ribosomal subunit. Also, fMet peptides (e.g., fMet-Leu-Phe) are unique to bacteria, are chemotactic, and attract neutrophils to the site of an infection.

CONTROL OF GENE EXPRESSION

Bacteria have developed mechanisms to adapt quickly and efficiently to changes and triggers from the environment. This allows them to coordinate and regulate the expression of genes for multicomponent structures or the enzymes of one or more metabolic pathways. For example, temperature change could signify entry into the human host and indicate the need for a global change in metabolism and upregulation of genes important for parasitism or virulence. Many bacterial genes are controlled at multiple levels and by multiple methods.

Promoters and operators are DNA sequences at the beginning of a gene or operon that are recognized by sigma factors, which are activator and repressor proteins that control expression of a gene or an operon. Thus all the genes coding for the enzymes of a particular pathway can be coordinately regulated.

Coordination of a large number of processes on a global level can also be mediated by small molecular activators, such as cyclic adenosine monophosphate (cAMP). Increased cAMP levels indicate low glucose levels and the need to use alternative metabolic pathways. Similarly, in a process called **quorum sensing,** each bacterium produces a specific small molecule, and when a sufficient number of bacteria are present, the concentration of the molecule will be sufficient to coordinate the expression of genes to support the colony rather than the individual bacterium. The trigger for biofilm production by *Pseudomonas* spp. is triggered by a critical concentration of *N*-acyl homoserine lactone (AHL) produced when sufficient numbers of bacteria (quorum) are present. Activation of biofilm, toxin production, and more virulent behavior by *Staphylococcus aureus* accompanies the increase in concentration of a cyclic peptide.

The genes for some virulence mechanisms are organized into a **pathogenicity island** under the control of a single promoter to coordinate their expression and ensure that all the proteins necessary for a structure or process are produced when needed. The many components of the type III secretion devices of *E. coli, Salmonella,* or *Yersinia* are grouped together within pathogenicity islands.

Transcription also can be regulated by the translation process. Unlike eukaryotes, the absence of a nuclear membrane in prokaryotes allows the ribosome to bind to the mRNA as it is being transcribed from the DNA. The position and speed of ribosomal movement along the mRNA can determine whether loops form in the mRNA, influencing the ability of the polymerase to continue transcription of new mRNA. This allows control of gene expression at both the transcriptional and translational levels.

Initiation of transcription may be under positive or negative control. Genes under **negative control** are expressed unless they are switched off by a **repressor protein.** This repressor protein prevents gene expression by binding to a specific DNA sequence within the operator, blocking the RNA polymerase from initiating transcription at the promoter sequence. Conversely, genes whose expression is under **positive control** are not transcribed unless an active regulator protein, called an **apoinducer,** is present. The apoinducer binds to a specific DNA sequence and assists the RNA polymerase in the initiation steps by an unknown mechanism.

Operons can be **inducible or repressible.** Introduction of a substrate **(inducer)** into the growth medium may induce an operon to increase the expression of the enzymes necessary for its metabolism. An abundance of the end products **(co-repressors)** of a pathway may signal that a pathway should be shut down or repressed by reducing the synthesis of its enzymes.

The *E. coli lac* operon includes all the genes necessary for lactose metabolism, as well as the control mechanisms for turning off (in the presence of glucose) or turning on (in the presence of galactose or an inducer) these genes only when they are needed. The *lac* operon includes a repressor sequence, a promoter sequence, and structural genes for the β-galactosidase enzyme, a permease, and an acetylase (Fig. 13.4). Normally the bacteria use glucose, not lactose. In the absence of lactose, the operon is repressed by the binding of the repressor protein to the operator sequence, impeding the RNA polymerase function. In the absence of glucose, however, the addition of lactose reverses this repression. Full expression of the *lac* operon also requires a protein-mediated positive-control mechanism. In *E. coli,* when glucose decreases in the cell, cAMP increases to promote usage of other sugars for metabolism. Binding of cAMP to a protein called the **catabolite gene-activator protein (CAP)** allows it to bind to a specific DNA sequence present in the promoter. The CAP-cAMP complex enhances binding of the RNA polymerase to the promoter, allowing an increase in the frequency of transcription initiation.

The tryptophan operon **(*trp* operon)** contains the structural genes necessary for tryptophan biosynthesis and is under dual transcriptional control mechanisms (Fig. 13.5). Although tryptophan is essential for protein synthesis, too much tryptophan in the cell can be toxic; therefore its synthesis must be regulated. At the DNA level, the repressor protein is activated by an increased intracellular concentration of tryptophan to prevent transcription. At the protein synthesis level, rapid translation of a "test peptide" situated at the beginning of the mRNA in the presence of tryptophan allows formation of a double-stranded loop in the RNA, which terminates transcription. The same loop is formed if no protein synthesis is occurring, a situation in which tryptophan synthesis would similarly not be required. This regulates tryptophan synthesis at the mRNA level in a process termed **attenuation,** in which mRNA synthesis is prematurely terminated.

Expression of the components of virulence mechanisms also are coordinately regulated from an operon. Simple triggers (e.g., temperature, osmolarity, pH, nutrient availability) or the concentration of specific small molecules (e.g., oxygen, iron) can turn on or turn off the transcription of a single gene or a group of genes.

Salmonella invasion genes within a pathogenicity island are turned on by high osmolarity and low oxygen, which are conditions present in the GI tract or an endosomal

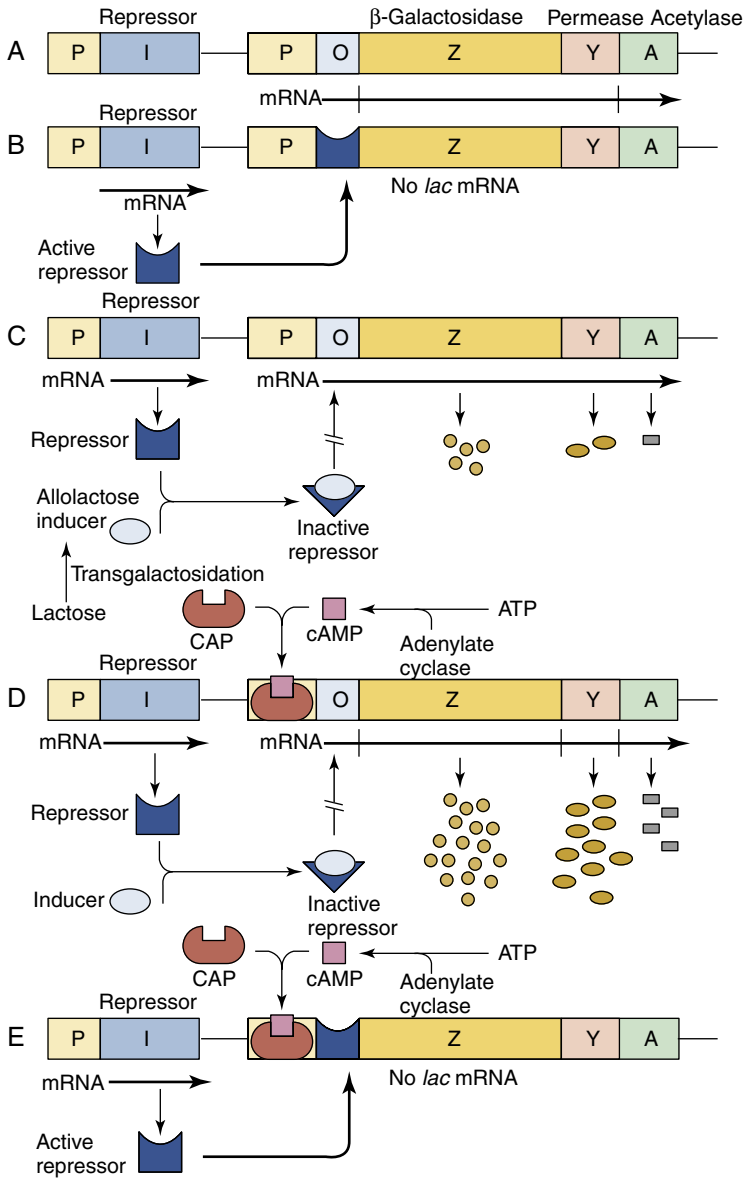

Fig. 13.4 (A) The lactose *(lac)* operon is transcribed as a polycistronic messenger RNA *(mRNA)* from the promoter *(P)* and translated into three proteins: β-galactosidase *(Z),* permease *(Y),* and acetylase *(A).* The *(I)* gene encodes the repressor protein. (B) The lactose operon is not transcribed in the absence of an allolactose inducer because the repressor competes with the RNA polymerase at the operator site *(O).* (C) The repressor, complexed with the inducer, does not recognize the operator because of a conformation change in the repressor. The *lac* operon is thus transcribed at a low level. (D) *Escherichia coli* is grown in a poor medium in the presence of lactose as the carbon source. Both the inducer and the CAP-cAMP complex are bound to the promoter, which is fully "turned on," and a high level of *lac* mRNA is transcribed and translated. (E) Growth of *E. coli* in a poor medium without lactose results in the binding of the CAP-cAMP complex to the promoter region and binding of the active repressor to the operator sequence because no inducer is available. The result will be that the *lac* operon will not be transcribed. *ATP,* Adenosine triphosphate; *cAMP,* cyclic adenosine monophosphate; *CAP,* catabolite gene-activator protein.

vesicle within a macrophage. *E. coli* senses its exit from the gut of a host by a drop in temperature and inactivates its adherence genes. Low iron levels can activate expression of hemolysin in *E. coli* or diphtheria toxin from *Corynebacterium diphtheriae* potentially to kill cells and provide iron. Iron binds to and is a co-repressor for the diphtheria toxin and operons encoding iron sequestering proteins.

Quorum sensing as a means for regulating expression of virulence factors and biofilm production by *S. aureus* and *Pseudomonas* spp. were discussed earlier. An example of coordinated control of virulence genes for *S. aureus* based on the growth rate, availability of metabolites, and the presence of a quorum is presented in Fig. 13.6.

REPLICATION OF DNA

Replication of the bacterial genome is triggered by a cascade of events linked to the growth rate of the cell. Replication of bacterial DNA is initiated at a specific sequence in the chromosome called *oriC*. The replication process requires many enzymes, including an enzyme **(helicase)** to unwind the DNA at the origin to expose the DNA, an enzyme **(primase)** to synthesize primers to start the process, and the enzyme or enzymes **(DNA-dependent DNA polymerases)** that synthesize a copy of the DNA, but only if there is a **primer sequence** to add onto and only in the **5′ to 3′ direction.**

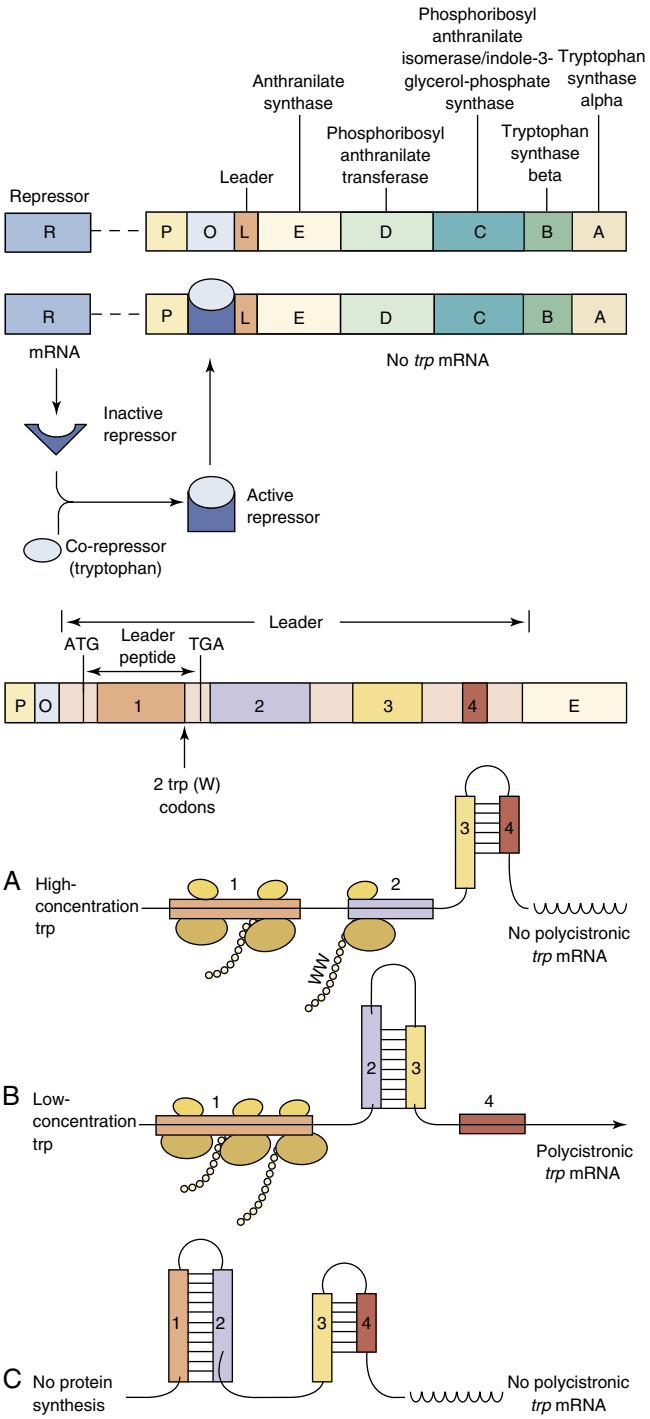

Fig. 13.5 Regulation of the tryptophan *(trp)* operon. (A) The *trp* operon encodes the five enzymes necessary for tryptophan biosynthesis. This *trp* operon is under dual control. (B) The conformation of the inactive repressor protein is changed after its binding by the co-repressor tryptophan. The resulting active repressor *(R)* binds to the operator *(O),* blocking any transcription of the *trp* mRNA by the RNA polymerase. (C) The *trp* operon also is under the control of an attenuation-antitermination mechanism. Upstream of the structural genes are the promoter *(P),* the operator, and a leader *(L),* which can be transcribed into a short peptide containing two tryptophans *(W),* near its distal end. The leader mRNA possesses four repeats (1, 2, 3, and 4), which can pair differently according to the tryptophan availability, leading to an early termination of transcription of the *trp* operon or its full transcription. In the presence of a high concentration of tryptophan, regions 3 and 4 of the leader mRNA can pair, forming a terminator hairpin, and no transcription of the *trp* operon occurs. However, in the presence of little or no tryptophan the ribosomes stall in region 1 when translating the leader peptide because of the tandem of tryptophan codons. Then regions 2 and 3 can pair, forming the antiterminator hairpin and leading to transcription of the *trp* genes. Finally, the regions 1:2 and 3:4 of the free leader mRNA can pair, also leading to cessation of transcription before the first structural gene *trpE*. *A,* Adenine; *G,* guanine; *T,* thymidine.

New DNA is synthesized **semiconservatively,** using both strands of the parental DNA as templates. New DNA synthesis occurs at **growing forks** and proceeds **bidirectionally.** One strand (the leading strand) is copied continuously in the 5′ to 3′ direction, whereas the other strand (the lagging strand) must be synthesized as many pieces of DNA using RNA primers (Okazaki fragments). The lagging-strand DNA must be extended in the 5′ to 3′ direction as its template becomes available. Then the pieces are ligated together by the enzyme DNA ligase (Fig. 13.7). To maintain the high degree of accuracy required for replication, the DNA polymerases possess "proofreading" functions that allow the enzyme to confirm that the appropriate nucleotide was inserted and to correct any errors that were made. During log-phase growth in a rich medium, many initiations of chromosomal replication may occur before cell division. This process produces a series of nested bubbles of new daughter chromosomes, each with its pair of growth forks of new DNA synthesis. The polymerase moves down the DNA strand, incorporating the appropriate (complementary) nucleotide at each position. Replication is complete when the two replication forks meet 180 degrees from the origin. The process of DNA replication puts great torsional strain on the chromosomal circle of DNA; this strain is relieved by **topoisomerases** (e.g., gyrase), which supercoil the DNA. Topoisomerases are essential to the bacteria and are targets for the fluoroquinolone antibiotics.

BACTERIAL GROWTH

Bacterial replication is a coordinated process in which two equivalent daughter cells are produced. For growth to occur, there must be sufficient metabolites to support synthesis of the bacterial components and especially the nucleotides for DNA synthesis. A cascade of regulatory events (synthesis of key proteins and RNA), much like a countdown at the Kennedy Space Center, must occur on schedule to initiate a replication cycle. *However, once it is initiated, DNA synthesis must run to completion, even if all nutrients have been removed from the medium.*

Chromosome replication is initiated at the membrane, and each daughter chromosome is anchored to a different portion of membrane. *Bacterial membrane, peptidoglycan synthesis, and cell division are linked together such that inhibition of peptidoglycan synthesis also will inhibit cell division.* As the bacterial membrane grows, the daughter chromosomes are pulled apart. Commencement of chromosome replication also initiates the process of cell division, which can be visualized by the start of septum formation between the two daughter cells (Fig. 13.8; see also Chapter 12). New initiation events may occur even before completion of chromosome replication and cell division.

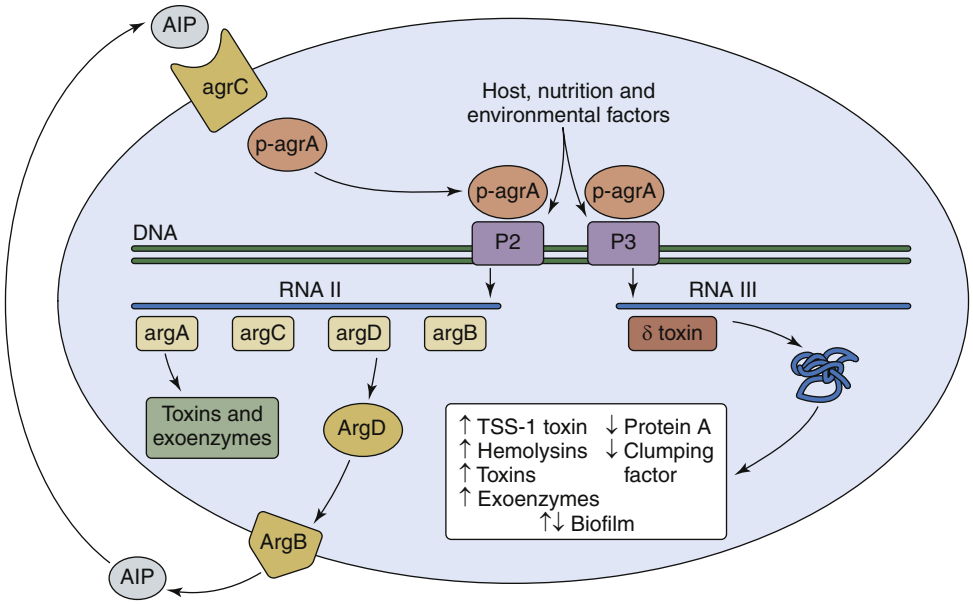

Fig. 13.6 Control of virulence genes in *Staphylococcus aureus*. *S. aureus* coordinates the expression of virulence factors to suit an individual bacterium or one within a colony, as influenced by its environment. The presence of a colony is indicated by a quorum sensing system encoded by the **agr** (accessory gene regulator) operon. The autoinducing peptide **(AIP)** binds to the **AgrC** receptor, which phosphorylates **AgrA**. The pAgrA binds to **promoters P2 on the agr operon and P3**. RNA II encodes the agr proteins. **AgrD** is processed by **AgrB** into the AIP, which then recapitulates the cycle. The RNAIII encodes the δ **toxin** and the RNAIII and AgrA coordinately regulates expression of many virulence factors. Transcription of RNA II and RNA III also are influenced by other factors (growth rate, nutrients, and reactive oxygen species) relevant to colonization and spread in the host.

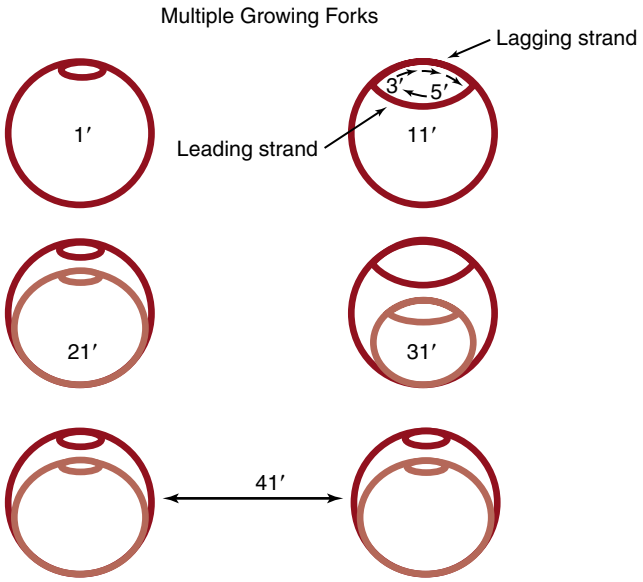

Fig. 13.7 Bacterial DNA replication. New DNA synthesis occurs at growing forks and proceeds bidirectionally. DNA synthesis progresses in the 5′ to 3′ direction continuously (leading strand) or in pieces (lagging strand). Assuming it takes 40 minutes to complete one round of replication, and assuming new initiation every 20 minutes, initiation of DNA synthesis precedes cell division. Multiple growing forks may be initiated in a cell before complete septum formation and cell division. The daughter cells are "born pregnant."

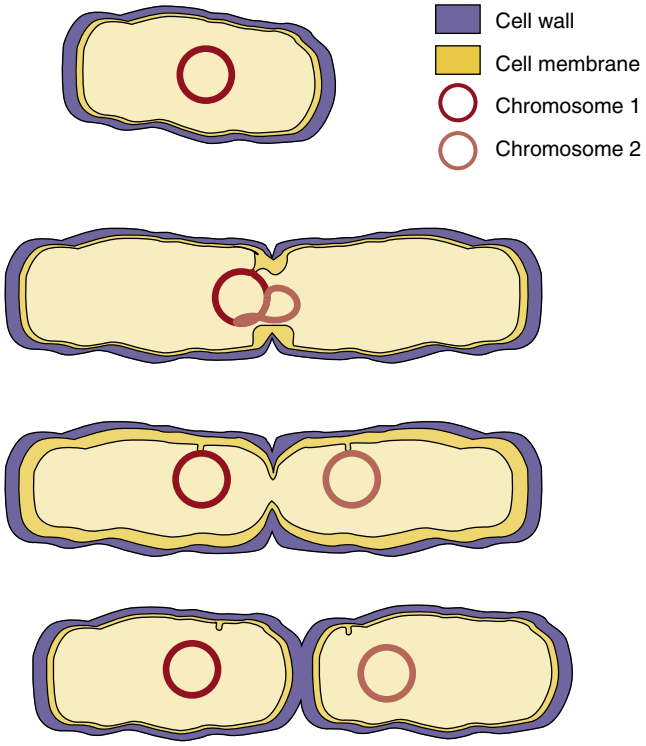

Fig. 13.8 Bacterial cell division. Replication requires extension of the cell wall and replication of the chromosome and septum formation. Membrane attachment of the DNA pulls each daughter strand into a new cell.

Depletion of metabolites (starvation) or a buildup of toxic by-products (e.g., ethanol) triggers production of chemical **alarmones,** which cause protein and other synthesis to stop, but degradative processes continue. DNA synthesis continues until all initiated chromosomes are completed, despite the detrimental effect on the cell. Ribosomes are cannibalized for deoxyribonucleotide precursors, peptidoglycan and proteins are degraded for metabolites, and the cell shrinks. Septum formation may be initiated, but cell division may not occur. Many cells die. Similar signals may initiate **sporulation** in species capable of this process (see

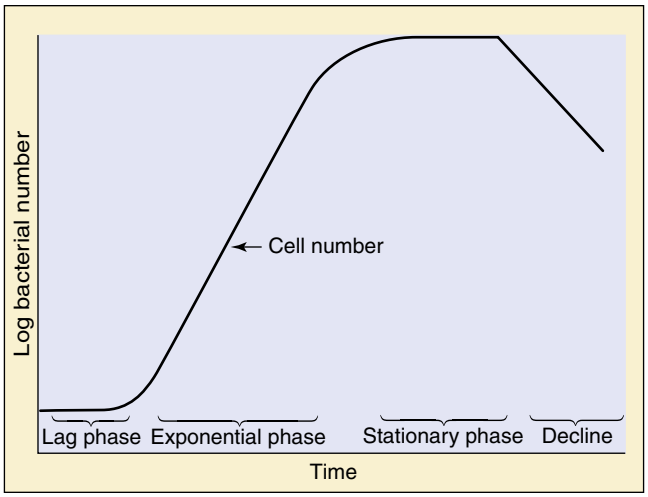

Fig. 13.9 Phases of bacterial growth, starting with an inoculum of stationary-phase cells.

Chapter 12). For some bacterial species, starvation promotes uptake of foreign DNA (transformation) that may encode the means to survive the challenge.

Population Dynamics

When bacteria are added to a new medium, they require time to adapt to the new environment before they begin dividing (Fig. 13.9). This hiatus is known as the **lag phase** of growth. During the **logarithmic (log) or exponential phase,** the bacteria will grow and divide with a **doubling time** characteristic of the strain, and determined by the conditions. The number of bacteria will increase to 2^n, in which n is the number of generations (doublings). The culture eventually runs out of metabolites, or a toxic substance builds up in the medium; the bacteria then stop growing and enter the **stationary phase,** followed by the **death phase.** During the death phase, some bacteria stop dividing but remain viable and are often insensitive to antibiotics.

Bacterial Genetics

MUTATION, REPAIR, AND RECOMBINATION

Accurate replication of DNA is important to the survival of the bacteria, but mistakes and accidental damage to the DNA occur. The bacteria have efficient DNA repair systems, but mutations and alterations to the DNA still occur. Most of these mutations have little effect on the bacteria or are detrimental, but some mutations may provide a selective advantage for survival of the bacteria when challenged by the environment, the host, or antibiotic therapy.

Mutations and Their Consequences

A mutation is any change in the base sequence of the DNA. A single base change can result in a **transition** in which one purine is replaced by another purine or in which a pyrimidine is replaced by another pyrimidine. A **transversion** in which, for example, a purine is replaced by a pyrimidine and vice versa may also result. A **silent mutation** is a change at the DNA level that does not result in any change of amino acid in the encoded protein. This type of mutation occurs because more than one codon may encode an amino acid. A **missense mutation** results in a different amino acid being inserted in the protein, but this may be a **conservative mutation** if the new amino acid has similar properties (e.g., valine replacing alanine). A **nonsense mutation** changes a codon encoding an amino acid to a stop codon (e.g., thymidine-adenine-guanine [TAG]), which will cause the ribosome to fall off the mRNA and end the protein prematurely. **Conditional mutations,** such as **temperature-sensitive mutations,** may result from a conservative mutation that changes the structure or function of an important protein at elevated temperatures.

More drastic changes can occur when numerous bases are involved. A small deletion or insertion that *is not in multiples of three* produces a **frameshift mutation.** This results in a change in the reading frame, usually leading to a useless peptide and premature truncation of the protein. **Null mutations,** which completely destroy gene function, arise when there is an extensive insertion, deletion, or gross rearrangement of the chromosome structure. Insertion of long sequences of DNA (many thousands of base pairs) by recombination, by transposition, or during genetic engineering can produce null mutations by separating the parts of a gene and inactivating the gene.

Many mutations occur spontaneously in nature (e.g., by polymerase mistakes); however, physical or chemical agents can also induce mutations. Among the physical agents used to induce mutations in bacteria are heat, which results in deamination of nucleotides; ultraviolet light, which causes pyrimidine dimer formation; and ionizing radiation, such as x-rays, which produce very reactive hydroxyl radicals that may be responsible for opening a ring of a base or causing single- or double-stranded breaks in the DNA.

Chemical mutagens can be grouped into three classes. **Nucleotide-base analogs** lead to mispairing and frequent DNA replication mistakes. For example, incorporation of 5-bromouracil into DNA instead of thymidine allows base pairing with guanine instead of adenine, changing a T-A base pair to a G-C base pair. **Frameshift mutagens,** such as polycyclic flat molecules like ethidium bromide or acridine derivatives, insert (or intercalate) between the bases as they stack with each other in the double helix. The increase in spacing of successive base pairs causes addition or deletion of a single base and leads to frequent mistakes during DNA replication. **DNA-reactive chemicals** act directly on the DNA to change the chemical structure of the base. These include nitrous acid (HNO_2) and alkylating agents, including nitrosoguanidine and ethyl methane sulfonate, which are known to add methyl or ethyl groups to the rings of the DNA bases. The modified bases may pair abnormally or not at all. The damage may also cause removal of the base from the DNA backbone.

Repair Mechanisms of DNA

A number of repair mechanisms have evolved in bacteria. Their goal is to reconnect broken DNA strands, but it may be error prone. These repair mechanisms can be divided into the following five groups:

1. **Direct DNA repair** is the enzymatic removal of damage, such as pyrimidine dimers and alkylated bases.

2. **Excision repair** is the removal of a DNA segment containing the damage, followed by synthesis of a new DNA strand. Two types of excision-repair mechanisms, generalized and specialized, exist.
3. **Recombinational** or **postreplication repair** replaces a missing or damaged section of DNA with the same or similar sequences that may be present during replication or on extrachromosomal DNA.
4. The **SOS response** is the induction of many genes (≈15) after DNA damage or interruption of DNA replication to promote recombination or error-prone repair.
5. **Error-prone repair** is the last resort of a bacterial cell before it dies. It is used to fill in gaps with a random sequence when a DNA template is not available for directing an accurate repair.

Clustered Regularly Interspaced Short Palindromic Repeats/CRISPR associated proteins (CRISPR/Cas) and similar systems are used to protect the bacterial chromosome against integration of bacteriophages and foreign plasmids. The CRISPR system provides sequences that hybridize to like sequences in the foreign DNA and then the Cas cleaves that DNA. This mechanism has been harnessed to provide sequence-targeted gene editing for gene replacement and modification therapy.

GENE EXCHANGE IN PROKARYOTIC CELLS

Many bacteria, especially many pathogenic bacterial species, are promiscuous with their DNA. The exchange of DNA between cells allows for the exchange of genes and characteristics between cells, producing new strains of bacteria. This exchange may be advantageous for the recipient, especially if the exchanged DNA encodes antibiotic resistance. The transferred DNA can be integrated into the recipient chromosome or stably maintained as an extrachromosomal element **(plasmid)** or a bacterial virus **(bacteriophage)** and passed on to daughter bacteria as an autonomously replicating unit.

Plasmids are small genetic elements that replicate independently of the bacterial chromosome. Most plasmids are circular double-stranded DNA molecules varying from 1500 to 400,000 base pairs. However, *Borrelia burgdorferi,* the causative agent of Lyme disease, and the related *B. hermsii* are unique among all eubacteria because they possess linear genomes and plasmids. Like the bacterial chromosomal DNA, plasmids can autonomously replicate and as such are referred to as **replicons.** Some plasmids, such as the *E. coli* F plasmid, are **episomes,** which means they can integrate into the host chromosome.

Plasmids carry genetic information that may not be essential but can provide a selective advantage to the bacteria. For example, plasmids may encode the production of antibiotic resistance mechanisms, bacteriocins, toxins, virulence determinants, and other genes that may provide the bacteria with a unique growth advantage over other microbes or within the host (Fig. 13.10). The number of copies of plasmid produced by a cell is determined by the particular plasmid. The **copy number** is the ratio of copies of the plasmid to the number of copies of the chromosome. This may be as few as one in the case of large plasmids or as many as 50 in smaller plasmids.

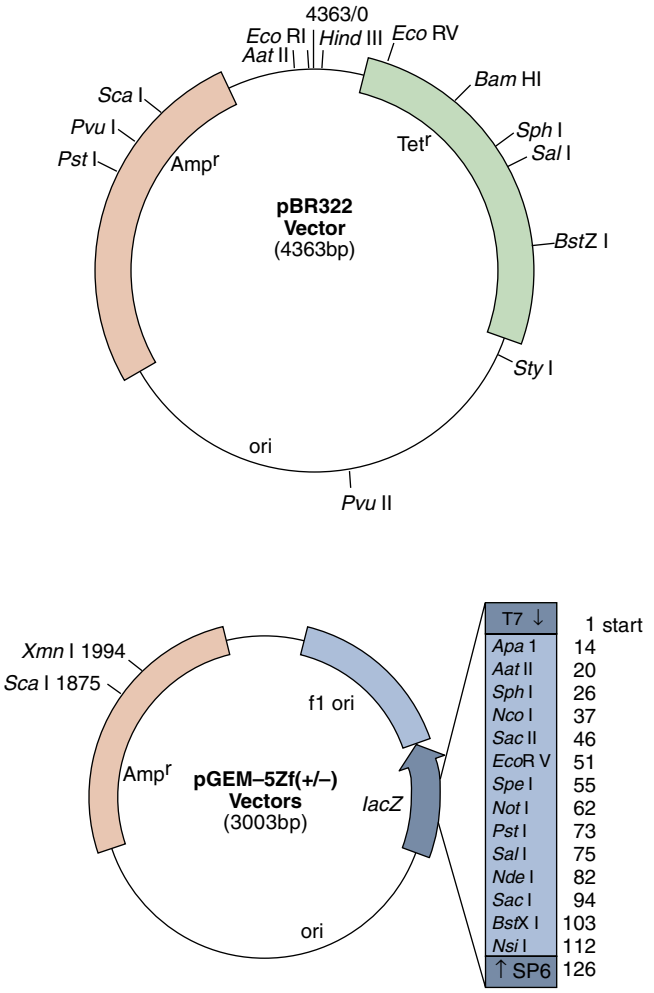

Fig. 13.10 Plasmids. The pBR322 plasmid is one of the plasmids used for cloning DNA. This plasmid encodes resistance to ampicillin *(Amp)* and tetracycline *(Tet)* and an origin of replication *(ori)*. The multiple cloning site in the pGEM-5Zf(+/–) plasmid provides different restriction enzyme cleavage sites for insertion of DNA within the β-galactosidase gene *(lacZ)*. The insert is flanked by bacteriophage promoters to allow directional messenger RNA expression of the cloned sequence.

Large plasmids (20 to 120 kb), such as the **fertility factor F** found in *E. coli* or the resistance transfer factor (80 kb), can often mediate their own transfer from one cell to another by a process called **conjugation** (see the section Conjugation later in this chapter). These conjugative plasmids encode all the necessary factors for their transfer including the pilus. Other plasmids can be transferred into a bacterial cell by means other than conjugation, such as transformation or transduction. These terms also are discussed later in the chapter.

Bacteriophages are bacterial viruses with a DNA or RNA genome usually protected by a membrane or protein shell. These extrachromosomal genetic elements can survive outside of a host cell and be transmitted from one cell to another. Bacteriophages infect bacterial cells and either replicate to large numbers and cause the cell to lyse **(lytic infection)** or, in some cases, **integrate** into the host genome without killing the host (the **lysogenic state**), such as the *E. coli* bacteriophage lambda. Some lysogenic bacteriophages carry toxin genes (e.g., corynephage beta carries the gene for the diphtheria toxin). Bacteriophage

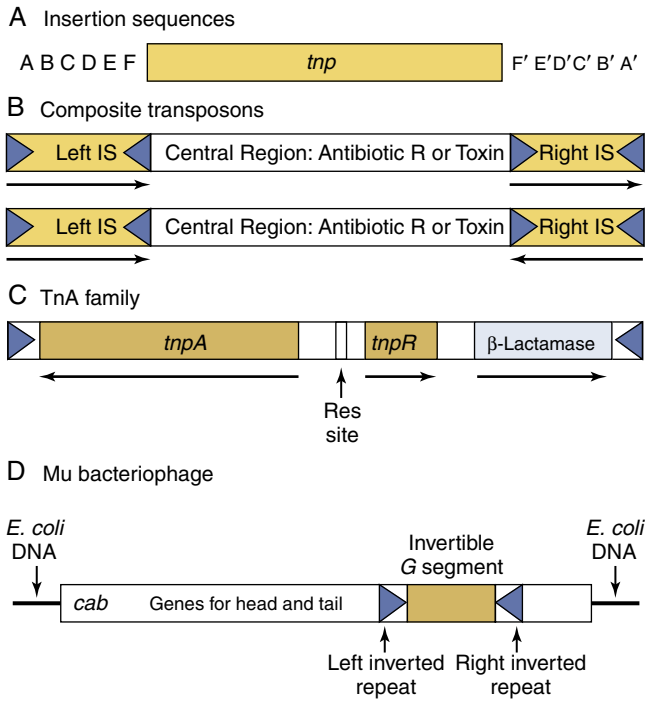

Fig. 13.11 Transposons. (A) The insertion sequences code only for a transposase *(tnp)* and possess inverted repeats (15 to 40 base pairs) at each end. (B) The composite transposons contain a central region coding for antibiotic resistances or toxins flanked by two insertion sequences *(IS),* which can be either directly repeated or reversed. (C) Tn*3,* which is a member of the Tn*A* transposon family. The central region encodes three genes, a transposase *(tnpA),* a resolvase *(tnpR),* and a β-lactamase, conferring resistance to ampicillin. A resolution site *(Res site)* is used during the replicative transposition process. This central region is flanked on both ends by direct repeats of 38 base pairs. (D) Phage-associated transposon is exemplified by the bacteriophage mu.

lambda remains lysogenic as long as a repressor protein is synthesized and prevents the phage genome from being excised to replicate and exit the cell. Damage to the host cell DNA by radiation or by another means, or inability to produce the repressor protein is a signal that the host cell is unhealthy and is no longer a good place for "freeloading."

Transposons (jumping genes) are mobile genetic elements (Fig. 13.11) that can transfer DNA within a cell, from one position to another in the genome, or between different molecules of DNA (e.g., plasmid to plasmid or plasmid to chromosome). Transposons are present in prokaryotes and eukaryotes. The simplest transposons are called *insertion sequences* and range in length from 150 to 1500 base pairs, with inverted repeats of 15 to 40 base pairs at their ends and the minimal genetic information necessary for their own transfer (i.e., the gene coding for the transposase). Complex transposons carry other genes, such as genes that provide resistance against antibiotics. Transposons sometimes insert into genes and inactivate those genes. If insertion and inactivation occur in a gene that encodes an essential protein, the cell dies.

Some pathogenic bacteria use a transposon-like mechanism to coordinate expression of a system of virulence factors. The genes for the activity may be grouped together in a **pathogenicity or virulence island** surrounded by transposon-like mobile elements, allowing them to move within the chromosome and to other bacteria. The entire genetic unit can be triggered by an environmental stimulus (e.g., pH, heat, contact with the host cell surface) as a way of coordinating the expression of a complex process. For example, the SPI-1 island of *Salmonella* is activated by environmental signals (e.g., pH) to express the 25 genes for a type III secretion device that allows the bacteria to enter nonphagocytic cells.

MECHANISMS OF GENETIC TRANSFER BETWEEN CELLS

The exchange of genetic material between bacterial cells may occur by one of three mechanisms (Fig. 13.12): (1) **transformation,** which is an active uptake and incorporation of exogenous or foreign DNA; (2) **conjugation,** which is the mating or quasi-sexual exchange of genetic information from one bacterium (the donor) to another bacterium (the recipient); or (3) **transduction,** which is the transfer of genetic information from one bacterium to another by a bacteriophage. Once inside a cell, a **transposon** can jump between different DNA molecules (e.g., plasmid to plasmid or plasmid to chromosome). Several of these mechanisms contributed to the generation of vancomycin-resistant *S. aureus* (Fig. 13.13 and Box 13.2).

Transformation

Transformation is the process by which bacteria take up fragments of naked DNA and incorporate them into their genomes. Transformation was the first mechanism of genetic transfer to be discovered in bacteria. In 1928, Griffith observed that pneumococcal virulence was related to the presence of a polysaccharide capsule and that extracts of encapsulated bacteria producing smooth colonies could transmit this trait to nonencapsulated bacteria, normally appearing as rough colonies. Griffith's studies led to Avery, MacLeod, and McCarty's identification of DNA as the transforming principle some 15 years later.

Certain species are naturally capable of taking up exogenous DNA (such species are then said to be competent), including *Haemophilus influenzae, Streptococcus pneumoniae, Bacillus* spp., and *Neisseria* spp. Competence develops toward the end of logarithmic growth. *E. coli* and most other bacteria lack the natural ability for DNA uptake, and competence must be induced by chemical methods or electroporation (use of high-voltage pulses) to facilitate uptake of plasmid and other DNA.

Conjugation

Conjugation results in one-way transfer of DNA from a donor (or male) cell to a recipient (or female) cell through the **sex pilus.** Conjugation occurs with most, if not all, eubacteria and usually between members of the same or related species, but it also has been demonstrated to occur between prokaryotes and cells from plants, animals, and fungi.

The mating type (sex) of the cell depends on the presence (male) or absence (female) of a conjugative plasmid, such as the **F plasmid** of *E. coli*. The F plasmid is defined as conjugative because it carries all the genes necessary for its own transfer, including the ability to make sex pili and to initiate DNA synthesis at the transfer origin *(oriT)* of the plasmid. The sex pilus is a specialized type IV secretion device.

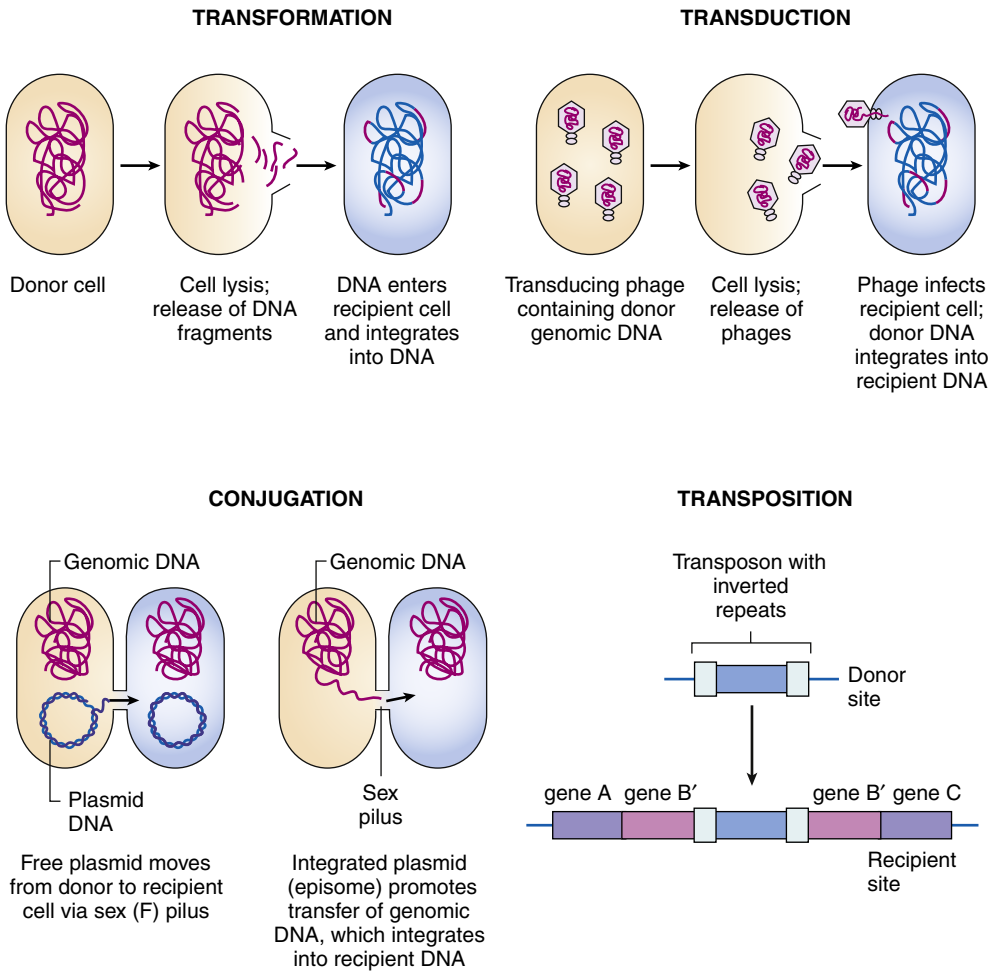

Fig. 13.12 Mechanisms of bacterial gene transfer. (From Rosenthal, K.S., Tan, J., 2002. Rapid Reviews Microbiology and Immunology. Mosby, St Louis, MO.)

On transfer of the F plasmid, the recipients become F^+ male cells. If a fragment of chromosomal DNA has been incorporated into the plasmid, it is designated an F prime (F′) plasmid. When it transfers into the recipient cell, it carries that fragment with it and converts it into an F′ male. If the F plasmid sequence is integrated into the bacterial chromosome, then the cell is designated as an Hfr (high-frequency recombination) cell.

The DNA that is transferred by conjugation is not a double helix; rather, it is a single-stranded molecule. Mobilization begins when a plasmid-encoded protein makes a single-stranded site-specific cleavage at the oriT. The nick initiates rolling circle replication, and the displaced linear strand is directed to the recipient cell. The transferred single-stranded DNA is recircularized and its complementary strand synthesized. Conjugation results in transfer of a part of the plasmid sequence and some portion of the bacterial chromosomal DNA. Because of the fragile connection between the mating pairs, the transfer is usually aborted before being completed, such that only the chromosomal sequences adjacent to the integrated F are transferred. Artificial interruption of a mating between an Hfr and an F^- pair has been helpful in constructing a consistent map of the *E. coli* chromosomal DNA. In such maps, the position of each gene is given in minutes (based on 100 minutes for complete transfer at 37° C), according to its time of entry into a recipient cell in relation to a fixed origin.

Transduction

Genetic transfer by transduction is mediated by bacterial viruses (bacteriophages) that pick up fragments of DNA and package them into bacteriophage particles. The DNA is delivered to infected cells and becomes incorporated into the bacterial genomes. Transduction can be classified as **specialized** if the phages in question transfer particular genes (usually those adjacent to their integration sites in the genome) or **generalized** if incorporation of DNA sequences is random because of accidental packaging of host DNA into the phage capsid. For example, a nuclease from the P1 phage degrades the host *E. coli* chromosomal DNA, and some of the DNA fragments are packaged into phage particles. The encapsulated DNA, instead of phage DNA, is injected into a new host cell, in which it can recombine with the homologous host DNA. Generalized transducing particles are valuable in the **genetic mapping** of bacterial chromosomes. The closer two genes are within the bacterial chromosome, the more likely it is that they will be co-transduced in the same fragment of DNA.

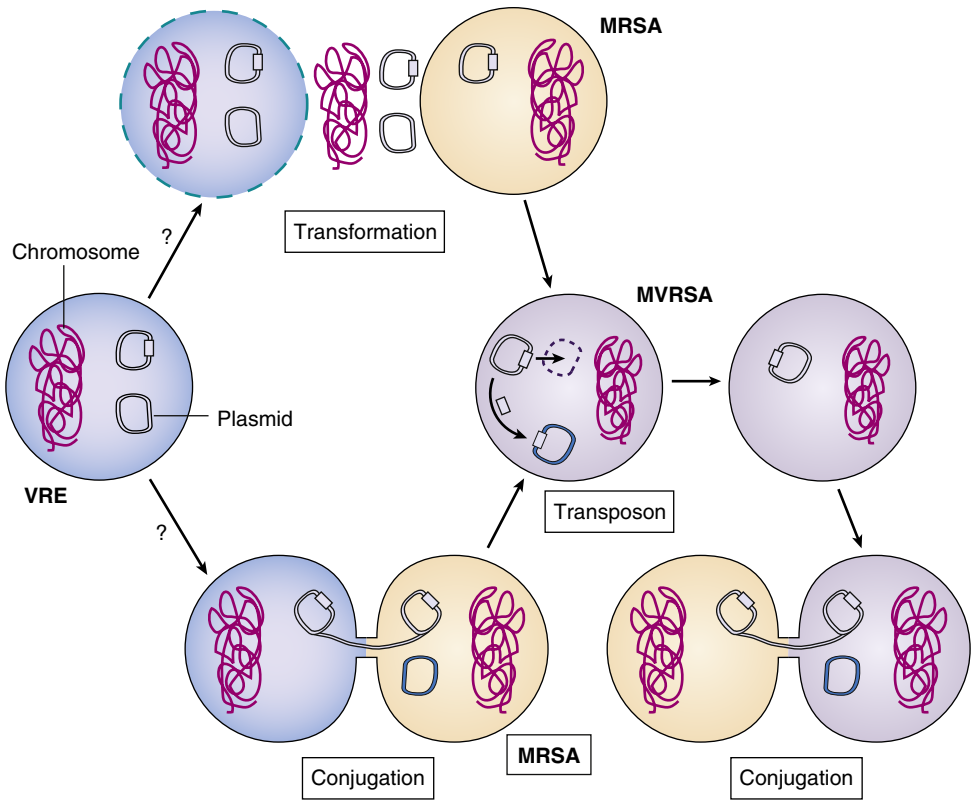

Fig. 13.13 Genetic mechanisms of evolution of methicillin- and vancomycin-resistant *Staphylococcus aureus (MRSA* and *MVRSA).* Vancomycin-resistant enterococcus *(VRE) (in blue)* contains plasmids with multiple antibiotic resistance and virulence factors. During co-infection, a MRSA *(in pink)* may have acquired the enterococcal resistance plasmid (e-plasmid) *(in purple)* by transformation (after lysis of the enterococcal cell and release of its DNA) or, more likely, by conjugation. A transposon in the e-plasmid containing the vancomycin resistance gene (white box within plasmid circle) jumped out and inserted into the multiple antibiotic resistance plasmid of the MRSA. The new plasmid is readily spread to other *S. aureus* bacteria by conjugation.

BOX 13.2 Generation of Vancomycin-Resistant *Staphylococcus aureus* by Multiple Genetic Manipulations

Until recently, vancomycin was the last-resort drug for *Staphylococcus aureus* strains resistant to β-lactam (penicillin-related) antibiotics (e.g., methicillin-resistant *S. aureus* [MRSA]). Isolates of *S. aureus* acquired the vancomycin resistance gene during a mixed infection with *Enterococcus faecalis* (see Fig. 13.13). The gene for vancomycin resistance was contained within a **transposon** (Tn1546on) a multiresistance conjugative plasmid. The plasmid was probably transferred by **conjugation** between *E. faecalis* and *S. aureus*. Alternatively, after lysis of the *E. faecalis, S. aureus* acquired the DNA by **transduction** and became **transformed** by the new DNA. The transposon then jumped from the *E. faecalis* plasmid, **recombined,** and **integrated** into the *S. aureus* multiresistance plasmid, and the *E. faecalis* DNA was degraded. The resulting *S. aureus* plasmid encodes resistance to β-lactams, vancomycin, trimethoprim, and gentamycin/kanamycin/tobramycin antibiotics and to quaternary ammonium disinfectants and can transfer to other *S. aureus* strains by **conjugation.** (For more information, refer to Weigel in the Bibliography of this chapter.)

RECOMBINATION

Incorporation of extrachromosomal (foreign) DNA into the chromosome occurs by recombination. There are two types of recombination: homologous and nonhomologous. **Homologous (legitimate) recombination** occurs between closely related DNA sequences and generally substitutes one sequence for another. The process requires a set of enzymes produced (in *E. coli*) by the *rec* genes. **Nonhomologous (illegitimate) recombination** occurs between dissimilar DNA sequences and generally produces insertions, or deletions, or both. This process usually requires specialized (sometimes site-specific) recombination enzymes, such as those produtced by many transposons and lysogenic bacteriophages.

Genetic Engineering

Genetic engineering, also known as recombinant DNA technology, uses the techniques and tools developed by the bacterial geneticists to purify, amplify, modify, and express specific gene sequences. The use of genetic engineering and "cloning" has revolutionized biology and medicine. The basic components of genetic engineering are (1) **cloning and expression vectors,** which can be used to deliver the DNA sequences into receptive bacteria and amplify the desired sequence; (2) the **DNA sequence** to be amplified and expressed; (3) **enzymes,** such as **restriction enzymes,** which are used to cleave DNA reproducibly at defined sequences (Table 13.1); and (4) **DNA ligase,** the enzyme that links the fragment to the cloning vector.

Cloning and expression vectors must allow foreign DNA to be inserted into them but must still be able to replicate normally in a bacterial or eukaryotic host. Many types of vectors are currently used. Plasmid vectors, such as pUC, pBR322, and pGEM (Fig. 13.14), are used for DNA

TABLE 13.1 Common Restriction Enzymes Used in Molecular Biology

Microorganism	Enzyme	Recognition Site
Acinetobacter calcoaceticus	*Acc* I	fx1
Bacillus amyloliquefaciens H	*Bam* HI	fx2
Escherichia coli RY13	*Eco* RI	fx3
Haemophilus influenzae Rd	*Hind* III	fx4
H. influenzae serotype c, 1160	*Hinc* II	fx5

Serratia marcescens	*Sma* I	fx7
Staphylococcus aureus 3A	*Sau* 3AI	fx8
Xanthomonas malvacearum	*Xma* I	fx9

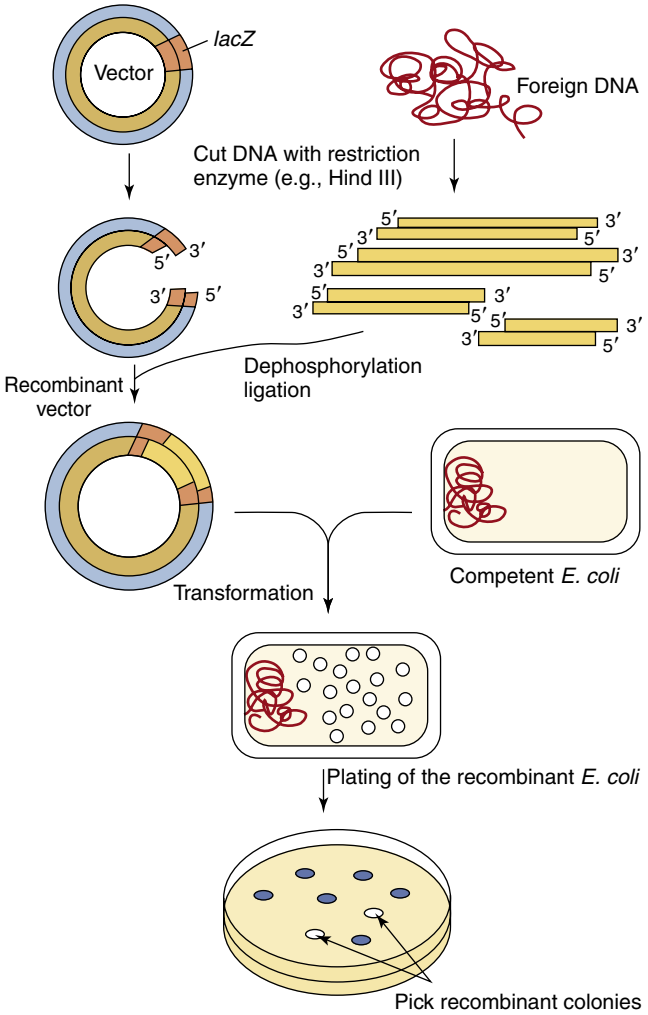

Fig. 13.14 Cloning of foreign DNA in vectors. The vector and the foreign DNA are first digested by a restriction enzyme. Insertion of foreign DNA into the *lacZ* gene inactivates the β-galactosidase gene, allowing subsequent selection. The vector is then ligated to the foreign DNA, using bacteriophage T4 DNA ligase. The recombinant vectors are transformed into competent *Escherichia coli* cells. The recombinant *E. coli* cells are plated onto agar containing antibiotic, an inducer of the *lac* operon, and a chromophoric substrate that turns blue in cells with a plasmid but not an insert; those cells with a plasmid containing the insert remain white.

fragments up to 20 kb. Bacteriophages, such as lambda, are used for larger fragments up to 25 kb, and **cosmid** vectors have combined some of the advantages of plasmids and phages for fragments up to 45 kb.

Most **cloning vectors** have been "engineered" to have a site for insertion of foreign DNA, a means of selection of the bacteria that have incorporated any plasmid (e.g., antibiotic resistance), and a means of distinguishing the bacteria that have incorporated those plasmids that contain inserted DNA. **Expression vectors** have DNA sequences to facilitate their replication in bacteria and eukaryotic cells and the transcription of the gene into mRNA.

The DNA to be cloned can be obtained by purification of chromosomal DNA from cells, viruses, or other plasmids or by selective amplification of DNA sequences by a technique known as *polymerase chain reaction* (PCR) (PCR is explained further in Chapter 5). Both the vector and the foreign DNA are cleaved with restriction enzymes (see Fig. 13.14). Restriction enzymes recognize a specific palindromic sequence and make a staggered cut that generates sticky ends or a blunt cut that generates blunt ends (see Table 13.1). Most cloning vectors have a sequence called the **multiple cloning site,** which can be cleaved by many restriction enzymes. Ligation of the vector with the DNA fragments generates a molecule called **recombinant DNA,** which is capable of replicating the inserted sequence. The total number of recombinant vectors obtained when cloning all the fragments that result from the cleavage of chromosomal DNA is known as a **genomic library** because there should be at least one representative of each gene in the library. An alternative approach to cloning the gene for a protein is to use a retrovirus enzyme called *reverse transcriptase* (RNA-dependent DNA polymerase) to convert the mRNA in the cell into a complementary DNA (cDNA). A **cDNA library** represents the genes that are expressed as mRNA in a particular cell.

The recombinant DNA is then transformed into a bacterial host, usually *E. coli,* and the plasmid-containing bacteria are selected for acquisition of antibiotic resistance (e.g., ampicillin resistance). The library can then be screened to find an *E. coli* clone possessing the desired DNA fragment. Various screening techniques can be used to identify the bacteria containing the appropriate recombinant DNA. The multiple cloning site used for inserting the foreign DNA is often part of the *lacZ* gene of the *lac* operon. Insertion of the foreign DNA into the *lacZ* gene inactivates the gene (acting almost like a transposon) and prevents the plasmid-directed synthesis of β-galactosidase in the recipient cell, which results in white bacterial colonies instead of blue colonies if β-galactosidase was produced and was able to cleave an appropriate chromophore.

Genetic engineering has been used to isolate and express the genes for useful proteins such as insulin, interferon, growth hormones, and interleukin in bacteria, yeast, or even insect cells. Similarly, large amounts of pure immunogen for a vaccine can be prepared without the need to work with the intact disease organisms.

The vaccine against hepatitis B virus represents the first successful use of recombinant DNA technology to make a vaccine approved for human use by the U.S. Food and Drug Administration. The hepatitis B surface antigen is produced by the yeast *Saccharomyces cerevisiae*.

Alternatively, the plasmid DNA capable of promoting expression of the desired immunogen (DNA vaccine) can be injected into an individual to let the host cells express the immunogen and generate an immune response. Recombinant DNA technology has also become essential to laboratory diagnosis, forensic science, agriculture, and many other disciplines.

Questions

1. How many moles of ATP are generated per mole of glucose in glycolysis, the TCA cycle, and electron transport? Which of these occur in anaerobic conditions and in aerobic conditions? Which is most efficient?

2. What products of anaerobic fermentation would be detrimental to host (human) tissue (e.g., *C. perfringens*)?

3. If the number of bacteria during log phase growth can be calculated by the following equation: $N_t = N_0 \times 2^{\frac{t}{d}}$ in which N_t is the number of bacteria after time (t), t/d is the amount of time divided by the doubling time, and N_0 is the initial number of bacteria, how many bacteria will be in the culture after 4 hours if the doubling time is 20 minutes and the initial bacterial inoculum contained 1000 bacteria?

4. What are the principal properties of a plasmid?

5. Give two mechanisms of regulation of bacterial gene expression. Use specific examples.

6. What types of mutations affect DNA, and what agents are responsible for such mutations?

7. Which mechanisms may be used by a bacterial cell for the exchange of genetic material? Briefly explain each mechanism.

8. Discuss the applications of molecular biotechnology to medicine, including contributions and uses in diagnoses.

14 Mechanisms of Bacterial Pathogenesis

To a bacterium, the human body is a collection of environmental niches that provides the warmth, moisture, and food necessary for growth. Bacteria have traits that enable them to enter (invade) the environment, remain in a niche (adhere or colonize), gain access to food sources (degradative enzymes), sequester metal ions (e.g., iron), and escape clearance by host immune and nonimmune protective responses (e.g., **capsule**). When sufficient numbers of bacteria are present **(quorum),** they turn on functions to support the colony, including production of a biofilm. Unfortunately, many of the mechanisms bacteria use to maintain their niche and the by-products of bacterial growth and colonization (e.g., acids, gas) can cause damage and problems for the human host. Many of these traits are **virulence factors** that enhance the ability of bacteria to remain in and harm the body to cause disease (Box 14.1). Although many bacteria cause disease by directly destroying tissue, some release toxins, which can disseminate in the blood to cause system-wide pathogenesis.

Not all bacteria or bacterial infections cause disease. The human body is colonized with numerous microbes **(normal flora, microbiota),** many of which serve important functions for their hosts. Normal flora bacteria aid in the digestion of food, produce vitamins (e.g., vitamin K), protect the host from colonization with pathogenic microbes, and activate appropriate host innate and immune responses. These endogenous bacteria normally reside in locations such as the gastrointestinal (GI) tract, mouth, skin, and upper respiratory tract, which can be considered to be outside the body (Fig. 14.1). Each individual has a characteristic microbiota that is selected and maintained by host factors and also regulates its own bacterial composition. The host innate and immune response reacts to certain metabolites and surface structures of bacteria to help maintain a healthy microbiota and eliminate pathogenic or inappropriate microbes. Excessive responses to bacteria cause immunopathogenesis and may be the major cause of the disease (e.g., sepsis). Even the normal flora can be problematic with most bacterial infections resulting from normal flora bacteria entering normally sterile sites of the body.

Some bacteria always cause disease because of expression of their virulence factors, whereas the bacterial strain and inoculum size of other types of bacteria may determine whether disease occurs. Some strains may be benign and others not (e.g., *Escherichia coli* O157/H7 produces a toxin and can cause hemolytic uremic syndrome). The threshold for disease production is different for different bacteria (e.g., <200 *Shigella* are required for shigellosis, but 10^8 *Vibrio cholerae* or *Campylobacter* organisms are required for disease of the GI tract). Host factors also can play a role. For example, although a million or more *Salmonella* organisms are necessary for gastroenteritis to become established in a healthy person, only a few thousand organisms are necessary in a person whose gastric pH has been neutralized with antacids or other means. Congenital defects, immunodeficiency states (see Chapter 10), and other disease-related conditions might also increase a person's susceptibility to infection.

Many bacteria only express their virulence factors under special conditions and genetically coordinate their expression (for *Staphylococcus aureus*, see Fig. 13.6). For example, production of type III secretion devices (described later) by *Shigella flexneri* and *Salmonella typhimurium* are triggered by oxygen tension and pH, respectively, to ensure proximity to appropriate host membranes. Also, the biofilm produced by *Pseudomonas* is triggered when there are sufficient bacteria (a quorum) producing sufficient amounts of *N*-acyl homoserine lactone (AHL) to trigger expression of the genes for polysaccharide production. The components for complex structures and systems are often encoded together in a pathogenicity island. **Pathogenicity islands** are large genetic regions in the chromosome or on plasmids that contain sets of genes encoding numerous virulence factors that may require coordinated expression. These genes may be turned on by a single stimulus (e.g., temperature of the gut, pH of a lysosome). A pathogenicity island is usually within a transposon and can be transferred as a unit to different sites within a chromosome or to other bacteria. For example, the SPI-2 pathogenicity island of *Salmonella* is activated by the acidic pH of a phagocytic vesicle within a macrophage. This promotes expression of approximately 25 proteins that assemble into a syringe-like molecular device (type III secretion device) (Fig. 14.2) that injects proteins into the host cell to facilitate the bacteria's intracellular survival and growth.

The host innate and immune systems are constantly protecting the body's borders and internal regions of the body. Bacteria have evolved the means to escape many of these protections to establish their niche (normal flora) or invade and cause tissue infections (pathogens). *The longer a bacterium remains in the body, the greater its numbers, its ability*

to spread, its potential to cause tissue damage and disease, the larger the host immune and inflammatory response necessary to resolve the infection and the greater the immunopathogenesis and severity of the disease.

Selection pressures, such as treatment with antibiotics and other drugs, diet, and stress, can lead to changes in the composition of the microbiota, which can allow the outgrowth of inappropriate bacteria (e.g., *Clostridium difficile*, which can cause pseudomembranous colitis) and the onset of inappropriate immune responses (e.g., inflammatory bowel diseases).

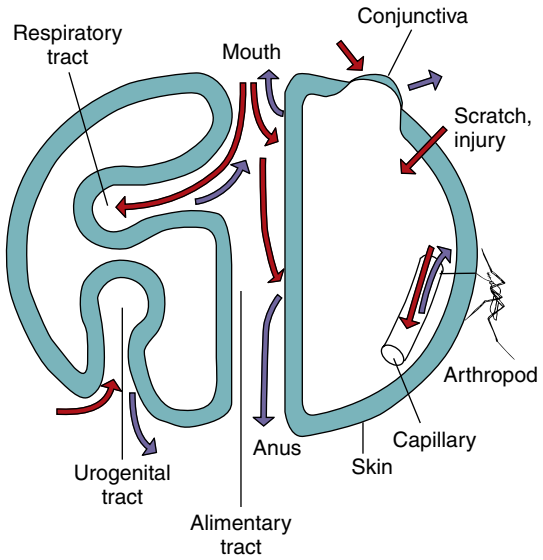

Fig. 14.1 Body surfaces as sites of microbial infection and shedding. *Red arrows* indicate infection; *purple arrows* indicate shedding. (Modified from Goering, R.V., Dockrell, H.M., Zuckerman, M., et al., 2019. Mims' Medical Microbiology, sixth ed. Elsevier, Philadelphia, PA.)

Certain **virulent bacteria** always cause disease because they produce toxins or have mechanisms that promote their growth in the host at the expense of the host's tissue or organ function (secreted degradative enzymes). **Opportunistic bacteria** take advantage of preexisting conditions, such as immunosuppression, to grow and cause serious disease. For example, burn victims and the lungs of patients with cystic fibrosis are at higher risk of *Pseudomonas aeruginosa* infection, and patients with acquired immunodeficiency syndrome (AIDS) are very susceptible to infection by intracellularly growing bacteria, such as the mycobacteria.

Disease results from the combination of damage or loss of tissue or organ function caused by the bacteria combined with the consequences of the innate and immune (inflammation) responses to the infection (Box 14.2). The **signs and symptoms of a disease** are determined by the change to the affected tissue. **Systemic responses** are produced by toxins and the cytokines produced in response to the infection. The **seriousness** of the disease depends on the importance of the affected organ and the extent of the damage caused by the infection. Infections of the central nervous system are especially serious.

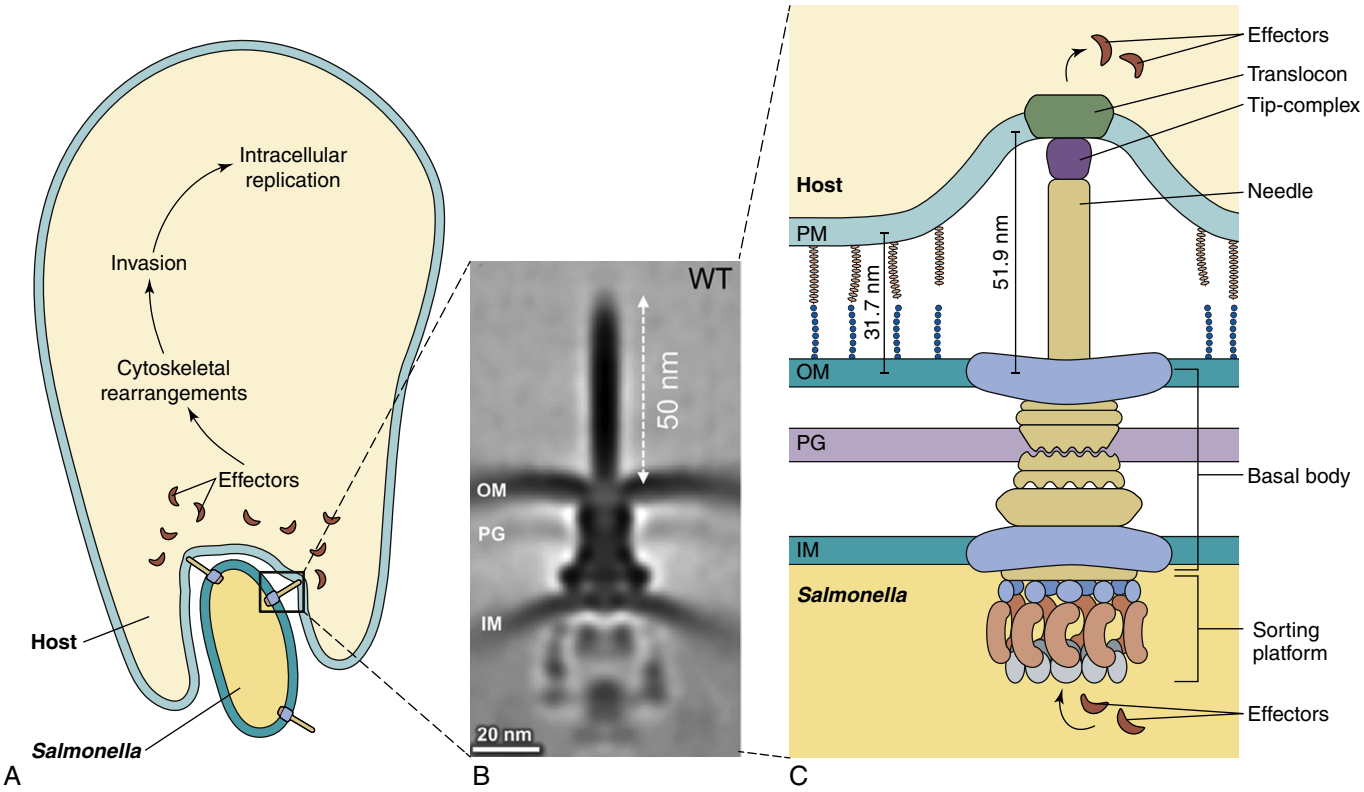

Fig. 14.2 Model of the type III secretion device (injectisome) from *Salmonella typhimurium* caught in the act of injecting into the host cell. Entry into the Human Body

For infection to become established, bacteria must first gain entry into the body (Table 14.1; see Fig. 14.1). Natural defense mechanisms include barriers (e.g., skin, mucus, ciliated epithelium) and secretions containing antibacterial substances (e.g., lysozyme, defensins, immunoglobulin [Ig] A) that hinder bacterial entry into the body. However, these barriers are sometimes broken (e.g., a tear in the skin, a tumor or ulcer in the bowel), providing a portal of entry for the bacteria, or the bacteria may have the means to compromise the barrier and invade the body. On invasion, the bacteria can travel in the bloodstream to other sites in the body.

The **skin** has a thick, horny layer of dead cells that protects the body from infection. However, cuts in the skin, produced accidentally or surgically or kept open with catheters or other surgical appliances, provide a means for the bacteria to gain access to the susceptible tissue underneath. For example, *S. aureus* and *S. epidermidis,* which are a part of the normal flora on skin, can enter the body through breaks in the skin and pose a major problem for people with indwelling catheters and intravenous lines.

The mouth, nose, ears, eyes, anus, and respiratory, GI, and urogenital tracts are natural openings in the skin through which bacteria can enter the body. They are protected by natural defenses such as the mucus and ciliated epithelium that line the upper respiratory tract, the lysozyme and other antibacterial secretions in tears and mucus, and the acid and bile in the GI tract, as well as secretory IgA. However, many bacteria are unaffected or have the means to evade these defenses. For example, the outer membrane of the gram-negative bacteria makes these bacteria more resistant to lysozyme, acid, and bile. The enterobacteria are thus enabled to colonize the GI tract. Entry of these endogenous bacteria to normally sterile sites of the body, such as the peritoneum and the bloodstream, often indicates a break in the normal barrier. An example of this is the patient whose colon tumor was diagnosed after detection of a bacteremia (blood-borne infection) or endocarditis caused by enteric bacteria.

Box 14.2 Bacterial Disease Production

1. Disease is caused by damage produced by the bacteria plus the consequences of innate and immune responses to the infection.
2. The signs and symptoms of a disease are determined by the function and importance of the affected tissue.
3. The length of the incubation period is the time required for the bacteria and/or the host response to cause sufficient damage to initiate discomfort or interfere with essential functions.

TABLE 14.1 Bacterial Port of Entry

Route	Examples
Ingestion	*Salmonella* spp., *Shigella* spp., *Yersinia enterocolitica,* enterotoxigenic *Escherichia coli, Vibrio* spp., *Campylobacter* spp., *Clostridium botulinum, Bacillus cereus, Listeria* spp., *Brucella* spp.
Inhalation	*Mycobacterium* spp., *Nocardia* spp., *Mycoplasma pneumoniae, Legionella* spp., *Bordetella, Chlamydophila psittaci, C. pneumoniae, Streptococcus* spp.
Trauma	*Clostridium tetani, Staphylococcus aureus*
Needlestick	*S. aureus, Pseudomonas* spp.
Arthropod bite	*Rickettsia, Ehrlichia, Coxiella, Francisella, Borrelia* spp., *Y. pestis*
Sexual transmission	*Neisseria gonorrhoeae, Chlamydia trachomatis, Treponema pallidum*

Colonization, Adhesion, and Invasion

Different bacteria colonize different parts of the body. This may be closest to the point of entry or caused by the presence of optimal growth conditions at the site. For example, *Legionella* is inhaled and grows in the lungs but does not readily spread because it cannot tolerate high temperatures (e.g., 35° C). Colonization of sites that are normally sterile implies the existence of a defect in a natural defense mechanism or a new portal of entry. Patients with cystic fibrosis have such defects because of the reduction in their ciliary mucoepithelial function and altered mucosal secretions; as a result, their lungs are colonized by *S. aureus* and *P. aeruginosa*.

In some cases, colonization requires special bacterial structures and functions to remain at the site, survive, and obtain food. Bacteria may use specific mechanisms to **adhere** to and colonize different body surfaces (Table 14.2). If the bacteria can adhere to epithelial or endothelial cell linings of the bladder, intestine, and blood vessels, then they cannot be washed away, and this adherence allows them to colonize the tissue. For example, natural bladder function eliminates any bacteria not affixed to the bladder wall. *E. coli* and other bacteria have **adhesins** that bind to specific receptors on the tissue surface and keep the organisms from being washed away. Many of these adhesin proteins are present at the tips of **fimbriae (pili)** and bind tightly to specific sugars on the target tissue; this sugar-binding activity defines these proteins as **lectins.** For example, most *E. coli* strains that cause pyelonephritis produce a fimbrial adhesin termed the *P fimbriae.* This adhesin can bind to α-D-galactosyl-β-D-galactoside (Gal-Gal), which is part of the P blood group antigen structure on human erythrocytes and uroepithelial cells. *Neisseria gonorrhoeae* pili are also important virulence factors; they bind to oligosaccharide receptors on epithelial cells. *Yersinia* organisms, *Bordetella pertussis,* and *Mycoplasma pneumoniae* express adhesin proteins that are not on fimbriae. *Streptococci, S. aureus, and other bacteria secrete proteins that bind components of the extracellular matrix of epithelial cells such as fibronectin, collagen, or laminin, termed* **MSCRAMMs** *(microbial surface components recognizing adhesive matrix molecules)*.

A special bacterial adaptation that facilitates colonization, especially of surgical appliances such as artificial valves or indwelling catheters, is a **biofilm.** Bacteria in biofilms are bound within a sticky web of polysaccharide that binds the cells together and to the surface. Production of a biofilm requires sufficient numbers of bacteria (quorum). When *P. aeruginosa* determine that the colony size is large enough

TABLE 14.2 Examples of Bacterial Adherence Mechanisms

Microbe	Adhesin	Receptor
Staphylococcus aureus	Clumping factor A	Fibrinogen
Staphylococcus spp.	MSCRAMM	Extracellular matrix components (fibronectin, laminin, collagen, etc.)
Streptococcus, group A	LTA–M protein complex F protein, MSCRAMM	Extracellular matrix components (fibronectin, laminin, collagen, etc.)
Streptococcus pneumoniae	Adhesins and other proteins	*N*-acetylhexosamine-galactose
Escherichia coli	Type 1 fimbriae Colonization factor antigen fimbriae P fimbriae	D-Mannose GM ganglioside 1 P blood group glycolipid
Neisseria gonorrhoeae	Fimbriae	GD_1 ganglioside
Treponema pallidum	P_1, P_2, P_3	Fibronectin
Chlamydia trachomatis	Cell-surface lectin	*N*-acetylglucosamine
Mycoplasma pneumoniae	Protein P1	Sialic acid
Vibrio cholerae	Type 4 pili	Fucose and mannose

LTA, Lipoteichoic acid; *MSCRAMM,* microbial surface components recognizing adhesive matrix molecules.

(quorum sensing) they produce a biofilm. Dental plaque is another example of a biofilm. The biofilm matrix can also protect the bacteria from host defenses and antibiotics.

Although bacteria do not have mechanisms that enable them to cross intact skin, several bacteria can cross mucosal membranes and other tissue barriers to enter normally sterile sites and more susceptible tissue. The bacteria use their flagella to swim through and proteases to digest the mucous layer to approach the epithelial lining. The **invasive bacteria** either destroy the membrane barrier, induce inflammation to permeabilize the barrier, or penetrate into the cells of the barrier. *Salmonella* and *Yersinia* organisms are enteric bacteria that use fimbriae to bind to M (microfold) cells of the colon and then inject proteins into the M cell that stimulate the cell membrane to surround and take in the bacteria. These bacteria produce a **type III secretion device** to inject pore-forming factors and effector molecules into the host cells. The effector proteins can facilitate uptake and invasion and promote intracellular survival and replication of the bacteria or the apoptotic death of the host cell. Enteropathogenic *E. coli* secretes proteins into the host cell that create a portable docking system for itself, and *Salmonella* uses the device to promote its uptake into a vesicle and live intracellularly within the macrophage. (Excellent videos of these processes can be seen at https://www.biointeractive.org/classroom-resources/how-pathogenic-e-coli-infection-begins and https://www.biointeractive.org/classroom-resources/how-salmonella-infection-begins.) Many of the proteins injected into these cells by the type III secretion device promote actin polymerization. For *Salmonella,* this promotes phagocytic uptake; for *Shigella* and *Listeria monocytogenes,* it promotes movement within the cell and to other cells. *Salmonella* and other bacteria promote invasion of the GI tract by weakening the tight junctions between mucoepithelial cells with bacterial proteins or by inducing inflammation, whereas *N. meningitidis* sequesters protein components to destabilize tight junctions of endothelial cells of the blood-brain barrier to gain access to the cerebral spinal fluid to progress from the bloodstream into the meninges.

Pathogenic Actions of Bacteria

TISSUE DESTRUCTION

By-products of bacterial growth, especially fermentation, include acids, gas, and other substances that are toxic to tissue. In addition, *many bacteria release degradative enzymes* to break down tissue, providing food for the organisms' growth and also promoting bacterial spread. For example, *C. perfringens* organisms are part of the normal flora of the GI tract but are also opportunistic pathogens that can establish infection in oxygen-depleted tissues and cause gas gangrene. These anaerobic bacteria produce enzymes (e.g., phospholipase C, collagenase, proteases, hyaluronidase), several toxins, and acid and gas from bacterial metabolism, which destroy the tissue. Staphylococci produce many different enzymes that modify the tissue environment. These enzymes include hyaluronidase, fibrinolysin, and lipases. Streptococci also produce enzymes, including streptolysins S and O, hyaluronidase, DNases, and streptokinases.

TOXINS

Toxins are bacterial products that directly harm tissue or trigger destructive biological activities. Toxins and toxin-like activities include degradative enzymes that cause lysis of cells or specific receptor-binding proteins that initiate toxic reactions in a specific target tissue. In addition, superantigen toxins and endotoxin (lipid A portion of lipopolysaccharide [LPS]) promote excessive or inappropriate stimulation of innate or immune responses.

In many cases, the toxin is completely responsible for causing the characteristic symptoms of the disease. For

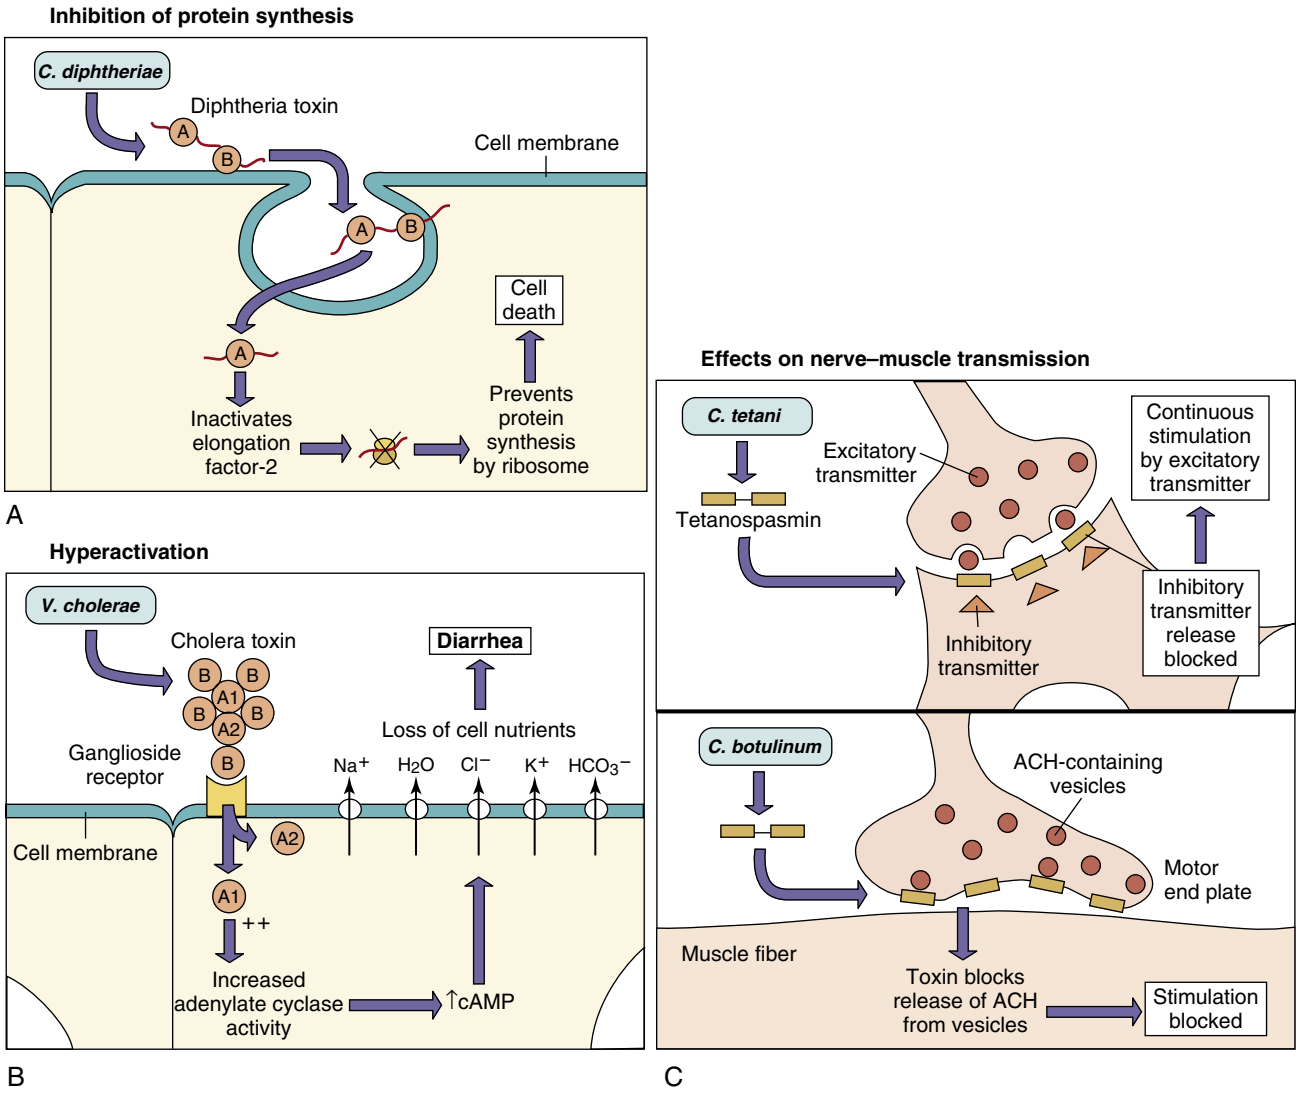

Fig. 14.3 (A–C) The mode of action of dimeric A-B exotoxins. The bacterial A-B toxins often consist of a two-chain molecule. The B chain binds and promotes entry of the A chain into cells, and the A chain has inhibitory activity against some vital function. *ACH,* Acetylcholine; *cAMP,* cyclic adenosine monophosphate; *C. botulinum, Clostridium botulinum; C. diphtheriae, Corynebacterium diphtheriae; C. tetani, Clostridium tetani; V. cholerae, Vibrio cholerae.* (Modified from Goering, R.V., Dockrell, H.M., Zuckerman, M., et al., 2019. Mims' Medical Microbiology, sixth ed. Elsevier, Philadelphia, PA.)

example, the **preformed toxin** present in food mediates the food poisoning caused by *S. aureus* and *B. cereus* and the botulism caused by *C. botulinum*. The symptoms caused by preformed toxin occur much sooner than for other forms of gastroenteritis because the effect is like eating a poison and the bacteria do not need to grow for the symptoms to occur. Because a toxin can be spread systemically through the bloodstream, symptoms may arise at a site distant from the site of infection, such as occurs in tetanus, which is caused by *C. tetani*.

EXOTOXINS

Exotoxins are proteins that can be produced by gram-positive or gram-negative bacteria and include cytolytic enzymes and receptor-binding proteins that alter a function or kill the cell. In many cases, the toxin gene is encoded on a plasmid (tetanus toxin of *C. tetani,* heat-labile [LT] and heat-stabile [ST] toxins of enterotoxigenic *E. coli*) or a lysogenic phage (*Corynebacterium diphtheriae* and *C. botulinum*). *For many bacteria, the effects of the toxin determines the disease* (e.g., *C. diphtheriae*, *C. tetani*).

Cytolytic toxins include membrane-disrupting enzymes such as the α-toxin (phospholipase C) produced by *C. perfringens,* which breaks down sphingomyelin and other membrane phospholipids. Hemolysins insert into and disrupt erythrocyte and other cell membranes. Pore-forming toxins, including streptolysin O, can promote leakage of ions and water from the cell and disrupt cellular functions or cause cell lysis.

Many toxins are dimeric, with A and B subunits **(A-B toxins).** The **B** portion of the A-B toxins binds to a specific cell-surface receptor, and then the A subunit is transferred into the interior of the cell, in which it acts to promote cell injury *(B for binding, A for action).* The tissues targeted by these toxins are very defined and limited (Fig. 14.3 and Table 14.3). The biochemical targets of A-B toxins include ribosomes, transport mechanisms, and intracellular signaling (cyclic adenosine monophosphate [cAMP] production, G-protein function), with effects ranging from diarrhea to

TABLE 14.3 Properties of A-B–Type Bacterial Toxins

Toxin	Organism	Gene Location	Subunit Structure	Target Cell Receptor	Biological Effects
Anthrax toxin	*Bacillus anthracis*	Plasmid	Three separate proteins (EF, LF, PA)	TEM-8; CMG2	EF + PA: increase in target cell cAMP level, localized edema; LF + PA: death of target cells and experimental animals
Botulinum toxin	*Clostridium botulinum*	Phage	A-B	Polysialogangliosides plus synaptotagmin (coreceptors)	Decrease in peripheral presynaptic acetylcholine release, flaccid paralysis
Cholera toxin	*Vibrio cholerae*	Chromosomal	$A\text{-}B_5$	Ganglioside (GM_1)	Alteration of G-protein to activate adenylate cyclase, increase in cAMP level, secretory diarrhea
Diphtheria toxin	*Corynebacterium diphtheriae*	Phage	A-B	Growth factor receptor precursor	Inhibition of protein synthesis, cell death
Heat-labile enterotoxins	*Escherichia coli*	Plasmid	Similar or identical to cholera toxin	See cholera	See cholera
Pertussis toxin	*Bordetella pertussis*	Chromosomal	$A\text{-}B_5$	Surface glycoproteins with terminal sialic acid residues	Activation of adenylate cyclase by incapacitating inhibitory G-protein; increase in cAMP level, modified cell function, or cell death
Pseudomonas exotoxin A	*Pseudomonas aeruginosa*	Chromosomal	A-B	α_2-MR	Similar or identical to diphtheria toxin
Shiga toxin	*Shigella dysenteriae*	Chromosomal	$A\text{-}B_5$	Gb3	Inhibition of protein synthesis, cell death
Tetanus toxin	*Clostridium tetani*	Plasmid	A-B	Polysialogangliosides plus 15-kDa glycoprotein (coreceptors)	Decrease in neurotransmitter release from inhibitory neurons, spastic paralysis

α_2-MR, α_2-Macroglobulin receptor; *cAMP,* cyclic adenosine monophosphate; *CMG2,* capillary morphogenesis protein 2; *EF,* edema factor; *Gb3,* globotriaosylceramide; *LF,* lethal factor; *PA,* protective antigen, *PEM-8,* tumor endothelial marker-8.

loss of neuronal function to death. The functional properties of cytolytic and other exotoxins are discussed in greater detail in the chapters dealing with the specific diseases involved.

Superantigens are a special group of toxins (Fig. 14.4). These molecules activate T cells by binding simultaneously to a T-cell receptor and a major histocompatibility complex class II (MHC II) molecule on an antigen-presenting cell without requiring antigen. *Superantigens activate large numbers of T cells to release large amounts (cytokine storm) of interleukins (IL) (including IL-1, IL-2, and IL-6),* tumor necrosis factor-α (TNF-α), interferon (IFN)-γ, and various chemokines, causing *life-threatening fever, shock, rash, and autoimmune-like responses.* This superantigen stimulation of T cells can also lead to death of the activated T cells, resulting in the loss of specific T-cell clones and loss of their immune responses. Superantigens include the toxic shock syndrome toxin of *S. aureus,* staphylococcal enterotoxins, and the erythrogenic toxin A or C of *S. pyogenes.*

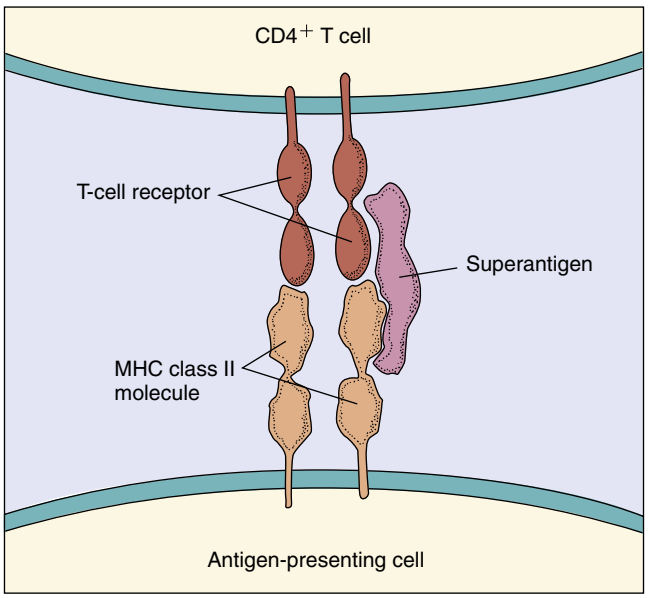

Fig. 14.4 Superantigen binding to the external regions of the T-cell receptor and the major histocompatibility complex *(MHC)* class II molecules.

PATHOGEN-ASSOCIATED MOLECULAR PATTERNS

The presence of bacterial cell wall components acts as a signal of infection that provides a powerful multialarm warning to the body to activate the host's protective systems. The molecular patterns in these structures **(pathogen-associated molecular patterns [PAMPs])** bind to Toll-like receptors (TLRs) and other molecules and stimulate the production of cytokines (see Chapters 8 and 10). In some cases, the host response is excessive and may even be life-threatening. The **lipid A portion of LPS** and **lipooligosaccharide (LOS)** produced by gram-negative bacteria is a powerful activator of acute-phase

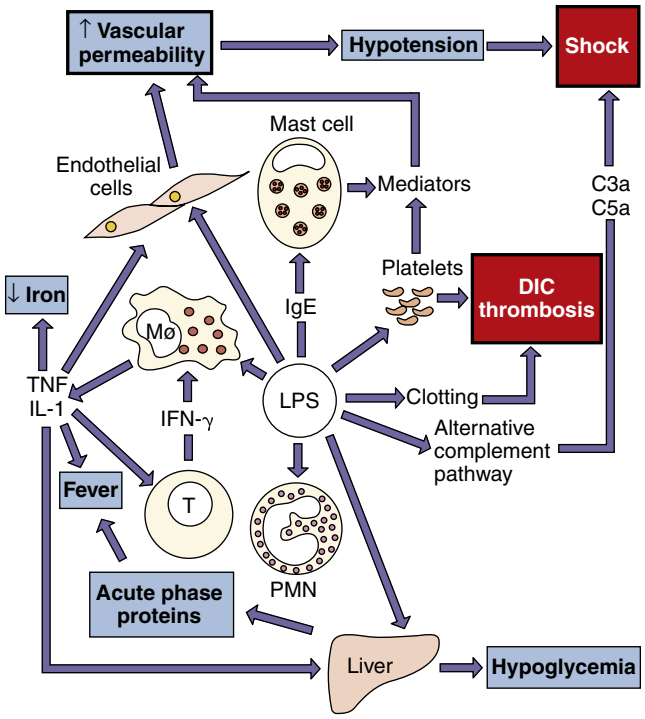

Fig. 14.5 Many activities of lipopolysaccharide *(LPS).* This bacterial endotoxin activates almost every immune mechanism, as well as the clotting pathway, which together make LPS one of the most powerful immune stimuli known. *DIC,* Disseminated intravascular coagulation; *IFN-γ,* interferon-γ; *IgE,* immunoglobulin E; *IL-1,* interleukin-1; *PMN,* polymorphonuclear (neutrophil) leukocytes; *TNF,* tumor necrosis factor. (Modified from Goering, R.V., Dockrell, H.M., Zuckerman, M., et al., 2019. Mims' Medical Microbiology, sixth ed. Elsevier, Philadelphia, PA.)

and inflammatory reactions and is termed **endotoxin.** It is important to appreciate that endotoxin is not the same as exotoxin and that *only gram-negative bacteria make endotoxin.* Weaker, endotoxin-like responses may result from gram-positive bacterial structures, including **lipoteichoic acids.**

Gram-negative bacteria release LPS or LOS during infection. Its endotoxin binds to specific receptors (CD14 and TLR4) on macrophages, B cells, and other cells and stimulates production and release of **acute-phase cytokines,** such as IL-1, TNF-α, IL-6, and prostaglandins (Fig. 14.5). Endotoxin also stimulates the growth (mitogenic) of B cells.

At low concentrations, endotoxin stimulates the development of protective responses such as fever, vasodilation, and activation of immune and inflammatory responses (Box 14.3). However, the endotoxin levels in the blood of patients with **gram-negative bacteremia** (bacteria in the blood) can be very high, and the systemic response to these can be overpowering, resulting in sepsis, shock, and possibly death. High concentrations of endotoxin can also activate the alternative pathway of complement and production of anaphylatoxins (C3a, C5a), contributing to systemic vasodilation and capillary leakage. In combination with TNF-α and IL-1, this can lead to **hypotension** and **shock. Disseminated intravascular coagulation (DIC)** can also result from the activation of blood coagulation pathways. The high fever, petechiae (skin lesions resulting from capillary leakage), and potential symptoms of shock (resulting from increased vascular permeability) associated with *N. meningitidis* infection can be related to the large amounts of LOS and its endotoxin released during infection.

Immunopathogenesis

In many cases, the symptoms of a bacterial infection are produced by excessive innate, immune, and inflammatory responses triggered by the infection. When limited and controlled, the acute-phase response to cell wall components is a protective antibacterial response. However, these responses also cause fever and malaise, and when systemic and out of control, the acute-phase response and inflammation can cause life-threatening symptoms associated with sepsis and meningitis (see Fig. 14.5). Activated neutrophils, macrophages, and complement can cause tissue damage at the site of the infection. Activation of complement can also cause release of anaphylatoxins that initiate vascular permeability and capillary breakage. Fluid buildup, dead cells, and **pus**, formed by dead neutrophils, limit access of immune and antibiotic treatments to the infection. Granuloma formation induced by CD4 T cells and macrophages in response to *Mycobacterium tuberculosis* can also lead to disruption of tissue and organ structure and function. Systemic effects, such as cytokine storms, can be generated by superantigens and endotoxin and can cause shock and disruption of body function. Autoimmune responses can be triggered by some bacterial proteins, such as the M protein of *S. pyogenes,* which antigenically mimics heart tissue. The anti-M protein antibodies cross-react with and can initiate damage to the heart to cause rheumatic fever. Immune complexes deposited in the glomeruli of the kidney cause poststreptococcal glomerulonephritis. For *Chlamydia, Treponema* (syphilis), *Borrelia* (Lyme disease), and other bacteria, the host immune response is the principal cause of disease symptoms in patients.

Mechanisms for Escaping Host Defenses

Bacteria are parasites, and evasion of host protective responses is a selective advantage. Logically, the longer a bacterial infection remains in a host, the more time the bacteria have to grow and cause damage. Therefore bacteria that can evade or incapacitate the host defenses have a greater potential for causing disease. Bacteria evade recognition and killing by phagocytic cells, inactivate or evade the complement system and antibody, and even grow inside cells to hide from host responses (Box 14.4).

Bacteroides fragilis
Cryptococcus neoformans (yeast)

The capsule is one of the most important virulence factors (Box 14.5). These slime layers function by shielding the bacteria from immune and phagocytic responses. Capsules are typically made of polysaccharides, which are poor immunogens. The *S. pyogenes* capsule, for example, is made of hyaluronic acid, which mimics human connective tissue, masking the bacteria and keeping them from being recognized by the immune system. The capsule also acts like a slimy football jersey because it is hard to grasp and tears away when grabbed by a phagocyte. The capsule also protects a bacterium from destruction within the phagolysosome of a macrophage or leukocyte. All of these properties can extend the time bacteria spend in blood (bacteremia) before being eliminated by host responses. Mutants of normally encapsulated bacteria that lose the ability to make a capsule also lose their virulence; examples of such bacteria are *Streptococcus pneumoniae* and *N. meningitidis.* A **biofilm,** which is made from capsular material, protects a colony of bacteria and can prevent antibody, complement, phagocytic cells, and antimicrobial therapy from getting to the bacteria.

Bacteria can evade antibody responses by **antigenic variation,** by **inactivation of antibody,** or **by intracellular growth.** *N. gonorrhoeae* can vary the structure of surface antigens to evade antibody responses and also produces a protease that degrades IgA. *S. aureus* expresses on its surface and releases IgG-binding proteins, protein A and protein G, which binds to the Fc portion of antibody to prevent antibody from activating complement or being an opsonin and masks the bacteria from detection. Bacteria that grow intracellularly include mycobacteria, francisellae, brucellae, chlamydiae, and rickettsiae (Box 14.6). Unlike most bacteria, control of these infections requires T-helper cell immune responses to activate macrophages to kill or create a wall (granuloma) around the infected cells (as for *M. tuberculosis*).

Bacteria evade complement action by preventing access of the components to the membrane, masking themselves, and inhibiting activation of the cascade. The thick peptidoglycan of gram-positive bacteria and the long O antigen of LPS of most gram-negative bacteria (not *Neisseria* spp.) limit access to complement and protect the bacterial membrane from being damaged. By degrading the C5a component of complement, *S. pyogenes* can limit the chemotaxis of leukocytes to the site of infection.

Phagocytes (neutrophils, macrophages) are the most important antibacterial defense, but many bacteria can circumvent phagocytic killing in various ways or kill the phagocyte. They can produce enzymes capable of lysing phagocytic cells (e.g., the streptolysin produced by *S. pyogenes* or the α-toxin produced by *C. perfringens*), inhibit uptake by phagocytosis (e.g., the effects of the **capsule** and the **M protein** produced by *S. pyogenes*), or block intracellular killing. Bacterial mechanisms for protection from intracellular killing include blocking fusion of the lysosome with the phagosome to prevent contact with its bactericidal contents (*Mycobacterium* spp.); having a protective capsule or lipid-rich waxy cell wall (mycobacteria and nocardia); produce catalase, like staphylococci, to break down the hydrogen peroxide produced by the myeloperoxidase system; or other means to resist the bactericidal lysosomal enzymes or substances. *Listeria monocytogenes* lyse the phagosome with a toxin and enter the cell's cytoplasm before being exposed to lysosomal enzymes (Fig. 14.6 and Table 14.4). Many of the bacteria that are internalized but survive phagocytosis can use the cell as a place to grow and hide from immune responses and as a means of being disseminated throughout the body.

S. aureus can also escape host defenses by walling off the site of infection. *S. aureus* can produce coagulase, which is an enzyme that promotes the conversion of fibrin to fibrinogen to produce a clotlike barrier; this feature distinguishes *S. aureus* from *S. epidermidis. S. aureus* and *S. pyogenes* and other bacteria are pyogenic (pus formers),

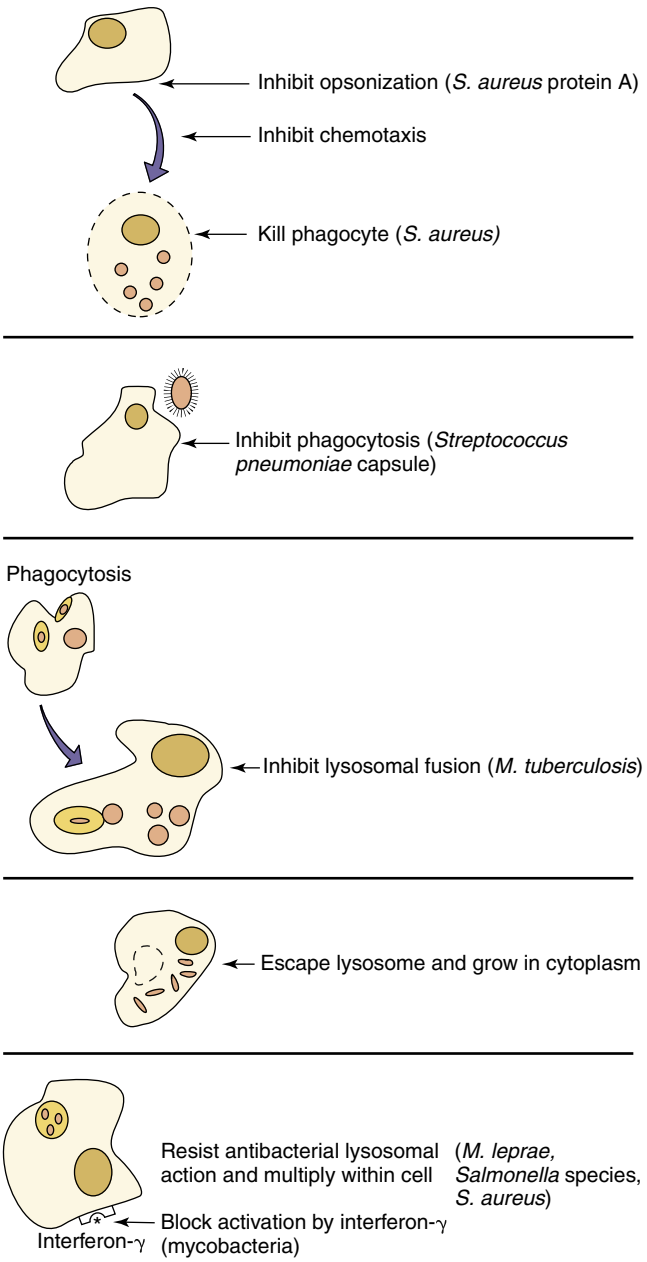

Fig. 14.6 Bacterial mechanisms for escaping phagocytic clearance. Selected examples of bacteria that use the indicated antiphagocytic mechanisms are given. *M. leprae, Mycobacterium leprae; M. tuberculosis, Mycobacterium tuberculosis; S. aureus, Staphylococcus aureus.*

Adaptation to cytoplasmic replication	*Listeria, Francisella,* and *Rickettsia* spp.

and pus formation on the death of neutrophils limits antibody or antibiotic access to the bacteria. *M. tuberculosis* is able to survive in a host by promoting the development of a granuloma, within which viable bacteria may reside for the life of the infected person. The bacteria may resume growth if there is a decline in the immune status of the person.

Summary

The primary virulence factors of bacteria are the capsule, adhesins, invasins, degradative enzymes, toxins, and mechanisms for escaping elimination by host defenses. Bacteria may only have one virulence mechanism. For example, *C. diphtheriae* has only one virulence mechanism, which is diphtheria toxin. Other bacteria express many virulence factors. *S. aureus* is an example of such a bacterium; it expresses adhesins, degradative enzymes, toxins, catalase, and coagulase, which are responsible for producing a spectrum of diseases. In addition, different strains within a bacterial species may express different virulence mechanisms. For example, the symptoms and sequelae of gastroenteritis (diarrhea) caused by *E. coli* may include invasion and bloody stools, cholera-like watery stools, and even severe hemorrhagic disease, depending on the specific infecting strain.

Excellent videos, prepared by the Howard Hughes Medical Institute, of the action of *E. coli* and *Salmonella* type III secretion devices promoting adhesion and intracellular growth can be seen at https://www.biointeractive.org/classroom-resources/how-pathogenic-e-coli-infection-begins and https://www.biointeractive.org/classroom-resources/how-salmonella-infection-begins. A video of *Salmonella* virulence mechanisms: www.youtube.com/watch?v=j5GvvQJVD_Y.

Questions

1. Name three routes by which exogenous pathogens can infect a person. List five examples of organisms that use each route.

2. How are microbes able to resist immunologic clearance? Give at least one specific example of each mechanism.

3. What are the two general types of exotoxins? List examples of each type.

4. Most antibacterial vaccines elicit antibodies that prevent infection, spread, or the virulence factors of a bacteria. Design a vaccine for *S. aureus* that would prevent infection and virulence factors and facilitate uptake by phagocytes (opsonization).

15 Role of Bacteria in Disease

This chapter summarizes material presented in Chapters 18 to 35, which focus on individual organisms and the diseases they cause. We believe this is an important process in understanding how individual organisms produce disease; however, when a patient develops an infection, a physician approaches diagnosis by assessing the clinical presentation and constructing a list of organisms that are most likely to cause the disease. The etiology of some diseases can be attributed to a single organism (e.g., tetanus, *Clostridium tetani*). More commonly, however, multiple organisms can produce a similar clinical picture (e.g., sepsis, pneumonia, gastroenteritis, meningitis). The clinical management of infections is predicated on the ability to develop an accurate differential diagnosis; that is, it is critical to know which organisms are most commonly associated with a particular infectious process.

The development of an infection depends on the complex interactions of (1) the host's susceptibility to infection, (2) the organism's virulence potential, and (3) the opportunity for interaction between host and organism. It is impossible to summarize in a single chapter the complex interactions that lead to the development of disease in each organ system; that is the domain of comprehensive texts in infectious disease. Instead, this chapter is intended to serve as a very broad overview of the bacteria commonly associated with infections at specific body sites and with specific clinical manifestations (Tables 15.1 to 15.5). Because many factors influence the relative frequency with which specific organisms cause disease (e.g., age, underlying disease, epidemiologic factors, host immunity), no attempt is made to define all the factors associated with disease caused by specific organisms. That material is provided, in part, in the chapters that follow and in infectious disease texts. Furthermore, the roles of fungi, viruses, and parasites are not considered in this chapter; instead, they are considered in the later sections of this book.

Tables 15.1 and 15.2 illustrate the complexity of summarizing the role of bacteria in infectious diseases. Simply stated, Table 15.1 is a list of bacteria and the diseases they cause and Table 15.2 is a list of diseases and the bacteria associated with the diseases. Unfortunately, neither list is comprehensive; more diseases are associated with many of the bacteria, and the list of bacteria responsible for most of the diseases is not complete. These two tables represent different approaches to understanding the role of bacteria in infectious disease. The overall approach taken in this book is to study the organisms, learning their biology in the context of their ability to cause disease. We have taken this traditional approach because we feel this provides a foundation for the student to understand the disease process. However, we recognize that the patient presents with a disease syndrome, and the student must remember which organisms can be responsible. For this reason, Table 15.2 is presented. In this textbook, we use a summary chapter of pathogens and diseases to introduce each major class of organisms (i.e., bacteria, viruses, fungi, parasites). In clinical practice, a particular disease can be caused by different classes of organisms; thus the student should consider using all four chapters to gain an appreciation of the complexity of developing a differential diagnosis. We hope that using these chapters as an introduction may provide students with a useful framework for cataloging the variety of organisms responsible for similar diseases.

TABLE 15.1 Overview of Selected Bacterial Pathogens

Organism	Clinical Features	Epidemiologic Features	Treatment
AEROBIC AND FACULTATIVELY ANAEROBIC GRAM-POSITIVE COCCI			
Enterococcus faecalis and *E. faecium*	Urinary tract infections, peritonitis, bacteremia, endocarditis	Elderly patients and patients who have been hospitalized for extended periods receiving broad-spectrum antibiotics	Penicillin/ampicillin or vancomycin; combined with gentamicin for endocarditis or severe infections; linezolid, daptomycin, tigecycline
Staphylococcus aureus	Suppurative infections: impetigo, folliculitis, furuncles, carbuncles, wounds Disseminated infections: bacteremia, endocarditis, pneumonia, empyema, osteomyelitis, septic arthritis Toxin-mediated infections: toxic shock syndrome, scalded skin syndrome, food poisoning	Colonize human skin and mucosal surfaces; survive on environmental surfaces; able to grow at temperature extremes and in high salt concentrations	Localized infections: trimethoprim/sulfamethoxazole, doxycycline, clindamycin or linezolid Systemic infections: oxacillin (if susceptible) or vancomycin; daptomycin, tigecycline, or linezolid
Staphylococcus, coagulase-negative	Wound infections, urinary tract infections, catheter and shunt infections, prosthetic device infections	Colonize human skin and mucosal surfaces; survive on environmental surfaces; able to grow at temperature extremes	As with *S. aureus*

Continued

TABLE 15.1 Overview of Selected Bacterial Pathogens—cont'd

Organism	Clinical Features	Epidemiologic Features	Treatment
Streptococcus pyogenes (group A)	Suppurative infections: pharyngitis, scarlet fever, sinusitis, skin and soft-tissue infection (impetigo, erysipelas, cellulitis, necrotizing fasciitis), toxic shock–like syndrome; bacteremia Nonsuppurative infections: rheumatic fever, glomerulonephritis	Diverse populations	Penicillin V, amoxicillin; macrolides, cephalosporins, clindamycin, vancomycin; surgical debridement for necrotizing fasciitis
S. agalactiae (group B)	Neonatal disease (early onset, late onset): bacteremia, pneumonia, meningitis; postpartum endometritis, wound infection, skin and soft-tissue infection, urinary tract infections	Neonates; pregnant women; patients with diabetes, cancer, or alcoholism	Penicillin; cephalosporins or vancomycin
Viridans streptococci	Abscess formation; septicemia in neutropenic patients; subacute endocarditis; odontogenic infections; dental caries	Patients with abnormal heart valves; neutropenic patients	Penicillin; penicillin plus aminoglycoside; broad-spectrum cephalosporin, vancomycin
S. pneumoniae	Pneumonia, sinusitis, otitis media, meningitis, bacteremia, endocarditis, spontaneous bacterial peritonitis, septic arthritis	Diverse: neonates, children, adults with chronic diseases, elderly	Penicillin; levofloxacin, cephalosporins, clindamycin; broad-spectrum cephalosporins, vancomycin
AEROBIC OR FACULTATIVELY ANAEROBIC GRAM-POSITIVE RODS			
Bacillus anthracis	Anthrax: cutaneous, GI, inhalation	Animal workers; microbiological accidents; bioterrorism	Cutaneous anthrax: amoxicillin Inhalation anthrax: ciprofloxacin or doxycycline plus rifampin, vancomycin, penicillin, imipenem, clindamycin, or clarithromycin
B. cereus	Food poisoning; ocular infections; bacteremia; pneumonia	Contaminated food; traumatic eye injury with introduction of contaminated soil; injection drug use	Food poisoning: symptomatic treatment Other infections: fluoroquinolones or vancomycin, clindamycin, gentamicin
Corynebacterium diphtheriae	Diphtheria: respiratory, cutaneous	Spread by respiratory droplets to unimmunized individuals	Penicillin or erythromycin to eliminate organism and terminate toxin production; immunize with diphtheria toxoid
C. jeikeium	Opportunistic infections; bacteremia	Immunocompromised patients at increased risk	Vancomycin
C. urealyticum	Urinary tract infections, including pyelonephritis with calculi; bacteremia	Risk factors include immunosuppression, underlying genitourinary disorders, antecedent urologic procedures, prior antibiotic therapy	Vancomycin
Erysipelothrix rhusiopathiae	Erysipeloid (localized skin lesion); generalized cutaneous infection; septicemia	Occupational disease of butchers, meat processors, farmers, poultry workers, fish handlers, and veterinarians	Localized infection: penicillin, ciprofloxacin, clindamycin Disseminated infection: ceftriaxone, imipenem
Listeria monocytogenes	Early-onset neonatal disease: granulomatosis infantiseptica Late-onset neonatal disease: meningitis with septicemia; flulike illness in adults; bacteremia or disseminated disease in pregnant women or patients with cell-mediated immune defect; meningitis	Immunocompromised hosts, elderly persons, neonates, pregnant women; ingestion of contaminated food	Gentamicin plus penicillin or ampicillin
ACID-FAST BACTERIA			
Mycobacterium avium complex	Localized pulmonary disease; disseminated disease with multiorgan involvement	Localized disease in patients with chronic pulmonary disease; disseminated disease in AIDS and other immunocompromised patients	Clarithromycin or azithromycin combined with rifabutin or ethambutol
M. leprae	Leprosy: range from tuberculoid form to lepromatous form	Close contact with infected individuals most likely responsible for spread	Dapsone and rifampicin for tuberculoid form; add clofazimine for lepromatous form
M. tuberculosis complex	Tuberculosis: pulmonary, extrapulmonary	All ages with HIV-infected patients at greatest risk for active disease	Multidrug therapy with INH, rifampin, ethambutol, and pyrazinamide, followed by INH plus rifampin; multidrug-resistant strains

TABLE 15.1 Overview of Selected Bacterial Pathogens—cont'd

Organism	Clinical Features	Epidemiologic Features	Treatment
Nocardia	Bronchopulmonary disease; brain abscess Primary or secondary cutaneous infections: mycetoma, lymphocutaneous infections, cellulitis, subcutaneous abscess	Opportunistic pathogen in immunocompetent patients with chronic pulmonary disease or immunocompromised patients with T-cell deficiencies	Trimethoprim/sulfamethoxazole for cutaneous infections in immunocompetent patients; add amikacin, imipenem, or broad-spectrum cephalosporin for disseminated infection or infection in immunocompromised patient
Rhodococcus equi	Bronchopulmonary disease; opportunistic infections in immunocompetent patients	Pathogen most commonly found in immunocompromised patients (e.g., AIDS patients, transplant recipients)	Combination therapy with vancomycin, carbapenems, aminoglycosides, ciprofloxacin, rifampin
AEROBIC GRAM-NEGATIVE COCCI			
Neisseria gonorrhoeae	Gonorrhea, septic arthritis; pelvic inflammatory disease; perihepatitis; septicemia	Sexual transmission, asymptomatic carriage	Ceftriaxone plus azithromycin or doxycycline
N. meningitidis	Meningitis, septicemia (meningococcemia); pneumonia, arthritis, urethritis	Carrier state, aerosol transmission, most common in children and young adults	Ceftriaxone or cefotaxime
AEROBIC AND FACULTATIVELY ANAEROBIC GRAM-NEGATIVE RODS			
Acinetobacter	Opportunistic infections: pneumonia, septicemia, urinary tract infections, wound infections	Nosocomial infections	Imipenem or ceftazidime combined with aminoglycosides for serious infections; multidrug resistance increasingly common
Aeromonas	Wound infections, gastroenteritis	Healthy and immunocompromised patients	Ciprofloxacin; trimethoprim/sulfamethoxazole, gentamicin, or amikacin as alternative therapy
Bartonella bacilliformis	Carrión disease (Oroya fever) + "Peruvian wart"	Bite of infected sandfly	Chloramphenicol + penicillin
B. henselae	BA, subacute endocarditis, CSD	Healthy (endocarditis, CSD) and immunocompromised patients (BA)	Azithromycin; erythromycin or doxycycline
B. quintana	TF, BA, subacute endocarditis	Healthy (TF, endocarditis) or immunocompromised patients (BA)	Azithromycin; erythromycin or doxycycline
Bordetella pertussis, B. parapertussis	Pertussis (whooping cough)	Aerosol transmission; severe diseases in infants, milder in adults	Supportive therapy, erythromycin (or other macrolide) to decrease infectivity; azithromycin for contact prophylaxis
Brucella	Brucellosis	Exposure to infected goats, sheep, cattle, or other animals; bioterrorism	Doxycycline plus rifampin; trimethoprim/sulfamethoxazole
Burkholderia cepacia complex	Pulmonary infections, opportunistic infections	Compromised individuals, especially cystic fibrosis and chronic granulomatous disease patients	Trimethoprim/sulfamethoxazole; piperacillin, ceftazidime, or ciprofloxacin as alternative therapy if trimethoprim/sulfamethoxazole resistant
B. pseudomallei	Melioidosis (asymptomatic to severe pulmonary disease)	Opportunistic pathogen	Trimethoprim/sulfamethoxazole + ceftazidime
Campylobacter jejuni, C. coli, C. upsaliensis	Gastroenteritis	Zoonotic infection following ingestion of contaminated food, milk, or water	Self-limited; severe infections treated with azithromycin; tetracycline or fluoroquinolones used as alternative therapy
C. fetus	Septicemia, meningitis, gastroenteritis, spontaneous abortion	Infects elderly, immunocompromised patients	Aminoglycosides, carbapenems, chloramphenicol
Cardiobacterium hominis	Subacute endocarditis	Opportunistic pathogen in patients with previously damaged heart valve	Penicillin or ampicillin
Eikenella corrodens	Subacute endocarditis, wound infections	Human bite wounds; opportunistic pathogen in patients with previously damaged heart valve	Penicillin, cephalosporins, tetracycline, or fluoroquinolones
Escherichia coli: enteropathogenic (EPEC)	Watery diarrhea and vomiting	Infants in developing countries	Unknown

Continued

TABLE 15.1 Overview of Selected Bacterial Pathogens—cont'd

Organism	Clinical Features	Epidemiologic Features	Treatment
E. coli: Shiga toxin–producing (STEC)	Watery diarrhea, hemorrhagic colitis, hemolytic uremic syndrome	Foodborne, waterborne outbreaks in developed countries	Antibiotics contraindicated
E. coli: enterotoxigenic (ETEC)	Watery diarrhea	Childhood diarrhea in developing countries; travelers' diarrhea	Ciprofloxacin shortens course (high level of resistance)
E. coli: enteroaggregative (EAEC)	Diarrhea with mucus	Childhood diarrhea	Fluoroquinolones used in AIDS patients
E. coli: enteroinvasive (EIEC)	Watery diarrhea, hemorrhagic colitis	Childhood diarrhea in developing countries	Antibiotics reduce duration of disease and infectivity
E. coli: uropathogenic	Cystitis, pyelonephritis	Sexually active women	Trimethoprim/sulfametho xazole, fluoroquinolones
E. coli: meningitis associated	Acute meningitis	Neonates	Extended-spectrum cephalosporins
Francisella tularensis	Tularemia: ulceroglandular, oculoglandular, pneumonic	Tick bites, exposure to infected rabbits, bioterrorism	Doxycycline or ciprofloxacin for mild infections; add gentamicin for serious infections
Haemophilus influenzae	Encapsulated type b strains: meningitis, septicemia, cellulitis, epiglottitis Unencapsulated strains: otitis media, sinusitis, bronchitis, pneumonia	Aerosol transmission in young unimmunized children; spread from upper respiratory tract in elderly patients with chronic respiratory disease	Broad-spectrum cephalosporin, azithromycin, or fluoroquinolone; many strains resistant to ampicillin
Helicobacter pylori	Gastritis, peptic and duodenal ulcers; gastric adenocarcinoma	Infections particularly common among people in low socioeconomic class or in developing countries	Multidrug therapy: omeprazole + amoxicillin + clarithromycin
Kingella kingae	Subacute endocarditis	Opportunistic pathogen in patients with previously damaged heart valve	β-Lactam with β-lactamase inhibitor, cephalosporins, macrolides, tetracycline, fluoroquinolone
Klebsiella pneumoniae	Pneumonia, urinary tract infections	Nosocomial infection; alcoholism	Cephalosporins, carbapenems, fluoroquinolones; multidrug-resistant strains increasingly common
Legionella pneumophila	Legionnaires' disease (pneumonia), Pontiac fever (flulike illness)	Waterborne; elderly and immunocompromised patients	Macrolides (erythromycin, azithromycin, clarithromycin); fluoroquinolones as alternative therapy
Moraxella catarrhalis	Bronchopneumonia, ear or eye infections	Children, patients with compromised pulmonary system	Cephalosporins, amoxicillin/clavulanic acid
Proteus mirabilis	Urinary tract infections, wound infections	Structural abnormality in urinary tract	Amoxicillin, trimethoprim/sulfamethoxazole, cephalosporins, fluoroquinolones
Pseudomonas aeruginosa	Pulmonary; primary skin and soft-tissue infection: burn wounds, folliculitis, osteochondritis; urinary tract infections; ear or eye infections; bacteremia; endocarditis	Nosocomial infections	Combination therapy generally required (e.g., aminoglycoside with extended-spectrum cephalosporins, piperacillin-tazobactam, or carbapenem); multidrug-resistant strains increasingly common
Salmonella enterica	Diarrhea; enteric fever (serovar Typhi)	Contaminated food; immunocompromised patients at higher risk for bacteremia	May prolong carrier state in simple diarrhea treatment; fluoroquinolones for enteric fever
Serratia, Enterobacter	Pneumonia, urinary tract infections, wound infections	Nosocomial infections	Carbapenems, piperacillin-tazobactam
Shigella	Bacillary dysentery	Contaminated food or water; person-to-person spread	Ampicillin, trimethoprim/sulfamethoxazole, fluoroquinolones
Stenotrophomonas maltophilia	Wide variety of local and systemic infections	Nosocomial infections	Trimethoprim/sulfamethoxazole; doxycycline or ceftazidime as alternative
Streptobacillus moniliformis	Rat-bite fever; Haverhill fever	Bite of rat or other small rodent; ingestion of contaminated food or water	Penicillin, tetracycline
Vibrio cholerae	Severe watery diarrhea, septicemia	Children and adults in developing countries	Rehydration; azithromycin, doxycycline, or ciprofloxacin as alternative
V. parahaemolyticus	Water diarrhea, wound infection	Seafood-borne outbreaks	Rehydration for diarrhea; doxycycline + ceftriaxone for wound infection
V. vulnificus	Wound infections, primary septicemia	Compromised individuals with preexisting hepatic or chronic diseases	Minocycline or doxycycline + ceftriaxone or cefotaxime

TABLE 15.1 Overview of Selected Bacterial Pathogens—cont'd

Organism	Clinical Features	Epidemiologic Features	Treatment
ANAEROBES			
Actinomyces	Actinomycosis: cervicofacial, thoracic, abdominal, pelvic, central nervous system	Colonizes human mucosal surface (oropharynx, intestine, vagina)	Surgical debridement; penicillin; carbapenems, macrolides, or clindamycin as alternative drugs
Bacteroides fragilis	Polymicrobial infections of abdomen, female genital tract, cutaneous and soft tissues	Normal inhabitant of the GI tract	Metronidazole; carbapenems; piperacillin/tazobactam
Clostridium botulinum	Botulism: foodborne, infant, wound	Found in environment (e.g., soil, water, sewage) and GI tract of animals and humans	Ventilatory support + metronidazole or penicillin + trivalent botulinum antitoxin
C. difficile	Antibiotic-associated diarrhea; pseudomembranous colitis	Colonized human GI tract and female genital tract; contaminates hospital environment; prior antibiotic use	Discontinue implicated antibiotics; metronidazole or vancomycin
C. perfringens	Soft-tissue infections: cellulitis, myositis, myonecrosis; food poisoning; enteritis necroticans; septicemia	Found in environment (e.g., soil, water, sewage) and GI tract of animals and humans	Surgical debridement + penicillin
C. tetani	Tetanus: generalized, localized, neonatal	Found in environment (e.g., soil, water, sewage) and GI tract of animals and humans	Wound debridement + penicillin or metronidazole + vaccination with tetanus toxoid + passive immunization
Propionibacterium acnes	Acne; opportunistic infections (e.g., of catheters, shunts, and other prosthetic devices)	Colonizes human skin and mucosal surfaces	Acne treated with benzoyl peroxide + clindamycin or erythromycin
Anaplasma, Ehrlichia, Rickettsia, Coxiella, Chlamydia			
Anaplasma phagocytophilum	Anaplasmosis (granulocytic ehrlichiosis)	Transmission by tick bite (*Ixodes*)	Doxycycline; rifampin as alternative therapy
Chlamydia trachomatis	Trachoma; neonatal conjunctivitis and pneumonia; urethritis; cervicitis; proctitis; salpingitis; lymphogranuloma venereum	Trachoma in developing countries; exposure to infected secretions during birth or sexual contact	Doxycycline, erythromycin, or azithromycin; fluoroquinolones
C. pneumoniae	Pneumonia; cardiovascular disease (?)	Children, young adults	Macrolides; doxycycline, levofloxacin
C. psittaci	Pneumonia	Exposure to birds and their secretions	Doxycycline or macrolides
Coxiella burnetii	Q fever: acute (fever, headache, chills, myalgias, granulomatous hepatitis) or chronic (endocarditis, hepatic dysfunction)	Persons exposed to infected livestock; primarily acquired by inhalation; relatively uncommon in United States	Acute disease: doxycycline Chronic disease: doxycycline + hydroxychloroquine; fluoroquinolones used as alternative to doxycycline
Ehrlichia chaffeensis	Monocytic ehrlichiosis	Transmission by tick bite (*Amblyomma*)	Doxycycline; rifampin used as alternative therapy
Mycoplasma genitalium	Urethritis, cervicitis, pelvic inflammatory disease	Transmission during sexual activity	Azithromycin, fluoroquinolones
M. pneumoniae	Tracheobronchitis; pharyngitis; atypical pneumonia	Symptomatic disease more common in children than adults; severe disease in patients with hypogammaglobulinemia	Erythromycin, doxycycline, fluoroquinolones
Rickettsia rickettsii	Rocky Mountain spotted fever	Most prevalent in hikers and other individuals who spend a lot of time outdoors; transmission by tick bite (*Dermacentor* in United States)	Doxycycline; fluoroquinolones used as alternative therapy
SPIROCHETES			
Borrelia burgdorferi, B. garinii, B. afzelii	Lyme disease: erythema migrans; cardiac, neurologic, or rheumatologic abnormalities	Transmission by ticks (*Ixodes*)	Early: amoxicillin, doxycycline, cefuroxime; late: ceftriaxone, cefotaxime, or penicillin G
B. recurrentis	Epidemic relapsing fever	Transmission by human body louse; no animal host	Tetracyclines; penicillins
Borrelia species	Endemic relapsing fever	Transmission by tick bite (*Ornithodoros*); rodent and small mammal reservoir	Tetracyclines; penicillins
Leptospira interrogans	Leptospirosis: mild, viral-like illness to severe multiorgan illness (Weil disease)	Transmission by exposure to infected urine or tissues of rodents, dogs, farm animals, wild animals	Penicillin; doxycycline
Treponema pallidum	Syphilis: primary, secondary, tertiary, congenital	Transmission congenitally or through sexual contact	Penicillins; doxycycline or azithromycin as alternative therapy

AIDS, Acquired immunodeficiency syndrome; *BA,* bacillary angiomatosis; *CSD,* cat-scratch disease; *EAEC,* enteroaggregative *E. coli; EIEC,* enteroinvasive *E. coli; EPEC,* enteropathogenic *E. coli; ETEC,* enterotoxigenic *E. coli; GI,* gastrointestinal; *HIV,* human immunodeficiency virus; *INH:* isoniazid; *STEC,* Shiga toxin–producing *E. coli*; *TF,* trench fever.

TABLE 15.2 Summary of Bacterial Diseases

System Affected	Pathogens
UPPER RESPIRATORY INFECTIONS	
Pharyngitis	***Streptococcus pyogenes,*** *Neisseria gonorrhoeae,* group C *Streptococcus, Arcanobacterium haemolyticum, Chlamydia pneumoniae, Corynebacterium diphtheriae, C. ulcerans, Mycoplasma pneumoniae, Francisella tularensis*
Sinusitis	***Streptococcus pneumoniae, Haemophilus influenzae, Moraxella catarrhalis,*** **mixed anaerobes and aerobes,** *Staphylococcus aureus,* group A *Streptococcus, Pseudomonas aeruginosa* and other gram-negative rods
Epiglottitis	*Haemophilus influenzae, Streptococcus pneumoniae, Staphylococcus aureus*
EAR INFECTIONS	
Otitis externa	***Pseudomonas aeruginosa, Staphylococcus aureus,*** group A *Streptococcus*
Otitis media	***Streptococcus pneumoniae, Haemophilus influenzae, Moraxella catarrhalis,*** *Staphylococcus aureus,* group A *Streptococcus,* mixed anaerobes and aerobes
EYE INFECTIONS	
Conjunctivitis	***Staphylococcus aureus, Streptococcus pneumoniae, Haemophilus aegyptius,*** *Neisseria gonorrhoeae, Pseudomonas aeruginosa, Francisella tularensis, Chlamydia trachomatis*
Keratitis	***Staphylococcus aureus, Streptococcus pneumoniae, Pseudomonas aeruginosa,*** group A *Streptococcus, Proteus mirabilis* and other Enterobacteriaceae, *Bacillus* species, *Neisseria gonorrhoeae*
Endophthalmitis	***Bacillus cereus, Staphylococcus aureus, Pseudomonas aeruginosa,*** coagulase-negative *Staphylococcus, Propionibacterium* species, *Corynebacterium* species
PLEUROPULMONARY AND BRONCHIAL INFECTIONS	
Bronchitis	***Moraxella catarrhalis, Haemophilus influenzae, Streptococcus pneumoniae,*** *Bordetella pertussis, Mycoplasma pneumoniae, Chlamydia pneumoniae*
Empyema	***Staphylococcus aureus, Streptococcus pneumoniae,*** **group A *Streptococcus,*** *Bacteroides fragilis, Klebsiella pneumoniae* and other Enterobacteriaceae, *Actinomyces* species, *Nocardia* species, *Mycobacterium tuberculosis* and other species
Pneumonia	***Streptococcus pneumoniae, Staphylococcus aureus, Klebsiella pneumoniae*****, other Enterobacteriaceae,** *Moraxella catarrhalis, Haemophilus influenzae, Neisseria meningitidis, Mycoplasma pneumoniae, Chlamydia trachomatis, C. pneumoniae, C. psittaci, Pseudomonas aeruginosa, Burkholderia* species, *Legionella* species, *Francisella tularensis, Bacteroides fragilis, Nocardia* species, *Rhodococcus equi, Mycobacterium tuberculosis* and other species, *Coxiella burnetii, Rickettsia rickettsii,* many other bacteria
URINARY TRACT INFECTIONS	
Cystitis and pyelonephritis	***Escherichia coli, Proteus mirabilis,*** **other Enterobacteriaceae,** *Pseudomonas aeruginosa, Staphylococcus saprophyticus, S. aureus, S. epidermidis,* group B *Streptococcus, Enterococcus* species, *Aerococcus urinae, Mycobacterium tuberculosis*
Renal calculi	***Proteus mirabilis,*** *Morganella morganii, Klebsiella pneumoniae, Corynebacterium urealyticum, Staphylococcus saprophyticus, Ureaplasma urealyticum*
Renal abscess	***Staphylococcus aureus,*** mixed anaerobes and aerobes, *Mycobacterium tuberculosis*
Prostatitis	***Escherichia coli,*** *Klebsiella pneumoniae,* other Enterobacteriaceae, *Enterococcus* species, *Neisseria gonorrhoeae, Mycobacterium tuberculosis* and other species
INTRAABDOMINAL INFECTIONS	
Peritonitis	***Escherichia coli, Bacteroides fragilis*** and other species, ***Enterococcus*** **species,** *Klebsiella pneumoniae,* other Enterobacteriaceae, *Pseudomonas aeruginosa, Streptococcus pneumoniae, Staphylococcus aureus, Fusobacterium* species, *Clostridium* species, *Peptostreptococcus* species, *Neisseria gonorrhoeae, Chlamydia trachomatis, Mycobacterium tuberculosis*
Dialysis-associated peritonitis	**Coagulase-negative *Staphylococcus,*** *Staphylococcus aureus, Streptococcus* species, *Corynebacterium* species, *Propionibacterium* species, *Escherichia coli* and other Enterobacteriaceae, *Pseudomonas aeruginosa, Acinetobacter* species
CARDIOVASCULAR INFECTIONS	
Endocarditis	**Viridans *Streptococcus,*** **coagulase-negative *Staphylococcus,*** *Staphylococcus aureus, Aggregatibacter* species, *Cardiobacter hominis, Eikenella corrodens, Kingella kingae, Streptococcus pneumoniae, Abiotrophia* species, *Rothia mucilaginosa, Enterococcus* species, *Bartonella* species, *Coxiella burnetii, Brucella* species, *Erysipelothrix rhusiopathiae,* Enterobacteriaceae, *Pseudomonas aeruginosa, Corynebacterium* species, *Propionibacterium* species
Myocarditis	***Staphylococcus aureus,*** *Corynebacterium diphtheriae, Clostridium perfringens,* group A *Streptococcus, Borrelia burgdorferi, Neisseria meningitidis, Mycoplasma pneumoniae, Chlamydia pneumoniae, C. psittaci, Rickettsia rickettsii, Orientia tsutsugamushi*
Pericarditis	***Staphylococcus aureus,*** *Streptococcus pneumoniae, Neisseria gonorrhoeae, N. meningitidis, Mycoplasma pneumoniae, M. tuberculosis* and other species
SEPSIS	
General sepsis	***Staphylococcus aureus,*** **coagulase-negative *Staphylococcus, Escherichia coli, Klebsiella*** **species**, *Enterobacter* species, *Proteus mirabilis,* other Enterobacteriaceae, *Streptococcus pneumoniae* and other species, *Enterococcus* species, *Pseudomonas aeruginosa,* many other bacteria

TABLE 15.2 Summary of Bacterial Diseases—cont'd

System Affected	Pathogens
Transfusion-associated sepsis	**Coagulase-negative *Staphylococcus,*** *Staphylococcus aureus, Yersinia enterocolitica, Pseudomonas fluorescens* group, *Salmonella* species, other Enterobacteriaceae, *Campylobacter jejuni* and other species, *Bacillus cereus* and other species
Septic thrombophlebitis	***Staphylococcus aureus, Bacteroides fragilis,*** *Klebsiella* species, *Enterobacter* species, *Pseudomonas aeruginosa, Fusobacterium* species, *Campylobacter fetus*
CENTRAL NERVOUS SYSTEM INFECTIONS	
Meningitis	**Group B *Streptococcus, Streptococcus pneumoniae, Neisseria meningitidis, Listeria monocytogenes, Haemophilus influenzae, Escherichia coli,*** other Enterobacteriaceae, *Staphylococcus aureus,* coagulase-negative *Staphylococcus, Propionibacterium* species, *Nocardia* species, *Mycobacterium tuberculosis* and other species, *Borrelia burgdorferi, Leptospira* species, *Treponema pallidum, Brucella* species
Encephalitis	*Listeria monocytogenes, Treponema pallidum, Leptospira* species, *Actinomyces* species, *Nocardia* species, *Borrelia* species, *Rickettsia rickettsii, Coxiella burnetii, Mycoplasma pneumoniae, Mycobacterium tuberculosis* and other species
Brain abscess	***Staphylococcus aureus, Fusobacterium* species, *Peptostreptococcus* species, other anaerobic cocci,** Enterobacteriaceae, *Pseudomonas aeruginosa,* viridans *Streptococcus, Bacteroides* species, *Prevotella* species, *Porphyromonas* species, *Actinomyces* species, *Clostridium perfringens, Listeria monocytogenes, Nocardia* species, *Rhodococcus equi, Mycobacterium tuberculosis* and other species
Subdural empyema	***Staphylococcus aureus, Streptococcus pneumoniae,*** group B *Streptococcus, Neisseria meningitidis,* mixed anaerobes and aerobes
SKIN AND SOFT-TISSUE INFECTIONS	
Impetigo	**Group A *Streptococcus, Staphylococcus aureus***
Folliculitis	***Staphylococcus aureus, Pseudomonas aeruginosa***
Furuncles and carbuncles	***Staphylococcus aureus***
Paronychia	***Staphylococcus aureus,* group A *Streptococcus,*** *Pseudomonas aeruginosa*
Erysipelas	**Group A *Streptococcus***
Cellulitis	**Group A *Streptococcus, Staphylococcus aureus,*** *Haemophilus influenzae,* many other bacteria
Necrotizing cellulitis and fasciitis	**Group A *Streptococcus, Clostridium perfringens*** and other species, *Bacteroides fragilis,* other anaerobes, Enterobacteriaceae, *Pseudomonas aeruginosa*
Bacillary angiomatosis	***Bartonella henselae, Bartonella quintana***
Infections of burns	***Pseudomonas aeruginosa,*** *Enterobacter* species, *Enterococcus* species, *Staphylococcus aureus,* group A *Streptococcus,* many other bacteria
Bite wounds	***Eikenella corrodens, Pasteurella multocida,*** *P. canis, Capnocytophaga canis*, *Staphylococcus aureus,* group A *Streptococcus,* mixed anaerobes and aerobes, many gram-negative rods
Surgical wounds	***Staphylococcus aureus,*** coagulase-negative *Staphylococcus,* groups A and B streptococci, *Clostridium perfringens, Corynebacterium* species, many other bacteria
Traumatic wounds	***Bacillus* species, *Staphylococcus aureus,*** group A *Streptococcus,* many gram-negative rods, rapidly growing mycobacteria
GASTROINTESTINAL INFECTIONS	
Antibiotic-associated diarrhea	***Clostridium difficile,*** *Staphylococcus aureus*
Gastritis	***Helicobacter pylori***
Gastroenteritis	***Salmonella* species, *Shigella* species, *Campylobacter jejuni* and *coli, Escherichia coli* (STEC, EIEC, ETEC, EPEC, EAEC), *Vibrio cholerae, V. parahaemolyticus, Bacillus cereus,*** *Yersinia enterocolitica, Edwardsiella tarda, Pseudomonas aeruginosa, Aeromonas* species, *Plesiomonas shigelloides, Bacteroides fragilis, Clostridium botulinum, C. perfringens*
Food intoxication	***Staphylococcus aureus, Bacillus cereus,*** *Clostridium botulinum, C. perfringens*
Proctitis	***Neisseria gonorrhoeae,*** *Chlamydia trachomatis, Treponema pallidum*
BONE AND JOINT INFECTIONS	
Osteomyelitis	***Staphylococcus aureus,*** *Salmonella* species, *Mycobacterium tuberculosis* and other species, β-hemolytic *Streptococcus, Streptococcus pneumoniae, Escherichia coli,* and other Enterobacteriaceae, *Pseudomonas aeruginosa,* many less common bacteria
Arthritis	***Staphylococcus aureus, Neisseria gonorrhoeae,*** *Streptococcus pneumoniae, Salmonella* species, *Pasteurella multocida, Mycobacterium* species

TABLE 15.2 Summary of Bacterial Diseases—cont'd

System Affected	Pathogens
Prosthetic-associated infections	***Staphylococcus aureus,* coagulase-negative *Staphylococcus,*** group A *Streptococcus,* viridans *Streptococcus, Corynebacterium* species, *Propionibacterium* species, *Peptostreptococcus* species, other anaerobic cocci
GENITAL INFECTIONS	
Genital ulcers	***Treponema pallidum, Haemophilus ducreyi,*** *Chlamydia trachomatis, Francisella tularensis, Klebsiella granulomatis, Mycobacterium tuberculosis*
Urethritis	***Neisseria gonorrhoeae, Chlamydia trachomatis, Mycoplasma genitalium,*** *Ureaplasma urealyticum*
Vaginitis	***Mycoplasma hominis, Mobiluncus* species, other anaerobic species,** *Gardnerella vaginalis*
Cervicitis	***Neisseria gonorrhoeae, Chlamydia trachomatis, Mycoplasma genitalium,*** *N. meningitidis,* group B *Streptococcus, Mycobacterium tuberculosis, Actinomyces* species
GRANULOMATOUS INFECTIONS	
General	***Mycobacterium tuberculosis* and other species, *Nocardia* species, *Treponema pallidum,*** *Brucella* species, *Francisella tularensis, Listeria monocytogenes, Burkholderia pseudomallei, Actinomyces* species, *Bartonella henselae, Tropheryma whipplei, Chlamydia trachomatis, Coxiella burnetii*

Note: Organisms in boldface are the most common pathogens.
EAEC, Enteroaggregative *E. coli; EIEC,* enteroinvasive *E. coli; EPEC,* enteropathogenic *E. coli; ETEC,* enterotoxigenic *E. coli; STEC,* Shiga toxin–producing (enterohemorrhagic) *E. coli*.

TABLE 15.3 Selected Bacteria Associated with Foodborne Diseases

Organism	Implicated Food(s)
Aeromonas species	Meats, produce, dairy products
Bacillus cereus	Fried rice, meats, vegetables
Brucella species	Unpasteurized dairy products, meat
Campylobacter species	Poultry, unpasteurized dairy products
Clostridium botulinum	Vegetables, fruits, fish, honey
C. perfringens	Beef, poultry, pork, gravy
Escherichia coli	Beef, unpasteurized milk, fruits and juices, vegetables, lettuce
Francisella tularensis	Rabbit meat
Listeria monocytogenes	Unpasteurized dairy products, coleslaw, poultry, cold-cut meats
Plesiomonas shigelloides	Seafood
***Salmonella* species**	Poultry, unpasteurized dairy products
Shigella species	Eggs, lettuce
Staphylococcus aureus	Ham, poultry, egg dishes, pastries
Streptococcus, group A	Egg dishes
***Vibrio* species**	Shellfish
Yersinia enterocolitica	Unpasteurized dairy products, pork

Note: Organisms in boldface are the most common foodborne pathogens.

TABLE 15.4 Selected Bacteria Associated with Waterborne Diseases

Organism	Disease
Aeromonas species	Gastroenteritis, wound infections, septicemia
Campylobacter species	Gastroenteritis
Escherichia coli	Gastroenteritis
Francisella tularensis	Tularemia
***Legionella* species**	Respiratory disease
***Leptospira* species**	Systemic disease
Mycobacterium marinum	Cutaneous infection
Plesiomonas shigelloides	Gastroenteritis
***Pseudomonas* species**	Dermatitis
Salmonella species	Gastroenteritis
Shigella species	Gastroenteritis
***Vibrio* species**	Gastroenteritis, wound infection, septicemia
Yersinia enterocolitica	Gastroenteritis

Note: Organisms in boldface are the most common waterborne pathogens.

TABLE 15.5 Arthropod-Associated Disease

ARTHROPOD	Organism	Disease
Tick	*Anaplasma phagocytophilum*	Human anaplasmosis (formerly called human granulocytic ehrlichiosis)
	Borrelia afzelii	Lyme disease
	B. burgdorferi	Lyme disease
	B. garinii	Lyme disease
	Borrelia, other species	Endemic relapsing fever
	Coxiella burnetii	Q fever
	Ehrlichia chaffeensis	Human monocytic ehrlichiosis
	E. ewingii	Canine (human) granulocytic ehrlichiosis
	Francisella tularensis	Tularemia
	Rickettsia rickettsii	Rocky Mountain spotted fever
Flea	*R. prowazekii*	Sporadic typhus
	R. typhi	Murine typhus
	Yersinia pestis	Plague
Lice	*Bartonella quintana*	Trench fever
	Borrelia recurrentis	Epidemic relapsing fever
	R. prowazekii prowazekii	Epidemic typhus
Mite	*Orientia tsutsugamushi*	Scrub typhus
	Rickettsia akari	Rickettsialpox
Sand-fly	*Bartonella bacilliformis*	Bartonellosis (Carrión disease)

16 Laboratory Diagnosis of Bacterial Diseases

The laboratory diagnosis of bacterial diseases requires that the appropriate specimen is collected, delivered expeditiously to the laboratory in the appropriate transport system, and processed in a manner that will maximize detection of the most likely pathogens. Collection of the proper specimen and its rapid delivery to the clinical laboratory are primarily the responsibility of the patient's physician, whereas the clinical microbiologist selects the appropriate transport systems and detection method (e.g., microscopy, culture, antigen or antibody detection, nucleic acid–based tests). These responsibilities are not mutually exclusive. The microbiologist should be prepared to instruct the physician about what specimens should be collected if a particular diagnosis is suspected, and the physician must provide the microbiologist with information about the clinical diagnosis so that the right tests are selected. This chapter provides an overview of specimen collection and transport, as well as the methods used in the microbiology laboratory for the detection and identification of bacteria. Because it is beyond the scope of this chapter to cover this subject exhaustively, the student is referred to the citations in the Bibliography and the individual chapters that follow for more detailed information.

Specimen Collection, Transport, and Processing

Guidelines for proper collection and transport of specimens are summarized in the following text and Table 16.1.

BLOOD

The culture of blood is one of the most important procedures performed in the clinical microbiology laboratory. The success of this test is directly related to the methods used to collect the blood sample. The most important factor that determines the success of a blood culture is the volume of blood processed. For example, 40% more cultures are positive for organisms if 20 ml rather than 10 ml of blood are cultured because more than half of all septic patients have less than one organism per milliliter of blood. Approximately 20 ml of blood should be collected from an adult for each blood culture, and proportionally smaller volumes should be collected from children and neonates. Because many hospitalized patients are susceptible to infections with organisms colonizing their skin, careful disinfection of the patient's skin is important.

Bacteremia and **fungemia** are defined as the presence of bacteria and fungi, respectively, in the blood, and these infections are referred to collectively as **septicemia.** Clinical studies have shown that septicemia can be continuous or intermittent. **Continuous septicemia** occurs primarily in patients with intravascular infections (e.g., endocarditis, septic thrombophlebitis, infections associated with intravascular catheter) or with overwhelming sepsis (e.g., septic shock). **Intermittent septicemia** occurs in patients with localized infections (e.g., lungs, urinary tract, soft tissues). Intermittent septicemia may be a misnomer because it is likely the number of organisms in the blood fluctuates rather than being completely absent. The timing of blood collection does not appear to be important, although the collection should be performed when the patient is not receiving antibiotics if this is feasible. It is recommended for optimum success that two to three blood samples should be collected.

Most blood samples are inoculated directly into bottles filled with enriched nutrient broths. To ensure the maximal recovery of important organisms, two bottles of media should be inoculated for each culture (10 ml of blood per bottle). When these inoculated bottles are received in the laboratory, they are incubated at 37°C and inspected at regular intervals for evidence of microbial growth. In most laboratories this is accomplished using automated blood culture instruments. When growth is detected, the broths are subcultured to isolate the organism for identification and antimicrobial susceptibility testing. Most clinically significant isolates are detected within the first 1 to 2 days of incubation; however, all cultures should be incubated for a minimum of 5 to 7 days. More prolonged incubation is generally unnecessary. Because few organisms are typically present in the blood of a septic patient, it is not worthwhile to perform a Gram stain of the blood.

CEREBROSPINAL FLUID

Bacterial meningitis is a serious disease associated with high morbidity and mortality if the etiologic diagnosis is delayed. Because some common pathogens are labile (e.g., *Neisseria meningitidis, Streptococcus pneumoniae*), specimens of cerebrospinal fluid (CSF) should be processed immediately after they are collected. Under no circumstance should the specimen be refrigerated or placed directly into an incubator. The patient's skin is disinfected before lumbar puncture, and the CSF is collected into sterile screw-capped tubes. When the specimen is received in the microbiology laboratory, it is concentrated by centrifugation, and the sediment is used to inoculate bacteriologic media and prepare a Gram stain. The laboratory technologist should notify the physician immediately if organisms are observed microscopically or in culture. Nucleic acid amplification tests (NAATs) are now commonly performed to detect bacteria, viruses, and fungi in CSF; thus the specimen should be transported to the laboratory in the appropriate container.

A variety of other normally sterile fluids may be collected for bacteriologic culture, including abdominal (peritoneal), chest (pleural), synovial, and pericardial fluids. If a large volume of fluid can be collected by aspiration

TABLE 16.1 Bacteriology Specimen Collection for Bacterial Pathogens

Specimen	Transport System	Specimen Volume	Other Considerations
Blood: routine bacterial culture	Blood culture bottle with nutrient media	Adults: 20 ml/culture Children: 5-10 ml/culture Neonates: 1 ml/culture	Skin should be disinfected with 70% alcohol followed by 0.5%-2% chlorhexidine; 2-3 cultures collected for each septic event; blood is divided equally into two bottles of nutrient media
Blood: intracellular bacteria (e.g., *Brucella, Francisella, Neisseria* spp.)	Same as that for routine blood cultures; lysis-centrifugation system	Same as that for routine blood cultures	Considerations are the same as those for routine blood cultures; release of intracellular bacteria may improve the organism's recovery; *Neisseria* spp. are inhibited by the anticoagulant (sodium polyanetholesulfonate)
Blood: *Leptospira* sp.	Sterile heparinized tube	1-5 ml	The specimen is useful only during the first week of illness; afterward, urine should be cultured
Cerebrospinal fluid	Sterile screw-capped tube	Bacterial culture: 1-5 ml Mycobacterial culture: as large a volume as possible	The specimen must be collected aseptically and delivered immediately to the laboratory; it should not be exposed to heat or refrigeration
Other normally sterile fluids (e.g., abdominal, chest, synovial, pericardial)	Small volume: sterile screw-capped tube Large volume: blood culture bottle with nutrient medium	As large a volume as possible	Specimens are collected with a needle and syringe; a swab is not recommended because the quantity of collected specimen is inadequate; air should not be injected into culture bottle because it will inhibit growth of anaerobes
Catheter	Sterile screw-capped tube or specimen cup	N/A	The entry site should be disinfected with alcohol; the catheter should be aseptically removed on receipt of the specimen in the laboratory; the catheter is rolled across a blood agar plate and then discarded
Respiratory: throat	Swab immersed in transport medium	N/A	The area of inflammation is swabbed; exudate is collected if present; contact with saliva should be avoided because it can inhibit recovery of group A streptococci
Respiratory: epiglottis	Collection of blood for culture	Same as for blood culture	Swabbing the epiglottis can precipitate complete airway closure; blood cultures should be collected for specific diagnosis.
Respiratory: sinuses	Sterile anaerobic tube or vial	1-5 ml	Specimens must be collected with a needle and syringe; culture of nasopharynx or oropharynx has no value; the specimen should be cultured for aerobic and anaerobic bacteria
Respiratory: lower airways	Sterile screw-capped bottle; anaerobic tube or vial only for specimens collected by avoiding upper tract flora	1-2 ml	Expectorated sputum: if possible, the patient rinses mouth with water before collection of the specimen; the patient should cough deeply and expectorate lower airway secretions directly into a sterile cup; the collector should avoid contamination with saliva Bronchoscopy specimen: anesthetics can inhibit growth of bacteria, so specimens should be processed immediately; if a "protected" bronchoscope is used, anaerobic cultures can be performed Direct lung aspirate: specimens can be processed for aerobic and anaerobic bacteria
Ear	Capped needleless syringe; sterile screw-capped tube	Whatever volume is collected	The specimen should be aspirated with a needle and syringe; culture of the external ear has no predictive value for otitis media
Eye	Inoculate plates at bedside (seal and transport to laboratory immediately)	Whatever volume is collected	For infections on surface of eye, specimens are collected with a swab or by corneal scrapings; for deep-seated infections, aspiration of aqueous or vitreous fluid is performed; all specimens should be inoculated onto appropriate media at collection; delays will result in significant loss of organisms
Exudates (transudates, drainage, ulcers)	Swab immersed in transport medium; aspirate in sterile screw-capped tube	Bacteria: 1-5 ml Mycobacteria: 3-5 ml	Contamination with surface material should be avoided; specimens are generally unsuitable for anaerobic culture
Wounds (abscess, pus)	Aspirate in sterile screw-capped tube or sterile anaerobic tube or vial	1-5 ml of pus	Specimens should be collected with a sterile needle and syringe; a curette is used to collect specimen at base of wound
Tissues	Sterile screw-capped tube; sterile anaerobic tube or vial	Representative sample from center and border of lesion	The specimen should be aseptically placed into the appropriate sterile container; an adequate quantity of specimen must be collected to recover small numbers of organisms

TABLE 16.1 Bacteriology Specimen Collection for Bacterial Pathogens—cont'd

Specimen	Transport System	Specimen Volume	Other Considerations
Urine: midstream	Sterile urine container	Bacteria: 1 ml Mycobacteria: ≥10 ml	Contamination of the specimen with bacteria from the urethra or vagina should be avoided; the first portion of the voided specimen is discarded; organisms can grow rapidly in urine, so specimens must be transported immediately to the laboratory, held in bacteriostatic preservative, or refrigerated
Urine: catheterized	Sterile urine container	Bacteria: 1 ml Mycobacteria: ≥10 ml	Catheterization is not recommended for routine cultures (risk of inducing infection); the first portion of collected specimen is contaminated with urethral bacteria, so it should be discarded (similar to midstream voided specimen); the specimen must be transported rapidly to the laboratory
Urine: suprapubic aspirate	Sterile anaerobic tube or vial	Bacteria: 1 ml Mycobacteria: ≥10 ml	This is an invasive specimen, so urethral bacteria are avoided; it is the only valid method available for collecting specimens for anaerobic culture; it is also useful for collection of specimens from children or adults unable to void uncontaminated specimens
Genitals	Specially designed swabs for *Neisseria gonorrhoeae* and *Chlamydia* probes	N/A	The area of inflammation or exudate should be sampled; the endocervix (not vagina) and urethra should be cultured for optimal detection; the first voided urine specimen can be used for diagnosis of urethritis
Feces (stool)	Sterile screw-capped container	N/A	Rapid transport to the laboratory is necessary to prevent production of acid (bactericidal for some enteric pathogens) by normal fecal bacteria; it is unsuitable for anaerobic culture; because a large number of different media will be inoculated, a swab should not be used for specimen collection

N/A, Not applicable.

(e.g., abdominal or chest fluids), it should be inoculated into blood culture bottles containing nutrient media. A small portion also should be sent to the laboratory in a sterile tube so that appropriate stains (e.g., Gram, acid-fast) can be prepared. Many organisms are associated with infections at these sites, including polymicrobial mixtures of aerobic and anaerobic organisms. For this reason, biological staining is useful for identifying the organisms responsible for the infection. Because relatively few organisms may be in the sample (because of the dilution of organisms or microbial elimination by the host immune response), it is important to culture as large a volume of fluid as possible. However, if only small quantities of fluid are collected, then the specimen can be inoculated directly onto agar media and a tube of enriched broth media. Because anaerobes may also be present in the sample (particularly samples obtained from patients with intraabdominal or pulmonary infections), the specimen should not be exposed to oxygen and should be processed for anaerobes.

UPPER RESPIRATORY TRACT SPECIMENS

Most bacterial infections of the pharynx are caused by group A *Streptococcus*. Other bacteria that may cause pharyngitis include *Corynebacterium diphtheriae, Bordetella pertussis, N. gonorrhoeae, Chlamydia pneumoniae,* and *Mycoplasma pneumoniae*. However, special techniques are generally required to recover these organisms. Other potentially pathogenic bacteria, such as *Staphylococcus aureus, S. pneumoniae, Haemophilus influenzae,* Enterobacteriaceae, and *Pseudomonas aeruginosa,* may be present in the oropharynx but rarely cause pharyngitis.

A Dacron or calcium alginate swab should be used to collect pharyngeal specimens. The tonsillar areas, posterior pharynx, and any exudate or ulcerative area should be sampled. Contamination of the specimen with saliva should be avoided because bacteria in saliva can overgrow or inhibit the growth of group A streptococci. If a pseudomembrane is present (e.g., as with *C. diphtheriae* infections), a portion should be dislodged and submitted for culture. Group A streptococci and *C. diphtheriae* are very resistant to drying, so special precautions are not required for transport of the specimen to the laboratory. In contrast, specimens collected for the recovery of *B. pertussis* and *N. gonorrhoeae* should be inoculated onto culture media immediately after they are collected and before they are sent to the laboratory. Specimens obtained for the isolation of *C. pneumoniae* and *M. pneumoniae* should be transported in a special transport medium.

Group A streptococci can be detected directly in the clinical specimen through the use of immunoassays for the group-specific antigen. These tests are very specific and the current immunoassays using digital reading devices as very sensitive. NAAT are also available for detection of group A streptococci.

Other upper respiratory tract infections can involve the epiglottis and sinuses. Complete airway obstruction can be precipitated by attempts to culture the epiglottis (particularly in children); thus these cultures should never be performed. The specific diagnosis of a sinus infection requires

(1) direct aspiration of the sinus, (2) appropriate anaerobic transport of the specimen to the laboratory (using a system that avoids exposing anaerobes to oxygen and drying), and (3) prompt processing. In practice, these specimens are rarely collected and most infections are treated empirically. Culture of the nasopharynx or oropharynx is not useful and should not be performed. *S. pneumoniae, H. influenzae, Moraxella catarrhalis, S. aureus,* and anaerobes are the most common pathogens that cause sinusitis.

LOWER RESPIRATORY TRACT SPECIMENS

A variety of techniques can be used to collect lower respiratory tract specimens including expectoration, induction with saline, bronchoscopy, and direct aspiration through the chest wall. Because upper airway bacteria may contaminate expectorated sputa, specimens should be inspected microscopically to assess the magnitude of oral contamination. Specimens containing many squamous epithelial cells and no predominant bacteria in association with inflammatory cells should not be processed for culture. The presence of squamous epithelial cells indicates that the specimen has been contaminated with saliva. Such contamination can be avoided by obtaining the specimen using specially designed bronchoscopes or direct lung aspiration. If an anaerobic lung infection is suspected, these invasive procedures must be used because contamination of the specimen with upper airway microbes would render the specimen worthless. Most lower respiratory tract pathogens grow rapidly (within 2 to 3 days); however, some slow-growing bacteria, such as mycobacteria or nocardiae, will require extended incubation.

EAR AND EYE

Tympanocentesis (i.e., aspiration of fluid from the middle ear) is required to make the specific diagnosis of a middle ear infection. This is unnecessary in most patients because the most common pathogens that cause these infections (*S. pneumoniae, H. influenzae,* and *M. catarrhalis*) can be treated empirically. Outer ear infections are typically caused by *P. aeruginosa* ("swimmer's ear") or *S. aureus*. The proper specimen to be obtained for culture is a scraping of the involved area of the ear.

Collection of specimens for the diagnosis of ocular infections is difficult because the sample obtained is generally very small and relatively few organisms may be present. Samples of the eye surface should be collected by a swab before topical anesthetics are applied, followed by corneal scrapings when necessary. Intraocular specimens are collected by directly aspirating the eye. The culture media should be inoculated when the specimens are collected and before they are sent to the laboratory. Although most common ocular pathogens grow rapidly (e.g., *S. aureus, S. pneumoniae, H. influenzae, P. aeruginosa, Bacillus cereus*), some may require prolonged incubation (e.g., coagulase-negative staphylococci) or use of specialized culture media *(N. gonorrhoeae*), or tissue culture cells *(C. trachomatis).*

WOUNDS, ABSCESSES, AND TISSUES

Open, draining wounds can often be contaminated with potentially pathogenic organisms unrelated to the specific infectious process. Therefore it is important to collect samples from deep in the wound after the surface has been cleaned. Whenever possible, a swab should be avoided because it is difficult to obtain a representative sample without contamination with organisms colonizing the surface. Likewise, aspirates from a closed abscess should be collected from both the center and the wall of the abscess. Simply collecting pus from an abscess is generally nonproductive because most organisms actively replicate at the base of the abscess rather than in the center. Drainage from soft-tissue infections can be collected by aspiration. If drainage material is not obtained, then a small quantity of saline can be infused into the tissue and then withdrawn for culture. Saline containing a bactericidal preservative should not be used.

Tissues should be obtained from representative portions of the infectious process, with multiple samples collected whenever possible. The tissue specimen should be transported in a sterile screw-capped container, and sterile saline should be added to prevent drying if a small sample (e.g., biopsy specimen) is collected. A sample of tissue should also be submitted for histologic examination. Because collection of tissue specimens requires invasive procedures, every effort should be made to collect the proper specimen and ensure that it is cultured for all clinically significant organisms that may be responsible for the infection. This requires close communication between the physician and microbiologist.

URINE

Urine is one of the most frequently submitted specimens for culture. Because a variety of bacteria colonize the urethra, the first portion of urine collected by voiding or catheterization should be discarded. Urinary tract pathogens can also grow in urine, so there should be no delay in transport of specimens to the laboratory. If the specimen cannot be cultured immediately, it should be refrigerated or placed into a bacteriostatic **urine preservative.** Once the specimen is received in the laboratory, 1 to 10 μl is inoculated onto each culture medium (generally one nonselective agar medium and one selective medium). This is done so that the number of organisms in the urine can be quantitated, which is useful for assessing the significance of an isolate, although small numbers of organisms in a patient with pyuria can be clinically significant. Numerous urine-screening procedures (e.g., biochemical tests, microscopy stains) have been developed and are used widely; however, the current procedures cannot be recommended because they are invariably insensitive in detecting clinically significant, low-grade bacteriuria.

GENITAL SPECIMENS

Despite the variety of bacteria associated with sexually transmitted diseases, most laboratories concentrate on detecting *N. gonorrhoeae* and *C. trachomatis*. Traditionally this was done by inoculating the specimen into a culture system selective for these organisms; however, this is a slow process, taking 2 or more days for a positive culture to be obtained and even more time for isolates to be identified. Culture was also found to be insensitive because the

organisms are extremely labile and die rapidly if transported under less than optimal conditions. For these reasons, a variety of nonculture methods are now used. The most popular methods are nucleic acid amplification procedures (e.g., amplification of species-specific deoxyribonucleic acid [DNA] sequences by the polymerase chain reaction or other methods) for both organisms. Detection of these amplified sequences is both sensitive and specific. Urine can be used for these tests but, in contrast with specimens collected for the diagnosis of cystitis, the first voided portion of urine should be tested for the diagnosis of urethritis.

The other major bacterium that causes sexually transmitted disease is *Treponema pallidum,* the etiologic agent of syphilis. This organism cannot be cultured in the clinical laboratory, so the diagnosis is made using microscopy or serology. Material from lesions must be examined using darkfield microscopy because the organism is too thin to be detected using brightfield microscopy. In addition, the organism dies rapidly when exposed to air and drying conditions, so the microscopic examination must be performed at the time the specimen is collected.

FECAL SPECIMENS

A large variety of bacteria can cause gastrointestinal infections. For these bacteria to be recovered in culture, an adequate stool sample must be collected (generally not a problem in a patient with diarrhea), transported to the laboratory in a manner that ensures viability of the infecting organism, and inoculated onto the appropriate selective media. Rectal swabs should not be submitted for culture because multiple selective media must be inoculated for the various possible pathogens to be recovered. The quantity of feces collected on a swab would be inadequate.

Stool specimens should be collected in a clean pan and then transferred into a tightly sealed waterproof container. The specimens should be transported promptly to the laboratory to prevent acidic changes in the stool (caused by bacterial metabolism), which are toxic for some organisms (e.g., *Shigella*). If a delay is anticipated, then the feces should be mixed with a preservative, such as phosphate buffer mixed with glycerol or Cary-Blair transport medium. In general, however, rapid transport of the specimen to the laboratory is always superior to the use of any transport medium.

It is important to notify the laboratory if a particular enteric pathogen is suspected; this will help the laboratory select the appropriate specialized culture medium. For example, although *Vibrio* species can grow on the common media used for the culture of stool specimens, use of media selective for *Vibrio* facilitates rapid detection and identification of this organism. In addition, some organisms are not isolated routinely by the laboratory procedures (e.g., enterotoxigenic *Escherichia coli* can grow on routine culture media but would not be readily distinguished from nonpathogenic *E. coli*). Likewise, other organisms would not be expected to be in a stool sample because their disease is caused by toxin produced in food, not by growth of the organism in the gastrointestinal tract (e.g., *S. aureus, B. cereus*). The microbiologist should be able to select the appropriate test (e.g., culture, toxin assay) if the specific pathogen is indicated. *Clostridium difficile* is a significant cause of antibiotic-associated gastrointestinal disease. Although the organism can be cultured from stool specimens if the specimens are delivered promptly to the laboratory, the most specific way to diagnose the infection is by detecting in fecal extracts the *C. difficile* toxins responsible for the disease or the genes that code for these toxins. The most sensitive and specific tests for diagnosing *C. difficile* disease is detection of the toxin genes by NAAT.

Because many bacteria, both pathogenic and nonpathogenic, are present in fecal specimens, it often takes at least 3 days for the enteric pathogen to be isolated and identified. For this reason, stool cultures are used to confirm the clinical diagnosis, and therapy, if indicated, should not be delayed pending culture results. An alternative to culture or immunoassays is the use of high multiplex NAAT, which can detect the most common bacterial, viral, and parasitic enteric pathogens in 1 to 3 hours directly from fecal swabs. These tests are rapidly becoming the test of choice because they are more sensitive than culture, able to detect common pathogens that are not readily distinguished from normal enteric bacteria (e.g., pathogenic *E. coli* versus normal enteric *E. coli*), and provide results in hours rather than days.

Bacterial Detection and Identification

Detection of bacteria in clinical specimens is accomplished by five general procedures: (1) microscopy, (2) detection of bacterial antigens, (3) culture, (4) detection of specific bacterial nucleic acids, and (5) detection of an antibody response to the bacteria (serology). The specific techniques used for these procedures were presented in the preceding chapters and will not be repeated in this chapter. However, Table 16.2 summarizes the relative value of each procedure for the detection of organisms discussed in Chapters 18 to 35.

Although many organisms can be specifically identified by a variety of techniques, the most common procedure used in diagnostic laboratories is to identify an organism isolated in culture by biochemical tests. In large teaching hospital laboratories and reference laboratories, many biochemical test procedures have been replaced recently with sequencing bacterial-specific genes (e.g., 16S rRNA gene) or using proteomic tools such as matrix-assisted laser desorption ionization (MALDI) mass spectrometry. We believe most students using this textbook are not interested in these details of microbial identification, but those who are interested should refer to textbooks such as the *ASM Manual of Clinical Microbiology*.

It is important for all students to appreciate that empirical antimicrobial therapy can be refined based on preliminary identification of an organism using microscopic and macroscopic morphology and selected rapid biochemical tests. Refer to Table 16.3 for specific examples.

Antimicrobial Susceptibility Tests

The results of in vitro antimicrobial susceptibility testing are valuable for selecting chemotherapeutic agents active against the infecting organism. Extensive work has been performed in an effort to standardize testing methods and improve the clinical predictive value of the results. Despite

these efforts, in vitro tests are simply a measurement of the effect of the antibiotic against the organism under specific conditions. Selection of an antibiotic and the patient's outcome are influenced by a variety of interrelated factors including the pharmacokinetic properties of the antibiotic, drug toxicity, the clinical disease, and the patient's general medical status. Thus some organisms that are "susceptible" to an antibiotic will persist in an infection and some organisms that are "resistant" to an antibiotic will be eliminated. For example, because oxygen is required for aminoglycosides to enter a bacterial cell, these antibiotics are ineffective in an anaerobic abscess. Likewise, very high concentrations of antibiotics can be achieved in urine, so resistant bacteria responsible for urinary tract infections can be eliminated by the high urine concentrations of some antibiotics.

Two general forms of antimicrobial susceptibility tests are performed in the clinical laboratory: **broth dilution tests** and **agar diffusion tests.** For broth dilution tests, a series of dilutions of an antibiotic are prepared in a nutrient medium and then inoculated with a standardized concentration of the test bacterium. After overnight incubation, the lowest concentration of antibiotic able to inhibit the growth of the bacteria is referred to as the **minimum inhibitory concentration (MIC).** For agar diffusion tests, a standardized concentration of bacteria is spread over the surface of an agar medium, and then paper disks or strips impregnated with antibiotics are placed on the agar surface. After overnight incubation, an area of inhibited growth is observed surrounding the paper disks or strips. The size of the area of inhibition corresponds to the activity of the antibiotic; the more susceptible the organism is to the antibiotic, the larger the area of inhibited growth. By standardizing the test conditions for agar diffusion tests, the area of inhibition corresponds to the MIC value. Indeed, one commercial company has developed a test in which the MIC value is calculated directly from the zone of inhibited growth around a strip

TABLE 16.3 Preliminary Identification of Bacteria Isolated in Culture

Organism	Properties
Staphylococcus aureus	Gram-positive cocci in clusters; large, β-hemolytic colonies; catalase-positive, coagulase-positive
Streptococcus pyogenes	Gram-positive cocci in long chains; small colonies with large zone of β-hemolysis; catalase-negative, PYR-positive
S. pneumoniae	Gram-positive cocci in pairs and short chains; small, α-hemolytic colonies; catalase-negative, soluble in bile
Enterococcus spp.	Gram-positive cocci in pairs and short chains; large, α-hemolytic or nonhemolytic colonies; catalase-negative, PYR-positive
Listeria monocytogenes	Small, gram-positive rods; small, weakly β-hemolytic colonies; characteristic (tumbling) motility
Nocardia spp.	Weakly staining (Gram and modified acid-fast), thin, filamentous, branching rods; slow growth; fuzzy colonies (aerial hyphae)
Rhodococcus equi	Weakly staining (Gram and modified acid-fast); initially nonbranching rods, cocci in older cultures; slow growth; pink-red colonies
Mycobacterium tuberculosis	Strongly acid-fast rods; slow growth; nonpigmented colonies; identified using specific molecular probes
Enterobacteriaceae	Gram-negative rods with "bipolar" staining (more intense at ends); typically single cells; large colonies; growth on MacConkey agar (may/may not ferment lactose); oxidase-negative
Pseudomonas aeruginosa	Gram-negative rods with uniform staining; typically in pairs; large spreading, fluorescent green colonies, usually β-hemolytic, fruity smell (grapelike); growth on MacConkey agar (nonfermenter); oxidase-positive
Stenotrophomonas maltophilia	Gram-negative rods with uniform staining; typically in pairs; lavender-green color on blood agar; growth on MacConkey agar (nonfermenter); oxidase-negative
Acinetobacter spp.	Large, gram-negative coccobacilli arranged as single cells or pairs; will retain crystal violet and may resemble fat, gram-positive cocci in pairs; growth on blood agar and MacConkey agar (may oxidize lactose and resemble weakly purple); oxidase-negative
Campylobacter spp.	Thin, curved, gram-negative rods arranged in pairs (S-shaped pairs); growth on highly selective media for *Campylobacter*; no growth on routine media (blood, chocolate, or MacConkey agars)
Haemophilus spp.	Small, gram-negative coccobacilli arranged as single cells; growth on chocolate agar but not blood or MacConkey agars; oxidase-positive
Brucella spp.	Very small, gram-negative coccobacilli arranged as single cells; slow-growing; no growth on MacConkey agar; biohazard
Francisella spp.	Very small, gram-negative coccobacilli arranged as single cells; slow-growing; no growth on blood or MacConkey agars; biohazard
Legionella spp.	Weakly staining, thin, gram-negative rods; slow-growing; growth on specialized agar; no growth on blood, chocolate, or MacConkey agars
Clostridium perfringens	Large, rectangular rods with spores not observed; rapid growth of spreading colonies with "double zone" of hemolysis (large zone of α-hemolysis with inner zone of β-hemolysis); strict anaerobe
Bacteroides fragilis group	Weakly staining, pleomorphic (variable lengths), gram-negative rods; rapid growth stimulated by bile in media; strict anaerobe

PYR, L-Pyrrolidonyl arylamidase.

with a gradient of antibiotic concentrations from the top to the bottom of the strip.

Broth dilution tests were originally performed in test tubes and were very labor intensive. Commercially prepared systems are now available in which antibiotic dilutions are prepared in microtiter trays and inoculation of the trays and interpretation of MICs are automated. Disadvantages of these systems are that the range of different antibiotics is determined by the manufacturer, and the number of dilutions of an individual antibiotic is limited. Thus results may not be available for newly introduced antibiotics. Diffusion tests are labor intensive and interpretation of the size of the area of inhibition can be subjective; however, the advantage of these tests is that virtually any antibiotic can be tested. The ability of both susceptibility testing methods to predict clinical response to an antibiotic is equivalent, so test selection is determined by practical considerations.

Questions

1. What is the most important factor that influences recovery of microorganisms in blood collected from patients with sepsis?
2. Which organisms are important causes of bacterial pharyngitis?
3. What criteria should be used to assess the quality of a lower respiratory tract specimen?
4. What methods are used to detect the three most common bacteria that cause sexually transmitted diseases?

17 Antibacterial Agents

This chapter provides an overview of the mechanisms of action and spectrum of the most commonly used antibacterial antibiotics, as well as a description of the common mechanisms of bacterial resistance. The terminology appropriate for this discussion is summarized in Box 17.1, and the basic mechanisms and sites of antibiotic activity are summarized in Table 17.1 and Fig. 17.1, respectively.

The year 1935 was an important one for the chemotherapy of systemic bacterial infections. Although antiseptics had been applied topically to prevent the growth of microorganisms, the existing antiseptics were ineffective against systemic bacterial infections. In 1935, the dye protosil was shown to protect mice against systemic streptococcal infection and to be curative in patients suffering from such infections. It was soon found that protosil was cleaved in the body to release *p*-aminobenzene sulfonamide (sulfanilamide), which was shown to have antibacterial activity. This first "sulfa" drug ushered in a new era in medicine. Compounds produced by microorganisms (antibiotics) were eventually discovered to inhibit the growth of other microorganisms. For example, Alexander Fleming was the first to realize the mold *Penicillium* prevented the multiplication of staphylococci. A concentrate from a culture of this mold was prepared, and the remarkable antibacterial activity and lack of toxicity of the first antibiotic, penicillin, were demonstrated. Streptomycin and the tetracyclines were developed in the 1940s and 1950s, followed rapidly by the development of additional aminoglycosides, semisynthetic penicillins, cephalosporins, quinolones, and other antimicrobials. All these antibacterial agents greatly increased the range of infectious diseases that could be prevented or treated. Although the development of new antibacterial antibiotics has lagged in recent years, some new classes of agents have been introduced, including the ketolides (e.g., **telithromycin**), glycylcyclines **(tigecycline),** and lipopeptides **(daptomycin).**

Unfortunately, with the introduction of new chemotherapeutic agents, bacteria have shown a remarkable ability to develop resistance. The most common resistance mechanisms are summarized in Box 17.2. Thus antibiotic therapy will not be the magical cure for all infections, as predicted; rather, it is only one weapon, albeit an important one, against infectious diseases. It is also important to recognize that because resistance to antibiotics is often not predictable, physicians must rely on their clinical experience for the initial selection of **empirical therapy** and then refine their treatment by selecting antibiotics demonstrated to be active by in vitro susceptibility tests. Guidelines for the management of infections caused by specific organisms are discussed in the relevant chapters of this text.

Inhibition of Cell Wall Synthesis

The most common mechanism of antibiotic activity is interference with bacterial cell wall synthesis. Most of the cell wall–active antibiotics are classified as β-lactam antibiotics (e.g., penicillins, cephalosporins, cephamycins, carbapenems, monobactams, β-lactamase inhibitors). They are so named because they share a common β-lactam ring structure. Other antibiotics that interfere with construction of the bacterial cell wall include vancomycin, daptomycin, bacitracin, and the antimycobacterial agents isoniazid, ethambutol, cycloserine, and ethionamide.

β-LACTAM ANTIBIOTICS

The major structural component of most bacterial cell walls is the peptidoglycan layer. The basic structure is a chain of 10 to 65 disaccharide residues consisting of alternating molecules of *N*-acetylglucosamine and *N*-acetylmuramic acid. These chains are then cross-linked with peptide bridges that create a rigid mesh coating for the bacteria. The building of the chains and cross-links is catalyzed by specific enzymes (e.g., transpeptidases, transglycosylases, carboxypeptidases) that are members of a large family of **serine proteases.** These regulatory enzymes are also called **penicillin-binding proteins (PBPs)** because they are the targets of β-lactam antibiotics. When growing bacteria are exposed to these antibiotics, the antibiotic binds to specific PBPs in the bacterial cell wall and inhibits assembly of the peptidoglycan chains. This, in turn, activates autolysins that degrade the cell wall, resulting in bacterial cell death. Thus the β-lactam antibiotics generally act as bactericidal agents.

Bacteria can become resistant to β-lactam antibiotics by three general mechanisms: (1) decreased concentration of the antibiotic at the cell wall target site, (2) decreased binding of the antibiotic to the PBP, and (3) hydrolysis of the antibiotic by bacterial enzymes, **β-lactamases.** The first mechanism of resistance is seen only in gram-negative bacteria. Gram-negative bacteria have an outer membrane that overlies the peptidoglycan layer. Penetration of β-lactam antibiotics into gram-negative rods requires transit through pores in this outer membrane. Changes in the proteins **(porins)** that form the walls of the pores can alter the size of the pore opening or charge of these channels and result in exclusion of the antibiotic. Additionally, active efflux or pumping out of the antibiotic can decrease the antibiotic concentration in the cell.

Resistance can also be acquired by modification of the β-lactam antibiotic binding to the PBP. This can be mediated by (1) an overproduction of PBP (a rare occurrence), (2) acquisition of a new PBP (e.g., methicillin resistance in

BOX 17.1 Terminology

Antibacterial spectrum: Range of activity of an antimicrobial against bacteria. A **broad-spectrum** antibacterial drug can inhibit a variety of gram-positive and gram-negative bacteria, whereas a **narrow-spectrum** drug is active against a limited variety of bacteria.

Bacteriostatic antibiotic: Antibiotic that inhibits the growth of bacteria but does not kill.

Bactericidal antibiotic: Antibiotic that kills bacteria.

Minimum inhibitory concentration (MIC): Determined by exposing a standardized suspension of bacteria to a series of antimicrobial dilutions. The lowest antibiotic concentration that inhibits the growth of the bacteria is the MIC.

Minimum bactericidal concentration (MBC): Determined by exposing a standardized suspension of bacteria to a series of antimicrobial dilutions. The lowest antibiotic concentration that kills 99.9% of the population is referred to as the MBC.

Antibiotic combinations: Combinations of antibiotics that may be used to (1) broaden the antibacterial spectrum for empirical therapy or the treatment of polymicrobial infections, (2) prevent the emergence of resistant organisms during therapy, and (3) achieve a synergistic killing effect.

Antibiotic synergism: Combinations of two antibiotics that have enhanced bactericidal activity when tested together compared with the activity of each antibiotic.

Antibiotic antagonism: Combination of antibiotics in which the activity of one antibiotic interferes with the activity of the other (e.g., the sum of the activity is less than the activity of the most active individual drug).

β-Lactamase: An enzyme that hydrolyzes the β-lactam ring in the β-lactam class of antibiotics, inactivating the antibiotic. The enzymes specific for penicillins, cephalosporins, and carbapenems are the **penicillinases, cephalosporinases,** and **carbapenemases,** respectively.

TABLE 17.1 Basic Mechanisms of Antibiotic Action

Antibiotic	Action
DISRUPTION OF CELL WALL	
Penicillins Cephalosporins Cephamycins Carbapenems Monobactams	Bind PBPs and enzymes responsible for peptidoglycan synthesis
β-Lactam/β-lactamase inhibitors	Bind β-lactamases and prevent enzymatic inactivation of β-lactam
Vancomycin	Inhibits cross-linkage of peptidoglycan layers
Daptomycin	Causes depolarization of cytoplasmic membrane, resulting in disruption of ionic concentration gradients
Bacitracin	Inhibits bacterial cytoplasmic membrane and movement of peptidoglycan precursors
Polymyxins	Inhibit bacterial membranes
Isoniazid Ethionamide	Inhibit mycolic acid synthesis
Ethambutol	Inhibits arabinogalactan synthesis
Cycloserine	Inhibits cross-linkage of peptidoglycan layers
INHIBITION OF PROTEIN SYNTHESIS	
Aminoglycosides	Produce premature release of peptide chains from 30S ribosome
Tetracyclines	Prevent polypeptide elongation at 30S ribosome
Glycylcyclines	Bind to 30S ribosome and prevent initiation of protein synthesis
Oxazolidinone	Prevents initiation of protein synthesis at 50S ribosome
Macrolides Ketolides Clindamycin Streptogramins	Prevent polypeptide elongation at 50S ribosome
INHIBITION OF NUCLEIC ACID SYNTHESIS	
Quinolones	Bind α subunit of DNA gyrase
Rifampin Rifabutin	Prevent transcription by binding DNA-dependent RNA polymerase
Metronidazole	Disrupts bacteria DNA (is cytotoxic compound)
ANTIMETABOLITE	
Sulfonamides	Inhibit dihydropteroate synthase and disrupt folic acid synthesis
Dapsone	Inhibits dihydropteroate synthase
Trimethoprim	Inhibits dihydrofolate reductase and disrupts folic acid synthesis

DNA, Deoxyribonucleic acid; *PBPs,* penicillin-binding proteins; *RNA,* ribonucleic acid.

Staphylococcus aureus), or (3) modification of an existing PBP through recombination (e.g., penicillin resistance in *Streptococcus pneumoniae*) or a point mutation (penicillin resistance in *Enterococcus faecium*).

Finally, bacteria can produce **β-lactamases** that inactivate the β-lactam antibiotics. Interestingly, the β-lactamases are in the same family of serine proteases as the PBPs. More than 200 different β-lactamases have been described. Some are specific for penicillins (i.e., penicillinases), cephalosporins (i.e., cephalosporinases), or carbapenems (i.e., carbapenemases), whereas others have a broad range of activity, including some that are capable of inactivating most β-lactam antibiotics. An exhaustive discussion of β-lactamases is beyond the scope of this chapter; however, a brief discussion is germane for understanding the limitations of β-lactam antibiotics. By one classification scheme, β-lactamases have been separated into four classes (A to D). The most common class A β-lactamases are SHV-1 and TEM-1, which are penicillinases found in common gram-negative rods (e.g., *Escherichia, Klebsiella*), with minimal activity against cephalosporins. Unfortunately, simple point mutations in the genes encoding these enzymes have created β-lactamases with activity against all penicillins and cephalosporins. These β-lactamases are referred to as **extended-spectrum β-lactamases (ESBLs)** and are particularly troublesome because most are encoded on plasmids that can be transferred from organism to organism. The class B β-lactamases are zinc-dependent metalloenzymes that have a broad spectrum of activity against all β-lactam antibiotics, including the cephamycins and carbapenems. The **class C β-lactamases** are primarily cephalosporinases that are encoded on the bacterial chromosome. Expression of these enzymes is generally repressed, although this can

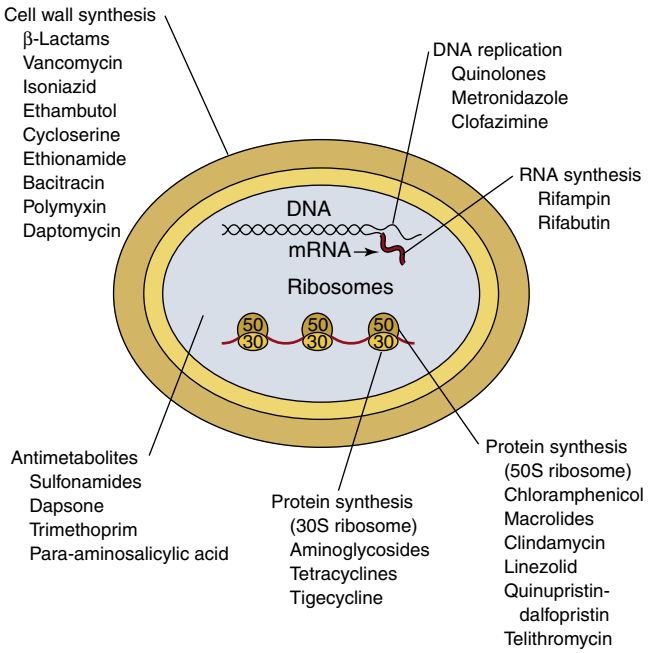

Fig. 17.1 Basic sites of antibiotic activity.

be altered by exposure to certain "inducing" β-lactam antibiotics or by mutations in the genes controlling expression of the enzymes. Expression of this class of β-lactamases is particularly troublesome because they are active against the most potent expanded-spectrum cephalosporins. The class D β-lactamases are penicillinases found primarily in gram-negative rods.

Penicillins

Penicillin antibiotics (Table 17.2) are highly effective antibiotics with an extremely low toxicity. The basic compound is an organic acid with a β-lactam ring obtained from culture of the mold *Penicillium chrysogenum.* If the mold is grown by a fermentation process, large amounts of 6-aminopenicillanic acid (the β-lactam ring is fused with a thiazolidine ring) are produced. Biochemical modification of this intermediate yields antibiotics that have increased resistance to stomach acids, increased absorption in the gastrointestinal tract, resistance to destruction by penicillinase, or a broader spectrum of activity that includes gram-negative bacteria.

Penicillin G is inactivated by gastric acid; thus it is used mainly as an intravenous drug for the treatment of infections caused by a limited number of susceptible organisms. Penicillin V is more resistant to acid and is the preferred oral form for the treatment of susceptible bacteria. **Penicillinase-resistant penicillins** such as methicillin and oxacillin are used to treat infections caused by susceptible staphylococci. Unfortunately, resistance to this group of antibiotics has become commonplace in both hospital-acquired and community-acquired staphylococcal infections. Ampicillin was the first **broad-spectrum penicillin,** although the spectrum of activity against gram-negative rods was limited primarily to *Escherichia, Proteus,* and *Haemophilus* species. Selected penicillins have been combined with **β-lactamase inhibitors.** The β-lactamase inhibitors (e.g., clavulanic acid, sulbactam, tazobactam, avibactam) are relatively inactive by themselves, but when combined with some penicillins (i.e., ampicillin, amoxicillin, ticarcillin, piperacillin) or cephalosporins (e.g., ceftazidime) they are effective in treating some infections caused by β-lactamase–producing bacteria. The inhibitors irreversibly bind and inactivate susceptible bacterial β-lactamases (although not all are bound by these inhibitors), permitting the companion drug to disrupt bacterial cell wall synthesis.

BOX 17.2 Mechanisms of Antibiotic Resistance

Inactivation of the antibiotic by bacterial enzymes
Barriers prevent antibiotic access to the target
Bacteria pump antibiotic out of cell before bacterial growth is inhibited
Antibiotic target is altered so it is not recognized by the antibiotic
Antibiotic target is produced in excess so bacterial growth is not affected by the antibiotic
Antibiotic target is no longer needed for bacterial survival
Bacteria enter stage of dormancy in the presence of the antibiotic

TABLE 17.2 Penicillins

Antibiotics	Spectrum of Activity
Natural penicillins: benzylpenicillin (penicillin G), phenoxymethylpenicillin (penicillin V)	Active against all β-hemolytic streptococci and most other species; limited activity against staphylococci; active against meningococci and most gram-positive anaerobes; poor activity against aerobic and anaerobic gram-negative rods
Penicillinase-resistant penicillins: methicillin, nafcillin, oxacillin, cloxacillin, dicloxacillin	Similar to the natural penicillins, except enhanced activity against staphylococci
Broad-spectrum penicillins: ampicillin, amoxicillin	Activity against gram-positive cocci equivalent to the natural penicillins; active against some gram-negative rods
β-Lactam with β-lactamase inhibitor (ampicillin-sulbactam, amoxicillin-clavulanate, ticarcillin-clavulanate, piperacillin-tazobactam, ceftazidime-avibactam)	Activity similar to natural β-lactams, plus improved activity against β-lactamase–producing staphylococci and selected gram-negative rods; not all β-lactamases are inhibited; piperacillin/tazobactam and ceftazidime-avibactam are the most active

Cephalosporins and Cephamycins

The cephalosporins (Table 17.3) are β-lactam antibiotics derived from 7-aminocephalosporanic acid (the β-lactam ring is fused with a dihydrothiazine ring) that was originally isolated from the mold *Cephalosporium.* The cephamycins are closely related to the cephalosporins, except that they contain oxygen in place of sulfur in the dihydrothiazine ring, rendering them more stable to β-lactamase hydrolysis. The cephalosporins and cephamycins have the same mechanism of action as the penicillins; however, they have a wider antibacterial spectrum, are resistant to many β-lactamases, and have improved pharmacokinetic properties (e.g., longer half-life).

TABLE 17.3 Selected Examples of Cephalosporins and Cephamycins

Antibiotics	Spectrum of Activity
Narrow spectrum (cephalexin, cephalothin, cefazolin, cephapirin, cephradine)	Activity equivalent to oxacillin against gram-positive bacteria; some gram-negative activity (e.g., *Escherichia coli, Klebsiella, Proteus mirabilis*)
Expanded-spectrum cephalosporins (cefaclor, cefuroxime)	Activity equivalent to oxacillin against gram-positive bacteria; improved gram-negative activity to include *Enterobacter, Citrobacter,* and additional *Proteus* species
Expanded-spectrum cephamycins (cefotetan, cefoxitin)	Activity similar to expanded-spectrum cephalosporins but less susceptible to β-lactamases
Broad spectrum (cefixime, cefotaxime, ceftriaxone, ceftazidime)	Activity equivalent to oxacillin against gram-positive bacteria; improved gram-negative activity to include *Pseudomonas*
Extended spectrum (cefepime, cefpirome)	Activity equivalent to oxacillin against gram-positive bacteria; marginally improved gram-negative activity

Biochemical modifications in the basic antibiotic molecule resulted in the development of antibiotics with improved activity and pharmacokinetic properties. The cephalosporins have enhanced activity against gram-negative bacteria compared with the penicillins. This activity, in turn, varies among the different "generations" of cephalosporins. The activity of **narrow-spectrum,** first-generation antibiotics is primarily restricted to *Escherichia coli, Klebsiella* species, *Proteus mirabilis,* and oxacillin-susceptible gram-positive cocci. Many of the **expanded-spectrum,** second-generation antibiotics have additional activity against *Haemophilus influenzae, Enterobacter, Citrobacter,* and *Serratia* species, and some anaerobes, such as *Bacteroides fragilis.* The **broad-spectrum,** third-generation antibiotics and **extended-spectrum,** fourth-generation antibiotics are active against most Enterobacteriaceae and *Pseudomonas aeruginosa.* Extended-spectrum antibiotics offer the advantage of increased stability to β-lactamases. Unfortunately, gram-negative bacteria have rapidly developed resistance to most cephalosporins and cephamycins (primarily as the result of β-lactamase production), which has significantly compromised the use of all these agents.

Carbapenems and Monobactams

Other classes of β-lactam antibiotics (Table 17.4) are the **carbapenems** (e.g., imipenem, meropenem, ertapenem, doripenem) and **monobactams** (e.g., aztreonam). The carbapenems are important, widely prescribed broad-spectrum antibiotics that are active against many groups of organisms. In contrast, the monobactams are narrow-spectrum antibiotics that are active only against aerobic, gram-negative bacteria. Anaerobic bacteria and gram-positive bacteria are resistant. The advantage of narrow-spectrum antibiotics is that they can be used to treat susceptible organisms without disruption of the patient's normal, protective bacterial population. Despite this advantage, monobactams are not widely used.

TABLE 17.4 Other β-Lactam Antibiotics

Antibiotics	Spectrum of Activity
Carbapenems (imipenem, meropenem, ertapenem, doripenem)	Broad-spectrum antibiotics active against most aerobic and anaerobic gram-positive and gram-negative bacteria except oxacillin-resistant staphylococci, most *Enterococcus faecium,* and selected gram-negative rods (e.g., some *Burkholderia, Stenotrophomonas,* some *Pseudomonas*)
Monobactam (aztreonam)	Active against selected aerobic gram-negative rods but inactive against anaerobes or gram-positive cocci

In recent years, resistance to carbapenems mediated by production of carbapenemases has become widespread. As mentioned earlier, the β-lactamases are separated into four classes, A to D. The class A carbapenemase has been found in a broad range of bacteria, including *Pseudomonas* and Enterobacteriaceae (the most common one is the *Klebsiella pneumoniae* carbapenemase **[KPC]**), renders organisms producing this carbapenemase resistant to all β-lactams, and is only reliably detected using molecular methods to detect the resistance genes. The class B carbapenemase is a metallo-β-lactamase (requires zinc for activity), is widely distributed in gram-negative bacteria, and also cannot be detected reliably by conventional susceptibility tests. Organisms producing class B carbapenemases (most common is **New Delhi metallo-β-lactamase [NDM],** named for its origin) are resistant to most β-lactam antibiotics. Finally, the class D carbapenemases are primarily found in *Acinetobacter* and encode resistance to all β-lactam antibiotics. This group of carbapenemases is important because *Acinetobacter* strains producing this carbapenemase are generally resistant to all antibiotics, with few exceptions.

GLYCOPEPTIDES

Vancomycin, originally obtained from *Streptomyces orientalis,* is a complex glycopeptide that disrupts cell wall peptidoglycan synthesis in growing gram-positive bacteria. Vancomycin interacts with the D-alanine-D-alanine termini of the pentapeptide side chains, which interferes sterically with formation of the bridges between peptidoglycan chains. Vancomycin is used for the management of infections caused by oxacillin-resistant staphylococci and other gram-positive bacteria resistant to β-lactam antibiotics. Vancomycin is inactive against gram-negative bacteria because the molecule is too large to pass through the outer membrane pores and reach the peptidoglycan target site. In addition, some organisms are intrinsically resistant to vancomycin (e.g., *Leuconostoc, Lactobacillus, Pediococcus,* and *Erysipelothrix*) because the pentapeptide terminates in D-alanine-D-lactate, which does not bind vancomycin. Intrinsic resistance is also found in some species of enterococci that contain a D-alanine-D-serine terminus (i.e., *E. gallinarum, E. casseliflavus*). Finally, some species of enterococci (particularly *E. faecium* and *E. faecalis*) have acquired resistance to vancomycin. The genes for this resistance (primarily *vanA* and *vanB*), which also mediate changes

in the pentapeptide terminus, can be carried on plasmids and have seriously compromised the usefulness of vancomycin for the treatment of enterococcal infections. More importantly, the gene for vancomycin resistance contained within a transposon on a multiresistance conjugative plasmid has been transferred in vivo from *E. faecalis* to a multiresistant *S. aureus.* The transposon then moved from the *E. faecalis* plasmid and recombined and integrated into the *S. aureus* resistance plasmid. This resulted in an *S. aureus* plasmid that encoded resistance to β-lactams, vancomycin, aminoglycosides, and other antibiotics (a plasmid that could be transferred to other staphylococci by conjugation). Interestingly, these resistant strains of *Staphylococcus* have primarily been restricted to Michigan; however, if this resistance becomes widespread, the medical implications are profound.

LIPOPEPTIDES

Daptomycin, a naturally occurring cyclic lipopeptide produced by *S. roseosporus,* binds irreversibly to the cytoplasmic membrane, resulting in membrane depolarization and disruption of the ionic gradients, leading to cell death. It has potent activity against gram-positive bacteria, but gram-negative bacteria are resistant to daptomycin because the drug cannot penetrate through the cell wall to the cytoplasmic membrane. Daptomycin has good activity against multidrug-resistant staphylococci, streptococci, and enterococci (including vancomycin-resistant strains).

POLYPEPTIDES

Bacitracin, which was isolated from *Bacillus licheniformis,* is a mixture of polypeptides used in topically applied products (e.g., creams, ointments, sprays) for the treatment of skin infections caused by gram-positive bacteria (particularly those caused by *Staphylococcus* and group A *Streptococcus*). Gram-negative bacteria are resistant to this agent. Bacitracin inhibits cell wall synthesis by interfering with dephosphorylation and recycling of the lipid carrier responsible for moving the peptidoglycan precursors through the cytoplasmic membrane to the cell wall. It may also damage the bacterial cytoplasmic membrane and inhibit ribonucleic acid (RNA) transcription. Resistance to the antibiotic is most likely caused by failure of the antibiotic to penetrate into the bacterial cell.

The **polymyxins** are a group of cyclic polypeptides derived from *B. polymyxa.* These antibiotics insert into bacterial membranes like detergents by interacting with lipopolysaccharides and the phospholipids in the outer membrane, producing increased cell permeability and eventual cell death. **Polymyxins B** and **E (colistin)** are capable of causing serious nephrotoxicity. Thus their use was limited historically to treatment of localized infections such as external otitis, eye infections, and skin infections caused by sensitive organisms. However, because some organisms such as carbapenemase-producing gram-negative bacteria are only susceptible to colistin, this antibiotic is now frequently used to treat some systemic infections. Unfortunately, resistance to colistin is also becoming widespread, rendering these organisms resistant to almost all antibiotics.

ISONIAZID, ETHIONAMIDE, ETHAMBUTOL, AND CYCLOSERINE

Isoniazid, ethionamide, ethambutol, and cycloserine are cell wall–active antibiotics used for the treatment of mycobacterial infections. **Isoniazid** (isonicotinic acid hydrazide [INH]) is bactericidal against actively replicating mycobacteria. Although the exact mechanism of action is unknown, the synthesis of mycolic acid is affected (desaturation of the long-chain fatty acids and elongation of fatty acids and hydroxy lipids are disrupted). **Ethionamide,** a derivative of INH, also blocks mycolic acid synthesis. **Ethambutol** interferes with the synthesis of arabinogalactan in the cell wall, and **cycloserine** inhibits two enzymes, D-alanine-D-alanine synthetase and alanine racemase, which catalyze cell wall synthesis. Resistance to these four antibiotics results primarily from reduced drug uptake into the bacterial cell or alteration of the target sites.

Inhibition of Protein Synthesis

The primary action of the agents in the second largest class of antibiotics is inhibition of protein synthesis (see Table 17.1).

AMINOGLYCOSIDES

The aminoglycoside antibiotics (Table 17.5) consist of amino sugars linked through glycosidic bonds to an aminocyclitol ring. Streptomycin, neomycin, kanamycin, and tobramycin were originally isolated from *Streptomyces* species, and gentamicin and sisomicin were isolated from *Micromonospora* species. Amikacin and netilmicin are synthetic derivatives of kanamycin and sisomicin, respectively. These antibiotics exert their effort by passing through the bacterial outer membrane (in gram-negative bacteria), cell wall, and cytoplasmic membrane to the cytoplasm, in which they inhibit bacterial protein synthesis by irreversibly binding to the 30S ribosomal proteins. This attachment to the ribosomes has two effects: production of aberrant proteins as the result of misreading of the messenger RNA (mRNA), and interruption of protein synthesis by causing premature release of the ribosome from mRNA.

The aminoglycosides are bactericidal because of their ability to bind irreversibly to ribosomes and are commonly used to treat serious infections caused by many gram-negative rods (e.g., Enterobacteriaceae, *Pseudomonas, Acinetobacter*) and some gram-positive organisms. Penetration through the cytoplasmic membrane is an aerobic, energy-dependent process, so anaerobes are resistant to aminoglycosides, and susceptible organisms in an anaerobic environment (e.g., abscess) do not respond to treatment. Streptococci and enterococci are resistant to aminoglycosides because the aminoglycosides fail to penetrate through the cell wall of these bacteria. Treatment of these organisms requires coadministration of an aminoglycoside with an inhibitor of cell wall synthesis (e.g., penicillin, ampicillin, vancomycin) that facilitates uptake of the aminoglycoside.

The most commonly used antibiotics in this class are **amikacin, gentamicin,** and **tobramycin.** All three aminoglycosides are used to treat systemic infections caused

TABLE 17.5 Inhibitors of Protein Synthesis

Antibiotics	Spectrum of Activity
Aminoglycosides (streptomycin, kanamycin, gentamicin, tobramycin, amikacin)	Primarily used to treat infections with gram-negative rods; kanamycin with limited activity; tobramycin slightly more active than gentamicin versus *Pseudomonas;* amikacin most active; streptomycin and gentamicin combined with cell wall–active antibiotic to treat enterococcal infections; streptomycin active versus mycobacteria and selected gram-negative rods
Aminocyclitol (spectinomycin)	Active versus *Neisseria gonorrhoeae*
Tetracyclines (tetracycline, doxycycline, minocycline)	Broad-spectrum antibiotics active against gram-positive and some gram-negative bacteria (*Neisseria,* some Enterobacteriaceae), mycoplasmas, chlamydiae, and rickettsiae
Glycylcyclines (tigecycline)	Spectrum similar to tetracyclines but more active against gram-negative bacteria and rapidly growing mycobacteria
Oxazolidinone (linezolid)	Active against *Staphylococcus* (including methicillin-resistant and vancomycin-intermediate strains), *Enterococcus, Streptococcus,* gram-positive rods, and *Clostridium* and anaerobic cocci; not active against gram-negative bacteria
Macrolides (erythromycin, azithromycin, clarithromycin, roxithromycin)	Broad-spectrum antibiotics active against gram-positive and some gram-negative bacteria, *Neisseria, Legionella, Mycoplasma, Chlamydia, Chlamydophila, Treponema,* and *Rickettsia;* clarithromycin and azithromycin active against some mycobacteria
Ketolides (telithromycin)	Broad-spectrum antibiotic with activity similar to macrolides; active against some macrolide-resistant staphylococci and enterococci
Lincosamide (clindamycin)	Broad-spectrum activity against aerobic gram-positive cocci and anaerobes
Streptogramins (quinupristin-dalfopristin)	Primarily active against gram-positive bacteria; good activity against methicillin-susceptible and methicillin-resistant staphylococci, streptococci, vancomycin-susceptible and vancomycin-resistant *Enterococcus faecium* (no activity against *E. faecalis*), *Haemophilus, Moraxella*, and anaerobes (including *Bacteroides fragilis*); not active against Enterobacteriaceae or other gram-negative rods

by susceptible gram-negative bacteria. **Amikacin** has the best activity and is frequently reserved for treatment of infections caused by gram-negative bacteria that are resistant to gentamicin and tobramycin. **Streptomycin** is not readily available, but it has been used for the treatment of tuberculosis, tularemia, and gentamicin-resistant streptococcal or enterococcal infections (in combination with a penicillin).

Resistance to the antibacterial action of aminoglycosides can develop in one of four ways: (1) mutation of the ribosomal binding site, (2) decreased uptake of the antibiotic into the bacterial cell, (3) increased expulsion of the antibiotic from the cell, or (4) enzymatic modification of the antibiotic. The most common mechanism of resistance is enzymatic modification of aminoglycosides. This is accomplished by the action of phosphotransferases (aminoglycoside phosphotransferases [APHs]), adenyltransferases (adenine nucleotide translocases [ANTs]), and acetyltransferases (acetyl-CoA carboxylases [AACs]) on the amino and hydroxyl groups of the antibiotic. The differences in antibacterial activity among the aminoglycosides are determined by their relative susceptibility to these enzymes. The other mechanisms by which bacteria develop resistance to aminoglycosides are relatively uncommon. Resistance caused by alteration of the bacterial ribosome requires systematic mutation of the multiple copies of the ribosomal genes that exist in the bacterial cell. Resistance caused by inhibited transport of the antibiotic into the bacterial cell is occasionally observed with *Pseudomonas,* but it is more commonly seen with anaerobic bacteria. This mechanism produces low-level cross-resistance to all aminoglycosides. Active efflux of aminoglycosides occurs only in gram-negative bacteria and is rarely observed.

TETRACYCLINES

The tetracyclines (see Table 17.5) are broad-spectrum, bacteriostatic antibiotics that inhibit protein synthesis in bacteria by binding reversibly to the 30S ribosomal subunits, blocking the binding of aminoacyl-transfer RNA (tRNA) to the 30S ribosome–mRNA complex. Tetracyclines (i.e., **tetracycline, doxycycline, minocycline**) are effective in the treatment of infections caused by *Chlamydia, Mycoplasma,* and *Rickettsia* species and other selected gram-positive and gram-negative bacteria. All tetracyclines have a similar spectrum of activity, with the primary difference among the antibiotics being in their pharmacokinetic properties (doxycycline and minocycline are easily absorbed and have a long half-life). Resistance to the tetracyclines can stem from decreased penetration of the antibiotic into the bacterial cell, active efflux of the antibiotic out of the cell, alteration of the ribosomal target site, or enzymatic modification of the antibiotic. Mutations in the chromosomal gene encoding the outer membrane porin protein, OmpF, can lead to low-level resistance to the tetracyclines, as well as to other antibiotics (e.g., β-lactams, quinolones, chloramphenicol).

Researchers have identified a variety of genes in different bacteria that control active efflux of tetracyclines from the cell. This is the most common cause of resistance. Resistance to the tetracyclines can also result from production of proteins similar to elongation factors that protect the 30S ribosome. When this happens, the antibiotic can still bind to the ribosome, but protein synthesis is not disrupted.

GLYCYLCLINES

Tigecycline, the first representative of this new class of antibiotics, is a semisynthetic derivative of minocycline. It inhibits protein synthesis in the same manner as the

tetracyclines. Tigecycline has a higher binding affinity for the ribosome and is less affected by efflux or enzymatic modification. It has a broad spectrum of activity against gram-positive, gram-negative, and anaerobic bacteria, although *Proteus, Morganella, Providencia*, and *P. aeruginosa* are generally resistant.

OXAZOLIDINONES

The oxazolidinones are a narrow-spectrum class of antibiotics, with **linezolid** being the agent currently used. Linezolid blocks initiation of protein synthesis by interfering with formation of the initiation complex consisting of tRNA, mRNA, and the ribosome. The drug binds to the 50S ribosomal subunit, which distorts the binding site for tRNA, inhibiting formation of the 70S initiation complex. Because of this unique mechanism, cross-resistance with other protein inhibitors does not occur. Linezolid has activity against staphylococci, streptococci, and enterococci (including those strains resistant to penicillins, vancomycin, and the aminoglycosides). Because the multidrug-resistant enterococci are difficult to treat, the use of linezolid is generally reserved for these infections, although the development of resistance is recognized.

CHLORAMPHENICOL

Chloramphenicol has a broad antibacterial spectrum similar to that of tetracycline, but it is not commonly used in the United States. The reason for its limited use is that along with interfering with bacterial protein synthesis, it disrupts protein synthesis in human bone marrow cells and can produce blood dyscrasias, such as aplastic anemia. Chloramphenicol exerts its bacteriostatic effect by binding reversibly to the peptidyl transferase component of the 50S ribosomal subunit, blocking peptide elongation. Resistance to chloramphenicol is observed in bacteria producing plasmid-encoded chloramphenicol acetyltransferase, which catalyzes the acetylation of the 3-hydroxy group of chloramphenicol. The product is incapable of binding to the 50S subunit. Less commonly, chromosomal mutations alter the outer membrane porin proteins, causing gram-negative rods to be less permeable.

MACROLIDES

Erythromycin, derived from *S. erythreus,* is the model macrolide antibiotic (see Table 17.5). The basic structure of this class of antibiotics is a macrocyclic lactone ring bound to two sugars, desosamine and cladinose. Modification of the macrolide structure led to the development of **azithromycin, clarithromycin,** and **roxithromycin.** Macrolides exert their effect by their reversible binding to the 23S ribosomal RNA (rRNA) of the 50S ribosomal subunit, which blocks polypeptide elongation. Resistance to macrolides most commonly stems from methylation of the 23S rRNA, preventing binding by the antibiotic. Other mechanisms of resistance include inactivation of the macrolides by enzymes (e.g., esterases, phosphorylases, glycosidase) or mutations in the 23S rRNA and ribosomal proteins. Macrolides are bacteriostatic antibiotics with a broad spectrum of activity. They have been used to treat pulmonary infections caused by *Mycoplasma, Legionella,* and *Chlamydia* species, as well as to treat infections caused by *Campylobacter* species and gram-positive bacteria in patients allergic to penicillin. Most gram-negative bacteria are resistant to the macrolides. Azithromycin and clarithromycin have also been used to treat infections caused by mycobacteria (e.g., *Mycobacterium avium* complex).

KETOLIDES

Ketolides are semisynthetic derivatives of erythromycin, modified to increase stability in acid. **Telithromycin** is currently the only ketolide available for use in the United States. As with the macrolides, telithromycin binds to the 50S ribosomal subunit and blocks protein synthesis. Its use is currently restricted to treatment of community-acquired pneumonia. It is active against *S. pneumoniae, Legionella, Mycoplasma,* and *Chlamydia,* but use of the drug is limited by its associated toxicity.

CLINDAMYCIN

Clindamycin (in the family of lincosamide antibiotics) is a derivative of lincomycin, which was originally isolated from *S. lincolnensis.* Like chloramphenicol and the macrolides, clindamycin blocks protein elongation by binding to the 50S ribosome. It inhibits peptidyl transferase by interfering with the binding of the amino acid–acyl-tRNA complex. Clindamycin is active against staphylococci and anaerobic gram-negative rods, but it is generally inactive against aerobic gram-negative bacteria. Methylation of the 23S rRNA is the source of bacterial resistance. Because both erythromycin and clindamycin can induce this enzymatic resistance (also plasmid mediated), cross-resistance between these two classes of antibiotics is observed.

STREPTOGRAMINS

The streptogramins are a class of cyclic peptides produced by *Streptomyces* species. These antibiotics are administered as a combination of two components, group A and group B streptogramins, which act synergistically to inhibit protein synthesis. The antibiotic currently available in this class is **quinupristin-dalfopristin.** Dalfopristin binds to the 50S ribosomal subunit and induces a conformational change that facilitates binding of quinupristin. Dalfopristin prevents peptide chain elongation, and quinupristin initiates premature release of peptide chains from the ribosome. This combination drug is active against staphylococci, streptococci, and *E. faecium* (but not *E. faecalis*). Use of the antibiotic has been restricted primarily to treating vancomycin-resistant *E. faecium* infections.

Inhibition of Nucleic Acid Synthesis

QUINOLONES

The quinolones (Table 17.6) are one of the most widely used classes of antibiotics. These are synthetic chemotherapeutic agents that inhibit bacterial deoxyribonucleic acid (DNA) topoisomerase type II (gyrase) or topoisomerase type IV,

TABLE 17.6 Quinolones

Antibiotics	Spectrum of Activity
Narrow spectrum (nalidixic acid)	Active against selected gram-negative rods; no useful gram-positive activity
Broad spectrum (ciprofloxacin, levofloxacin)	Broad-spectrum antibiotics with activity against gram-positive and gram-negative bacteria
Extended spectrum (moxifloxacin)	Broad-spectrum antibiotics with enhanced activity against gram-positive bacteria (particularly streptococci and enterococci) compared with early quinolones; activity against gram-negative rods similar to that of ciprofloxacin and related quinolones

which are required for DNA replication, recombination, and repair. The DNA gyrase-A subunit is the primary quinolone target in gram-negative bacteria, whereas topoisomerase type IV is the primary target in gram-positive bacteria. The first quinolone used in clinical practice was **nalidixic acid.** This drug was used to treat urinary tract infections caused by a variety of gram-negative bacteria, but resistance to the drug developed rapidly, causing it to fall out of use. This drug has now been replaced by newer, more active quinolones, such as **ciprofloxacin, levofloxacin,** and **moxifloxacin.** Modifying the two-ring quinolone nucleus made these newer quinolones (referred to as *fluoroquinolones*). These antibiotics have excellent activity against gram-positive and gram-negative bacteria, although resistance can develop rapidly in *Pseudomonas,* oxacillin-resistant staphylococci, and enterococci. In particular, the newer extended-spectrum quinolones have significant activity against gram-positive bacteria.

Resistance to the quinolones is mediated by chromosomal mutations in the structural genes for DNA gyrase and topoisomerase type IV. Other mechanisms include decreased drug uptake caused by mutations in the membrane permeability regulatory genes, and overexpression of efflux pumps that actively eliminate the drug. Each of these mechanisms is primarily chromosomally mediated.

RIFAMPIN AND RIFABUTIN

Rifampin, a semisynthetic derivative of rifamycin B produced by *S. mediterranei,* binds to DNA-dependent RNA polymerase, and inhibits initiation of RNA synthesis. Rifampin is bactericidal for *M. tuberculosis* and is very active against aerobic gram-positive cocci, including staphylococci and streptococci.

Because resistance can develop rapidly, rifampin is usually combined with one or more other effective antibiotics. Rifampin resistance in gram-positive bacteria results from a mutation in the chromosomal gene that codes for the β subunit of RNA polymerase. Gram-negative bacteria are resistant intrinsically to rifampin because of decreased uptake of the hydrophobic antibiotic. **Rifabutin,** a derivative of rifamycin, has a similar mode and spectrum of activity. It is particularly active against *M. avium.*

METRONIDAZOLE

Metronidazole was originally introduced as an oral agent for the treatment of *Trichomonas* vaginitis. However, it was also found to be effective in the treatment of amebiasis, giardiasis, and serious anaerobic bacterial infections (including those caused by *B. fragilis*). Metronidazole has no significant activity against aerobic or facultatively anaerobic bacteria. The antimicrobial properties of metronidazole stem from the reduction of its nitro group by bacterial nitroreductase, producing cytotoxic compounds that disrupt the host DNA. Resistance results either from decreased uptake of the antibiotic or from elimination of the cytotoxic compounds before they can interact with host DNA.

ANTIMETABOLITES

The **sulfonamides** are antimetabolites that compete with *p*-aminobenzoic acid, preventing synthesis of the folic acid required by certain microorganisms. Because mammalian organisms do not synthesize folic acid (required as a vitamin), sulfonamides do not interfere with mammalian cell metabolism. **Trimethoprim** is another antimetabolite that interferes with folic acid metabolism by inhibiting dihydrofolate reductase, preventing the conversion of dihydrofolate to tetrahydrofolate. This inhibition blocks the formation of thymidine, some purines, methionine, and glycine. Trimethoprim is commonly combined with sulfamethoxazole to produce a synergistic combination active at two steps in the synthesis of folic acid. **Dapsone** and ***p*-aminosalicylic** acid are also antifolates that have proved to be useful for treating mycobacterial infections.

Sulfonamides are effective against a broad range of gram-positive and gram-negative organisms, such as *Nocardia, Chlamydia,* and some protozoa. Short-acting sulfonamides, such as sulfisoxazole, are among the drugs of choice for the treatment of acute urinary tract infections caused by susceptible bacteria, such as *E. coli.* Trimethoprim-sulfamethoxazole is effective against a large variety of gram-positive and gram-negative microorganisms and is the drug of choice for the treatment of acute and chronic urinary tract infections. The combination is also effective in the treatment of infections caused by *Pneumocystis jirovecii,* bacterial infections of the lower respiratory tract, otitis media, and uncomplicated gonorrhea.

Resistance to these antibiotics can stem from a variety of mechanisms. Bacteria such as *Pseudomonas* are resistant as the result of permeability barriers. A decreased affinity of dihydrofolate reductase can be the source of trimethoprim resistance. In addition, bacteria that use exogenous thymidine (e.g., enterococci) are also intrinsically resistant.

Other Antibiotics

Clofazimine is a lipophilic antibiotic that binds to mycobacterial DNA. It is highly active against *M. tuberculosis,* is a first-line drug for the treatment of *M. leprae* infections, and has been recommended as a secondary antibiotic for the treatment of infections caused by other mycobacterial species.

Pyrazinamide (PZA) is active against *M. tuberculosis* at a low pH, such as that found in phagolysosomes. The active form of this antibiotic is pyrazinoic acid, which is produced when PZA is hydrolyzed in the liver. The mechanism by which PZA exerts its effect is unknown.

Questions

1. Describe the mode of action of the following antibiotics: penicillin, vancomycin, isoniazid, gentamicin, tetracycline, erythromycin, polymyxin, ciprofloxacin, and sulfamethoxazole.

2. Name the three mechanisms bacteria use to become resistant to β-lactam antibiotics. What is the mechanism responsible for oxacillin resistance in *Staphylococcus*? Imipenem resistance in *Pseudomonas*? Penicillin resistance in *S. pneumoniae*?

3. By what three mechanisms have organisms developed resistance to aminoglycosides?

4. What mechanism is responsible for resistance to the quinolones?

5. How do trimethoprim and the sulfonamides differ in their mode of action?

18 Staphylococcus *and Related Gram-Positive Cocci*

A 26-year-old marine recruit presents to the base medic with large, pus-filled lesions surrounded by erythema on both legs. Infection with Staphylococcus aureus is suspected.

1. What structural properties are unique to this species of *Staphylococcus?*
2. How do the cytotoxins produced by this organism produce the clinical manifestations seen in this patient?
3. Three additional distinct toxins are described in strains of *S. aureus.* What diseases are associated with these toxins?
4. Resistance to what major class of antibiotics is now common in community-acquired infections with *S. aureus?*

Answers to these questions are available on Student Consult.com.

The gram-positive cocci are a heterogeneous collection of bacteria. Features they have in common are their spherical

Summaries Clinically Significant Organisms

STAPHYLOCOCCUS AUREUS

Trigger Words

Coagulase, cytotoxins, exfoliative toxins, enterotoxins, toxic shock syndrome toxin, MRSA

Biology and Virulence

- Catalase-positive, gram-positive cocci arranged in clusters
- Species characterized by the presence of coagulase and protein A
- Virulence factors include structural components that facilitate adherence to host tissues and avoid phagocytosis, and a variety of toxins and hydrolytic enzymes (refer to Table 18.3)
- Hospital- and community-acquired infections with MRSA are a significant worldwide problem

Epidemiology

- Normal flora on human skin and mucosal surfaces
- Organisms can survive on dry surfaces for long periods (because of thickened peptidoglycan layer and absence of outer membrane)
- Person-to-person spread through direct contact or exposure to contaminated fomites (e.g., bed linens, clothing)
- Risk factors include presence of a foreign body (e.g., splinter, suture, prosthesis, catheter), previous surgical procedure, and use of antibiotics that suppress the normal microbial flora
- Patients at risk for specific diseases include infants (scalded skin syndrome), young children with poor personal hygiene (impetigo and other cutaneous infections), patients with intravascular catheters (bacteremia and endocarditis) or shunts (meningitis), and patients with compromised pulmonary function or an antecedent viral respiratory infection (pneumonia)
- MRSA is now the most common cause of community-acquired skin and soft-tissue infections

Diseases

- Diseases include toxin-mediated diseases (food poisoning, toxic shock syndrome, and scalded skin syndrome), pyogenic diseases (impetigo, folliculitis, furuncles, carbuncles, and wound infections), and other systemic diseases

Diagnosis

- Microscopy useful for pyogenic infections but not blood infections or toxin-mediated infections
- Staphylococci grow rapidly when cultured on nonselective media
- Selective media (e.g., chromogenic agar, mannitol-salt agar) can be used to recover *Staphylococcus aureus* in contaminated specimens
- Nucleic acid amplification tests are useful for screening patients for carriage of methicillin-sensitive *S. aureus* (MSSA) and MRSA
- *S. aureus* is identified by biochemical tests (e.g., coagulase), molecular probes, or mass spectrometry

Treatment, Prevention, and Control

- Localized infections managed by incision and drainage; antibiotic therapy indicated for systemic infections
- Empirical therapy should include antibiotics active against MRSA strains
- Oral therapy can include trimethoprim-sulfamethoxazole, doxycycline or minocycline, clindamycin, or linezolid; vancomycin is drug of choice for intravenous therapy, with daptomycin, tigecycline, or linezolid acceptable alternatives
- Treatment is symptomatic for patients with food poisoning (although the source of infection should be identified so that appropriate preventive procedures can be enacted)
- Proper cleansing of wounds and use of disinfectant help prevent infections
- Thorough hand washing and covering of exposed skin helps medical personnel prevent infection or spread to other patients

COAGULASE-NEGATIVE STAPHYLOCOCCI

Trigger Words

Opportunistic, slime layer, subacute

Biology and Virulence

- Catalase-positive, coagulase-negative, gram-positive cocci arranged in clusters
- Relatively avirulent, although production of a "slime" layer can allow adherence to foreign bodies (e.g., catheters, grafts, prosthetic valves and joints, shunts) and protection from phagocytosis and antibiotics

Epidemiology

- Normal human flora on skin and mucosal surfaces
- Organisms can survive on dry surfaces for long periods
- Person-to-person spread through direct contact or exposure to contaminated fomites, although most infections are with the patient's own organisms
- Patients are at risk when a foreign body is present
- The organisms are ubiquitous, so there are no geographic or seasonal limitations

Diseases

- Infections include subacute endocarditis, infections of foreign bodies, and urinary tract infections

Diagnosis

- As with *S. aureus* infections

Treatment, Prevention, and Control

- The antibiotics of choice are oxacillin (or other penicillinase-resistant penicillin) or vancomycin for oxacillin-resistant strains
- Removal of the foreign body is often required for successful treatment
- Prompt treatment for endocarditis or shunt infections is necessary to prevent further tissue damage or immune complex formation

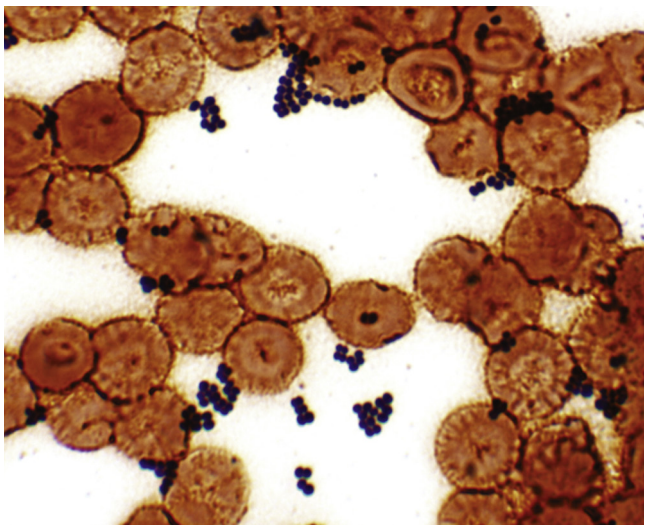

Fig. 18.1 Gram stain of *Staphylococcus* in a blood culture.

TABLE 18.1 Important Staphylococci

Organism	Historical Derivation
Staphylococcus	*staphylé*, bunch of grapes; coccus, grain or berry (grapelike cocci)
S. aureus	*aureus*, golden (golden or yellow)
S. epidermidis	*epidermidis*, outer skin (of the epidermis or outer skin)
S. lugdunensis	*Lugdunum*, Latin name for Lyon, France, where the organism was first isolated
S. saprophyticus	*sapros*, putrid; phyton, plant (saprophytic or growing on dead tissues)

TABLE 18.2 Common *Staphylococcus* Species and Their Diseases

Organism	Diseases
Staphylococcus aureus	Toxin mediated (food poisoning, scalded skin syndrome, and toxic shock syndrome), cutaneous (carbuncles, folliculitis, furuncles, impetigo, and wound infections), other (bacteremia, endocarditis, pneumonia, empyema, osteomyelitis, and septic arthritis)
S. epidermidis	Bacteremia; endocarditis; surgical wounds; opportunistic infections of catheters, shunts, and prosthetic devices
S. lugdunensis	Endocarditis
S. saprophyticus	Urinary tract infections

shape, their Gram-stain reaction, and an absence of endospores. The presence or absence of catalase, an enzyme that converts hydrogen peroxide into water and oxygen, is used to subdivide the various genera. The most important aerobic catalase-positive genus is *Staphylococcus* (discussed in this chapter), and the most important aerobic catalase-negative genera, *Streptococcus* and *Enterococcus*, are discussed in the next chapter.

Staphylococci are gram-positive cocci that grow in a characteristic pattern resembling a cluster of grapes (Fig. 18.1 and Table 18.1), although organisms in clinical specimens commonly appear as single cells, pairs, or short chains. Most staphylococci are large, 0.5 to 1.5 μm in diameter, and they are able to grow and potentially produce disease in a variety of conditions: aerobic and anaerobic atmosphere, in the presence of a high concentration of salt (e.g., 10% sodium chloride), and at temperatures ranging from 18° C to 40° C. The genus currently consists of more than 80 species and subspecies, many of which are found on the skin and mucous membranes of humans. Some species have very specific niches in which they are commonly found. For example, *S. aureus* colonizes the anterior nares, *S. capitis* is found where sebaceous glands are present (e.g., forehead), and *S. haemolyticus* and *S. hominis* are found in areas in which apocrine glands are present (e.g., axilla). Staphylococci are important pathogens in humans, causing opportunistic infections and a wide spectrum of life-threatening systemic diseases, including infections of the skin, soft tissues, bones, and urinary tract (Table 18.2). The species most commonly associated with human diseases are ***S. aureus*** (the most virulent and best known member of the genus), ***S. epidermidis, S. lugdunensis,*** and ***S. saprophyticus.*** **MRSA** is notorious for producing serious infections in hospitalized patients and outside the hospital in previously healthy children and adults. *S. aureus* colonies can have a yellow or gold color as the result of the carotenoid pigments that form during their growth, hence the species name. It is also the most common species in humans that produces the enzyme **coagulase;** therefore this property is a useful diagnostic test. When a colony of *S. aureus* is suspended in plasma, coagulase binds to a serum factor and this complex converts fibrinogen to fibrin, resulting in formation of a clot. Most other staphylococcal species do not produce coagulase and are referred to collectively as **coagulase-negative staphylococci.** This is a useful distinction because the coagulase-negative staphylococci are less virulent and primarily cause opportunistic infections.

Physiology and Structure

CAPSULE AND SLIME LAYER

The outermost layer of the cell wall of many staphylococci is covered with a **polysaccharide capsule.** A number of capsular serotypes have been identified in *S. aureus.* Serotypes 1 and 2 are associated with very thick capsules and mucoid-appearing colonies, but they are rarely associated with human disease. In contrast, serotypes 5 and 8 are associated with approximately 75% of infections in humans. The capsule protects the bacteria by inhibiting phagocytosis of the organisms by polymorphonuclear leukocytes (PMNs). A loose-bound, water-soluble film **(slime layer** or **biofilm)** consisting of monosaccharides, proteins, and small peptides is produced by most staphylococci in varying amounts. This extracellular substance binds the bacteria to tissues

and foreign bodies such as catheters, grafts, prosthetic valves and joints, and shunts and is particularly important for survival of the relatively avirulent coagulase-negative staphylococci.

PEPTIDOGLYCAN AND ASSOCIATED ENZYMES

An understanding of the structure of the gram-positive bacterial cell wall is important because this is the target of many important antibiotics. Half of the cell wall by weight is **peptidoglycan,** consisting of layers of glycan chains built with 10 to 12 alternating subunits of *N*-acetylmuramic acid and *N*-acetylglucosamine. Oligopeptide side chains are attached to the *N*-acetylmuramic acid subunits and are then cross-linked with peptide bridges. Unlike gram-negative bacteria, the peptidoglycan layer in gram-positive organisms consists of **many cross-linked layers,** which makes the cell wall more rigid. The **enzymes** that catalyze construction of the peptidoglycan layer are called **penicillin-binding proteins** because these are the targets of penicillins and other β-lactam antibiotics. Bacterial resistance to methicillin and related penicillins and cephalosporins is mediated by acquisition of a gene (*mec*A and *mec*C) that codes for a novel penicillin-binding protein, PBP2a, which has a low affinity for methicillin and related penicillins and cephalosporins (refer to the section "Treatment, Prevention, and Control" for additional details). The ***mec*A gene** is located on the staphylococcal cassette chromosome mec (SCC*mec*), and multiple gene sequences of this cassette are described. This information is relevant because **MRSA** strains, previously restricted to hospital-acquired infections, are now present in the community and responsible for the majority of staphylococcal infections. Although the hospital and community strains were initially distinct, movement into and out of the hospital is common, so no MRSA strain is found exclusively in either setting.

The peptidoglycan has endotoxin-like activity, stimulating the production of endogenous pyrogens, activation of complement, production of interleukin (IL)-1 from monocytes, and aggregation of PMNs (a process responsible for abscess formation).

TEICHOIC ACIDS AND LIPOTEICHOIC ACIDS

Teichoic acids are the other major component of the cell wall. Teichoic acids are **species-specific**, phosphate-containing polymers that are bound either covalently to *N*-acetylmuramic acid residues of the peptidoglycan layer or to the lipids in the cytoplasmic membrane **(lipoteichoic acids).** Although the teichoic acids are poor immunogens, a specific antibody response is stimulated when they are bound to peptidoglycan. The production of antibodies was used initially as a marker of *S. aureus* infection, but this insensitive test has been abandoned in recent years.

SURFACE ADHESION PROTEINS

A large collection of surface proteins have been identified in *S. aureus* that are important virulence factors because they adhere to host matrix proteins bound to host tissues (e.g., fibronectin, fibrinogen, elastin, collagen). Most of these surface adhesion proteins are covalently bound to the cell wall peptidoglycan in staphylococci and have been designated ***m*icrobial *s*urface *c*omponents *r*ecognizing *a*dhesive *m*atrix *m*olecules (MSCRAMM) proteins.** The nomenclature for the individual proteins is confusing; for example, staphylococcal protein A *(spa)* binds to the Fc receptor of immunoglobulin (Ig)G1, IgG2, and IgG4; fibronectin-binding protein A binds fibronectin as the name indicates; and *S. aureus* surface protein A has an undetermined function. The best characterized MSCRAMM proteins are staphylococcal protein A, fibronectin-binding proteins A and B, and clumping factor proteins A and B. The clumping factor proteins (also called **coagulase**) bind fibrinogen and convert it to insoluble fibrin, causing the staphylococci to clump or aggregate. All this can be a bit confusing so it is important to remember two facts: (1) *S. aureus* has a number of proteins on the bacterial surface that allow the organisms to bind to host cells and establish infection, and (2) some of these proteins are unique for *S. aureus* and serve to identify the organism.

CYTOPLASMIC MEMBRANE

The **cytoplasmic membrane** is made up of a complex of proteins, lipids, and a small amount of carbohydrates. It serves as an osmotic barrier for the cell and provides an anchorage for the cellular biosynthetic and respiratory enzymes.

Pathogenesis and Immunity

The ability of staphylococci to cause disease depends on the ability of the bacteria to **evade** immune clearance, produce surface proteins that mediate **adherence** of the bacteria to host tissues during colonization, and produce disease through the elaboration of specific toxins and hydrolytic enzymes leading to **tissue destruction** (Table 18.3). These properties, immunologic evasion, adherence, tissue destruction, are common to most pathogenic organisms.

REGULATION OF VIRULENCE GENES

Expression of virulence factors and biofilm formation in staphylococci is under the complex control of the **accessory gene regulator (*agr*) operon.** This quorum-sensing (bacterial density) control system allows expression of adhesion adherence proteins and promotes tissue colonization and intracellular growth when the density of bacteria is low and tissue invasion and production of hydrolytic enzymes and toxins when the density is high. The operon encodes autoinducer peptides (AIP1 to 4) that bind to cell-surface receptors and regulate protein expression based on the population density. The innate immune regulation of bacterial virulence is mediated by apolipoprotein B, which is the major structural protein of very low density and low-density lipoproteins (VLDL, LDL), which bind to AIPs and suppresses *agr* signaling. Thus, under optimal conditions, the bacterial density is maintained at a low concentration, providing the benefits of immune stimulation by colonizing staphylococci without the consequences of tissue invasion and destruction.

TABLE 18.3 *Staphylococcus aureus* Virulence Factors

Virulence Factors	Biological Effects
STRUCTURAL COMPONENTS	
Capsule	Inhibits chemotaxis and phagocytosis; inhibits proliferation of mononuclear cells
Slime layer	Facilitates adherence to foreign bodies
Peptidoglycan	Provides osmotic stability; stimulates production of endogenous pyrogen (endotoxin-like activity); leukocyte chemoattractant (abscess formation); inhibits phagocytosis
Teichoic acid	Binds to fibronectin
Protein A	Inhibits antibody-mediated clearance by binding IgG1, IgG2, and IgG4 Fc receptors; leukocyte chemoattractant; anticomplementary
TOXINS	
Cytotoxins	Toxic for many cells, including erythrocytes, fibroblasts, leukocytes, macrophages, and platelets
Exfoliative toxins (ETA, ETB)	Serine proteases that split the intercellular bridges in the stratum granulosum epidermis
Enterotoxins	Superantigens (stimulate proliferation of T cells and release of cytokines); stimulate release of inflammatory mediators in mast cells, increasing intestinal peristalsis and fluid loss, as well as nausea and vomiting
Toxic shock syndrome toxin-1	Superantigen (stimulates proliferation of T cells and release of cytokines); produces leakage or cellular destruction of endothelial cells
ENZYMES	
Coagulase	Converts fibrinogen to fibrin
Hyaluronidase	Hydrolyzes hyaluronic acids in connective tissue, promoting spread of staphylococci in tissue
Fibrinolysin	Dissolves fibrin clots
Lipases	Hydrolyze lipids
Nucleases	Hydrolyze DNA

DNA, Deoxyribonucleic acid; *Ig,* immunoglobulin.

DEFENSES AGAINST INNATE IMMUNITY

Opsonins (i.e., IgG, complement factor C3) in serum bind to encapsulated staphylococci, but the **capsule** protects the bacteria by inhibiting phagocytosis of the organisms by PMNs. However, in the presence of specific antibodies directed against the staphylococci, increased C3 is bound to the bacteria and leads to phagocytosis. The extracellular **slime layer** also interferes with phagocytosis of bacteria. The ability of **protein A** to bind immunoglobulins effectively prevents antibody-mediated immune clearance of the *S. aureus*. Additionally, extracellular protein A can bind antibodies and form immune complexes, with the subsequent consumption of the complement.

STAPHYLOCOCCAL TOXINS

S. aureus produces many toxins, including five cytolytic or membrane-damaging toxins (alpha, beta, delta, gamma, and P-V leukocidin), two exfoliative toxins (A and B), numerous enterotoxins (A to E, G to X, plus multiple variants), and TSST-1. The cytolytic toxins are described as hemolysins, but this is a misnomer because the activities of the first four toxins are not restricted solely to red blood cells, and P-V leukocidin is unable to lyse erythrocytes. Cytotoxins can lyse neutrophils, resulting in the release of lysosomal enzymes that subsequently damage surrounding tissues. One cytotoxin, P-V leukocidin, is linked to severe pulmonary and cutaneous infections.

Exfoliative toxin A, the enterotoxins, and TSST-1 belong to a class of polypeptides known as **superantigens.** These toxins bind to class II major histocompatibility complex (MHC II) molecules on macrophages, which in turn interact with the ***v***ariable regions of the **β** subunit of specific **T-c**ell ***r***eceptors **(VβTCR).** This results in a massive release of cytokines by both macrophages (IL-1β and tumor necrosis factor [TNF]-α) and T cells (IL-2, interferon [IFN]-γ, and TNF-β). Release of IL-1β is associated with fever, and release of TNF-α and TNF-β is associated with hypotension and shock.

Cytotoxins

Alpha toxin, which is encoded on both the bacterial chromosome and a plasmid, is a 33,000-Da polypeptide produced by most strains of *S. aureus* that cause human disease. The toxin disrupts the smooth muscle in blood vessels and is toxic to many types of cells, including erythrocytes, leukocytes, hepatocytes, and platelets. Alpha toxin binds to the cell surface, aggregates into a heptamer (seven toxin molecules) forming a 1- to 2-nm pore, and allows the rapid efflux of K^+ and influx of Na^+, Ca^{2+}, and other small molecules, which leads to osmotic swelling and cell lysis. Alpha toxin is believed to be an important mediator of tissue damage in staphylococcal disease.

Beta toxin, also called **sphingomyelinase C,** is a 35,000-Da heat-labile protein produced by most strains of *S. aureus* responsible for disease in humans and animals. This enzyme has a specificity for sphingomyelin and lysophosphatidylcholine and is toxic to a variety of cells, including erythrocytes, fibroblasts, leukocytes, and macrophages. It catalyzes the hydrolysis of membrane phospholipids in susceptible cells, with lysis proportional to the concentration of sphingomyelin exposed on the cell surface. This is believed to be responsible for the differences in species susceptibility to the toxin. The effect on erythrocytes occurs primarily at low temperatures, so this toxin may be less efficient than other hemolysins.

Delta toxin is a 3000-Da polypeptide produced by almost all *S. aureus* strains and other staphylococci (e.g., *S. epidermidis, S. haemolyticus*). The toxin has a wide spectrum of cytolytic activity, affecting erythrocytes, many other mammalian cells, and intracellular membrane structures. This relatively nonspecific membrane toxicity is consistent with the belief that the toxin acts as a surfactant, disrupting cellular membranes by means of a detergent-like action.

Gamma toxin (made by almost all *S. aureus* strains) and **P-V leukocidin** are bicomponent toxins composed of two polypeptide chains: the S (slow-eluting proteins) component and F (fast-eluting proteins) component. Three unique S proteins (HlgA [hemolysin gamma A], HlgC, and LukS-PV) and two F proteins (HlgB and LukF-PV) have been identified. Bacteria capable of producing both toxins can encode all these proteins, with the potential for producing six

distinct toxins. All six toxins can lyse neutrophils and macrophages, whereas the greatest hemolytic activity is associated with HlgA/HlgB, HlgC/HlgB, and HlgA/LukF-PV. The PV leukocidin toxin (LukS-PV/LukF-PV) is leukotoxic but has no hemolytic activity. Cell lysis by the gamma and PV leukocidin toxins is mediated by pore formation, with subsequent increased permeability to cations and osmotic instability.

Exfoliative Toxins

SSSS, a spectrum of diseases characterized by exfoliative dermatitis, is mediated by exfoliative toxins. The prevalence of toxin production in *S. aureus* strains varies geographically but is generally less than 5%. Two distinct forms of exfoliative toxin (ETA and ETB) have been identified, and either can produce disease. ETA is heat stable and the gene is phage associated, whereas ETB is heat labile and located on a plasmid. The toxins are **serine proteases** that split desmoglein-1, which is a member of a family of cell adhesion structures (desmosomes) responsible for forming the intercellular bridges in the stratum granulosum epidermis. The toxins are not associated with cytolysis or inflammation, so neither staphylococci nor leukocytes are typically present in the involved layer of the epidermis (this is an important **diagnostic clue**). After exposure of the epidermis to the toxin, protective neutralizing antibodies develop, leading to resolution of the toxic process. SSSS is seen mostly in young children and only rarely in older children and adults.

Enterotoxins

Numerous distinct **staphylococcal enterotoxins** have been identified, with enterotoxin A most commonly associated with food poisoning. Enterotoxins C and D are found in contaminated milk products, and enterotoxin B causes staphylococcal pseudomembranous enterocolitis. Less is known about the prevalence or clinical importance of the other enterotoxins. The enterotoxins are designed perfectly for causing foodborne disease (stable to heating at 100° C for 30 minutes and resistant to hydrolysis by gastric and jejunal enzymes). Thus once a food product has been contaminated with enterotoxin-producing staphylococci and the toxins have been produced, neither mild reheating of the food nor exposure to gastric acids will be protective. These toxins are produced by 30% to 50% of all *S. aureus* strains. The precise mechanism of toxin activity is not understood. These toxins are **superantigens** capable of inducing nonspecific activation of T cells and massive cytokine release. Characteristic histologic changes in the stomach and jejunum include infiltration of neutrophils into the epithelium and underlying lamina propria, with loss of the brush border in the jejunum. Stimulation of release of inflammatory mediators from mast cells is believed to be responsible for the emesis that is characteristic of staphylococcal food poisoning.

Toxic Shock Syndrome Toxin-1

TSST-1 is a 22,000-Da heat- and proteolysis-resistant, chromosomally mediated exotoxin. It is estimated that 90% of *S. aureus* strains responsible for menstruation-associated TSS and half of the strains responsible for other forms of TSS produce TSST-1. Enterotoxin B and (rarely) enterotoxin C are responsible for approximately half the cases of nonmenstruation-associated TSS. Expression of TSST-1 in vitro requires an elevated oxygen concentration and neutral pH. This is likely the reason TSS is relatively uncommon compared with the incidence of *S. aureus* wound infections (a setting in which the environment of an abscess is relatively anaerobic and acidic). TSST-1 is a **superantigen** that stimulates release of cytokines, producing leakage of endothelial cells at low concentrations and a cytotoxic effect to the cells at high concentrations. The ability of TSST-1 to penetrate mucosal barriers, even though the infection remains localized in the vagina or at the site of a wound, is responsible for the systemic effects of TSS. Death in patients with TSS is caused by hypovolemic shock leading to multiorgan failure.

STAPHYLOCOCCAL ENZYMES

S. aureus strains possess two forms of **coagulase:** bound and free. Coagulase bound to the staphylococcal cell wall can directly convert fibrinogen to insoluble fibrin and cause the staphylococci to clump. The cell-free coagulase accomplishes the same result by reacting with a globulin plasma factor **(coagulase-reacting factor)** to form staphylothrombin, which is a thrombin-like factor. This factor catalyzes the conversion of fibrinogen to insoluble fibrin. The role of coagulase in the pathogenesis of disease is speculative, but coagulase may cause the formation of a fibrin layer around a staphylococcal abscess, localizing the infection and protecting the organisms from phagocytosis. Some other species of staphylococci produce coagulase, but these are primarily animal pathogens and uncommonly recovered in human infections.

Staphylococci produce a variety of other enzymes that hydrolyze host tissue components and aid in bacterial spread. **Hyaluronidase** hydrolyzes hyaluronic acids, which are present in the acellular matrix of connective tissue. **Fibrinolysin,** also called staphylokinase, can dissolve fibrin clots. All strains of *S. aureus* and more than 30% of the strains of coagulase-negative S*taphylococcus* produce several different **lipases** that hydrolyze lipids and ensure survival of staphylococci in the sebaceous areas of the body. *S. aureus* also produces a thermostable **nuclease** that can hydrolyze viscous deoxyribonucleic acid (DNA).

Epidemiology

Staphylococci are **ubiquitous.** All persons have coagulase-negative staphylococci on their skin, and transient colonization of moist skinfolds with *S. aureus* is common. Colonization of the umbilical stump, skin, and perineal area of neonates with *S. aureus* is common. *S. aureus* and coagulase-negative staphylococci are also found in the nares, oropharynx, gastrointestinal tract, and urogenital tract. Short-term or persistent *S. aureus* carriage in older children and adults is more common in the anterior **nasopharynx** than in the oropharynx. Approximately 15% of normal healthy adults are persistent nasopharyngeal carriers of *S. aureus,* with a higher incidence reported for hospitalized patients, medical personnel, persons with

eczematous skin diseases, and those who regularly use needles, either illicitly (e.g., drug abusers) or for medical reasons (e.g., patients with insulin-dependent diabetes, patients receiving allergy injections, or those undergoing hemodialysis). Adherence of the organism to the mucosal epithelium is regulated by the staphylococcal cell-surface adhesins.

Because staphylococci are found on the skin and in the nasopharynx, shedding of the bacteria is common and is responsible for many hospital-acquired infections. Staphylococci are susceptible to high temperatures and disinfectants and antiseptic solutions; however, the organisms can survive on dry surfaces for long periods. The organisms can be transferred to a susceptible person either through direct contact or through contact with fomites (e.g., contaminated clothing, bed linens). Therefore medical personnel must use proper hand-washing techniques to prevent transfer of staphylococci from themselves to patients or among patients.

Beginning in the 1980s, strains of MRSA spread rapidly in susceptible hospitalized patients, dramatically changing the therapy available for preventing and treating staphylococcal infections. Although MRSA infections were relatively uncommon among healthy individuals in the community, a dramatic change was observed in 2003 when new strains of MRSA were reported to be responsible for outbreaks of community-acquired cutaneous infections and severe pneumonia. Interestingly, the strains were not related to strains circulating in hospitals, and strains isolated in each country were genetically unique. Unfortunately, the community strains have moved into hospitals in the last decade, complicating the control measures previously established. Hospitalized patients are now susceptible to infections caused by strains either acquired in the community or the hospital.

Clinical Diseases

STAPHYLOCOCCUS AUREUS

The clinical manifestations of some *S. aureus* diseases are almost exclusively the result of toxin activity (e.g., SSSS, staphylococcal food poisoning, and TSS), whereas other diseases result from proliferation of the organisms, leading to abscess formation and tissue destruction (e.g., cutaneous infections, endocarditis, pneumonia, empyema, osteomyelitis, septic arthritis) (Box 18.1 and Fig. 18.2). In the presence of a foreign body (e.g., splinter, catheter, shunt, prosthetic valve or joint), the introduction of small numbers of staphylococci can establish disease. Likewise, patients with congenital diseases associated with an impaired chemotactic or phagocytic response (e.g., Job syndrome, Wiskott-Aldrich syndrome, chronic granulomatous disease) are more susceptible to staphylococcal diseases.

Staphylococcal Scalded Skin Syndrome

In 1878, Gottfried Ritter von Rittershain described 297 infants younger than 1 month old who had bullous exfoliative dermatitis. The disease he described, now called **Ritter disease** or SSSS, is characterized by the abrupt onset of a localized perioral erythema (redness and inflammation around the mouth) that spreads over the entire body within 2 days. Slight pressure displaces the skin (a positive Nikolsky sign), and large bullae or **cutaneous blisters** form soon thereafter, followed by desquamation of the epithelium (Fig. 18.3). The blisters contain clear fluid but no organisms or leukocytes, which is a finding consistent with the fact that the disease is caused by the bacterial toxin. The epithelium becomes intact again within 7 to 10 days, when antibodies against the toxin appear. Scarring does not occur because only the top layer of epidermis is affected.

BOX 18.1 Staphylococcal Diseases: Clinical Summaries

Staphylococcus aureus

Toxin-Mediated Diseases

Scalded skin syndrome: Disseminated desquamation of epithelium in infants; blisters with no organisms or leukocytes
Food poisoning: After consumption of food contaminated with heat-stable enterotoxin, rapid onset of severe vomiting, diarrhea, and abdominal cramping, with resolution within 24 hours
Toxic shock: multisystem intoxication characterized initially by fever, hypotension, and a diffuse, macular, erythematous rash; high mortality without prompt antibiotic therapy and elimination of the focus of infection

Suppurative Infections

Impetigo: localized cutaneous infection characterized by pus-filled vesicle on an erythematous base
Folliculitis: impetigo involving hair follicles
Furuncles or boils: large, painful, pus-filled cutaneous nodules
Carbuncles: Coalescence of furuncles with extension into subcutaneous tissues and evidence of systemic disease (fever, chills, bacteremia)
Bacteremia and endocarditis: Spread of bacteria into the blood from a focus of infection; endocarditis characterized by damage to the endothelial lining of the heart
Pneumonia and empyema: Consolidation and abscess formation in the lungs; seen in the very young and elderly and in patients with underlying or recent pulmonary disease; a severe form of necrotizing pneumonia with septic shock and high mortality is now recognized
Osteomyelitis: Destruction of bones, particularly the metaphyseal area of long bones
Septic arthritis: Painful erythematous joint with collection of purulent material in the joint space

Coagulase-Negative *Staphylococcus* Species

Wound infections: Characterized by erythema and pus at the site of a traumatic or surgical wound; infections with foreign bodies can be caused by *S. aureus* and coagulase-negative staphylococci
Urinary tract infections: Dysuria and pyuria in young sexually active women (*S. saprophyticus*), in patients with urinary catheters (other coagulase-negative staphylococci), or after seeding of the urinary tract by bacteremia (*S. aureus*)
Catheter and shunt infections: Chronic inflammatory response to bacteria coating a catheter or shunt (most commonly with coagulase-negative staphylococci)
Prosthetic device infections: Chronic infection of device characterized by localized pain and mechanical failure of the device (most commonly with coagulase-negative staphylococci)

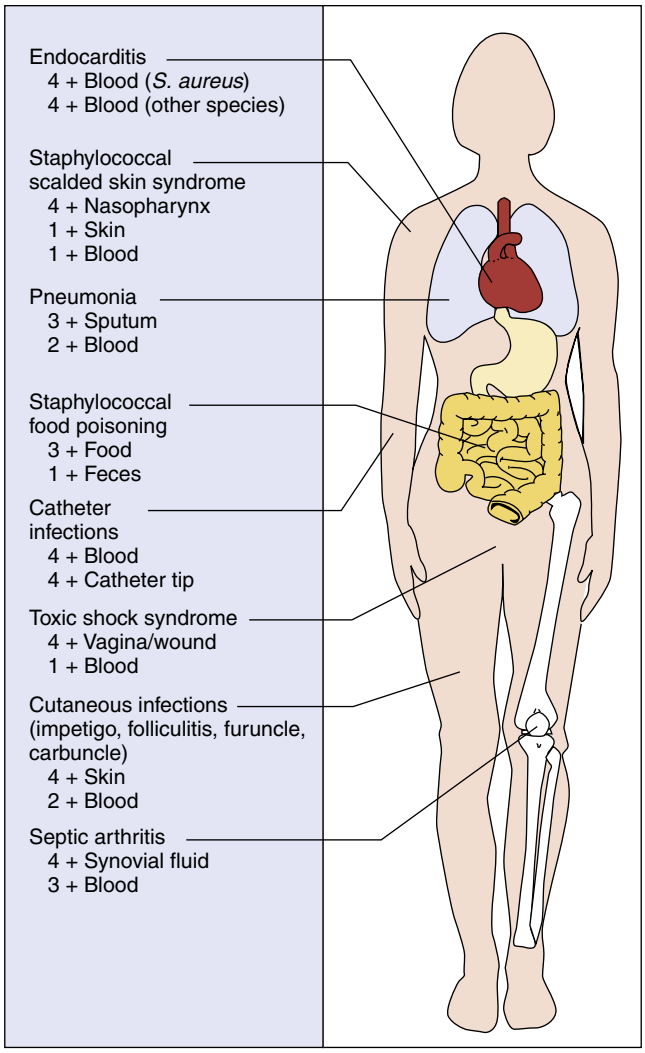

Fig. 18.2 Staphylococcal diseases. Isolation of staphylococci from sites of infection. *1+*, Less than 10% positive cultures; *2+*, 10% to 50% positive cultures; *3+*, 50% to 90% positive cultures; *4+*, more than 90% positive cultures.

Fig. 18.3 Staphylococcal scalded skin syndrome. (From Mandell, G., Bennett, J., Dolin, R., 2005. Principles and practice of infectious disease, sixth ed. Churchill Livingstone, Philadelphia, PA.)

Fig. 18.4 Bullous impetigo, which is a localized form of staphylococcal scalded skin syndrome. (From Emond, R.T., Rowland, H.A.K., Welsby, P., 1995. Colour Atlas of Infectious Diseases, third ed. Wolfe, London.)

This is a disease primarily of neonates and young children, with the mortality rate less than 5%. When death does occur, it is a result of secondary bacterial infection of the denuded skin areas. Infections in adults usually occur in immunocompromised hosts or patients with renal disease and, in contrast with infants, mortality is as high as 60%.

Bullous impetigo is a localized form of SSSS. In this syndrome, specific strains of toxin-producing *S. aureus* (e.g., phage type 71) are associated with formation of superficial skin blisters (Fig. 18.4). Unlike patients with the disseminated manifestations of SSSS, *S. aureus* is present in the localized blisters of patients with bullous impetigo. The erythema does not extend beyond the borders of the blister and the Nikolsky sign is not present. The disease occurs primarily in infants and young children and is highly communicable.

Staphylococcal Food Poisoning

Staphylococcal food poisoning, one of the most common foodborne illnesses, is an **intoxication** rather than an infection (Clinical Case 18.1). Disease is caused by bacterial toxin present in food rather than from a direct effect of the organisms on the patient. The most commonly contaminated foods are **processed meats** such as ham and salted pork, **custard**-filled **pastries, potato salad,** and **ice cream.** Growth of *S. aureus* in salted meats is consistent with the ability of this organism to grow in the presence of high salt concentrations. Unlike many other forms of food poisoning in which an animal reservoir is important, staphylococcal food poisoning results from contamination of the food by a human carrier. Although contamination can be prevented by not allowing individuals with an obvious staphylococcal skin infection to prepare food, approximately half of the infections originate from carriers with asymptomatic nasopharyngeal colonization. After the staphylococci have been introduced into the food (through

a sneeze or contaminated hand), the food must remain at room temperature or warmer for the organisms to grow and release the toxin. The contaminated food will not appear or taste tainted. Subsequent heating of the food will kill the bacteria but not inactivate the **heat-stable toxin.**

After ingestion of contaminated food, the onset of disease is abrupt and rapid, with a mean incubation period of 4 hours, which again is consistent with a disease mediated by preformed toxin. Further toxin is not produced by ingested staphylococci so the disease has a rapid course, with symptoms generally lasting less than 24 hours. Severe vomiting, diarrhea, and abdominal pain or nausea are characteristic of staphylococcal food poisoning. Sweating and headache may occur, but fever is not seen. The diarrhea is watery and nonbloody, and dehydration may result from the considerable fluid loss.

The toxin-producing organisms can be cultured from the contaminated food if the organisms are not killed during food preparation. The enterotoxins are heat-stable, so contaminated food can be tested for toxins at a public health facility; however, these tests are rarely performed, so diagnosis of staphylococcal food poisoning is primarily based on the clinical picture.

Treatment is for relief of abdominal cramping and diarrhea and for fluid replacement. Antibiotic therapy is not indicated because, as already noted, the disease is mediated by preformed toxin and not by replicating organisms. Neutralizing antibodies to the toxin can be protective and limited cross-protection occurs among the different enterotoxins. Short-lived immunity means that second episodes of staphylococcal food poisoning can occur, particularly with serologically distinct enterotoxins.

Clinical Case 18.1 **Staphylococcal Food Poisoning**

A report published in the Centers for Disease Control and Prevention's *Morbidity and Mortality Weekly Report* (*MMWR* 46:1189–1191, 1997) illustrated many important features of staphylococcal food poisoning. A total of 18 persons attending a retirement party became ill approximately 3 to 4 hours after eating. The most common symptoms were nausea (94%), vomiting (89%), and diarrhea (72%). Relatively few individuals had fever or headache (11%). The symptoms lasted a median of 24 hours. The illness was associated with eating ham at the party. A sample of the cooked ham was positive for staphylococcal enterotoxin type A. A food preparer had cooked the ham at home, transported it to her workplace and sliced it while it was still hot, and then refrigerated the ham in a large plastic container covered with foil. The ham was served cold the next day. Cooking the ham would kill any contaminating *S. aureus,* so it is likely the ham was contaminated after it was cooked. The delays involved in refrigerating the ham and the fact it was stored in a single container allowed the organism to proliferate and produce enterotoxin. Type A toxin is the most common toxin associated with human disease. The rapid onset and short duration of nausea, vomiting, and diarrhea is typical of this disease. Care must be used to avoid contamination of salted meats such as ham because reheating the food at a later time will not inactivate the heat-stable toxin.

Certain strains of *S. aureus* can also cause **enterocolitis,** which is manifested clinically by watery diarrhea, abdominal cramps, and fever. The majority of strains producing this disease produce both enterotoxin A and the bicomponent leukotoxin LukE/LukD. In contrast to staphylococcal food poisoning, staphylococcal enterocolitis is directly related to the growth of *S. aureus* in the colon. Enterocolitis occurs primarily in patients who have received broad-spectrum antibiotics that suppress the normal colonic flora and permit the growth of *S. aureus.* The diagnosis of staphylococcal enterocolitis is confirmed after more common causes of infection have been excluded (e.g., *Clostridium difficile* colitis) and abundant *S. aureus* is detected in the stool of affected patients. Fecal leukocytes and white plaques with ulceration are seen on the colonic mucosa.

Toxic Shock Syndrome

The first outbreak of this disease occurred in 1928 in Australia, in which the disease developed in 21 children, 12 of whom died after an injection with an *S. aureus*–contaminated vaccine (Clinical Case 18.2). Fifty years later, J.K. Todd observed what he called **toxic shock syndrome** in seven children with systemic disease and the first reports of TSS in menstruating women were published in the summer of 1980. These reports were followed by a dramatic increase in reports of TSS, particularly in women. Subsequently, it was discovered that TSST-1–producing strains of *S. aureus* could multiply rapidly in hyperabsorbent tampons and release toxin. After the recall of these tampons, the incidence of disease, particularly in menstruating women, decreased rapidly. At present, fewer than 100 cases of TSS are reported annually in the United States. Although it was originally reported that coagulase-negative staphylococci could cause TSS, it is now believed that this disease is restricted to *S. aureus.*

Clinical Case 18.2 **Staphylococcal Toxic Shock Syndrome**

Todd and associates (*Lancet* 2:1116–1118, 1978) were the first investigators to describe a pediatric disease they called "toxic shock syndrome" (TSS). This patient illustrates the clinical course of the disease. A 15-year-old girl was admitted to the hospital with a 2-day history of pharyngitis and vaginitis associated with vomiting and watery diarrhea. She was febrile and hypotensive on admission, with a diffuse erythematous rash over her entire body. Laboratory tests were consistent with acidosis, oliguria, and disseminated intravascular coagulation with severe thrombocytopenia. Her chest radiograph showed bilateral infiltrates suggestive of "shock lung." She was admitted to the hospital intensive care unit, in which she was stabilized and improved gradually over a 17-day period. On the third day, fine desquamation started on her face, trunk, and extremities and progressed to peeling of the palms and soles by the 14th day. All cultures were negative except from the throat and vagina, from which *Staphylococcus aureus* was isolated. This case illustrates the initial presentation of TSS, the multiorgan toxicity, and the protracted period of recovery.

The disease is initiated with the localized growth of toxin-producing strains of *S. aureus* in the vagina or a wound, followed by release of the toxin into blood. Toxin production requires an aerobic atmosphere and neutral pH. Clinical manifestations start abruptly and include fever; hypotension; and a diffuse, macular, erythematous rash. Multiple organ systems (e.g., central nervous, gastrointestinal, hematologic, hepatic, musculature, renal) are also involved, and the entire skin, including the palms and soles, desquamates (Fig. 18.5). A particularly virulent form of TSS is **purpura fulminans.** This disease is characterized by large purpuric skin lesion, fever, hypotension, and disseminated intravascular coagulation. More commonly, purpura fulminans is associated with overwhelming *Neisseria meningitidis* infections.

As the etiology and epidemiology of this disease have become better understood, the initial high fatality rate has been decreased to approximately 5%. However, the risk of recurrent disease is as high as 65% unless the patient is specifically treated with an effective antibiotic. Serologic studies have demonstrated that more than 90% of adults have antibodies to TSST-1; however, more than 50% of patients with TSS fail to develop protective antibodies after their disease resolves. These unprotected patients are at risk for **recurrent disease.**

Cutaneous Infections

The most common diseases caused by *S. aureus* are localized **pyogenic cutaneous infections** including impetigo, folliculitis, furuncles, and carbuncles. **Impetigo,** a superficial infection that mostly affects young children, occurs primarily on the face and limbs. Initially, a small macule (flattened red spot) is seen, and then a pus-filled vesicle **(pustule)** on an erythematous base develops. Crusting occurs after the pustule ruptures. Multiple vesicles at different stages of development are common because of the secondary spread of the infection to adjacent skin sites (Fig. 18.6). Impetigo is usually caused by *S. aureus,* although group A streptococci, either alone or with *S. aureus,* are responsible for 20% of cases.

Folliculitis is a pyogenic infection in the hair follicles. The base of the follicle is raised and reddened, and there is a small collection of pus beneath the epidermal surface. If this occurs at the base of the eyelid, it is called a **sty. Furuncles** (boils), an extension of folliculitis, are large, painful, raised nodules that have an underlying collection of dead and necrotic tissue. These can drain spontaneously or after surgical incision.

Carbuncles occur when furuncles coalesce and extend to the deeper subcutaneous tissue (Fig. 18.7). Multiple sinus tracts are usually present. Unlike patients with folliculitis and furuncles, patients with carbuncles have chills and fevers, indicating the systemic spread of staphylococci via bacteremia to other tissues.

Staphylococcal **wound infections** can also occur in patients after a surgical procedure or after trauma when organisms colonizing the skin or from an external source are introduced into the wound. The staphylococci are generally not able to establish an infection in an immunocompetent person unless a foreign body (e.g., stitches, a splinter, dirt) is present in the wound. Infections are characterized by edema, erythema, pain, and an accumulation of purulent material. The infection can be easily managed if the wound is reopened, the foreign matter removed, the purulence drained, and the surface cleaned with a disinfectant. If signs such as fever and malaise are observed or if the wound does not clear in response to localized management, then antibiotic therapy directed against *S. aureus* is indicated.

With the spread of **MRSA strains in the community,** these organisms are now the most common cause of skin and soft-tissue infections in patients presenting to U.S. hospital emergency departments.

Fig. 18.5 Toxic shock syndrome. A case of fatal infection with cutaneous and soft-tissue involvement is shown.

Fig. 18.6 Pustular impetigo. Note the vesicles at different stages of development, including pus-filled vesicles on an erythematous base and dry, crusted lesions. (From Emond, R.T., Rowland, H.A.K., Welsby, P., 1995. Colour Atlas of Infectious Diseases, third ed. Wolfe, London.)

Fig. 18.7 *Staphylococcus aureus* carbuncle. This carbuncle developed on the buttock over a 7- to 10-day period and required surgical drainage plus antibiotic therapy. (From Cohen, J., Powderly, W.G., Opal, S.M., 2010. Infectious Diseases, third ed. Mosby, Philadelphia, PA.)

Clinical Case 18.3 *Staphylococcus aureus* Endocarditis

Chen and Li (*N Engl J Med* 355:e27, 2006) described a 21-year-old woman with a history of intravenous drug abuse, human immunodeficiency virus (HIV), and a CD4 count of 400 cells/mm^3 who developed endocarditis caused by *S. aureus*. The patient had a 1-week history of fever, chest pain, and hemoptysis. Physical exam revealed a 3/6 pansystolic murmur and rhonchi in both lung fields. Multiple bilateral cavitary lesions were observed by chest radiography, and cultures of blood and sputum were positive for methicillin-susceptible *S. aureus*. The patient was treated with oxacillin for 6 weeks, with resolution of the endocarditis and pulmonary abscesses. This case illustrated the acute onset of *S. aureus* endocarditis, risk factors of intravenous drug abuse, and the frequency of complications caused by septic emboli.

Bacteremia and Endocarditis

S. aureus is a common cause of **bacteremia** (Clinical Case 18.3). Although bacteremias caused by most other organisms originate from an identifiable focus of infection (e.g., infection of the lungs, urinary tract, gastrointestinal tract), the initial foci of infection in approximately a third of patients with *S. aureus* bacteremias are not known. Most likely, the infection spreads to the blood from an innocuous-appearing skin infection. More than 50% of the cases of *S. aureus* bacteremia are acquired in the hospital after a surgical procedure or from a contaminated intravascular catheter. *S. aureus* bacteremias, particularly prolonged episodes, are associated with dissemination to other body sites, including the heart.

Acute **endocarditis** caused by *S. aureus* is a serious disease, with a mortality rate approaching 50% unless promptly diagnosed. Although patients with *S. aureus* endocarditis may initially have nonspecific influenza-like symptoms, their condition can deteriorate rapidly and include disruption of cardiac output and peripheral evidence of septic embolization. The patient's prognosis is poor unless appropriate medical and surgical intervention is instituted immediately. An exception to this is *S. aureus* endocarditis in parenteral drug abusers, whose disease normally involves the right side of the heart (tricuspid valve) rather than the left. The initial symptoms may be mild but fever, chills, and pleuritic chest pain caused by pulmonary emboli are generally present. Clinical cure of the endocarditis is the rule, although it is common for complications to occur as the result of secondary spread of the infection to other organs.

Pneumonia and Empyema

S. aureus respiratory disease can develop after the aspiration of oral secretions or from the hematogenous spread of the organism from a distant site. Previous infections with *S. aureus* such as recurrent skin infections, nasal or skin colonization with *S. aureus*, or underlying pulmonary disease are risk factors for pneumonia. **Aspiration pneumonia** is seen primarily in the very young, the elderly, and patients with cystic fibrosis, influenza, chronic obstructive pulmonary disease, and bronchiectasis. The clinical and radiographic presentations of the pneumonia are not unique. Radiographic examination reveals the presence of patchy infiltrates with consolidation or abscesses, with the latter consistent with the organism's ability to secrete cytotoxic toxins and enzymes and to form localized abscesses. **Hematogenous pneumonia** is common for patients with bacteremia or endocarditis. Community-acquired MRSA is responsible for a severe form of **necrotizing pneumonia** with massive hemoptysis, septic shock, and a high mortality rate. Although this disease occurs most commonly in children and young adults, it is not restricted to these age groups.

Empyema occurs in 10% of patients with pneumonia, and *S. aureus* is responsible for a third of all cases. Drainage of the purulent material is sometimes difficult because the organism can become consolidated in loculated areas.

Osteomyelitis and Septic Arthritis

S. aureus **osteomyelitis** results from hematogenous dissemination to bone or it can be a secondary infection resulting from trauma or the extension of disease from an adjacent area. Hematogenous spread in children generally results from a cutaneous staphylococcal infection and usually involves the metaphyseal area of long bones, which is a highly vascularized area of bony growth. This infection is characterized by the sudden onset of localized pain over the involved bone and by high fever. Blood cultures are positive in approximately 50% of cases.

The hematogenous osteomyelitis seen in adults commonly occurs in the form of vertebral osteomyelitis and rarely in the form of an infection of the long bones. Intense back pain with fever is the initial symptom. Radiographic evidence of osteomyelitis in children and adults is not seen until 2 to 3 weeks after the initial symptoms appear. **Brodie abscess** is a sequestered focus of staphylococcal osteomyelitis that arises in the metaphyseal area of a long bone and occurs only in adults. Staphylococcal osteomyelitis that occurs after trauma or a surgical procedure is generally

accompanied by inflammation and purulent drainage from the wound or the sinus tract overlying the infected bone. Because the staphylococcal infection may be restricted to the wound, isolation of the organism from this site is not conclusive evidence of bony involvement. With appropriate antibiotic therapy and surgery, the cure rate for staphylococcal osteomyelitis is excellent.

S. aureus is the primary cause of **septic arthritis** in young children and in adults who are receiving intraarticular injections or who have mechanically abnormal joints. Secondary involvement of multiple joints is indicative of hematogenous spread from a localized focus. *S. aureus* is replaced by *N. gonorrhoeae* as the most common cause of septic arthritis in sexually active persons. Staphylococcal arthritis is characterized by a painful erythematous joint, with purulent material obtained on aspiration. Infection is usually demonstrated in the large joints (e.g., shoulder, knee, hip, elbow). The prognosis in children is excellent, but in adults it depends on the nature of the underlying disease and the occurrence of any secondary infectious complications.

STAPHYLOCOCCUS EPIDERMIDIS AND OTHER COAGULASE-NEGATIVE STAPHYLOCOCCI

Endocarditis

S. epidermidis, S. lugdunensis, and related coagulase-negative staphylococci can infect prosthetic and, less commonly, native heart valves (Clinical Case 18.4). Infections of native valves are believed to result from the inoculation of organisms onto a damaged heart valve (e.g., a congenital malformation, damage resulting from rheumatic heart disease). ***S. lugdunensis*** is the staphylococcal species most commonly associated with native valve endocarditis, although this disease is more commonly caused by streptococci. In contrast, staphylococci are a major cause of **endocarditis of artificial valves.** The organisms are introduced at the time of valve replacement, and the infection characteristically has an indolent course, with clinical signs and symptoms not developing for as long as 1 year after the procedure. Although the heart valve can be infected, more commonly the infection occurs at the site in which the valve is sewn to the heart tissue. Thus infection with abscess formation can lead to separation of the valve at the suture line and to mechanical heart failure. The prognosis is guarded for patients who have this infection, and prompt medical and surgical management is critical.

Catheter and Shunt Infections

More than 50% of all infections of catheters and shunts are caused by coagulase-negative staphylococci. These infections have become a major medical problem because long-dwelling catheters and shunts are common for the medical management of critically ill patients. The coagulase-negative staphylococci are particularly well adapted for causing these infections because they can produce a polysaccharide slime that bonds them to catheters and shunts and protects them from antibiotics and inflammatory cells. A persistent bacteremia is generally observed in patients with infections of shunts and catheters because the organisms have continual access to the blood. Immune complex–mediated glomerulonephritis occurs in patients with long-standing disease.

Clinical Case 18.4 ***Staphylococcus lugdunensis* Endocarditis**

Seenivasan and Yu (*Eur J Clin Microbiol Infect Dis* 22:489–491, 2003) described a typical report of native valve endocarditis caused by *S. lugdunensis*, which is a coagulase-negative *Staphylococcus* with a predilection for causing endocarditis. The 36-year-old woman was an active cocaine user who presented with an acute onset of weakness in the right extremities. She reported fever with chills, malaise, and shortness of breath over the preceding 10 weeks. On admission to the hospital, she had tachycardia, hypotension, a temperature of 39° C, a pansystolic murmur, and right-sided hemiparesis. A computed tomography scan of the brain revealed a large infarct in the left basal ganglia. Four sets of blood cultures were positive with *S. lugdunensis*. The isolate was penicillin resistant and susceptible to all other tested antibiotics. Because the patient had a penicillin allergy, treatment was initiated with vancomycin and gentamicin. The patient became afebrile at 3 days, and subsequent blood cultures were negative. Gentamicin was discontinued after 1 week, and the patient received a total of 6 weeks of therapy with vancomycin. Over the next 7 months, the patient developed progressive mitral regurgitation that necessitated mitral valve replacement. *S. lugdunensis* is more virulent compared with other coagulase-negative staphylococci, causing disease most commonly in native heart valves and with secondary complications (e.g., a brain infarct caused by septic emboli) more frequently reported. Persistent bacteremia is characteristic of intravascular infections such as endocarditis.

Prosthetic Joint Infections

Infections of artificial joints, particularly the hip, can be caused by coagulase-negative staphylococci. The patient usually experiences only localized pain and mechanical failure of the joint. Systemic signs such as fever and leukocytosis are not prominent, and blood cultures are usually negative. Treatment consists of joint replacement and antimicrobial therapy. The risk of reinfection of the new joint is considerably increased in such patients.

Urinary Tract Infections

S. saprophyticus has a predilection for causing urinary tract infections in young, sexually active women and is rarely responsible for infections in other patients. It is also infrequently found as an asymptomatic colonizer of the urinary tract. Infected women usually have dysuria (pain on urination), pyuria (pus in urine), and numerous organisms in the urine. Typically, patients respond rapidly to antibiotics, and reinfection is uncommon.

Laboratory Diagnosis

MICROSCOPY

Staphylococci are **gram-positive cocci** that form **clusters** when grown on agar media but commonly appear as single cells or small groups of organisms in clinical specimens. Successful detection of organisms in a clinical specimen depends on the type of infection (e.g., abscess, bacteremia, impetigo) and the quality of the material submitted for analysis. If the clinician scrapes the base of the abscess with a swab or curette, then an abundance of organisms should be observed in the gram-stained specimen. Aspirated pus or superficial specimens collected with swabs consist primarily of necrotic material with relatively few organisms, so these specimens are not as useful. Relatively few organisms are generally present in the blood of bacteremic patients (an average of <1 organism per milliliter of blood), so blood specimens should be cultured, but blood examined by Gram stain is not useful. Staphylococci are seen in the nasopharynx of patients with SSSS and in the vagina of patients with TSS, but these staphylococci cannot be distinguished from the organisms that normally colonize these sites. Diagnosis of these diseases is made by the clinical presentation of the patient, with isolation of *S. aureus* in culture confirmatory. Staphylococci are implicated in food poisoning by the clinical presentation of the patient (e.g., rapid onset of vomiting and abdominal cramps) and a history of specific food ingestion (e.g., salted ham). Gram stains of the food or patient stool specimens are generally not useful.

NUCLEIC ACID–BASED TESTS

Commercial nucleic acid amplification tests are available for the direct detection and identification of *S. aureus* in clinical specimens. However, these tests are primarily used to detect nasal carriage of methicillin-sensitive *S. aureus* (MSSA) and MRSA, identifying patients at increased risk of developing staphylococcal disease (e.g., bacteremia, surgical wound infections) during hospitalization.

CULTURE

Clinical specimens should be inoculated onto nutritionally enriched agar media supplemented with sheep blood. Staphylococci grow rapidly on nonselective media incubated aerobically or anaerobically, with large, smooth colonies seen within 24 hours (Fig. 18.8). As noted earlier, *S. aureus* colonies will gradually turn **yellow,** particularly when the cultures are incubated at room temperature for a few days; however, this is rarely done in clinical labs today. Almost all isolates of *S. aureus* and some strains of coagulase-negative staphylococci produce hemolysis on sheep blood agar. The hemolysis is caused by cytotoxins, particularly alpha toxin. If there is a mixture of organisms in the specimen (e.g., wound or respiratory specimen), *S. aureus* can be isolated selectively on a variety of special media including **chromogenic agar** (where *S. aureus* colonies are a characteristic color) or **mannitol-salt agar,** which is supplemented with mannitol (fermented by *S. aureus* but not by most other staphylococci) and 7.5% sodium chloride (inhibits the growth of most other organisms).

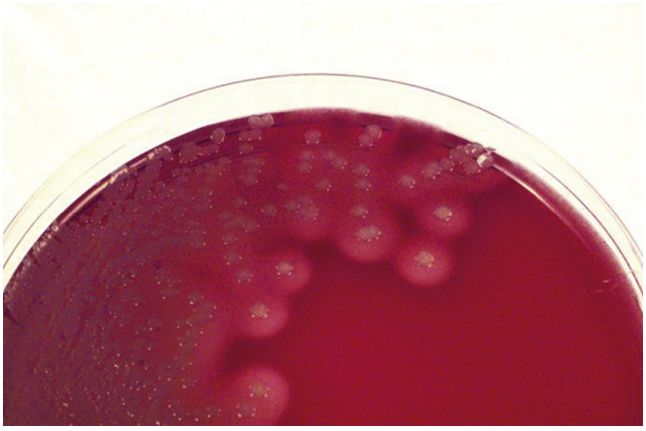

Fig. 18.8 *Staphylococcus aureus* grown on a sheep blood agar plate. Note the colonies are large and β-hemolytic.

IDENTIFICATION

Relatively simple biochemical tests (e.g., positive reactions for **coagulase,** protein A, heat-stable nuclease, mannitol fermentation) can be used to identify *S. aureus*. Colonies resembling *S. aureus* are identified in most laboratories by mixing a suspension of organisms with a drop of plasma and observing clumping of the organisms (positive coagulase test). Alternatively, plasma placed in a test tube can be inoculated with the organism and examined at 4 and 24 hours for formation of a clot (positive tube coagulase test). Identification of the coagulase-negative staphylococci is more complex, traditionally requiring the use of commercial identification systems. More recently mass spectrometry has been used to identify the staphylococci, as well as many other species of organisms, with a high level of accuracy and rapid time to results (generally identified in minutes). Historically, the analysis of genomic DNA by pulsed-field gel electrophoresis or similar technique was the most commonly used method for characterizing isolates at the subspecies levels; however, whole genome sequencing is rapidly becoming the preferred tool for subtyping organisms for epidemiologic studies.

ANTIBODY DETECTION

Antibodies to cell wall teichoic acids are present in many patients with long-standing *S. aureus* infections. However, this test has been discontinued in most hospitals because it is less sensitive than culture and nucleic acid–based tests.

Treatment, Prevention, and Control

Staphylococci quickly developed drug resistance after penicillin was introduced, and today less than 10% of the strains are susceptible to this antibiotic. This resistance is mediated by **penicillinase** (β-lactamase specific for penicillins), which hydrolyzes the β-lactam ring of penicillin. Because of the problems with penicillin-resistant staphylococci, **semisynthetic penicillins** resistant to β-lactamase hydrolysis (e.g., methicillin, nafcillin, oxacillin, dicloxacillin) were developed. Unfortunately, staphylococci developed resistance to

these antibiotics as well. Currently, the majority of *S. aureus* responsible for hospital- and community-acquired infections are resistant to these semisynthetic penicillins, and these MRSA strains are resistant to all β-lactam antibiotics (i.e., penicillins, cephalosporins, carbapenems). Not all bacteria in a resistant population may express their resistance in traditional susceptibility tests **(heterogeneous resistance);** therefore the definitive method for identifying a resistant isolate is detection of the *mecA* or *mecC* genes that code for the penicillin-binding proteins that confer resistance.

Patients with localized skin and soft-tissue infections can generally be managed by incision and drainage of the abscesses. If the infection involves a larger area or systemic signs are present, then antibiotic therapy is indicated. Because MRSA strains are responsible for a significant proportion of hospital- and community-acquired infections, empirical therapy should include antibiotics active against MRSA strains. Oral therapy can include trimethoprim-sulfamethoxazole, a long-acting tetracycline such as doxycycline or minocycline, clindamycin, or linezolid. Resistance to clindamycin is common in some communities, and use of linezolid is limited by its cost and toxicity. Vancomycin is the drug of choice for intravenous therapy, with daptomycin, tigecycline, or linezolid acceptable alternatives.

Staphylococci have demonstrated the remarkable ability to develop resistance to most antibiotics. Until recently, the one antibiotic that remained uniformly active against staphylococci was vancomycin, which is the current antibiotic of choice for treating serious infections caused by staphylococci resistant to methicillin. Unfortunately, isolates of *S. aureus* have now been found with two forms of **resistance to vancomycin.** Low-level resistance is observed in *S. aureus* strains with a thicker, more disorganized cell wall. It is postulated that vancomycin is trapped in the cell wall matrix and is unable to reach the cytoplasmic membrane, where it can disrupt cell wall synthesis. High-level resistance is mediated by the *vanA* gene operon that was acquired from vancomycin-resistant enterococci. These bacteria have a modified peptidoglycan layer that does not bind vancomycin. Presently, this resistance is very uncommon; however, if these resistant staphylococci become widespread, then antibiotic treatment of these highly virulent bacteria would be difficult.

Staphylococci are ubiquitous organisms present on the skin and mucous membranes, and their introduction through breaks in the skin occurs often. However, the number of organisms required to establish an infection **(infectious dose)** is generally large unless a foreign body (e.g., dirt, a splinter, stitches) is present in the wound. Proper cleansing of the wound and application of an appropriate disinfectant (e.g., germicidal soap, iodine solution, hexachlorophene) will prevent most infections in healthy individuals.

The spread of staphylococci from person to person is more difficult to prevent. An example of this is surgical wound infections, which can be caused by relatively few organisms because foreign bodies and devitalized tissue may be present. Although it is unrealistic to sterilize operating room personnel and the environment, the risk of contamination during an operative procedure can be minimized through proper handwashing and the covering of exposed skin surfaces. The spread of methicillin-resistant organisms can also be difficult to control because asymptomatic nasopharyngeal carriage is the most common source of these organisms.

Case Study and Questions

An 18-year-old man fell on his knee while playing basketball. The knee was painful, but the overlying skin was unbroken. The knee was swollen and remained painful the next day, so he was taken to the local emergency department. Clear fluid was aspirated from the knee, and the physician prescribed symptomatic treatment. Two days later, the swelling returned, the pain increased, and erythema developed over the knee. Because the patient also felt systemically ill and had an oral temperature of 38.8° C, he returned to the emergency department. Aspiration of the knee yielded cloudy fluid, and cultures of the fluid and blood were positive for *S. aureus.*

1. Name two possible sources of this organism.
2. Staphylococci cause a variety of diseases, including cutaneous infections, endocarditis, food poisoning, SSSS, and TSS. How do the clinical symptoms of these diseases differ from the infection in this patient? Which of these diseases are intoxications?
3. What toxins have been implicated in staphylococcal diseases? Which staphylococcal enzymes have been proposed as virulence factors?
4. Which structures in the staphylococcal cell and which toxins protect the bacterium from phagocytosis?
5. What is the antibiotic of choice for treating staphylococcal infections? (Give two examples.)

19 Streptococcus *and* Enterococcus

An 8-year-old boy presented to his pediatrician with a low-grade fever and a diffuse erythematous rash over his chest, which developed 2 days after he complained of a painful sore throat. An exudate was present over the tonsillar area of the throat and covered his tongue. The clinical diagnosis of scarlet fever was confirmed by positive antigen test for group A Streptococcus from a throat specimen. The genera Streptococcus and Enterococcus include a large number of species capable of causing a wide spectrum of diseases.

1. What sites of the human body are normally colonized with *Streptococcus pyogenes*, *S. agalactiae*, and *S. pneumoniae*? How does this relate to infections caused by these bacteria?
2. The viridans streptococci (i.e., α-hemolytic and nonhemolytic streptococci) are subdivided into five groups. What are the groups and the specific diseases associated with each group?
3. Enterococci, like many other bacteria, can cause urinary tract infections but primarily in hospitalized patients. What characteristics of this bacterium are responsible for the predilection for disease in this population?
4. What biochemical properties are used to separate enterococci from the staphylococci and streptococci?

Answers to these questions are available on Student Consult.com.

Summaries Clinically Significant Organisms

Streptococcus pyogenes (Group A)

Trigger Words

Group A, pharyngitis, pyoderma, rheumatic fever, glomerulonephritis

Biology and Virulence

- Rapidly growing gram-positive cocci arranged in chains; group-specific carbohydrate (A antigen) and type-specific proteins (M protein) in cell wall
- Virulence determined by ability to avoid phagocytosis (mediated primarily by capsule, M and M-like proteins, and C5a peptidase), adhere to and invade host cells (M protein, lipoteichoic acid, and F protein), and produce toxins (streptococcal pyrogenic exotoxins, streptolysin S, streptolysin O, streptokinase, and DNases)

Epidemiology

- Transient colonization in upper respiratory tract and skin surface, with disease caused by recently acquired strains (before protective antibodies are produced)
- Pharyngitis and soft-tissue infections typically caused by strains with different M proteins
- Person-to-person spread by respiratory droplets (pharyngitis) or through breaks in skin after direct contact with infected person, fomite, or arthropod vector
- Individuals at higher risk for disease include children 5 to 15 years old (pharyngitis); children 2 to 5 years old with poor personal hygiene (pyoderma); patients with soft-tissue infection (streptococcal toxic shock syndrome); patients with prior streptococcal pharyngitis (rheumatic fever, glomerulonephritis) or soft-tissue infection (glomerulonephritis)

Diseases

- Responsible for suppurative diseases (pharyngitis, soft-tissue infections, streptococcal toxic shock) and nonsuppurative diseases (rheumatic fever, glomerulonephritis)

Diagnosis

- Microscopy is useful in soft-tissue infections but not pharyngitis or nonsuppurative complications
- Direct tests for the group A antigen are useful for the diagnosis of streptococcal pharyngitis
- Isolates identified by catalase (negative), positive L-pyrrolidonyl arylamidase (PYR) reaction, susceptibility to bacitracin, and presence of group-specific antigen (group A antigen)
- Antistreptolysin O test is useful for confirming rheumatic fever or glomerulonephritis associated with streptococcal pharyngitis; anti-DNase B test should be performed for glomerulonephritis associated with pharyngitis or soft-tissue infections

Treatment, Prevention, and Control

- Penicillin V or amoxicillin used to treat pharyngitis; oral cephalosporin or macrolide for penicillin-allergic patients; intravenous penicillin plus clindamycin used for systemic infections
- Oropharyngeal carriage occurring after treatment can be re-treated; treatment is not indicated for prolonged asymptomatic carriage because antibiotics disrupt normal protective flora
- Starting antibiotic therapy within 10 days in patients with pharyngitis prevents rheumatic fever
- For glomerulonephritis, no specific antibiotic treatment or prophylaxis is indicated
- For patients with a history of rheumatic fever, antibiotic prophylaxis is required before procedures (e.g., dental) that can induce bacteremias leading to endocarditis

Streptococcus agalactiae (Group B)

Trigger Words

Group B, neonatal disease, screening pregnant women

Biology and Virulence

- Rapidly growing gram-positive cocci arranged in chains; group-specific carbohydrate (B antigen) and type-specific capsular carbohydrates (Ia, Ib, and II-VIII)
- Virulence determined primarily by ability to avoid phagocytosis (mediated by capsule)

Epidemiology

- Asymptomatic colonization of the upper respiratory tract and genitourinary tract
- Early-onset disease acquired by neonates from mother during pregnancy or at time of birth
- Neonates are at higher risk for infection if (1) there is premature rupture of membranes, prolonged labor, preterm birth, or disseminated maternal group B streptococcal disease, and (2) mother is without type-specific antibodies and has low complement levels
- Women with genital colonization are at risk for postpartum disease
- Men and nonpregnant women with diabetes mellitus, cancer, or alcoholism are at increased risk for disease
- No seasonal incidence

Continued

Summaries Clinically Significant Organisms

Diseases

- Responsible for neonatal disease (early-onset and late-onset disease with meningitis, pneumonia, and bacteremia), infections in pregnant women (endometritis, wound infections, and urinary tract infections), and other adults (bacteremia, pneumonia, bone and joint infections, and skin and soft-tissue infections)

Diagnosis

- Microscopy useful for meningitis (cerebrospinal fluid), pneumonia (lower respiratory secretions), and wound infections (exudates)
- Antigen tests are less sensitive than microscopy and should not be used
- Culture most sensitive test; a selective broth (i.e., LIM) is needed for optimal detection of vaginal carriage
- Polymerase chain reaction–based assays to detect vaginal carriage in pregnant women are commercially available; currently require use of enrichment broth for optimum sensitivity
- Isolates identified by demonstration of group-specific cell wall carbohydrate or positive nucleic acid amplification test

Treatment, Prevention, and Control

- Penicillin G is the drug of choice; empirical therapy with broad-spectrum antibiotics (broad-spectrum cephalosporin + aminoglycoside) used until specific pathogen identified; combination of penicillin and aminoglycoside is used in patients with serious infections; a cephalosporin or vancomycin is used for patients allergic to penicillin
- For high-risk babies, penicillin is given at least 4 hours before delivery
- No vaccine is currently available

STREPTOCOCCUS PNEUMONIAE

Trigger Words

Diplococci, capsule, pneumonia, meningitis, vaccine

Biology and Virulence

- Elongated gram-positive cocci arranged in pairs (diplococci) and short chains; cell wall includes teichoic acid rich in phosphorylcholine (C polysaccharide), which is required for the activity of an autolytic enzyme, amidase
- Virulence determined by ability to colonize oropharynx (surface protein adhesions), spread into normally sterile tissues (pneumolysin, immunoglobulin [Ig]A protease), stimulate local inflammatory response (teichoic acid, peptidoglycan fragments, pneumolysin), and evade phagocytic killing (polysaccharide capsule)
- Responsible for pneumonia, sinusitis and otitis media, meningitis, and bacteremia

Epidemiology

- Most infections are caused by endogenous spread from the colonized nasopharynx or oropharynx to distal site (e.g., lungs, sinuses, ears, blood, meninges); person-to-person spread through infectious droplets is rare
- Colonization is highest in young children and their contacts
- Individuals with antecedent viral respiratory tract disease or other conditions that interfere with bacterial clearance from respiratory tract are at increased risk for pulmonary disease
- Children and the elderly are at greatest risk for meningitis
- People with hematologic disorder (e.g., malignancy, sickle cell disease) or functional asplenia are at risk for fulminant sepsis
- Although the organism is ubiquitous, disease is more common in cool months

Diagnosis

- Microscopy is highly sensitive, as is culture, unless the patient has been treated with antibiotics
- Antigen tests for pneumococcal C polysaccharide are sensitive with cerebrospinal fluid (meningitis) but not with urine (meningitis, pneumonia, other infections)
- Nucleic acid–based tests are the tests of choice for the diagnosis of meningitis, particularly in patients who have been treated with an antibiotic
- Culture requires use of enriched-nutrient media (e.g., sheep blood agar); organism susceptible to many antibiotics, so culture can be negative in partially treated patients
- Isolates identified by catalase (negative), susceptibility to optochin, and solubility in bile

Treatment, Prevention, and Control

- Penicillin is the drug of choice for susceptible strains, although resistance is increasingly common
- Vancomycin combined with ceftriaxone is used for empirical therapy; monotherapy with a cephalosporin, fluoroquinolone, or vancomycin can be used in patients with susceptible isolates
- Immunization with 13-valent conjugated vaccine is recommended for all children younger than 2 years; a 23-valent polysaccharide vaccine is recommended for adults at risk for disease

ENTEROCOCCUS

Trigger Words

Diplococci, gastrointestinal carriage, drug resistant, urinary tract infections, peritonitis

Biology and Virulence

- Gram-positive cocci arranged in pairs and short chains (morphologically similar to *S. pneumoniae*)
- Cell wall with group-specific antigen (group D glycerol teichoic acid)
- Virulence mediated by ability to adhere to host surfaces and form biofilms and by antibiotic resistance

Epidemiology

- Colonizes the gastrointestinal tracts of humans and animals; spreads to other mucosal surfaces if broad-spectrum antibiotics eliminate the normal bacterial population
- Cell wall structure typical of gram-positive bacteria, which allows survival on environmental surfaces for prolonged periods
- Most infections endogenous (from patient's bacterial flora); some caused by patient-to-patient spread
- Patients at increased risk include those hospitalized for prolonged periods and treated with broad-spectrum antibiotics (particularly cephalosporins, to which enterococci are naturally resistant)

Diseases

- Diseases include urinary tract infections, peritonitis (usually polymicrobic), wound infections, and bacteremia with or without endocarditis

Diagnosis

- Grows readily on common nonselective media; differentiated from related organisms by simple tests (catalase negative, PYR positive, resistant to bile and optochin)

Treatment, Prevention, and Control

- Therapy for serious infections requires combination of an aminoglycoside with a cell wall–active antibiotic (penicillin, ampicillin, or vancomycin); newer agents used for antibiotic-resistant bacteria include linezolid, daptomycin, tigecycline, and quinupristin/dalfopristin
- Antibiotic resistance to each of these drugs is becoming increasingly common, and infections with many isolates (particularly *Enterococcus faecium*) are not treatable with any antibiotics
- Prevention and control of infections require careful restriction of antibiotic use and implementation of appropriate infection-control practices

TABLE 19.1 Important Streptococci and Enterococci

Organism	Historical Derivation
Streptococcus	*streptus*, pliant; *coccus*, grain or berry (a pliant berry or coccus; refers to the appearance of long, flexible chains of cocci)
S. agalactiae	*agalactia*, want of milk (original isolate [called *S. mastitidis*] was responsible for bovine mastitis)
S. anginosus	*anginosus*, pertaining to angina
S. constellatus	*constellatus*, studded with stars (original isolate embedded in agar with smaller colonies surrounding the large colony; satellite formation does not occur around colonies on the surface of an agar plate)
S. dysgalactiae	*dys*, ill, hard; *galactia*, pertaining to milk (loss of milk secretion; isolates associated with bovine mastitis)
S. gallolyticus	*gallatum*, gallate; *lyticus*, to loosen (able to digest or hydrolyze methyl gallate)
S. intermedius	*intermedius*, intermediate (initial confusion about whether this was an aerobic or an anaerobic bacterium)
S. mitis	*mitis*, mild (incorrectly thought to cause mild infections)
S. mutans	*mutans*, changing (cocci that may appear rodlike, particularly when initially isolated in culture)
S. pneumoniae	*pneumon*, the lungs (causes pneumonia)
S. pyogenes	*pyus*, pus; *gennaio*, beget or producing (pus producing; typically associated with formation of pus in wounds)
S. salivarius	*salivarius*, salivary (found in the mouth in saliva)
Enterococcus	*enteron*, intestine; coccus, berry (intestinal coccus)
E. faecalis	*faecalis*, relating to feces
E. faecium	*faecium*, of feces
E. gallinarum	*gallinarum*, of hens (original source was intestines of domestic fowl)
E. casseliflavus	*casseli*, Kassel's; *flavus*, yellow (Kassel's yellow)

TABLE 19.2 Catalase-Negative, Gram-Positive Cocci and Their Diseases

Organism	Diseases
Abiotrophia	Bacteremia, endocarditis (native and prosthetic valves), nosocomial brain abscesses and meningitis, eye infections
Aerococcus	Bacteremia, endocarditis, urinary tract infections
Enterococcus	Bacteremia, endocarditis, urinary tract infections, peritonitis, wound infections
Granulicatella	Bacteremia, endocarditis (native and prosthetic valves), eye infections
Lactococcus	Bacteremia in immunocompromised patients, endocarditis (native and prosthetic valves), urinary tract infections, osteomyelitis
Leuconostoc	Opportunistic infections, including bacteremia, wound infections, central nervous system infections, and peritonitis
Pediococcus	Opportunistic infections, including bacteremia in severely immunocompromised patients
Streptococcus	Refer to Tables 19.3 and 19.4

The genera *Streptococcus* and *Enterococcus* are a diverse collection of gram-positive cocci typically arranged in pairs or chains (in contrast to the clusters formed by *Staphylococcus*) (Table 19.1). Most species are facultative anaerobes, and some grow only in an atmosphere enhanced with carbon dioxide (capnophilic growth). Their nutritional requirements are complex, necessitating the use of blood- or serum-enriched media for isolation. Carbohydrates are fermented, resulting in the production of lactic acid and, unlike *Staphylococcus* species, streptococci and enterococci are catalase negative. The number of genera of catalase negative, gram-positive cocci that are recognized as human pathogens continues to increase; however, *Streptococcus* and *Enterococcus* are the genera most frequently isolated and most commonly responsible for human disease. The other genera are relatively uncommon and are listed in Table 19.2, but they are not discussed further.

The classification of more than 100 species within the genus *Streptococcus* is complicated because three different overlapping schemes are used: (1) serologic properties: **Lancefield groupings** (originally A to W); (2) **hemolytic patterns:** complete (beta [β]) hemolysis, incomplete (alpha [α]) hemolysis, and no (gamma [γ]) hemolysis; and (3) **biochemical (physiologic) properties.** Although this is an oversimplification, it is practical to think that the streptococci are divided into two groups: (1) the β-hemolytic streptococci, which are classified by Lancefield grouping, and (2) the α-hemolytic and γ-hemolytic streptococci, which are classified by biochemical testing. The latter group is referred to collectively as **viridans streptococci,** which a name derived from *viridis* (Latin for green), referring to the green pigment formed by the partial hemolysis of blood agar.

Rebecca Lancefield developed the serologic classification scheme in 1933. β-Hemolytic strains possess group-specific cell wall antigens, most of which are carbohydrates. These antigens can be readily detected by immunologic assays and have been useful for the rapid identification of some important streptococcal pathogens. For example, one disease caused by *Streptococcus pyogenes* (classified as group A *Streptococcus* in the Lancefield typing scheme) is streptococcal pharyngitis ("strep throat"). The group antigen for this organism can be detected directly from throat swab specimens by a variety of rapid point-of-care immunoassays, which are commonly used diagnostic tests in physician office laboratories. The Lancefield typing scheme is used today primarily for only a few species of streptococci (e.g., primarily in groups A and B, with groups C, F, and G also important; Table 19.3).

The enterococci ("enteric cocci") were originally classified as **group D streptococci** because they share the **group D cell wall antigen,** which is a glycerol teichoic acid, with other streptococci. In 1984, the enterococci were reclassified into the genus *Enterococcus,* and there are currently 58 species in this genus; however, relatively few species are important human pathogens. The most commonly isolated and clinically important species are ***Enterococcus faecalis*** and ***E. faecium. E. gallinarum*** and ***E. casseliflavus*** are also common colonizers of the human intestinal tract and are important because these species are inherently resistant to vancomycin.

TABLE 19.3 Classification of Common β-Hemolytic Streptococci

Group	Representative Species	Diseases
A	*S. pyogenes*	Pharyngitis, skin and soft-tissue infections, bacteremia, rheumatic fever, acute glomerulonephritis
	S. anginosus group	Abscesses
B	*S. agalactiae*	Neonatal disease, endometritis, wound infections, urinary tract infections, bacteremia, pneumonia, skin and soft-tissue infections
C	*S. dysgalactiae*	Pharyngitis, acute glomerulonephritis
F, G	*S. anginosus* group	Abscesses
	S. dysgalactiae	Pharyngitis, acute glomerulonephritis

TABLE 19.4 Classification of Viridans Group of *Streptococcus*

Group	Representative Species	Diseases
Anginosus	*S. anginosus, S. constellatus, S. intermedius*	Abscesses in brain, oropharynx, or peritoneal cavity
Mitis	*S. mitis, S. pneumoniae, S. oralis*	Subacute endocarditis; sepsis in neutropenic patients; pneumonia; meningitis
Mutans	*S. mutans, S. sobrinus*	Dental caries; bacteremia
Salivarius	*S. salivarius*	Bacteremia; endocarditis
Bovis	*S. gallolyticus* subsp. *gallolyticus,* subsp. *pasteurianus*	Bacteremia associated with gastrointestinal cancer (subsp. *gallolyticus*); meningitis (subsp. *pasteurianus*)
Ungrouped	*S. suis*	Meningitis; bacteremia; streptococcal toxic shock syndrome

The viridans streptococci are subdivided into five clinically distinct groups (Table 19.4). Some species of the viridans streptococci can be β-hemolytic, as well as α-hemolytic and nonhemolytic, which unfortunately has resulted in classifying these bacteria by both their Lancefield grouping and as viridans streptococci. Although the classification of the streptococci is somewhat confusing, clinical disease is well defined for individual species, which will be the emphasis for the remainder of this chapter.

Streptococcus pyogenes

S. pyogenes causes a variety of suppurative (characterized by pus formation) and nonsuppurative diseases (Box 19.1). Although this organism is the most common cause of bacterial pharyngitis, the notoriety of *S. pyogenes,* popularly called "flesh-eating" bacteria, results from life-threatening myonecrosis caused by this organism.

PHYSIOLOGY AND STRUCTURE

Isolates of *S. pyogenes* are spherical cocci, 1 to 2 μm in diameter, arranged in short chains in clinical specimens and longer chains when grown in liquid media (Fig. 19.1). Growth is optimal on enriched-blood agar media, but it is inhibited if the medium contains a high concentration of glucose. After 24 hours of incubation, small 1- to 2-mm white colonies with large zones of β-hemolysis are observed (Fig. 19.2).

The antigenic structure of *S. pyogenes* has been extensively studied. The basic structural framework of the cell wall is the peptidoglycan layer, which is similar in composition to that found in other gram-positive bacteria. Within the cell wall are group-specific and type-specific antigens. The **group-specific carbohydrate** that constitutes approximately 10% of the dry weight of the cell **(Lancefield group A antigen)** is a dimer of *N*-acetylglucosamine and rhamnose. This antigen is used to classify group A streptococci and distinguish them from other streptococcal groups. **M protein** is the major type-specific protein associated with virulent strains. It consists of two polypeptide chains complexed in an alpha helix. The protein is anchored in the cytoplasmic membrane, extends through the cell wall, and protrudes above the cell surface. The carboxyl terminus, which is anchored in the cytoplasmic membrane, and the portion of the molecule in the cell wall are highly conserved (by amino acid sequence) among all group A streptococci. The amino terminus, which extends above the cell surface, is responsible for the antigenic differences observed among the unique serotypes of M proteins. M proteins are subdivided into class I and class II molecules. The class I M proteins share exposed antigens, whereas the class II M proteins do not have exposed shared antigens. Although strains with both classes of antigens can cause suppurative infections and glomerulonephritis, only bacteria with class I (exposed shared antigen) M proteins cause rheumatic fever. The epidemiologic classification of *S. pyogenes* is based on sequence analysis of the *emm* gene that encodes the M proteins. Other important components in the cell wall of *S. pyogenes* include **M-like surface proteins, lipoteichoic acid,** and **F protein.** A complex of more than 20 genes that comprise the *emm* gene superfamily encode the M-like proteins, as well as the M proteins and immunoglobulin-binding proteins. Lipoteichoic acid and F protein facilitate binding of host cells by complexing with fibronectin, which is present on the host cell surface.

Some strains of *S. pyogenes* have an outer hyaluronic acid **capsule** that is antigenically indistinguishable from hyaluronic acid in mammalian connective tissues. Because the capsule can protect the bacteria from phagocytic clearance, encapsulated strains are more likely to be responsible for severe systemic infections.

PATHOGENESIS AND IMMUNITY

The virulence of group A streptococci is determined by the ability of the bacteria to avoid opsonization and phagocytosis, adhere to and invade host cells, and produce a variety of toxins and enzymes.

BOX 19.1 Streptococcal and Enterococcal Diseases: Clinical Summaries

***Streptococcus pyogenes* (Group A)**

Suppurative Infections

Pharyngitis: reddened pharynx with exudates generally present; cervical lymphadenopathy can be prominent
Scarlet fever: diffuse erythematous rash beginning on the chest and spreading to the extremities; complication of streptococcal pharyngitis
Pyoderma: localized skin infection with vesicles progressing to pustules; no evidence of systemic disease
Erysipelas: localized skin infection with pain, inflammation, lymph node enlargement, and systemic symptoms
Cellulitis: infection of the skin that involves the subcutaneous tissues
Necrotizing fasciitis: deep infection of skin that involves destruction of muscle and fat layers
Streptococcal toxic shock syndrome: multiorgan systemic infection resembling staphylococcal toxic shock syndrome; however, most patients are bacteremic and with evidence of fasciitis
Other suppurative diseases: variety of other infections recognized including puerperal sepsis, lymphangitis, and pneumonia

Nonsuppurative Infections

Rheumatic fever: characterized by inflammatory changes of the heart (pancarditis), joints (arthralgias to arthritis), blood vessels, and subcutaneous tissues
Acute glomerulonephritis: acute inflammation of the renal glomeruli with edema, hypertension, hematuria, and proteinuria

Streptococcus agalactiae *(Group B)*

Early-onset neonatal disease: within 7 days of birth, infected newborns develop signs and symptoms of pneumonia, meningitis, and sepsis
Late-onset neonatal disease: more than 1 week after birth, neonates develop signs and symptoms of bacteremia with meningitis
Infections in pregnant women: most often present as postpartum endometritis, wound infections, and urinary tract infections; bacteremia and disseminated complications may occur
Infections in other adult patients: most common diseases include bacteremia, pneumonia, bone and joint infections, and skin and soft-tissue infections

Other β-Hemolytic Streptococci

Abscess formation in deep tissues: associated with *S. anginosus* group
Pharyngitis: associated with *S. dysgalactiae;* disease resembles that caused by *S. pyogenes;* can be complicated with acute glomerulonephritis

Viridans Streptococci

Abscess formation in deep tissues: associated with *S. anginosus* group
Septicemia in neutropenic patients: associated with *S. mitis* group
Subacute endocarditis: associated with *S. mitis* and *S. salivarius* groups
Dental caries: associated with *S. mutans* group
Malignancies of gastrointestinal tract: associated with *S. bovis* group (*S. gallolyticus* subsp. *gallolyticus*)
Meningitis: associated with *S. gallolyticus* subsp. *pasteurianus, S. suis,* and *S. mitis* group

Streptococcus pneumoniae

Pneumonia: acute onset with severe chills and sustained fever; productive cough with blood-tinged sputum; lobar consolidation
Meningitis: severe infection involving the meninges, with headache, fever, and sepsis; high mortality and severe neurologic deficits in survivors
Bacteremia: more common in patients with meningitis than with pneumonia, otitis, media, or sinusitis; overwhelming sepsis in asplenic patients

Enterococcus faecalis *and* Enterococcus faecium

Urinary tract infection: dysuria and pyuria, most commonly in hospitalized patients with an indwelling urinary catheter and receiving broad-spectrum cephalosporin antibiotics
Peritonitis: abdominal swelling and tenderness after abdominal trauma or surgery; patients typically are acutely ill and febrile and have positive blood cultures; typically a polymicrobic infection
Bacteremia: associated with either a localized infection or endocarditis
Endocarditis: infection of the heart endothelium or valves; associated with persistent bacteremia; can present acutely or chronically

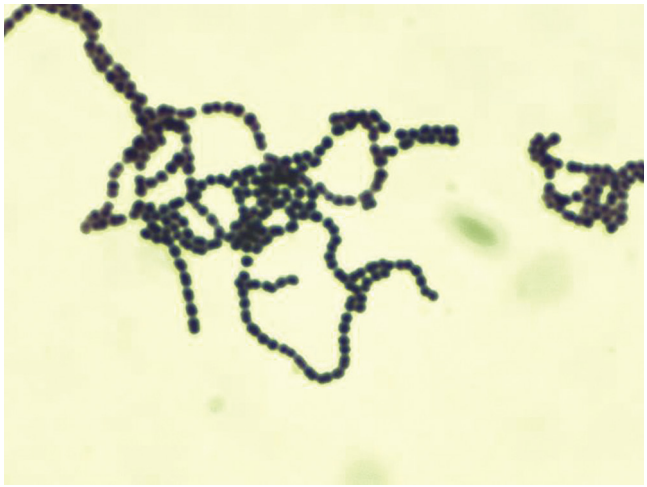

Fig. 19.1 Gram stain of *Streptococcus pyogenes*.

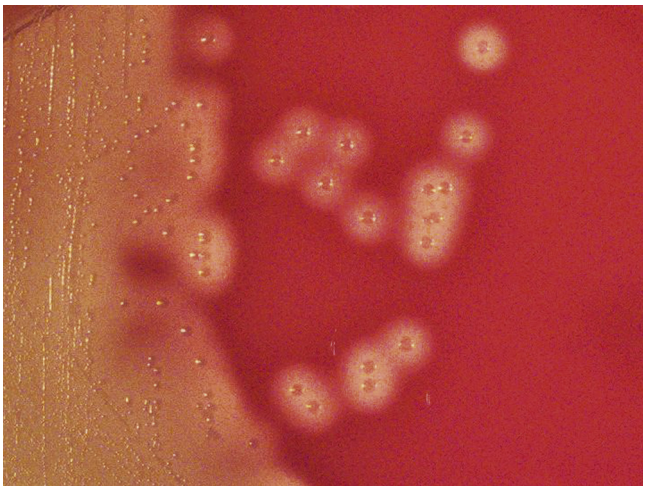

Fig. 19.2 *Streptococcus pyogenes* (group A) typically appears as small colonies with a large zone of hemolysis.

Initial Host–Parasite Interactions

S. pyogenes has multiple mechanisms for **avoiding opsonization and phagocytosis.** The **hyaluronic acid capsule** is a poor immunogen and interferes with phagocytosis. The **M proteins** also interfere with phagocytosis by blocking the binding of the complement component C3b, which is an important mediator of phagocytosis. C3b may also be degraded by factor H, which binds to the cell surface of the M protein. M-like proteins resemble M proteins in structure and are under the same regulatory control. These proteins interfere with phagocytosis by binding either the Fc fragment of antibodies or fibronectin, which blocks activation of complement by the alternate pathway and reduces the amount of bound C3b. Finally, *S. pyogenes* has **C5a peptidase** on the surface. This serine protease inactivates C5a, which is a chemoattractant of neutrophils and mononuclear phagocytes, and protects the bacteria from early clearance from infected tissues.

Many different bacterial antigens have been demonstrated to mediate **adherence to host cells,** and lipoteichoic acid, M proteins, and F protein are the most important. The initial adherence is a weak interaction between **lipoteichoic acid** and fatty acid binding sites on fibronectin and epithelial cells. Subsequent adherence involves **M protein, F protein,** and other adhesins that interact with specific host cell receptors.

S. pyogenes can **invade epithelial cells,** which is a process mediated by **M protein** and **F protein** and other bacterial antigens. This internalization is believed to be important for maintenance of persistent infections (e.g., recurrent streptococcal pharyngitis) and invasion into deep tissues.

Toxins and Enzymes

The **streptococcal pyrogenic exotoxins (Spe),** originally called *erythrogenic toxins,* are produced by lysogenic strains of streptococci and are similar to the toxin produced in *Corynebacterium diphtheriae.* Four immunologically distinct heat-labile toxins (SpeA, SpeB, SpeC, and SpeF) have been described in *S. pyogenes* and in rare strains of groups C and G streptococci. The toxins act as superantigens, interacting with both macrophages and helper T cells, with the enhanced release of proinflammatory cytokines. This family of exotoxins is believed to be responsible for many of the clinical manifestations of severe streptococcal diseases, including necrotizing fasciitis and streptococcal toxic shock syndrome, as well as the rash observed in patients with scarlet fever. It is unclear whether the rash results from the direct effect of the toxin on the capillary bed or, more likely, is secondary to a hypersensitivity reaction.

Streptolysin S is an oxygen-stable, nonimmunogenic, cell-bound hemolysin that can lyse erythrocytes, leukocytes, and platelets. It can also stimulate the release of lysosomal contents after engulfment, with subsequent death of the phagocytic cell. Streptolysin S is produced in the presence of serum (the S indicates serum stable) and is responsible for the characteristic β-hemolysis seen on blood agar media.

Streptolysin O is an oxygen-labile hemolysin capable of lysing erythrocytes, leukocytes, platelets, and cultured cells. This hemolysin is antigenically related to oxygen-labile toxins produced by *S. pneumoniae, Clostridium tetani, C. perfringens, Bacillus cereus,* and *Listeria monocytogenes.* Antibodies are readily formed against streptolysin O **(antistreptolysin O [ASO] antibodies)** (this feature differentiates it from streptolysin S), and they are useful for documenting recent group A streptococcal infection **(ASO test)**. Streptolysin O is irreversibly **inhibited by cholesterol** in skin lipids, so patients with cutaneous infections do not develop ASO antibodies.

At least two forms of **streptokinase (A and B)** have been described. These enzymes mediate the cleavage of plasminogen, releasing the protease plasmin that, in turn, cleaves fibrin and fibrinogen. Thus these enzymes can lyse blood clots and fibrin deposits and facilitate the rapid spread of *S. pyogenes* in infected tissues. Antibodies directed against these enzymes **(antistreptokinase antibodies)** are useful markers for infection.

Four immunologically distinct deoxyribonucleases **(DNases A to D)** have been identified. These enzymes are not cytolytic but can depolymerize free deoxyribonucleic acid (DNA) present in pus. This process reduces the viscosity of the abscess material and facilitates spread of the organisms. Antibodies developed against DNase B **(anti-DNase B test)** are an important marker for patients with cutaneous infections who fail to make antibodies against streptolysin O (see preceding text).

EPIDEMIOLOGY

The Centers for Disease Control and Prevention (CDC) has estimated that at least 10 million cases of noninvasive disease occur annually, with pharyngitis and pyoderma the most common infections, or about 15% of all patients with pharyngitis have an infection with *S. pyogenes* (almost all other infections are caused by viruses). Approximately 20% to 30% of patients with pyoderma (impetigo) have an infection with *S. pyogenes,* whereas the remainder are infected with *Staphylococcus aureus*.

Group A streptococci can colonize the oropharynx of healthy children and young adults in the absence of clinical disease; however, isolation of *S. pyogenes* in a patient with pharyngitis is generally considered significant. Asymptomatic colonization with *S. pyogenes* is transient, regulated by the person's ability to mount specific immunity to the M protein of the colonizing strain and the presence of competitive organisms in the oropharynx. Untreated patients produce antibodies against the specific bacterial M protein that can result in long-lived immunity; however, this antibody response is diminished in treated patients.

In general, *S. pyogenes* disease is caused by recently acquired strains that can establish an infection of the pharynx or skin before specific antibodies are produced or competitive organisms are able to proliferate. Pharyngitis caused by *S. pyogenes* is primarily a disease of children between the ages of 5 and 15 years, but infants and adults are also susceptible. The pathogen is spread from person to person through respiratory droplets. Crowding, such as in classrooms and day-care facilities, increases the opportunity for the organism to spread, particularly during the winter months. Soft-tissue infections (i.e., pyoderma, erysipelas, cellulitis, fasciitis) are typically preceded by initial skin colonization with group A streptococci, after which the

organisms are introduced into the superficial or deep tissues through a break in the skin.

CLINICAL DISEASES

Suppurative Streptococcal Disease

Pharyngitis

Pharyngitis generally develops 2 to 4 days after exposure to the pathogen, with an abrupt onset of sore throat, fever, malaise, and headache. The posterior pharynx can appear erythematous with an exudate, and cervical lymphadenopathy can be prominent. Despite these clinical signs and symptoms, differentiating streptococcal pharyngitis from viral pharyngitis is difficult. An accurate diagnosis can be made only with specific laboratory tests.

Scarlet fever is a complication of streptococcal pharyngitis that occurs when the infecting strain is infected with a bacteriophage that mediates production of a pyrogenic exotoxin. Within 1 to 2 days after the initial clinical symptoms of pharyngitis develop, a diffuse erythematous rash initially appears on the upper chest and then spreads to the extremities. The area around the mouth is generally spared **(circumoral pallor),** as are the palms and soles. A yellowish-white coating initially covers the tongue and is later shed, revealing a red, raw surface beneath **("strawberry tongue").** The rash, which blanches when pressed, is best seen on the abdomen and in skinfolds **(Pastia lines).** The rash disappears over the next 5 to 7 days and is followed by desquamation (shedding) of the superficial skin layer. Suppurative complications of streptococcal pharyngitis (e.g., abscess formation around the tonsils and back of the throat) are rare since the advent of antimicrobial therapy.

Pyoderma

Pyoderma (impetigo) is a confined, purulent *(pyo)* infection of the skin *(derma)* that primarily affects exposed areas (i.e., face, arms, legs). Infection begins when the skin is colonized with *S. pyogenes* after direct contact with an infected person or fomites (e.g., contaminated clothing, linens, or surfaces). The organism is introduced into the subcutaneous tissues through a break in the skin (e.g., scratch, insect bite). Vesicles develop, progressing to pustules (pus-filled vesicles), and then rupture and crust over. The regional lymph nodes can become enlarged, but systemic signs of infection (e.g., fever, sepsis, involvement of other organs) are uncommon. Secondary dermal spread of the infection caused by scratching is typical.

Pyoderma is seen primarily during the warm, moist months in young children with poor personal hygiene. Although *S. pyogenes* is responsible for most streptococcal skin infections, groups C and G streptococci have also been implicated. *S. aureus* is also commonly present in the lesions. The strains of streptococci that cause skin infections differ from those that cause pharyngitis, although pyoderma serotypes can colonize the pharynx and establish a persistent carriage state.

Erysipelas

Erysipelas (*erythros,* red; *pella,* skin) is an acute infection of the skin. Patients experience localized pain, inflammation (erythema, warmth), lymph node enlargement, and systemic signs (chills, fever, leukocytosis). The involved skin area is typically raised and distinctly differentiated from the uninvolved skin (Fig. 19.3). Erysipelas occurs most commonly in young children or older adults, historically on the face but now more commonly on the legs, and usually is preceded by infections of the respiratory tract or skin with *S. pyogenes* (less commonly with group C or G streptococci).

Fig. 19.3 Acute stage of erysipelas of the leg. Note the erythema in the involved area and bullae formation. (From Emond, R.T., Rowland, H.A.K., Welsby, P. 1995. Colour Atlas of Infectious Diseases, third ed. Wolfe, London.)

Cellulitis

Unlike erysipelas, **cellulitis** typically involves both the skin and deeper subcutaneous tissues, and the distinction between infected and noninfected areas of skin is not as clear. As in erysipelas, local inflammation and systemic signs are observed. Precise identification of the offending organism is necessary because many different organisms can cause cellulitis.

Necrotizing Fasciitis

Necrotizing fasciitis (also called *streptococcal gangrene*) is an infection that occurs deep in the subcutaneous tissue, spreads along the fascial planes, and is characterized by an extensive destruction of muscle and fat (Fig. 19.4). The organism (referred to in news media as flesh-eating bacteria) is introduced into the tissue through a break in the skin (e.g., minor cut or trauma, vesicular viral infection, burn, surgery). Initially, there is evidence of cellulitis, after which bullae form and gangrene (tissue necrosis associated with obstructed blood flow) and systemic symptoms develop. Toxicity, multiorgan failure, and death are the hallmarks of this disease; thus prompt medical intervention is necessary to save the patient. Unlike cellulitis, which can be treated with antibiotic therapy, fasciitis must also be treated aggressively with surgical debridement of infected tissue.

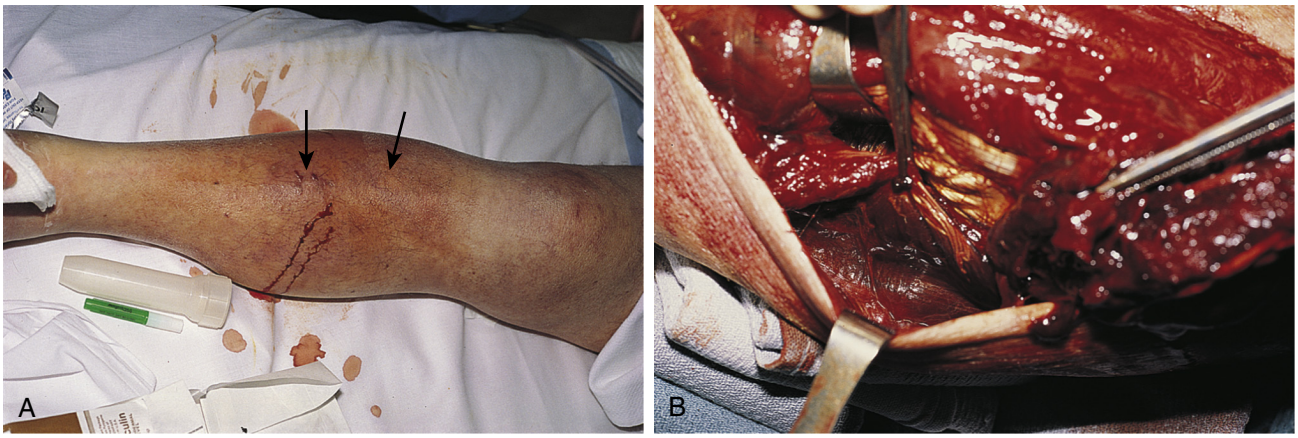

Fig. 19.4 Necrotizing fasciitis caused by *Streptococcus pyogenes*. The patient presented with a 3-day history of malaise, diffuse myalgia, and low-grade fever. Over 3 hours, the pain became excruciating and was localized to the calf. (A) Note the two small, purple bullae over the calf *(arrows)*. (B) Extensive necrotizing fasciitis was present on surgical exploration. The patient died despite aggressive surgical and medical management. (From Cohen, J., Powderly, W.G., Opal, S.M. 2010. Infectious Diseases, third ed. Mosby, Philadelphia, PA.)

Streptococcal Toxic Shock Syndrome

Although the incidence of severe *S. pyogenes* disease declined steadily after the advent of antibiotics, this trend changed dramatically in the late 1980s, when infections characterized by multisystem toxicity were reported (Clinical Case 19.1). Patients with this syndrome initially experience soft-tissue inflammation at the site of the infection, pain, and nonspecific symptoms such as fever, chills, malaise, nausea, vomiting, and diarrhea. The pain intensifies as the disease progresses to shock and organ failure (e.g., kidney, lungs, liver, heart); these features are similar to those of staphylococcal toxic shock syndrome. However, in contrast with staphylococcal disease, most patients with streptococcal disease are bacteremic and many have necrotizing fasciitis.

Although people of all age groups are susceptible to **streptococcal toxic shock syndrome,** increased risk for disease is observed for patients with human immunodeficiency virus (HIV) infection, cancer, diabetes mellitus, heart or pulmonary disease, and varicella zoster virus infection, as well as for intravenous drug abusers and those who abuse alcohol. The strains of *S. pyogenes* responsible for this syndrome differ from the strains causing pharyngitis because most of the former are M serotypes 1 or 3 and many have prominent mucopolysaccharide hyaluronic acid capsules (mucoid strains). The production of pyrogenic exotoxins, particularly SpeA and SpeC, is also a prominent feature of these organisms.

Clinical Case 19.1 Streptococcal Toxic Shock Syndrome

Streptococcal toxic shock syndrome is a frightening, deadly infection. This is illustrated by a patient reported by Cone and associates in 1987 (*N Engl J Med* 317:146–149, 1987). The patient was a 46-year-old man who was scratched on his forearm by his German shepherd dog and then reopened the wound while at work the next day. The following evening, he developed a low-grade fever, chills, backache, and myalgia. When he presented to the local emergency department, minimal erythema and a thin serous discharge were noted at the wound site. Cultures of the wound and blood were collected, and intravenous antibiotics were started. Within 10 hours, the patient became confused and hypotensive. He was transferred to the intensive care unit. Because the erythema over the wound had spread and multiple bullae formed on the wound surface, the patient was taken to surgery, during which yellowish fluid in the muscle tissues was drained. Cultures from the surgical site, as well as the original wound cultures, grew *Streptococcus pyogenes*. After surgical debridement, the patient continued to decline, with the development of abnormal liver function, renal failure, pulmonary distress, and cardiac abnormalities. The patient developed persistent hypotension and died 3 days after admission to the hospital. The fulminant progression of this disease and multiorgan failure underlines the need for aggressive medical intervention.

Other Suppurative Diseases

S. pyogenes has been associated with a variety of other suppurative infections, including puerperal sepsis, lymphangitis, and pneumonia. Although these infections are still seen, they became less common after the introduction of antibiotic therapy.

Bacteremia

S. pyogenes is one of the most common β-hemolytic streptococci isolated in blood cultures. Patients with localized infections (e.g., pharyngitis, pyoderma, erysipelas) rarely are bacteremic, but blood cultures are positive in most patients with necrotizing fasciitis or toxic shock syndrome (in contrast with staphylococcal toxic shock syndrome). The mortality in this population of patients approaches 40% in countries with a sophisticated medical infrastructure and is much higher in resource-limited countries.

Nonsuppurative Streptococcal Disease

Rheumatic Fever

Rheumatic fever is a nonsuppurative complication of *S. pyogenes* pharyngitis. It is characterized by inflammatory changes involving the heart, joints, blood vessels, and subcutaneous tissues. Involvement of the heart manifests as

a pancarditis (endocarditis, pericarditis, myocarditis) and is often associated with subcutaneous nodules. Chronic progressive damage to the heart valves may occur. Joint manifestations can range from arthralgias to frank arthritis, with multiple joints involved in a migratory pattern (i.e., involvement shifts from one joint to another).

The incidence of rheumatic fever in the United States has decreased from a peak of more than 10,000 cases per year reported in 1961 to 112 cases reported in 1994 (the last year of mandatory reporting). In contrast, disease in developing countries is much more common, with an estimated 100 cases per 100,000 children per year. Specific class I M protein types (e.g., types 1, 3, 5, 6, and 18) with an exposed shared antigenic site are responsible for rheumatic fever. In addition, rheumatic fever is associated with streptococcal pharyngitis but not cutaneous streptococcal infections. As would be expected, the epidemiologic characteristics of the disease mimic those of streptococcal pharyngitis. It is most common in young school-age children, with no male or female predilection, and occurs primarily during the cooler months of the year. The disease occurs most commonly in patients with severe streptococcal pharyngitis; however, as many as one-third of patients have asymptomatic or mild infection. Rheumatogenic strains induce a vigorous antibody response in all patients with pharyngitis. Rheumatic fever can recur with a subsequent streptococcal infection if antibiotic prophylaxis is not used. The risk for recurrence decreases with time.

Because no specific diagnostic test can identify patients with rheumatic fever, the diagnosis is made on the basis of clinical findings and documented evidence of a recent *S. pyogenes* infection, such as (1) positive throat culture or specific nucleic acid–based test; (2) detection of the group A antigen in a throat swab; or (3) an elevation of ASO, anti-DNase B, or anti-hyaluronidase antibodies. The absence of an elevated or rising antibody titer would be strong evidence against rheumatic fever.

Acute Glomerulonephritis

The second nonsuppurative complication of streptococcal disease is **glomerulonephritis,** which is characterized by acute inflammation of the renal glomeruli with edema, hypertension, hematuria, and proteinuria. Specific nephritogenic strains of group A streptococci are associated with this disease. In contrast to rheumatic fever, acute glomerulonephritis is a sequela of both pharyngeal and pyodermal streptococcal infections; however, the nephrogenic M serotypes differ for the two primary diseases. The epidemiologic characteristics of the disease are similar to those of the initial streptococcal infection. Diagnosis is determined on the basis of the clinical presentation and the finding of evidence of a recent *S. pyogenes* infection. Young patients generally have an uneventful recovery, but the long-term prognosis for adults is unclear. Progressive irreversible loss of renal function has been observed in adults.

LABORATORY DIAGNOSIS

Microscopy

Gram stains of affected tissue can be used to make a rapid preliminary diagnosis of *S. pyogenes* soft-tissue infections or pyoderma. The finding of gram-positive cocci in pairs and chains in association with leukocytes is important because streptococci are not observed in Gram stains of uninfected skin. In contrast, many species of streptococci are part of the normal population of the oropharynx, so observation of streptococci in a respiratory specimen from a patient with pharyngitis has no diagnostic significance.

Antigen Detection

A variety of immunologic tests using antibodies that react with the group-specific carbohydrate in the bacterial cell wall can be used to detect group A streptococci directly in throat swabs. These tests are rapid, inexpensive, and specific. Antigen tests are not used for cutaneous or nonsuppurative diseases.

Nucleic Acid–Based Tests

Commercial nucleic acid probe assay and nucleic acid amplification assays are available for the detection of *S. pyogenes* in pharyngeal specimens. Probe assays are less sensitive than culture, but amplification assays are as sensitive as culture and are the test of choice where available.

Culture

Despite the difficulty of collecting throat swab specimens from children, specimens must be obtained from the posterior oropharynx (e.g., tonsils). Fewer bacteria are present in the anterior areas of the mouth, and because the mouth (particularly saliva) is colonized with bacteria that inhibit the growth of *S. pyogenes,* contamination of even a properly collected specimen may obscure or suppress the growth of *S. pyogenes*. The recovery of *S. pyogenes* from patients with impetigo is not a problem. The crusted top of the lesion is raised, and the purulent material and base of the lesion are cultured. Culture specimens should not be obtained from open draining skin pustules because they might be superinfected with staphylococci. Organisms are readily recovered in the tissues and blood cultures obtained from patients with necrotizing fasciitis; however, relatively few organisms may be present in the skin of patients with erysipelas or cellulitis. As mentioned previously, streptococci have fastidious growth requirements and growth on the plates may be delayed, so prolonged incubation (2 to 3 days) should be used before a culture is considered negative.

Identification

Group A streptococci are identified definitively through the demonstration of the **group-specific carbohydrate,** typically performed with a rapid immunoassay or nucleic acid amplification test. This is generally sufficient for the diagnosis of *S. pyogenes* infection; however, differentiation of *S. pyogenes* from other species of streptococci with the group-specific A antigen can be determined by their susceptibility to **bacitracin** (an overnight test) or detection of the presence of the enzyme **L-pyrrolidonyl arylamidase (PYR)** (a 5-minute test). *S. pyogenes* is the only streptococcal species that is positive with these tests.

Antibody Detection

Patients with *S. pyogenes* disease produce antibodies to specific streptococcal enzymes. Although antibodies against the M protein are produced and are important for maintaining

immunity, these type-specific antibodies appear late in the clinical course of the disease and are not useful for diagnosis. In contrast, the measurement of antibodies against streptolysin O **(ASO test)** is useful for confirming rheumatic fever or acute glomerulonephritis resulting from a recent streptococcal pharyngeal infection. These antibodies appear 3 to 4 weeks after the initial exposure to the organism and then persist. An elevated ASO titer is not observed in patients who develop acute glomerulonephritis after streptococcal pyoderma (see previous discussion); thus the **anti-DNase B test** should be performed if streptococcal glomerulonephritis is suspected.

TREATMENT, PREVENTION, AND CONTROL

S. pyogenes is very sensitive to penicillin, so oral penicillin V or amoxicillin can be used to treat streptococcal pharyngitis. For penicillin-allergic patients, an oral cephalosporin or macrolide may be used. The combined use of intravenous penicillin with a protein synthesis–inhibiting antibiotic (e.g., clindamycin) is recommended for severe systemic infections. Resistance or poor clinical response has limited the usefulness of the tetracyclines and sulfonamides, and resistance to erythromycin and the newer macrolides (e.g., azithromycin, clarithromycin) is increasing in frequency. Drainage and aggressive surgical debridement must be promptly initiated in patients with serious soft-tissue infections.

Persistent oropharyngeal carriage of *S. pyogenes* can occur after a complete course of therapy. This state may stem from poor compliance with the prescribed course of therapy, reinfection with a new strain, or persistent carriage in a sequestered focus. Because penicillin resistance has not been observed in patients with oropharyngeal carriage, penicillin can be given for an additional course of treatment. If carriage persists, retreatment is not indicated because prolonged antibiotic therapy can disrupt the normal bacterial flora. Antibiotic therapy in patients with pharyngitis speeds the relief of symptoms and, if initiated within 10 days of the initial clinical disease, prevents rheumatic fever. Antibiotic therapy does not appear to influence the progression to acute glomerulonephritis.

Patients with a history of rheumatic fever require long-term **antibiotic prophylaxis** to prevent recurrence of the disease. Because damage to the heart valve predisposes these patients to endocarditis, they also require antibiotic prophylaxis before they undergo procedures that can induce transient bacteremias (e.g., dental procedures). Specific antibiotic therapy does not alter the course of acute glomerulonephritis, and prophylactic therapy is not indicated because recurrent disease is not observed in these patients.

Streptococcus agalactiae

S. agalactiae is the only species that has the group B antigen. This organism was first recognized as a cause of puerperal sepsis. Although this disease is now relatively uncommon, *S. agalactiae* has become better known as an important cause of septicemia, pneumonia, and meningitis in newborn children, as well as a cause of serious disease in adults (see Box 19.1).

PHYSIOLOGY AND STRUCTURE

Group B streptococci are gram-positive cocci (0.6 to 1.2 μm) that form short chains in clinical specimens and longer chains in culture, which are features that make them indistinguishable on Gram stain from *S. pyogenes.* They grow well on nutritionally enriched media and, in contrast to the colonies of *S. pyogenes,* the colonies of *S. agalactiae* are large with a narrow zone of β-hemolysis. Some strains (1% to 2%) are nonhemolytic, although their prevalence may be underestimated because nonhemolytic strains are not commonly screened for the group B antigen.

Strains of *S. agalactiae* can be characterized on the basis of three serologic markers: (1) the **group-specific cell wall polysaccharide B antigen** (Lancefield grouping antigen), (2) nine **type-specific capsular polysaccharides** (Ia, Ib, and II to VIII), and (3) **surface proteins** (the most common is the **c antigen**). The type-specific polysaccharides are important epidemiologic markers, with serotypes Ia, III, and V most commonly associated with colonization and disease. Knowledge of the specific serotypes associated with disease and of shifting patterns of serotype prevalence is important for vaccine development.

PATHOGENESIS AND IMMUNITY

The most important virulence factor of *S. agalactiae* is the **polysaccharide capsule** that interferes with phagocytosis until the patient develops type-specific antibodies. Antibodies against the type-specific capsular antigens are protective, which is a factor that partly explains the predilection of this organism for neonates. In the absence of maternal antibodies, the neonate is at risk for disease. In addition, genital colonization with group B streptococci has been associated with increased risk of premature delivery, and premature infants are at greater risk of disease. Functional classical and alternative complement pathways are required for killing group B streptococci, particularly types Ia, III, and V. As a result, there is a greater likelihood of systemic spread of the organism in colonized premature infants with physiologically **low complement levels** or for infants in whom the receptors for complement, or for the Fc fragment of immunoglobulin (Ig)G antibodies, are not exposed on neutrophils. It also has been found that the type-specific capsular polysaccharides of types Ia, Ib, and II streptococci have a terminal residue of sialic acid. **Sialic acid** can inhibit activation of the alternative complement pathway, interfering with the phagocytosis of these strains of group B streptococci.

EPIDEMIOLOGY

Group B streptococci colonize the lower gastrointestinal tract and the genitourinary tract. Transient vaginal carriage has been observed in 10% to 30% of pregnant women, although the observed incidence depends on the time during the gestation period when the sampling is done and the culture techniques used.

Approximately 60% of infants born to colonized mothers become colonized when they pass through the vaginal canal with their mothers' organisms. This is more likely when the

mother is colonized with large numbers of bacteria. Other associations for neonatal colonization are premature delivery, prolonged rupture of the amniotic sac (membrane), and intrapartum fever. Disease in infants younger than 7 days of age is called **early-onset disease;** disease appearing between 1 week and 3 months of life is considered **late-onset disease.** The serotypes most commonly associated with early-onset disease are Ia (35% to 40%), III (30%), and V (15%). Serotype III is responsible for most late-onset disease. Serotypes Ia and V are the most common in adult disease.

Colonization with subsequent development of disease in the neonate can occur in utero, at birth, or during the first few months of life. *S. agalactiae* is the most common cause of bacterial septicemia and meningitis in newborns. The use of intrapartum antibiotic prophylaxis is responsible for a dramatic decline in neonatal disease from approximately 1.7 infections per live birth in 1993 to 0.22 infections in 2016.

The risk of invasive disease in adults is greater in pregnant women than in men and nonpregnant women. Urinary tract infections, amnionitis, endometritis, and wound infections are the most common manifestations in pregnant women. Infections in men and nonpregnant women are primarily skin and soft-tissue infections, bacteremia, urosepsis (urinary tract infection with bacteremia), and pneumonia. Conditions that predispose to the development of disease in nonpregnant adults include diabetes mellitus, chronic liver or renal disease, cancer, and HIV infection.

CLINICAL DISEASES

Early-Onset Neonatal Disease

Clinical symptoms of group B streptococcal disease acquired in utero or at birth develop during the first week of life. Early-onset disease, characterized by **bacteremia, pneumonia,** or **meningitis,** is indistinguishable from sepsis caused by other organisms. Because pulmonary involvement is observed in most infants and meningeal involvement may be initially inapparent, examination of cerebrospinal fluid (CSF) is required for all infected children. The mortality rate has decreased to less than 5% because of rapid diagnosis and better supportive care; however, 15% to 30% of infants who survive meningitis have severe neurologic sequelae, including blindness, deafness, and mental retardation.

Late-Onset Neonatal Disease

Late-onset disease is acquired from an exogenous source (e.g., mother, another infant) and develops between 1 week and 3 months of age (Clinical Case 19.2). The predominant manifestation is **bacteremia with meningitis,** which resembles disease caused by other bacteria. Although the mortality rate is low (e.g., 3%), neurologic complications are common in children with meningitis (e.g., 25% to 50%).

Infections in Pregnant Women

Postpartum endometritis, wound infection, and **urinary tract infections** occur in women during and immediately after pregnancy. Because childbearing women are generally in good health, the prognosis is excellent for those who receive appropriate therapy. Secondary complications of bacteremia such as endocarditis, meningitis, and osteomyelitis are rare.

Clinical Case 19.2 Group B Streptococcal Disease in a Neonate

The following is a description of late-onset group B streptococcal disease in a neonate (Hammersen et al: *Eur J Pediatr* 126:189–197, 1977). An infant male weighing 3400 g was delivered spontaneously at term. Physical examinations of the infant were normal during the first week of life; however, the child started feeding irregularly during the second week. On day 13, the baby was admitted to the hospital with generalized seizures. A small amount of cloudy CSF was collected by lumbar puncture, and *Streptococcus agalactiae* serotype III was isolated from culture. Despite prompt initiation of therapy, the baby developed hydrocephalus, necessitating implantation of an atrioventricular shunt. The infant was discharged at age 3.5 months with retardation of psychomotor development. This patient illustrates neonatal meningitis caused by the most commonly implicated serotype of group B streptococci in late-onset disease and the complications associated with this infection.

Infections in Men and Nonpregnant Women

Compared with pregnant women who acquire group B streptococcal infection, men and nonpregnant women with group B streptococcal infections are generally older and have debilitating underlying conditions. The most common presentations are **bacteremia, pneumonia, bone and joint infections,** and **skin and soft-tissue infections.** Because these patients often have compromised immunity, mortality is higher in this population.

LABORATORY DIAGNOSIS

Antigen Detection

Tests for the direct detection of group B streptococci in urogenital specimens are available but are too insensitive to be used to screen mothers and predict which newborns are at increased risk for acquiring neonatal disease. Likewise, the antigen tests are too insensitive (<30%) to be used with CSF. A Gram stain of CSF has much better sensitivity and should be used.

Nucleic Acid–Based Tests

Polymerase chain reaction (PCR)–based nucleic acid amplification assays are approved by the U.S. Food and Drug Administration (FDA) for rectal/vaginal swabs from pregnant women. Testing is generally performed immediately before delivery to guide use of prophylactic therapy to protect the infants of colonized women.

Culture

Group B streptococci readily grow on a nutritionally enriched medium, producing large colonies after 24 hours of incubation; however, β-hemolysis may be difficult to detect or absent, posing a problem in the detection of the organism when other organisms are present in the culture (e.g., vaginal culture). Thus use of a selective enrichment broth medium with antibiotics added to suppress the growth of other organisms (e.g., LIM broth with colistin and nalidixic acid) followed by subculture to nonselective media

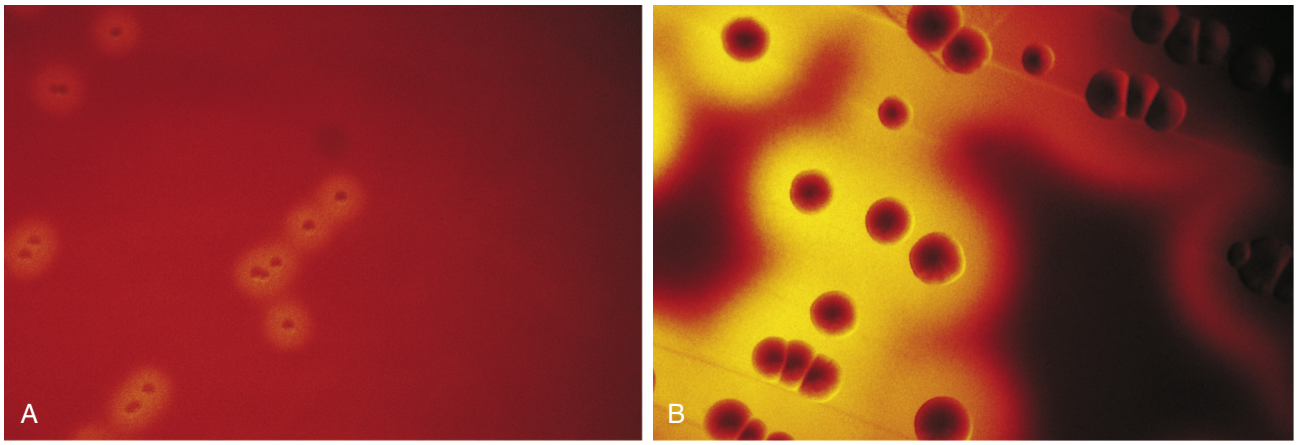

Fig. 19.5 Group C *Streptococcus.* (A) *S. anginosus,* small-colony species. (B) *S. dysgalactiae,* large-colony species.

such as a blood agar plate is currently recommended by the CDC for the detection of group B streptococci in women between weeks 35 and 37 of pregnancy.

Identification

Because *S. agalactiae* is the only member of the group B streptococci, isolates are identified definitively by the demonstration of the group-specific cell wall carbohydrate.

TREATMENT, PREVENTION, AND CONTROL

Group B streptococci are susceptible to **penicillin,** which is the drug of choice. Because other bacteria can be responsible for neonatal disease (e.g., *S. pneumoniae, Listeria,* gram-negative rods), broad-spectrum therapy should be selected for empirical therapy. A cephalosporin or vancomycin can be used in penicillin-allergic patients. Resistance to macrolides, clindamycin, and tetracyclines is common, so these drugs should not be selected unless demonstrated to be active in vitro.

In an effort to prevent neonatal disease, it is recommended that all pregnant women should be **screened for colonization** with group B streptococci at 35 to 37 weeks' gestation (refer to the following CDC document for additional information: www.cdc.gov/groupbstrep/guidelines/index.html). **Chemoprophylaxis** should be used for all women who are either colonized or at high risk. A pregnant woman is considered to be at high risk to give birth to a baby with invasive group B disease if she has previously given birth to an infant with the disease or risk factors for the disease are present at birth. These risk factors are (1) intrapartum temperature of at least 38° C, (2) membrane rupture at least 18 hours before delivery, and (3) vaginal or rectal culture positive for organisms at 35 to 37 weeks' gestation. Intravenous penicillin G or ampicillin administered at least 4 hours before delivery is recommended; cefazolin is used for penicillin-allergic women or clindamycin (if susceptible) or vancomycin for mothers at high risk for anaphylaxis. This approach ensures high protective antibiotic levels in the infant's circulatory system at the time of birth.

Because newborn disease is associated with decreased circulating antibodies in the mother, efforts have been directed at developing a polyvalent vaccine against serotypes Ia, Ib, II, III, and V. The capsular polysaccharides are poor immunogens; however, complexing them with a protein such as tetanus toxoid has improved the immunogenicity of the vaccine. Trials with this polyvalent vaccine demonstrated that protective levels of antibodies are induced in animal models; however, no licensed vaccine is currently available.

Other β-Hemolytic Streptococci

Among the other β-hemolytic streptococci, groups C, F, and G are most commonly associated with human disease. Organisms of particular importance are the *S. anginosus* group (includes *S. anginosus, S. constellatus,* and *S. intermedius*) and *S. dysgalactiae*. To illustrate the complexity of identifying streptococci, β-hemolytic members of the *S. anginosus* group can possess the group A, C, F, or G polysaccharide antigen (or not have any group-specific antigen), and *S. dysgalactiae* can have either the group C or G antigen. It should be noted that an individual isolate possesses only one group antigen. Isolates of the *S. anginosus* group grow as small colonies (requiring 2 days of incubation) with a narrow zone of β-hemolysis (Fig. 19.5A). These species are primarily associated with abscess formation and not pharyngitis, in contrast to the other group A *Streptococcus, S. pyogenes*. *S. dysgalactiae* produces large colonies with a large zone of β-hemolysis on blood agar media (see Fig. 19.5B), resembling *S. pyogenes.* Additionally, *S. dysgalactiae* causes pharyngitis, which is sometimes complicated by acute glomerulonephritis but never rheumatic fever.

Viridans Streptococci

The viridans group of streptococci is a heterogeneous collection of α-hemolytic and nonhemolytic streptococci (Fig. 19.6). Many species and subspecies have been identified, and most are classified into five subgroups. This classification scheme is clinically important because many of the species in the five subgroups are responsible for specific diseases (see Table 19.4). Some members of the viridans streptococci (e.g., *S. anginosus* group) can have β-hemolytic strains with the group-specific cell wall polysaccharides (thus contributing to the confusing taxonomy of this genus). In addition, *S.*

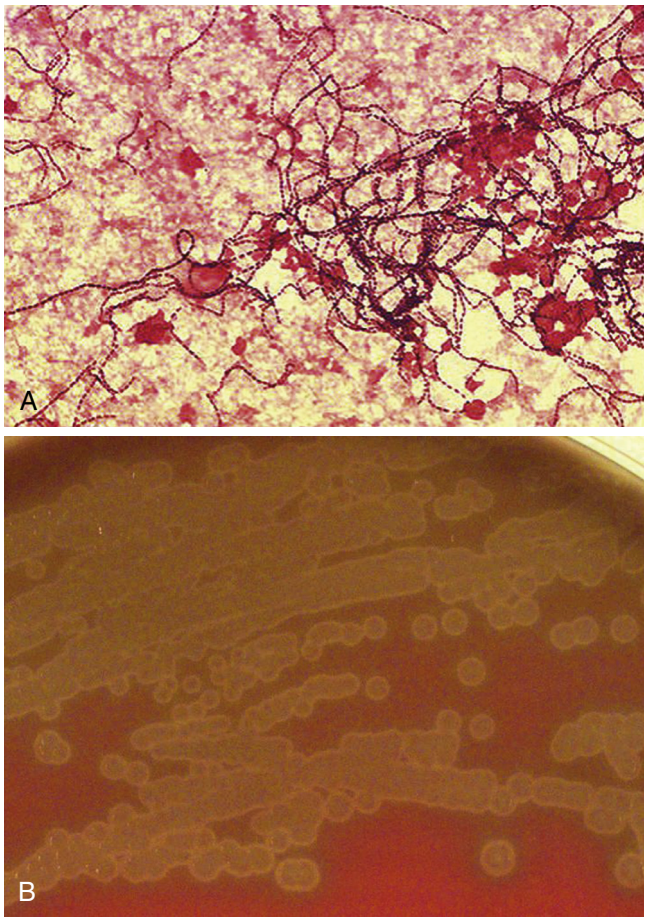

Fig. 19.6 *Streptococcus mitis.* (A) Gram stain from blood culture. (B) α-Hemolytic colonies.

pneumoniae is a member of the *S. mitis* subgroup, although most physicians and microbiologists do not think of *S. pneumoniae* as viridans streptococci; it will be discussed separately in this chapter.

The viridans streptococci colonize the oropharynx, gastrointestinal tract, and genitourinary tract. Similar to most other streptococci, viridans species are nutritionally fastidious, requiring complex media supplemented with blood products and, frequently, an incubation atmosphere with 5% to 10% carbon dioxide.

Although most viridans streptococci are highly susceptible to penicillin, with minimum inhibitory concentrations (MICs) of less than 0.1 μg/ml, moderately resistant (penicillin MIC of 0.2 to 2 μg/ml) and highly resistant (MIC > 2 μg/ml) streptococci have become common in the *S. mitis* group. Infections with isolates that are moderately resistant can generally be treated with a combination of penicillin and an aminoglycoside; however, alternative antibiotics such as a broad-spectrum cephalosporin or vancomycin must be used to treat serious infections.

Streptococcus pneumoniae

S. pneumoniae was isolated independently by Pasteur and Steinberg more than 100 years ago. Since that time, research with this organism has led to a greater understanding of molecular genetics, antibiotic resistance, and vaccine-related immunoprophylaxis. Unfortunately, pneumococcal disease is still a leading cause of morbidity and mortality.

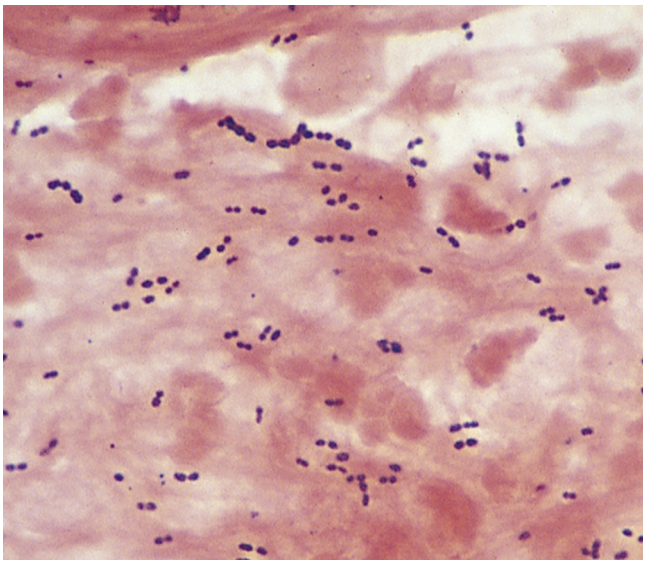

Fig. 19.7 Gram stain of *Streptococcus pneumoniae*.

PHYSIOLOGY AND STRUCTURE

The pneumococcus is an **encapsulated** gram-positive coccus. The cells are 0.5 to 1.2 μm in diameter, oval, and arranged in pairs (commonly referred to as **diplococci**) or short chains (Fig. 19.7). Older cells decolorize readily and can stain gram-negative. Colonial morphology varies, with colonies of encapsulated strains generally large (1 to 3 mm in diameter on blood agar; smaller on chocolatized or heated blood agar), round, and mucoid, and colonies of nonencapsulated strains smaller and flat. All colonies undergo autolysis with aging; that is, the central portion of the colony dissolves, leaving a dimpled appearance. Colonies appear α-hemolytic on blood agar if incubated aerobically and may be β-hemolytic if grown anaerobically. The α-hemolytic appearance results from production of **pneumolysin,** which is an enzyme that degrades hemoglobin and produces a green product.

The organism has fastidious nutritional requirements and can grow only on enriched media supplemented with blood products. *S. pneumoniae* can ferment carbohydrates, producing lactic acid as the primary metabolic by-product. *S. pneumoniae* grows poorly in media with high glucose concentrations because lactic acid rapidly reaches toxic levels in such preparations. Similar to all streptococci, the organism lacks catalase. Unless an exogenous source of catalase is provided (e.g., from blood), the accumulation of hydrogen peroxide inhibits the growth of *S. pneumoniae,* as observed on chocolatized blood agar.

Virulent strains of *S. pneumoniae* are covered with a complex **polysaccharide capsule.** The capsular polysaccharides have been used for the serologic classification of strains; currently, more than 90 serotypes are recognized. Purified capsular polysaccharides from the most commonly isolated serotypes are used in a **polyvalent vaccine.**

Individual strains of *S. pneumoniae* can switch capsular serotypes through genomic recombination and point mutations in the capsular genes. Recombination is also associated with acquisition of genes encoding penicillin resistance, so use of vaccines or antibiotic therapy can facilitate the selection and dissemination of new capsular serotypes.

The peptidoglycan layer of the cell wall of the pneumococcus is typical of gram-positive cocci. Attached to alternating subunits of *N*-acetylglucosamine and *N*-acetylmuramic acid are oligopeptide chains, which, in turn, are cross-linked by pentaglycine bridges. The other major component of the cell wall is teichoic acid. Two forms of teichoic acid exist in the pneumococcal cell wall, one exposed on the cell surface and a similar structure covalently bound to the plasma membrane lipids. The exposed teichoic acid is linked to the peptidoglycan layer and extends through the overlying capsule. This species-specific structure, called the **C polysaccharide,** is unrelated to the group-specific carbohydrate observed by Lancefield in β-hemolytic streptococci. The C polysaccharide precipitates a serum globulin fraction **(C-reactive protein [CRP])** in the presence of calcium. CRP is present in low concentrations in healthy people but in elevated concentrations in patients with acute inflammatory diseases (hence, monitoring the levels of CRP is used to predict inflammation). The teichoic acid bound to lipids in the bacterial cytoplasmic membrane is called the **F antigen** because it can cross-react with the Forssman surface antigens on mammalian cells. Both forms of teichoic acid are associated with phosphorylcholine residues. **Phosphorylcholine** is unique to the cell wall of *S. pneumoniae* and plays an important regulatory role in cell wall hydrolysis. Phosphorylcholine must be present for activity of the pneumococcal autolysin, **amidase,** during cell division.

PATHOGENESIS AND IMMUNITY

Although *S. pneumoniae* has been extensively studied, much remains to be learned about the pathogenesis of pneumococcal disease. The disease manifestations are caused primarily by the host response to infection rather than the production of organism-specific toxic factors. However, an understanding of how *S. pneumoniae* colonizes the oropharynx, spreads into normally sterile tissues, stimulates a localized inflammatory response, and evades being killed by phagocytic cells is crucial.

Colonization and Migration

S. pneumoniae is a human pathogen that colonizes the oropharynx and then, in specific situations, is able to spread to the lungs, paranasal sinuses, or middle ear. It can also be transported in the blood to distal sites such as the brain. The initial colonization of the oropharynx is mediated by the binding of the bacteria to epithelial cells by means of **surface protein adhesins.** Subsequent migration of the organism to the lower respiratory tract can be prevented if the bacteria are enveloped in mucus and removed from the airways by the action of ciliated epithelial cells. The bacteria counteract this envelopment by producing **secretory IgA protease** and **pneumolysin.** Secretory IgA traps bacteria in mucus by binding the bacteria to mucin with the Fc region of the antibody. The bacterial IgA protease prevents this interaction. **Pneumolysin,** a cytotoxin similar to the streptolysin O in *S. pyogenes,* binds cholesterol in the host cell membrane and creates pores. This activity can destroy the ciliated epithelial cells and phagocytic cells.

Tissue Destruction

A characteristic of pneumococcal infections is the mobilization of inflammatory cells to the focus of infection. Pneumococcal teichoic acid, peptidoglycan fragments, and pneumolysin mediate the process. **Teichoic acid** and the **peptidoglycan fragments** activate the alternative complement pathway, producing C5a, which mediates the inflammatory process. This activity is augmented by the bacterial enzyme **amidase,** which enhances release of the cell wall components. **Pneumolysin** activates the classic complement pathway, resulting in the production of C3a and C5a. In turn, cytokines such as interleukin (IL)-1 and tumor necrosis factor (TNF)-α are produced by the activated leukocytes, leading to the further migration of inflammatory cells to the site of infection and fever, tissue damage, and other signs characteristic of pneumococcal infection. The production of **hydrogen peroxide** by *S. pneumoniae* can also lead to tissue damage caused by reactive oxygen intermediates.

Finally, **phosphorylcholine** present in the bacterial cell wall can bind to receptors for platelet-activating factor that are expressed on the surface of endothelial cells, leukocytes, platelets, and tissue cells, such as those in the lungs and meninges. By binding these receptors, the bacteria can enter the cells, in which they are protected from opsonization and phagocytosis, and pass into sequestered areas, such as blood and the central nervous system. This activity facilitates the spread of disease.

Phagocytic Survival

S. pneumoniae survives phagocytosis because of the antiphagocytic protection afforded by its **capsule** and the pneumolysin-mediated suppression of the phagocytic cell oxidative burst, which is required for intracellular killing. The virulence of *S. pneumoniae* is a direct result of this capsule. Encapsulated (smooth) strains can cause disease in humans and experimental animals, whereas nonencapsulated (rough) strains are avirulent. Antibodies directed against the type-specific capsular polysaccharides protect against disease caused by immunologically related strains, so capsular switching allows a strain to avoid immune clearance. The capsular polysaccharides are soluble and have been called **specific soluble substances.** Free polysaccharides can protect viable organisms from phagocytosis by binding with opsonic antibodies.

EPIDEMIOLOGY

S. pneumoniae is a common inhabitant of the throat and nasopharynx in healthy people, with colonization more common in children than in adults and more common in adults living in a household with children. Colonization initially occurs at approximately 6 months of age. Subsequently, the child is transiently colonized with other serotypes of the organism. The duration of carriage decreases with each successive serotype carried, in part because of the development of serotype-specific immunity. Although new serotypes are acquired throughout the year, the incidence

of carriage and associated disease is highest during the cool months. The strains of pneumococci that cause the disease are the same as those associated with carriage.

Pneumococcal disease occurs when organisms colonizing the nasopharynx and oropharynx spread to the lungs (pneumonia), paranasal sinuses (sinusitis), ears (otitis media), or meninges (meningitis). Spread of *S. pneumoniae* in blood to other body sites can occur with all of these diseases. It is recognized that some serotypes have a higher predilection for invasive pneumococcal disease.

Although the introduction of vaccines for pediatric and adult populations has reduced the incidence of disease caused by *S. pneumoniae,* the organism is still a common cause of bacterial pneumonia acquired outside the hospital, meningitis, otitis media and sinusitis, and bacteremia. Disease is most common in children and the elderly with low levels of protective antibodies directed against the pneumococcal capsular polysaccharides. The World Health Organization (WHO) estimated that more than 750,000 children younger than age 5 years die each year of pneumococcal pneumonia or meningitis.

Pneumonia occurs when the endogenous oral organisms are aspirated into the lower airways. Although strains can spread on airborne droplets from one person to another in a closed population, epidemics are rare. Disease occurs when the natural defense mechanisms (e.g., epiglottal reflex, trapping of bacteria by the mucus-producing cells lining the bronchus, removal of organisms by the ciliated respiratory epithelium, and cough reflex) are circumvented, permitting organisms colonizing the oropharynx to gain access to the lungs. Pneumococcal disease is most commonly associated with an antecedent viral respiratory disease, such as influenza, or with other conditions that interfere with bacterial clearance, such as chronic pulmonary disease, alcoholism, congestive heart failure, diabetes mellitus, chronic renal disease, and splenic dysfunction or splenectomy.

CLINICAL DISEASES

Pneumonia

Pneumococcal **pneumonia** develops when the bacteria multiply in the alveolar spaces (Clinical Case 19.3). After aspiration, the bacteria grow rapidly in the nutrient-rich edema fluid. Erythrocytes leaking from congested capillaries accumulate in the alveoli, followed by the neutrophils, and then the alveolar macrophages. Resolution occurs when specific anticapsular antibodies develop, facilitating phagocytosis of the organism and microbial killing.

The onset of the clinical manifestations of pneumococcal pneumonia is abrupt, consisting of a severe shaking chill and sustained fever of 39° C to 41° C. The patient often has symptoms of a viral respiratory tract infection 1 to 3 days before the onset. Most patients have a productive cough with blood-tinged sputum, and they commonly have chest pain **(pleurisy)**. Because the disease is associated with aspiration, it is generally localized in the lower lobes of the lungs (hence the name **lobar pneumonia**; Fig. 19.8). However, children and the elderly can have a more generalized bronchopneumonia. Patients usually recover rapidly after the initiation of appropriate antimicrobial therapy, with complete radiologic resolution in 2 to 3 weeks.

Clinical Case 19.3 ***Streptococcus pneumoniae* Pneumonia**

Costa and associates (*Am J Hematol* 77:277–281, 2004) described a 68-year-old woman who was in good health until 3 days before hospitalization. She developed fever, chills, increased weakness, and a productive cough with pleuritic chest pain. On admission, she was febrile, had an elevated pulse and respiration rate, and was in moderate respiratory distress. Initial laboratory values showed leucopenia, anemia, and acute renal failure. Chest radiograph demonstrated infiltrates in the right and left lower lobes, with pleural effusions. Therapy with a fluoroquinolone was initiated, and blood and respiratory cultures were positive for *S. pneumoniae.* Additional tests (serum and urine protein electrophoresis) revealed the patient had multiple myeloma. The patient's infection resolved with a 14-day course of antibiotics. This patient illustrates the typical picture of pneumococcal lobar pneumonia and the increased susceptibility to infection in patients with defects in their ability to clear encapsulated organisms.

Fig. 19.8 Dense consolidation of left lower lobe in patient with pneumonia caused by *Streptococcus pneumoniae.* (From Mandell, G., Bennett, J., Dolin, R. 2015. Principles and Practice of Infectious Diseases, eighth ed. Elsevier, Philadelphia, PA.)

The overall mortality rate is 5%, although the likelihood of death is influenced by the serotype of the organism and the age and underlying disease of the patient. The mortality rate is considerably higher in patients with disease caused by *S. pneumoniae* type 3, as well as in elderly patients and patients with documented bacteremia. Patients with splenic dysfunction or splenectomy can also have severe pneumococcal disease because of decreased bacterial clearance from the blood and the defective production of early antibodies. In these patients, disease can be associated with a fulminant course and high mortality rate.

Abscesses do not commonly form in patients with pneumococcal pneumonia, except in those infected with specific serotypes (e.g., serotype 3). Pleural effusions are seen in approximately 25% of patients with pneumococcal pneumonia, and empyema (purulent effusion) is a rare complication.

Sinusitis and Otitis Media

S. pneumoniae is a common cause of acute infections of the paranasal sinuses and ear. The disease is usually preceded by a viral infection of the upper respiratory tract, after which polymorphonuclear neutrophils (leukocytes; PMNs) infiltrate and obstruct the sinuses and ear canal. Middle ear infection **(otitis media)** is primarily seen in young children, but bacterial **sinusitis** can occur in patients of all ages.

Meningitis

S. pneumoniae can spread into the central nervous system after bacteremia, infections of the ear or sinuses, or head trauma that causes a communication between the subarachnoid space and the nasopharynx. Although **pneumococcal meningitis** is relatively uncommon in neonates, *S. pneumoniae* is now a leading cause of disease in children and adults. Mortality and severe neurologic deficits are 4 to 20 times more common in patients with meningitis caused by *S. pneumoniae* than in those with meningitis resulting from other organisms.

Bacteremia

Bacteremia occurs in 25% to 30% of patients with pneumococcal pneumonia and in more than 80% of patients with meningitis. In contrast, bacteria are generally not present in the blood of patients with sinusitis or otitis media. Endocarditis can occur in patients with both normal or previously damaged heart valves. Destruction of valve tissue is common.

LABORATORY DIAGNOSIS

Microscopy

Gram stain of sputum specimens is a rapid way to diagnose pneumococcal pneumonia and meningitis. The organisms characteristically appear as elongated pairs of gram-positive cocci surrounded by a clear area consisting of the unstained capsule; however, they may also appear to be gram-negative because they tend not to stain well (particularly in older cultures). In addition, their morphology may be distorted in a patient receiving antibiotic therapy. A Gram stain consistent with *S. pneumoniae* can be confirmed with the **quellung** (German for "swelling") reaction, which is a test primarily of historical interest (i.e. a rarely performed test that is only remembered by professors preparing exam questions). In this test, polyvalent anticapsular antibodies are mixed with the bacteria, and then the mixture is examined microscopically. A greater refractiveness around the bacteria is a positive reaction for *S. pneumoniae*. An alternative test is to mix a drop of bile with a suspension of bacteria. Bile will dissolve *S. pneumoniae* and no organisms will be seen in the Gram stain (a rapid test that is significantly more useful).

Antigen Detection

Pneumococcal C polysaccharide is excreted in urine and can be detected using a commercially prepared immunoassay. Maximum sensitivity requires that the urine is concentrated by ultrafiltration before it is assayed. Sensitivity has been reported to be 70% in patients with bacteremic pneumococcal pneumonia; however, specificity can be low, particularly in pediatric patients. For this reason, the test is not recommended for children with suspected infections. The test has a sensitivity approaching 100% for patients with pneumococcal meningitis if CSF is tested; however, the test has poor sensitivity and specificity if urine is tested in these patients.

Nucleic Acid–Based Tests

PCR assays have been developed for identification of *S. pneumoniae* isolates in clinical specimens such as CSF. Commercial multiplex tests for the diagnosis of bacterial and viral meningitis have gained widespread use in recent years and may represent the most accurate, rapid diagnostic test.

Culture

Sputum specimens should be inoculated onto an enriched nutrient medium supplemented with blood. *S. pneumoniae* is recovered in the sputum cultures from only half of the patients who have pneumonia because the organism has fastidious nutritional requirements and is rapidly overgrown by contaminating oral bacteria. Selective media have been used with some success to isolate the organism from sputum specimens, but it takes some technical skill to distinguish *S. pneumoniae* from the other α-hemolytic streptococci that are often present in the specimen. An aspirate must be obtained from the sinus or middle ear for the organism responsible for sinusitis or otitis to be diagnosed definitively. Specimens taken from the nasopharynx or outer ear should not be cultured. It is not difficult to isolate *S. pneumoniae* from specimens of CSF if antibiotic therapy has not been initiated before the specimen is collected; however, as many as half of infected patients who have received even a single dose of antibiotics will have negative cultures. This is the reason the nucleic acid amplification tests are now recognized as the test of choice for diagnosis of meningitis.

Identification

Isolates of *S. pneumoniae* are lysed rapidly when the autolysins are activated after exposure to bile **(bile solubility test).** Thus the organism can be identified by placing a drop of bile on an isolated colony. Most colonies of *S. pneumoniae* are dissolved within a few minutes, whereas other α-hemolytic streptococci remain unchanged. *S. pneumoniae* can also be identified by its susceptibility to **optochin** (ethylhydrocupreine dihydrochloride). The isolate is streaked onto a blood agar plate, and a disk saturated with optochin is placed in the middle of the inoculum. A zone of inhibited bacterial growth is seen around the disk after overnight incubation. Additional biochemical, serologic, or molecular diagnostic tests can be performed for a definitive identification.

TREATMENT, PREVENTION, AND CONTROL

Historically **penicillin** was the treatment of choice for pneumococcal disease; however, in 1977, researchers in South Africa reported isolates of *S. pneumoniae* that were resistant to multiple antibiotics, including penicillin. Although high-level resistance to penicillin (MIC of at least 2 μg/ml) was relatively uncommon, this situation changed dramatically beginning in 1990. Now resistance to penicillin is observed for as many as half of the strains isolated in the United States

and in other countries. Resistance to penicillins is associated with a decreased affinity of the antibiotic for the penicillin-binding proteins present in the bacterial cell wall, and patients infected with resistant bacteria have an increased risk of an adverse outcome. Resistance to macrolides (e.g., erythromycin), tetracyclines, and to a lesser extent cephalosporins (e.g., ceftriaxone) has also become commonplace. Thus for serious pneumococcal infections, treatment with a combination of antibiotics is recommended until in vitro susceptibility results are available. **Vancomycin** combined with **ceftriaxone** is used commonly for empirical treatment, followed by monotherapy with an effective cephalosporin, fluoroquinolone, or vancomycin.

Efforts to prevent or control the disease have focused on the development of effective anticapsular vaccines. Two forms of vaccines are used: multivalent polysaccharide vaccines and multivalent conjugated vaccines. Polysaccharides are T-independent antigens, stimulating mature B lymphocytes but not T lymphocytes. Very young children respond poorly to T-independent antigens, so these polysaccharide vaccines are ineffective for this population. In contrast, conjugation of polysaccharides to proteins stimulates a T helper cell response, resulting in a strong primary response among infants and the elderly and effective booster response when reimmunized. This approach of using conjugated vaccines for pediatric immunizations has also been used for other neonatal pathogens, such as *Haemophilus influenzae.* A series of primary and booster vaccinations with the pneumococcal conjugated vaccine is recommended for children less than 2 years of age, whereas use of the pneumococcal polysaccharide vaccine as a booster vaccine is recommended for older children and adults. Refer to the CDC website for specific guidance. The effectiveness of these vaccines is determined by the prevalent serotypes of *S. pneumoniae* responsible for invasive disease in the population. Although these vaccines are generally effective in the United States and European populations, they are less effective in developing countries because the prevalent serotypes are not represented in the vaccines. Additionally, although the 23-valent vaccine is immunogenic in normal adults and immunity is long lived, the vaccine is less effective in some patients at high risk for pneumococcal disease including: (1) patients with asplenia, sickle cell disease, hematologic malignancy, and HIV infection; (2) patients who have undergone renal transplant; and (3) the elderly.

Enterococcus

PHYSIOLOGY AND STRUCTURE

The enterococci are gram-positive cocci, typically arranged in **pairs and short chains** (Fig. 19.9). The microscopic morphology of these isolates cannot be differentiated reliably from that of *S. pneumoniae.* The cocci grow both aerobically and anaerobically in a broad temperature range (10° C to 45° C), in a wide pH range (4.6 to 9.9), and in the presence of high concentrations of sodium chloride **(NaCl)** and **bile salts.** Thus there are very few clinical conditions that inhibit the growth of enterococci. Glucose is fermented with L-lactic acid as the predominant end product (enterococci are commonly referred to as *lactic acid bacteria*). After 24 hours of incubation, colonies on enriched sheep blood agar

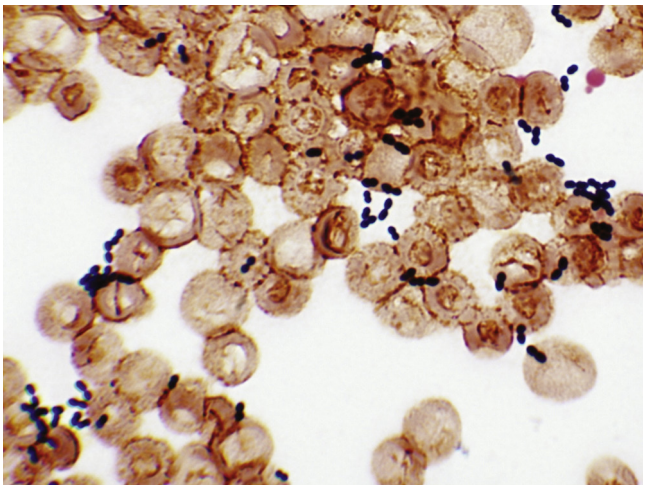

Fig. 19.9 Gram stain of blood culture with *Enterococcus faecalis.*

are large and can appear nonhemolytic, α-hemolytic, or, rarely, β-hemolytic.

PATHOGENESIS AND IMMUNITY

Although enterococci do not possess the broad range of virulence factors found in staphylococci or streptococci, life-threatening disease with antibiotic-resistant strains has become a serious problem in hospitalized patients. Virulence is mediated by two general properties: (1) the ability to adhere to tissues and form biofilms, and (2) antibiotic resistance. A number of factors have been described that mediate adherence and biofilm formation, including surface proteins, membrane glycolipids, gelatinase, and pili. In addition, the enterococci either are **inherently resistant to many commonly used antibiotics** (e.g., oxacillin, cephalosporins) or have acquired resistance genes (e.g., to aminoglycosides, vancomycin). Clearance of enterococci from blood and tissues is mediated by the rapid influx of neutrophils and opsonization of the bacteria, so patients who are immunocompromised are particularly susceptible to enterococcal infections.

EPIDEMIOLOGY

As their name implies, enterococci are enteric bacteria that are commonly recovered in feces collected from humans and from a variety of animals. *E. faecalis* is found in the large intestine in high concentrations (e.g., 10^5 to 10^7 organisms per gram of feces) and in the genitourinary tract. The distribution of *E. faecium* is similar to that of *E. faecalis,* but it is found in lower concentrations. Significant risk factors for enterococcal infections include the use of urinary or intravascular catheters, prolonged hospitalization, and the use of **broad-spectrum antibiotics,** particularly antibiotics that are inherently inactive against enterococci.

The prevalence of the many other enterococcal species is unknown, although they are believed to colonize the intestines in small numbers. Two species that are commonly recovered in the human intestines are *E. gallinarum* and *E. casseliflavus.* These relatively avirulent species are important because, although they are rarely associated with

human disease, they are inherently resistant to vancomycin and can be confused with the more important species, *E. faecalis* and *E. faecium.*

CLINICAL DISEASES

Enterococci are important pathogens, particularly in hospitalized patients; indeed, enterococci are one of the most common causes of infections acquired in the hospital **(nosocomial infection)** (see Box 19.1). The urinary tract is the most common site of enterococcal infections, and infections are frequently associated with urinary catheterization or instrumentation. These infections may be asymptomatic, uncomplicated cystitis, or cystitis associated with pyelonephritis. Peritoneal infections are typically polymicrobic (i.e., associated with other aerobic and anaerobic bacteria) and associated with leakage of intestinal bacteria either from trauma or because of disease that compromises the intestinal lining. Enterococci recovered in the blood may either be dissemination from a localized infection of the urinary tract, the peritoneum, or a wound, or it may represent primary infection of the endocardium (endocarditis). Endocarditis is a particularly serious infection because many enterococci are resistant to most commonly used antibiotics (Clinical Case 19.4).

Clinical Case 19.4 **Enterococcal Endocarditis**

Zimmer and associates (*Clin Infect Dis* 37:e29–e30, 2003) described the epidemiology of enterococcal infections and the difficulties in treating a patient with endocarditis. The patient was a 40-year-old man with hepatitis C, hypertension, and end-stage renal disease who developed fevers and chills during hemodialysis. In the 2 months before this episode, he was treated with ampicillin, levofloxacin, and gentamicin for group B streptococcal endocarditis. Cultures performed during the hemodialysis grew *Enterococcus faecalis* resistant to levofloxacin and gentamicin. Because the patient had an allergic reaction to ampicillin, he was treated with linezolid. Echocardiography showed vegetation on the mitral and tricuspid valves. Over a 3-week period, the patient's cardiac output deteriorated, so the patient was desensitized to ampicillin and therapy was switched to ampicillin and streptomycin. After 25 days of hospitalization, the patient's damaged heart valves were replaced, and therapy was extended for an additional 6 weeks. Thus use of broad-spectrum antibiotics predisposed this patient with previously damaged heart valves to endocarditis caused by *Enterococcus,* and treatment was complicated by resistance of the isolate to many commonly used antibiotics.

LABORATORY DIAGNOSIS

Enterococci grow readily on nonselective media such as blood agar and chocolate agar. Although enterococci may resemble *S. pneumoniae* on Gram-stained specimens, the organisms can be readily differentiated on the basis of simple biochemical reactions. For example, enterococci are resistant to optochin (*S. pneumoniae* is susceptible), do not dissolve when exposed to bile (*S. pneumoniae* is dissolved), and produce PYR (the only *Streptococcus* that is PYR positive is *S. pyogenes*). The **PYR test** is a commonly performed "5-minute spot" test. Catalase-negative, PYR-positive cocci arranged in pairs and short chains can be presumptively identified as enterococci. Phenotypic properties (e.g., pigment production, motility), biochemical tests, and nucleic acid sequencing are necessary to differentiate among *E. faecalis, E. faecium,* and the other *Enterococcus* species, but this topic is beyond the scope of this text.

TREATMENT, PREVENTION, AND CONTROL

Antimicrobial therapy for enterococcal infections is complicated because most antibiotics are not bactericidal at clinically relevant concentrations. Therapy for serious infections has traditionally consisted of the synergistic **combination of an aminoglycoside and a cell wall–active antibiotic** (e.g., ampicillin, vancomycin). However, some cell wall antibiotics have no activity against enterococci (e.g., nafcillin, oxacillin, cephalosporins), ampicillin and penicillin are generally ineffective against *E. faecium*, and vancomycin resistance (particularly in *E. faecium*) is commonplace. In addition, more than 25% of enterococci are resistant to the aminoglycosides, and resistance to aminoglycosides and vancomycin is particularly troublesome because it is mediated by plasmids and can be transferred to other bacteria.

Newer antibiotics have been developed that can treat enterococci resistant to ampicillin, vancomycin, or the aminoglycosides. These include linezolid, daptomycin, tigecycline, and quinupristin/dalfopristin. Unfortunately, resistance to linezolid is steadily increasing, and quinupristin/dalfopristin is not active against *E. faecalis* (the most commonly isolated enterococcal species). Enterococci susceptible to ampicillin and resistant to aminoglycosides can be treated with ampicillin plus daptomycin, imipenem, or linezolid. Enterococci resistant to ampicillin and susceptible to aminoglycosides can be treated with an aminoglycoside combined with vancomycin (if active), linezolid, or daptomycin. If the isolate is resistant to both ampicillin and aminoglycosides, then treatment can include daptomycin, linezolid, or vancomycin combined with another active agent.

It is difficult to prevent and control enterococcal infections. Careful restriction of antibiotic usage and the implementation of appropriate infection-control practices (e.g., isolation of infected patients, use of gowns and gloves by anyone in contact with patients) can reduce the risk of colonization with these bacteria, but the complete elimination of infections is unlikely. Additionally, it is extremely difficult to eradicate a vancomycin-resistant strain of *E. faecium* or *E. faecalis* once a patient is colonized.

Case Study and Questions

A 62-year-old man with a history of chronic obstructive pulmonary disease (COPD) came to the emergency department because of a fever of 40° C, chills, nausea, vomiting, and hypotension. The patient also produced tenacious yellowish sputum that had increased in quantity over the preceding 3 days. His respiratory rate was 18 breaths/min, and his blood pressure was 94/52 mm Hg. Chest radiographic examination showed extensive infiltrates in the left lower lung that involved both the lower lobe and the lingula. Multiple blood cultures and culture of the sputum yielded *S. pneumoniae.* The isolate was susceptible to cefazolin, vancomycin, and erythromycin but resistant to penicillin.

1. What predisposing condition made this patient more susceptible to pneumonia and bacteremia caused by *S. pneumoniae*? What other populations of patients are susceptible to these infections? What other infections does this organism cause, and what populations are most susceptible?
2. What is the mechanism most likely responsible for this isolate's resistance to penicillin?
3. What infections are caused by *S. pyogenes, S. agalactiae, S. anginosus, S. dysgalactiae,* and viridans streptococci?
4. What are the major virulence factors of *S. pneumoniae, S. pyogenes,* and *S. agalactiae*?
5. *S. pyogenes* can cause streptococcal toxic shock syndrome. How does this disease differ from the disease produced by staphylococci?
6. What two nonsuppurative diseases can develop after localized *S. pyogenes* disease?

20 *Bacillus*

Two hours after a dinner, a family of four developed acute abdominal cramps with nausea and vomiting. The illness lasted for less than a day.

1. *Bacillus cereus* is associated with two forms of food poisoning. Discuss the epidemiology and clinical presentation of each.
2. *B. cereus* is also associated with eye infections. Discuss the epidemiology and clinical presentation. What virulence factor is important in these infections?

Answers to these questions are available on Student Consult.com.

Summaries Clinically Significant Organisms

BACILLUS ANTHRACIS

Trigger Words

Spore former, capsule, edema toxin, lethal toxin, anthrax, bioterrorism

Biology and Virulence

- Spore-forming, nonmotile, nonhemolytic gram-positive rods
- Polypeptide capsule consisting of poly-D-glutamic acid observed in clinical specimens
- Virulent strains produce three exotoxins that combine to form edema toxin (combination of protective antigen and edema factor) and lethal toxin (protective antigen with lethal factor)
- The polypeptide capsule inhibits phagocytosis of bacteria

Epidemiology

- *B. anthracis* primarily infects herbivores, with humans as accidental hosts
- Rarely isolated in developed countries but is prevalent in impoverished areas in which vaccination of animals is not practiced
- The greatest danger of anthrax in industrial countries is the use of *B. anthracis* as an agent of bioterrorism

Diseases

- Three forms of anthrax are recognized: cutaneous (most common in humans), gastrointestinal (most common in herbivores), and inhalation (bioterrorism)

Diagnosis

- Organism is present in high concentrations in clinical specimens (microscopy typically positive) and grows readily in culture
- Preliminary identification is based on microscopic (gram-positive rods) and colonial (nonhemolytic, adherent colonies) morphology; confirmed by demonstrating capsule and either lysis with gamma phage, a positive direct fluorescent antibody test for the specific cell wall polysaccharide, or positive nucleic acid amplification assay

Treatment, Prevention, and Control

- Inhalation or gastrointestinal anthrax or bioterrorism-associated anthrax should be treated with ciprofloxacin or doxycycline, combined with one or two additional antibiotics (e.g., rifampin, vancomycin, penicillin, imipenem, clindamycin, clarithromycin)
- Naturally acquired cutaneous anthrax can be treated with amoxicillin
- Vaccination of animal herds and people in endemic areas can control disease, but spores are difficult to eliminate from contaminated soils
- Vaccination of animal herds and at-risk humans is effective, although the development of a less toxic vaccine is desired
- Alternative treatments interfering with the activity of anthrax toxins are under investigation

BACILLUS CEREUS

Trigger Words

Spore former, enterotoxin, gastroenteritis, eye infections

Biology and Virulence

- Spore-forming, motile, gram-positive rods
- Heat-stable and heat-labile enterotoxin
- Tissue destruction is mediated by cytotoxic enzymes, including cereolysin and phospholipase C

Epidemiology

- Ubiquitous in soils throughout the world
- People at risk include those who consume food contaminated with the bacterium (e.g., rice, meat, vegetables, sauces), those with penetrating injuries (e.g., to eye), those who receive intravenous injections, and immunocompromised patients exposed to *B. cereus*

Diseases

- Capable of causing gastrointestinal diseases (emetic and diarrheal forms), ocular infections, and an anthrax-like disease in immunocompetent patients

Diagnosis

- Isolation of the organism in implicated food product or nonfecal specimens (e.g., eye, wound)

Treatment, Prevention, and Control

- Gastrointestinal infections are treated symptomatically
- Ocular infectious or other invasive diseases require removal of foreign bodies and treatment with vancomycin, clindamycin, ciprofloxacin, or gentamicin
- Gastrointestinal disease is prevented by proper preparation of food (e.g., foods should be consumed immediately after preparation or refrigerated)

The family Bacillaceae consists of a diverse collection of more than 50 genera that share one common feature: the ability to form endospores (Fig. 20.1). For practical purposes, the students need to know only one clinically important genus, *Bacillus;* although there are almost 400 species and subspecies in this genus, only two will be the focus of this chapter: *B. anthracis* and *B. cereus* (Table 20.1). *B. anthracis,* the organism responsible for anthrax, is one of the most feared agents of biological warfare and, since the release of *B. anthracis* spores in the U.S. Postal Service in 2001, the potential danger associated with this organism is well known. *B. cereus,* the other clinically important species in this genus, is an organism responsible for gastroenteritis, traumatic eye infections, catheter-associated sepsis, and, rarely, severe pneumonia.

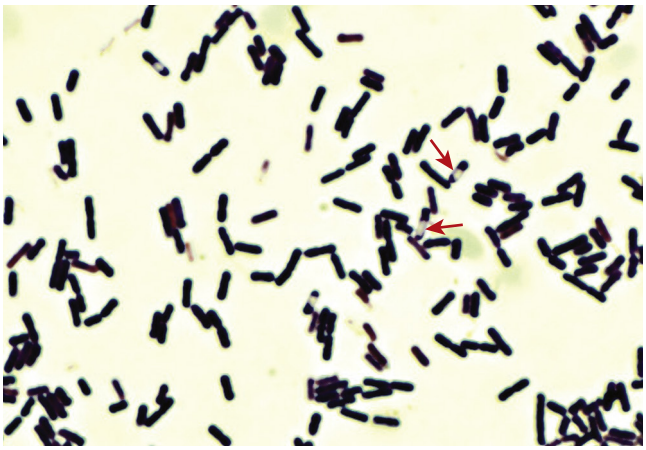

Fig. 20.1 *Bacillus cereus*. The clear areas in the gram-positive rods are unstained spores *(arrows).*

Bacillus anthracis

PHYSIOLOGY AND STRUCTURE

B. anthracis is a large (1 × 3 to 8 μm) organism arranged as single or paired rods (Fig. 20.2) or as long, serpentine chains. Although spores are readily observed in 2- to 3-day-old cultures, they are not seen in clinical specimens.

Because of the unique medical importance of *B. anthracis,* it is important to understand the functional details of this organism's toxins. Virulent *B. anthracis* carries genes for three toxin protein components on a large plasmid, pXO1. The individual proteins, **protective antigen (PA), edema factor (EF),** and **lethal factor (LF),** are nontoxic individually but form important toxins when structurally combined: PA plus EF forms **edema toxin,** and PA plus LF forms **lethal toxin.** PA is an 83-kDa protein that binds to one of two receptors on host cell surfaces that are present on many cells and tissues (e.g., brain, heart, intestine, lung, skeletal muscle, pancreas, macrophages). After PA binds to its receptor, host proteases cleave PA, releasing a small fragment and retaining the 63-kDa fragment (PA_{63}) on the cell surface. The PA_{63} fragments self-associate on the cell surface, forming a ring-shaped complex of seven fragments (pore precursor or "prepore"). This heptameric complex can then bind up to three molecules of LF and/or EF. Both factors recognize the same binding site of PA_{63}, so the binding is competitive. Formation of the complex stimulates endocytosis and movement to an acidic intracellular compartment. In this environment, the heptameric complex forms a transmembrane pore and releases LF and EF into the cell interior. **LF is a zinc-dependent protease** capable of cleaving mitogen-activated protein (MAP) kinase, leading to cell death. **EF is a calmodulin-dependent adenylate cyclase** that increases the intracellular cyclic adenosine monophosphate (cAMP) levels and results in edema. EF is related to the adenylate cyclases produced by *Bordetella pertussis* and *Pseudomonas aeruginosa.*

The other important virulence factor carried by *B. anthracis* is a prominent polypeptide **capsule** (consisting of poly-D-glutamic acid). This protein capsule is unique because most bacterial capsules are composed of polysaccharides (e.g., such as those on *Staphylococcus aureus*, *Streptococcus pneumoniae*, and *P. aeruginosa*). The capsule is observed in clinical specimens, but it is not produced in vitro unless special growth conditions are used. Three genes (*capA, capB,* and *capC*) are responsible for synthesis of this capsule and are carried on a second plasmid (pXO2). Only one serotype of capsule has been identified, presumably because the capsule is composed of only glutamic acid.

TABLE 20.1 Important *Bacillus* Species

Organism	Historical Derivation
Bacillus	*bacillum*, a small rod
B. anthracis	*anthrax*, charcoal, a carbuncle (refers to the black necrotic wound associated with cutaneous anthrax)
B. cereus	*cereus*, waxen, wax-colored (refers to colonies with a typical dull or frosted-glass surface)

PATHOGENESIS AND IMMUNITY

The major factors responsible for the virulence of *B. anthracis* are the capsule, edema toxin, and lethal toxin. The capsule inhibits phagocytosis of replicating cells. The adenylate cyclase activity of edema toxin is responsible for the fluid accumulation observed in anthrax. The zinc metalloprotease activity of lethal toxin stimulates macrophages to release tumor necrosis factor (TNF)-α, interleukin (IL)-1β, and other proinflammatory cytokines. Of the major proteins of *B. anthracis,* PA is the most immunogenic (hence the name, protective antigen). Both LF and EF inhibit the host's innate immune system.

EPIDEMIOLOGY

Anthrax is primarily a disease of herbivores; humans are infected through exposure to contaminated animals or animal products. The disease is a serious problem in countries in which animal vaccination is not practiced or is impractical (e.g., disease is established in African wildlife). In contrast, natural infections with *B. anthracis* are rarely seen in the United States, with only four cases reported between 2003 and 2015. This statistic may now be meaningless, with the deliberate contamination of the U.S. Postal Service with *B. anthracis* spores

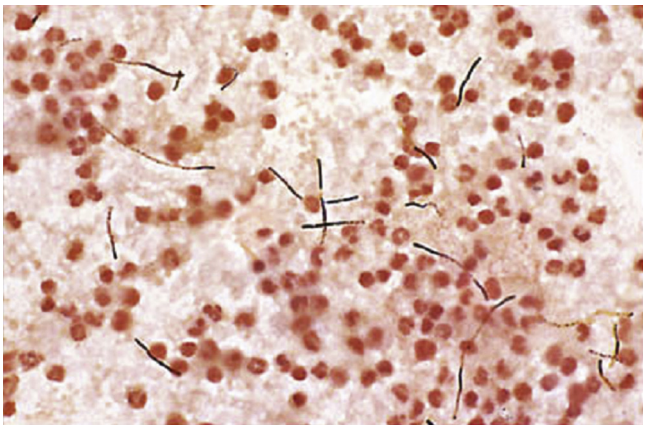

Fig. 20.2 *Bacillus anthracis* in the blood of a patient with inhalation anthrax.

in 2001. The risk of exposing a large population to the dangerous pathogen has increased dramatically in this era of bioterrorism. A number of nations and independent terrorist groups have biological warfare programs and have experimented with using *B. anthracis* as a weapon. Indeed, much of what we know about anthrax acquired via the inhalation route was learned from the accidental release in 1979 of spores in Sverdlovsk in the former Soviet Union (at least 79 cases of anthrax, with 68 deaths) and the terrorist contamination of employees of the U.S. Postal Service with letters containing *B. anthracis* (11 patients with inhalation anthrax and 11 patients with cutaneous anthrax).

Human *B. anthracis* disease (Box 20.1) is acquired by one of three routes: **inoculation, ingestion,** and **inhalation.** Approximately 95% of naturally acquired anthrax infections in humans result from inoculation of *Bacillus* spores through exposed skin from either contaminated soil or infected animal products, such as hides, goat hair, and wool.

Ingestion anthrax is very rare in humans, but ingestion is a common route of infection in herbivores. Because the organism can form resilient spores, contaminated soil or animal products can remain infectious for many years.

Inhalation anthrax was historically called **wool-sorters' disease** because most human infections resulted from inhalation of *B. anthracis* spores during the processing of goat hair. This is currently an uncommon source for human infections; however, inhalation is the most likely route of infection with biological weapons, and the infectious dose of the organism is believed to be low. Person-to-person transmission does not occur because bacterial replication occurs in the mediastinal lymph nodes rather than the bronchopulmonary tree.

CLINICAL DISEASES

Typically, **cutaneous anthrax** starts with the development of a painless papule at the site of inoculation that rapidly progresses to an ulcer surrounded by vesicles and then to a necrotic eschar (Fig. 20.3; Clinical Case 20.1). Systemic signs, painful lymphadenopathy, and massive edema may develop. The mortality rate in patients with untreated cutaneous anthrax is 20%.

Clinical symptoms of **gastrointestinal anthrax** are determined by the site of the infection. If organisms invade the upper intestinal tract, ulcers form in the mouth or esophagus, leading to regional lymphadenopathy, edema, and sepsis. If the organism invades the cecum or terminal ileum, the patient presents with nausea, vomiting, and malaise, which rapidly progress to systemic disease. The mortality associated with gastrointestinal anthrax is believed to approach 100%.

Unlike the other two forms of anthrax, **inhalation anthrax** can be associated with a prolonged latent period (2 months or more) in which spores can remain latent in the nasal passages. During this period the infected patient remains asymptomatic. In active disease the spores reach the lower airways, in which alveolar macrophages ingest the inhaled spores and transport them to the mediastinal lymph nodes. The initial clinical symptoms of disease are nonspecific including fever, myalgias, nonproductive cough, and malaise. The second stage of disease is more dramatic, with a rapidly worsening course of fever, edema, massive enlargement of the mediastinal lymph nodes (this is responsible for the widened mediastinum observed on chest radiography [Fig. 20.4]), respiratory failure, and sepsis. Although the route of infection is by inhalation, pneumonia rarely develops. Meningeal symptoms are seen in half of patients with inhalation anthrax. Almost all cases progress to shock and death within 3 days of initial symptoms unless anthrax is suspected and treatment is initiated immediately. Serologic evidence indicates that a subclinical or asymptomatic form of inhalation anthrax does not exist. Virtually all patients who develop disease progress to a fatal outcome unless there is immediate medical intervention.

BOX 20.1 *Bacillus* Diseases: Clinical Summaries

Bacillus anthracis

Cutaneous anthrax: painless papule progresses to ulceration with surrounding vesicles and then to eschar formation; painful lymphadenopathy, edema, and systemic signs may develop

Gastrointestinal anthrax: ulcers form at site of invasion (e.g., mouth, esophagus, intestine), leading to regional lymphadenopathy, edema, and sepsis

Inhalation anthrax: initial nonspecific signs followed by rapid onset of sepsis with fever, edema, and lymphadenopathy (mediastinal lymph nodes); meningeal symptoms in half the patients, and most patients with inhalation anthrax will die unless treatment is initiated immediately

Bacillus cereus

Gastroenteritis: emetic form characterized by rapid onset of vomiting and abdominal pain and a short duration; diarrheal form characterized by a longer onset and duration of diarrhea and abdominal cramps

Ocular infections: rapid, progressive destruction of the eye after traumatic introduction of the bacteria into the eye

Severe pulmonary disease: severe anthrax-like pulmonary disease in immunocompetent patients

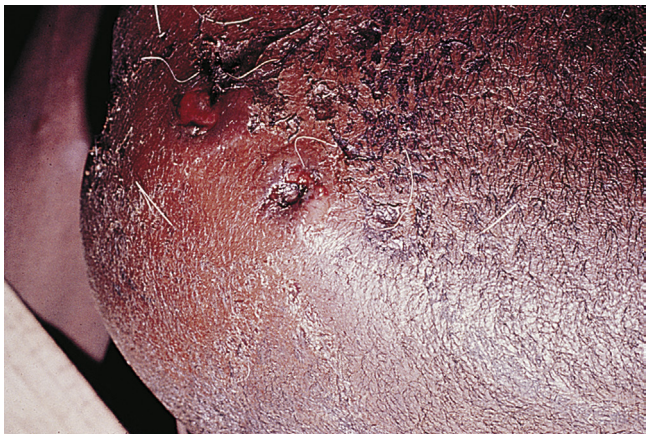

Fig. 20.3 Cutaneous anthrax demonstrating marked erythema, edema, and vesicle rupture. (From Cohen, J., Powderly, W.G., 2004. Infectious Diseases, second ed. Mosby, St Louis, MO.)

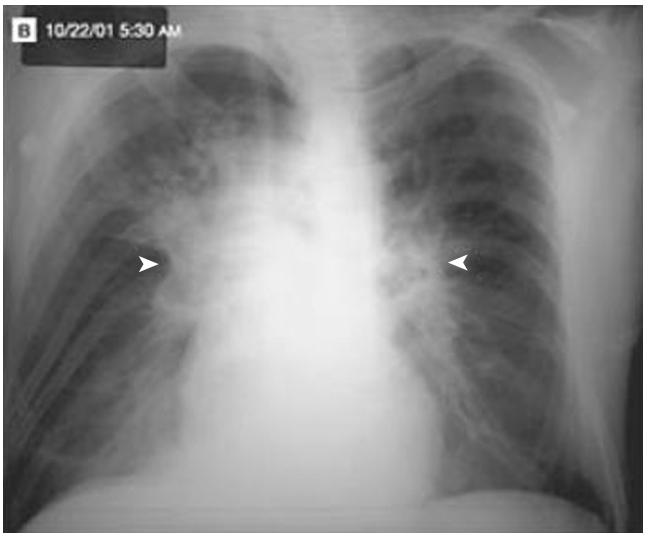

Fig. 20.4 Inhalation anthrax demonstrating enlarged mediastinal lymph nodes *(arrowheads)*.

Clinical Case 20.1 **Inhalation Anthrax**

Bush and associates (*N Engl J Med* 345:1607–1610, 2001) reported the first case of inhalation anthrax in the 2001 bioterrorism attack in the United States. The patient was a 63-year-old man living in Florida who had a 4-day history of fever, myalgias, and malaise without localizing symptoms. His wife brought him to the regional hospital because he awoke from sleep with fever, emesis, and confusion. On physical examination, he had a temperature of 39° C, blood pressure of 150/80 mm Hg, pulse of 110 beats/min, and respiration of 18 breaths/min. No respiratory distress was noted. Treatment was initiated for presumed bacterial meningitis. Basilar infiltrates and a widened mediastinum were noted on the initial chest radiograph. Gram stain of cerebrospinal fluid (CSF) revealed many neutrophils and large gram-positive rods. Anthrax was suspected, and penicillin treatment was initiated. Within 24 hours of admission, CSF and blood cultures were positive for *Bacillus anthracis*. During the first day of hospitalization, the patient had a grand mal seizure and was intubated. On the second hospital day, hypotension and azotemia developed, with subsequent renal failure. On the third hospital day, refractory hypotension developed and the patient had a fatal cardiac arrest. This patient illustrates the rapidity with which patients with inhalation anthrax can deteriorate despite a rapid diagnosis and appropriate antimicrobial therapy. Although the route of exposure is via the respiratory tract, patients do not develop pneumonia; instead, the abnormal chest radiograph is caused by hemorrhagic mediastinitis.

LABORATORY DIAGNOSIS

Infections with *B. anthracis* are characterized by overwhelming numbers of organisms present in wounds, involved lymph nodes, and blood. Anthrax is one of the few bacterial diseases in which organisms can be seen when peripheral blood is Gram stained (see Fig. 20.2). Therefore the detection of organisms by microscopy and culture is not a problem. The diagnostic difficulty is distinguishing *B. anthracis* from other members of the taxonomically related *B. cereus* group. A preliminary identification of *B. anthracis* is based on microscopic and colonial morphology. The organisms appear as long, thin, gram-positive rods arranged singly or in long chains. Spores are not observed in clinical specimens; they are only seen in cultures incubated in a low CO_2 atmosphere and can be seen best with the use of a special spore stain (e.g., malachite green stain; Fig. 20.5). The **capsule** of *B. anthracis* is produced in vivo but is not typically observed in culture. The capsule can be observed in clinical specimens using a contrasting stain, such as India ink (the ink particles are excluded by the capsule so that the background, but not the area around bacteria, appears black), M'Fadyean methylene blue stain, or a direct fluorescent antibody (DFA) test developed against the capsular polypeptide. Colonies cultured on sheep blood agar are characteristically large and nonpigmented and have a dry "ground-glass" surface and irregular edges. The colonies are quite sticky and adherent to the agar and, if the edge is lifted with a bacteriologic loop, it will remain standing like beaten egg whites. Colonies are **not hemolytic,** in contrast with *B. cereus. B. anthracis* will appear **nonmotile** in motility tests such as the microscopic observation of individual rods in a suspended drop of culture medium. The definitive identification of nonmotile, nonhemolytic organisms resembling *B. anthracis* is made in a public health reference laboratory. This is accomplished by demonstrating capsule production (by microscopy or DFA) and either specific lysis of the bacteria with gamma phage or a positive DFA test for a specific *B. anthracis* cell wall polysaccharide. In addition, nucleic acid amplification tests (e.g., polymerase chain reaction [PCR]) have been developed and are performed in reference laboratories.

TREATMENT, PREVENTION, AND CONTROL

Although penicillin was the drug of choice for *B. anthracis,* resistance in naturally occurring strains has been observed, as well as resistance to sulfonamides and extended-spectrum cephalosporins. In addition, resistance to other antibiotics can be selected in laboratory-derived strains, so this must be considered for bioterrorism-associated anthrax. The current empirical treatment recommendation is use of

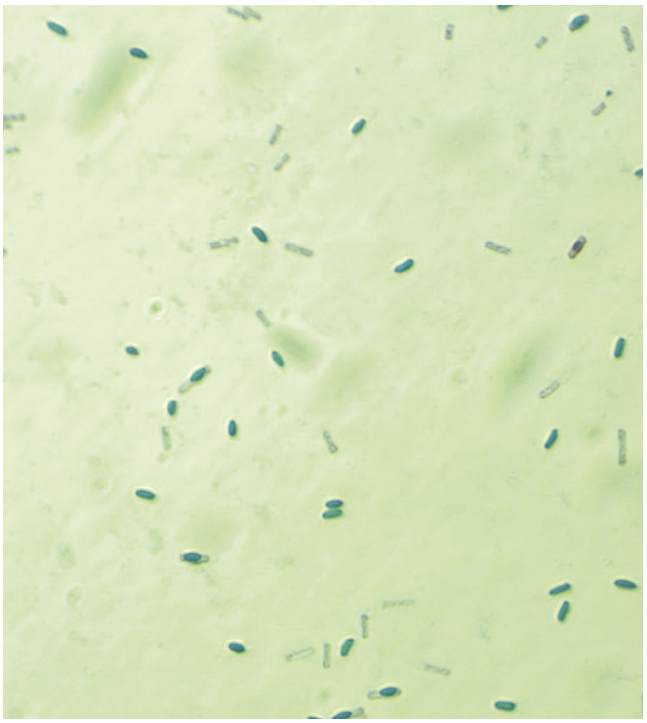

Fig. 20.5 *Bacillus cereus*. Spores retain the malachite green dye in this special spore stain, and the vegetative cells are gray or colorless.

ciprofloxacin or **doxycycline** combined with one or two additional antibiotics (e.g., rifampin, vancomycin, penicillin, imipenem, clindamycin, clarithromycin). Although penicillin resistance is observed for naturally acquired anthrax, oral penicillin **(amoxicillin)** is still recommended for naturally acquired cutaneous anthrax.

Control of naturally acquired human disease requires control of animal disease, which involves **vaccination of animal herds** in endemic regions and burning or burial of animals that die of anthrax. Complete eradication of anthrax is unlikely because the spores of the organism can exist for many years in soil and the threat of bioterrorist-related infections is a current reality.

Vaccination has also been used to protect (1) people who live in areas in which the disease is endemic, (2) people who work with animal products imported from countries with endemic anthrax, and (3) military personnel. Although the current vaccine appears to be effective, research to develop a less toxic vaccine is under way. Alternative approaches to inactivating anthrax toxins have focused on PA and its receptor target. Passive infusion of human monoclonal antibodies against *B. anthracis* PA prevented death in an animal model of inhalation anthrax and was well tolerated in human volunteers. Synthetic peptide complexes that target the cell surface receptors for PA also have been used to neutralize anthrax toxin in animal models. How these alternative approaches can be used to treat human disease remains to be demonstrated.

Bacillus cereus

Bacillus species other than *B. anthracis* are primarily opportunistic pathogens that have relatively low capacities for virulence. Although most of these species have been found to cause disease, *B. cereus* is clearly the most important pathogen, with gastroenteritis, ocular infections, and intravenous catheter-related sepsis being the diseases most commonly observed, as well as rare cases of severe pneumonia.

TABLE 20.2 *Bacillus cereus* Food Poisoning

Disease Features	Emetic Form	Diarrheal Form
Implicated food	Rice	Meat, vegetables
Incubation period (hours)	<6 (mean, 2)	>6 (mean, 9)
Symptoms	Vomiting, nausea, abdominal cramps	Diarrhea, nausea, abdominal cramps
Duration (hours)	8-10 (mean, 9)	20.36 (mean, 24)
Enterotoxin	Heat stable	Heat labile

PATHOGENESIS AND IMMUNITY

Gastroenteritis caused by *B. cereus* is mediated by one of **two enterotoxins** (Table 20.2). The **heat-stable,** proteolysis-resistant enterotoxin causes the **emetic form** of the disease, and the **heat-labile** enterotoxin causes the **diarrheal form** of the disease. The heat-labile enterotoxin is similar to the enterotoxins produced by *Escherichia coli* and *Vibrio cholerae;* each stimulates the adenylate cyclase–cAMP system in intestinal epithelial cells, leading to profuse watery diarrhea. The mechanism of action of the heat-stable enterotoxin is unknown.

The pathogenesis of *B. cereus* ocular infections is also incompletely defined. At least three toxins have been implicated: **necrotic toxin** (a heat-labile enterotoxin), **cereolysin** (a potent hemolysin named after the species), and **phospholipase C** (a potent lecithinase). It is likely that the rapid destruction of the eye that is characteristic of *B. cereus* infections results from the interaction of these toxins and other unidentified factors.

Bacillus species can colonize skin transiently and can be recovered as insignificant contaminants in blood cultures. In the presence of an intravascular foreign body, however, these organisms can be responsible for persistent bacteremia and signs of sepsis (i.e., fever, chills, hypotension, shock).

EPIDEMIOLOGY

B. cereus and other *Bacillus* species are ubiquitous organisms that are present in virtually all environments. Nearly all infections originate from an environmental source (e.g., contaminated soil). Isolation of bacteria from clinical specimens in the absence of characteristic disease usually represents insignificant contamination.

CLINICAL DISEASES

As mentioned previously, *B. cereus* is responsible for two forms of food poisoning: **vomiting disease (emetic form)** and **diarrheal disease (diarrheal form).** In most patients, the emetic form of disease results from consumption of **contaminated rice.** Most bacteria are killed

during the initial cooking of the rice, but the heat-resistant spores survive. If the cooked rice is not refrigerated, then the spores germinate and the bacteria can multiply rapidly. The heat-stable enterotoxin that is released is not destroyed when the rice is reheated. The emetic form of disease is an intoxication caused by ingestion of the enterotoxin, not the bacteria. Thus the incubation period after eating the contaminated rice is short (1 to 6 hours), and the duration of illness is also short (<24 hours). Symptoms consist of vomiting, nausea, and abdominal cramps. Fever and diarrhea are generally absent. Fulminant liver failure also has been associated with consumption of food contaminated with large amounts of emetic toxin, which impairs mitochondrial fatty acid metabolism. Fortunately, this is a rare complication.

The diarrheal form of *B. cereus* food poisoning is a true infection resulting from ingestion of the bacteria in contaminated meat, vegetables, or sauces. There is a longer incubation period during which the organism multiplies in the patient's intestinal tract, and the release of the heat-labile enterotoxin follows. This enterotoxin is responsible for the diarrhea, nausea, and abdominal cramps that develop. This form of disease generally lasts 1 day or longer.

B. cereus **ocular infections** usually occur after traumatic, penetrating injuries of the eye with a soil-contaminated object (Clinical Case 20.2). *Bacillus* panophthalmitis is a rapidly progressive disease that almost universally results in complete eye loss within 48 hours of the injury. Disseminated infections with ocular manifestations can also develop in intravenous drug abusers.

Other infections with *B. cereus* and other *Bacillus* species are intravenous catheter and central nervous system shunt infections and endocarditis (most common in drug abusers), as well as pneumonitis, bacteremia, and meningitis in severely immunosuppressed patients. It has also been reported that ingestion of **tea** by immunocompromised patients is associated with an increased risk for invasive *B. cereus* disease.

One rare disease of *B. cereus* that deserves special attention is **severe pneumonia mimicking anthrax in immunocompetent patients.** Four patients with this disease, all metal workers residing in Texas or Louisiana, have been described in the literature. Most interesting is that the strains contained the ***B. anthracis* pXO1 toxin genes** and all were **encapsulated,** although this was not the typical *B. anthracis* poly-γ-D-glutamic acid capsule. These strains demonstrate the potential danger and presumed ease of transferring *B. anthracis* virulence genes into the ubiquitous *B. cereus*.

LABORATORY DIAGNOSIS

Similar to *B. anthracis, B. cereus* and other species can be readily cultured from clinical specimens collected from patients with the emetic form of food poisoning. Because individuals can be transiently colonized with *B. cereus,* the implicated food (e.g., rice, meat, vegetables) must be cultured for confirmation of the existence of foodborne disease. In practice, neither cultures nor tests to detect the heat-stable or heat-labile enterotoxins are commonly performed, so most cases of *B. cereus* gastroenteritis are diagnosed by epidemiologic and clinical criteria.

Clinical Case 20.2 ***Bacillus cereus* Traumatic Endophthalmitis**

Endophthalmitis caused by the traumatic introduction of *Bacillus cereus* into the eye is unfortunately common. This is a typical presentation. A 44-year-old man suffered a traumatic eye injury while working in a vegetable garden, when a piece of metal was deflected into his left eye, damaging the cornea and anterior and posterior lens capsule. Over the next 12 hours, he developed increasing pain and purulence in his eye. He underwent surgery to relieve the ocular pressure, drain the purulence, and introduce intravitreal antibiotics (vancomycin, ceftazidime) and dexamethasone. Culture of the aspirated fluid was positive for *B. cereus*. Ciprofloxacin was added to his therapeutic regimen postoperatively. Despite the prompt surgical and medical intervention and subsequent intravitreal antibiotic injections, the intraocular inflammation persisted and evisceration was required. This patient illustrates the risks involved with penetrating eye injuries and the need to intervene aggressively if the eye is to be saved.

Bacillus organisms grow rapidly and are readily detected with the Gram stain and culture of specimens collected from infected eyes, intravenous culture sites, and other locations.

TREATMENT, PREVENTION, AND CONTROL

Because the course of *B. cereus* gastroenteritis is short and uncomplicated, symptomatic treatment is adequate. The treatment of other *Bacillus* infections is complicated because they have a rapid and progressive course and a high incidence of multidrug resistance (e.g., *B. cereus* carries genes for resistance to penicillins and cephalosporins). **Vancomycin, clindamycin, ciprofloxacin,** and **gentamicin** can be used to treat infections. Penicillins and cephalosporins are ineffective. Eye infections must be treated rapidly. Rapid consumption of foods after cooking and proper refrigeration of uneaten foods can prevent food poisoning.

Case Study and Questions

A 56-year-old female postal worker sought medical care for fever, diarrhea, and vomiting. She was offered symptomatic treatment and discharged from the community hospital emergency department. Five days later, she returned to the hospital with complaints of chills, dry cough, and pleuritic chest pain. A chest radiograph showed a small right infiltrate and bilateral effusions but no evidence of a widened mediastinum. She was admitted to the hospital, and the next day her respiratory status and pleural effusions worsened. A computed tomography scan of her chest revealed enlarged mediastinal and cervical lymph nodes. Pleural fluid and blood were collected for culture, and these cultures were positive within 10 hours for gram-positive rods in long chains.

1. The clinical impression is that this woman has inhalation anthrax. What tests should be performed to confirm identification of the isolate?

2. What are the three primary virulence factors found in *B. anthracis*?

3. Describe the mechanisms of action of the toxins produced by *B. anthracis.*

4. Describe the two forms of *B. cereus* food poisoning. What toxin is responsible for each form? Why is the clinical presentation of these two diseases different?

5. *B. cereus* can cause eye infections. What are two risk factors for this disease?

21 Listeria *and Related Gram-Positive Bacteria*

Listeria monocytogenes, *Erysipelothrix rhusiopathiae*, and *Corynebacterium diphtheriae* are three medically important gram-positive rods that produce very dissimilar diseases.

1. What patient populations are most susceptible to infections caused by *Listeria* and *Erysipelothrix*, and how are these infections acquired?
2. Treatment of *Listeria* infections is most similar to what other gram-positive pathogen?
3. Why is the laboratory diagnosis of *Erysipelothrix* infections difficult to make?
4. Why is diphtheria not seen in the United States but still found in other countries?
5. Why is a Gram stain of a throat exudate or blood culture not useful for the diagnosis of diphtheria? How would the diagnosis be made if diphtheria is suspected?
6. What virulence factor is responsible for the clinical manifestations of diphtheria?

Answers to these questions are available on Student Consult.com.

Summaries Clinically Significant Organisms

LISTERIA MONOCYTOGENES

Trigger Words

Coccobacilli, β-hemolytic, meningitis, opportunistic, foodborne illness

Biology and Virulence

- Gram-positive coccobacilli, often arranged in pairs resembling *Streptococcus pneumoniae*
- Facultative intracellular pathogen that can avoid antibody-mediated clearance
- Ability to grow at 4° C, in a wide pH range, and in the presence of salt can lead to high concentrations of the bacteria in contaminated foods
- Virulent strains produce cell attachment factors (internalins), hemolysins (listeriolysin O, two phospholipase C enzymes), and a protein that mediates actin-directed intracellular motility (ActA)

Epidemiology

- Isolated in soil, water, and vegetation and from a variety of animals, including humans (low-level gastrointestinal carriage)
- Disease associated with consumption of contaminated food products (e.g., contaminated milk and cheese, processed meats, raw vegetables [especially cabbage]) or transplacental spread from mother to neonate; sporadic cases and epidemics occur throughout the year
- Neonates, elderly, pregnant women, and patients with defects in cellular immunity are at increased risk for disease

Diseases

- Neonatal disease can result in in utero death or multiorgan abscesses, meningitis, and septicemia
- Other diseases include influenza-like symptoms, self-limited gastroenteritis, and meningitis in patients with defects in cell-mediated immunity

Diagnosis

- Microscopy is insensitive; culture may require incubation for 2 to 3 days or enrichment at I am not sure how to make the symbol for 4 degree C as in the sentence below.
- Characteristic properties include motility at room temperature, weak this should be the Greek symbol for beta-hemolysis, and growth at 4° C and at high-salt concentrations

Treatment, Prevention, and Control

- The treatment of choice for severe disease is penicillin or ampicillin, alone or in combination with gentamicin
- People at high risk should avoid eating raw or partially cooked foods of animal origin, soft cheese, and unwashed raw vegetables

ERYSIPELOTHRIX RHUSIOPATHIAE

Trigger Words

Pleomorphic rod, zoonotic, cutaneous infection, endocarditis

Biology and Virulence

- Slender, pleomorphic, gram-positive rods that form long (e.g., 60 µSlender, pleo)
- Production of neuraminidase believed to be important for attachment and penetration into epithelial cells, and polysaccharide-like capsule protects the bacteria from phagocytosis

Epidemiology

- Colonizes a variety of organisms, particularly swine and turkey
- Found in soil rich in organic matter or groundwater contaminated with wastes from colonized animals
- Uncommon pathogen in the United States
- Occupational disease of butchers, meat processors, farmers, poultry workers, fish handlers, and veterinarians

Diseases

- Disease in humans is most commonly (1) localized cutaneous infection, (2) generalized cutaneous disease, or (3) septicemia associated with subacute endocarditis involving previously undamaged heart valves

Diagnosis

- Long, filamentous, gram-positive rods seen on Gram stain of a biopsy collected at the advancing edge of the lesion
- Grows slowly on blood and chocolate agars incubated in 5% to 10% carbon dioxide

Treatment, Prevention, and Control

- Penicillin is drug of choice for both localized and systemic diseases; ciprofloxacin or clindamycin can be used for localized cutaneous infections for patients allergic to penicillin, and ceftriaxone or imipenem can be considered for disseminated infections
- Workers should cover exposed skin when handling animals and animal products
- Swineherds should be vaccinated

CORYNEBACTERIUM DIPHTHERIAE

Trigger Words

Diphtheria toxin, pharyngitis, vaccine

Biology and Virulence

- Gram-positive pleomorphic rods
- The major virulence factor is the diphtheria toxin, an A-B exotoxin; inhibits protein synthesis

Epidemiology

- Worldwide distribution maintained in asymptomatic carriers and infected patients
- Humans are the only known reservoir, with carriage in oropharynx or on skin surface
- Spread person to person by exposure to respiratory droplets or skin contact

Continued

Summaries Clinically Significant Organisms—cont'd

- Disease observed in unvaccinated or partially immune children or adults traveling to countries with endemic disease
- Diphtheria is very uncommon in the United States and other countries with active vaccination programs

Diseases

- Etiologic agent of diphtheria: respiratory and cutaneous forms

Diagnosis

- Microscopy is nonspecific; metachromatic granules observed in *C. diphtheriae* and other corynebacteria
- Culture should be performed on nonselective (blood agar) and selective (cysteine-tellurite agar, Tinsdale medium, colistin-nalidixic agar) media
- Presumptive identification of *C. diphtheriae* can be based on the presence of cystinase and absence of pyrazinamidase; definitive identification by biochemical tests or species-specific gene sequencing
- Demonstration of exotoxin is performed by Elek test or polymerase chain reaction assay

Treatment, Prevention, and Control

- Infections treated with diphtheria antitoxin to neutralize exotoxin, penicillin or erythromycin to eliminate *C. diphtheriae* and terminate toxin production, and immunization of convalescing patients with diphtheria toxoid to stimulate protective antibodies
- Administration of diphtheria vaccine and booster shots to susceptible population

The aerobic, non–spore-forming, gram-positive rods are a heterogeneous group of bacteria. Some are well-recognized human pathogens (e.g., *Listeria monocytogenes, Corynebacterium diphtheriae*), others are primarily animal pathogens that can cause human disease (e.g., *Erysipelothrix rhusiopathiae*), and some are opportunistic pathogens that typically infect hospitalized or immunocompromised patients (e.g., *Corynebacterium jeikeium*). Although the clinical presentation of the diseases can be characteristic, detection and identification of the organisms in the laboratory can be problematic. One technique that is useful for the preliminary identification of these bacteria involves their microscopic morphology. Gram-positive rods that are uniform in shape include *Listeria* and *Erysipelothrix;* irregularly shaped gram-positive rods typically are members of the genus *Corynebacterium* or closely related genera (Table 21.1). This chapter will focus on three species of gram-positive rods: *L. monocytogenes, E. rhusiopathiae,* and *C. diphtheriae*. The diseases caused by these and related bacteria are summarized in Table 21.2.

Listeria monocytogenes

The genus *Listeria* consists of 26 species and subspecies, and ***L. monocytogenes*** is the most significant human pathogen. *L. monocytogenes* is a short (0.4 to 0.5 × 0.5 to 2 μm), nonbranching, gram-positive, facultatively anaerobic rod capable of growth at a broad temperature range (1° C to 45° C) and in a high concentration of salt. The **short rods** appear singly, in pairs, or in short chains (Fig. 21.1) and can be mistaken for *Streptococcus pneumoniae*. This is important because both *S. pneumoniae* and *L. monocytogenes* can cause meningitis. The organisms are **motile** at room temperature but less so at 37° C, and they exhibit a characteristic end-over-end tumbling motion when a drop of broth is examined microscopically. *L. monocytogenes* exhibits **weak β-hemolysis** when grown on sheep blood agar plates. These differential characteristics (i.e., Gram-stain morphology, motility, β-hemolysis) are useful for the preliminary identification of *Listeria*. Although the bacteria are widely distributed in nature, human disease is uncommon and is restricted primarily to several well-defined populations: neonates, the elderly, pregnant women, and patients with defective cellular immunity.

PATHOGENESIS AND IMMUNITY

L. monocytogenes is a **facultative intracellular pathogen**. After ingestion of contaminated food, *L. monocytogenes* is able to survive exposure to proteolytic enzymes, stomach acid, and bile salts through the protective action of stress-response genes. These bacteria are then able to **adhere to host cells** via the interaction of proteins on the surface of the bacteria (i.e., internalin A [InlA]) with glycoprotein receptors on the host cell surface (e.g., epithelial cadherin [calcium-dependent adhesin]). Other internalins (e.g., InlB) can recognize receptors on a wider range of host cells. Studies with animal models have shown that infection is initiated in the enterocytes or M cells in Peyer patches. After penetration into the cells, the acid pH of the phagolysosome that surrounds the bacteria activates a bacterial pore-forming cytolysin **(listeriolysin O)** and two different **phospholipase C** enzymes, leading to release of the bacteria into the cell cytosol. The bacteria proceed to replicate and then move to the cell membrane. This movement is mediated by a bacterial protein, **ActA** (localized on the cell surface at one end of a bacterium), which coordinates **assembly of actin**. The distal ends of the actin tail remain fixed while assembly occurs adjacent to the end of the bacterium. Thus the bacterium is pushed to the cell membrane and a protrusion (filopod) is formed, pushing the bacterium into the adjacent cell. After the adjacent cell ingests the bacterium, the process of **phagolysosome lysis, bacterial replication**, and **directional movement** repeats. Entry into macrophages after passage through the intestinal lining carries the bacteria to the liver and spleen, leading to disseminated disease. The genes responsible for membrane lysis, intracellular replication, and directional movement are clustered together and regulated by a single gene, ***prfA*,** or the **"positive regulatory factor" gene.**

Humoral immunity is relatively unimportant for management of infections with *L. monocytogenes* because these bacteria can replicate in macrophages and move within cells, avoiding antibody-mediated clearance. For this reason, patients with defects in **cellular immunity,** but not in humoral immunity, are particularly susceptible to severe infections.

EPIDEMIOLOGY

L. monocytogenes is isolated from a variety of environmental sources and from the feces of mammals, birds, fish, and other animals. The primary source of infection with this organism is consumption of contaminated food; however, human-to-human transmission can occur primarily from mother to child in utero or at birth. Fecal carriage is estimated to occur in 1% to 5% of healthy people. Because the organism is ubiquitous, exposure and transient colonization are likely to occur in most individuals. Approximately

TABLE 21.1 *Listeria* and Related Bacteria

Organism	Historical Derivation
Listeria	*Listeria,* named after the English surgeon Lord Joseph Lister
L. monocytogenes	*monocytum,* a blood cell or monocyte; *gennaio,* produce (monocyte producing; membrane extracts stimulate monocyte production in rabbits, but this is not seen in human disease)
Erysipelothrix	*erythros,* red; *pella,* skin; *thrix,* hair (thin, hairlike organism that produces a red or inflammatory skin lesion)
E. rhusiopathiae	*rhusios,* red; *pathos,* disease (red disease)
Corynebacterium	*coryne,* a club; *bakterion*, a small rod (a small, club-shaped rod)
C. diphtheriae	*diphthera,* leather or skin (reference to the leathery membrane that forms initially on the pharynx)
C. jeikeium	*jeikeium* (species originally classified as group JK)
C. urealyticum	*urea*, urea; *lyticum*, lyse (capable of lysing urea; species rapidly hydrolyzes urea)
Arcanobacterium	*arcanus,* secretive; bacterium, rod (secretive bacterium; a slow-growing organism that can prove difficult to isolate)
Rothia mucilaginosa	Named after Roth, the bacteriologist who originally studied this group of organisms; *mucilaginosa,* slimy (slimy or mucoid organisms)
Tropheryma whipplei	*trophe,* nourishment; *eryma,* barrier; whipple, named after George Whipple who described it in 1907; it is a malabsorption disease; also called Whipple disease

TABLE 21.2 Human Disease Associated with *Listeria* and Related Bacteria

Organism	Diseases
Listeria monocytogenes	Neonatal disease (spontaneous abortion, disseminated abscesses and granulomas, meningitis, septicemia); influenza-like illness in healthy adults; bacteremia or disseminated disease with meningitis in pregnant women and patients with cell-mediated immune defects
Erysipelothrix rhusiopathiae	Erysipeloid (painful, pruritic inflammatory skin lesion); generalized cutaneous disease; a diffuse cutaneous infection with fever and arthralgias; septicemia typically associated with endocarditis
Corynebacterium diphtheriae	Diphtheria (respiratory, cutaneous); pharyngitis and endocarditis (nontoxigenic strains)
C. jeikeium (group JK)	Septicemia, endocarditis, wound infections, foreign body (catheter, shunt, prosthesis) infections
C. urealyticum	Urinary tract infections (including pyelonephritis and alkaline-encrusted cystitis), septicemia, endocarditis, wound infections
Arcanobacterium	Pharyngitis, cellulitis, wound infections, abscess formation, septicemia, endocarditis
Rothia	Endocarditis, foreign-body infections
Tropheryma	Whipple disease

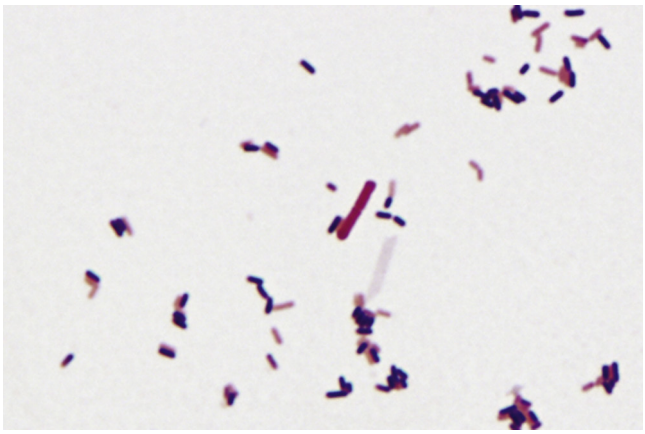

Fig. 21.1 Gram stain of *Listeria monocytogenes* in culture. *Listeria* appear as small gram-positive rods; some readily decolorize and appear gram-negative. The much larger gram-negative rod in the center of the photograph is *Escherichia coli*.

750 infections are reported annually in the United States; however, many mild infections are not reported. Large outbreaks associated with **contaminated food products** are well documented. For example, 30 million pounds of contaminated meat were recalled in one U.S. outbreak in 1999, and 16 million pounds of processed turkey and chicken meat were recalled in a second multistate outbreak in 2000. In 2018, the largest confirmed *Listeria* outbreak was reported in South Africa in which 982 confirmed cases and 189 deaths were associated with consumption of contaminated processed meat (bologna). The incidence of disease is also disproportionate in **high-risk populations,** such as neonates, the elderly, pregnant women, and patients with severe defects in cell-mediated immunity (e.g., transplants, lymphomas, acquired immunodeficiency syndrome [AIDS]).

Human listeriosis is a sporadic disease seen throughout the year, with focal epidemics and sporadic cases of listeriosis associated with consumption of undercooked processed meat (e.g., turkey franks, cold cuts); unpasteurized or contaminated milk or cheese; and unwashed raw vegetables, including cabbage. Although fresh produce is an uncommon cause of outbreaks, disease associated with consumption of contaminated cantaloupe was reported in 147 individuals in 2011 (86% were 60 years of age or older; 22% fatality rate). Because *Listeria* can grow in a wide pH range and at cold temperatures, foods with small numbers of organisms can become heavily contaminated during prolonged refrigeration. Disease can occur if the food is uncooked or inadequately cooked (e.g., microwaved beef and turkey franks) before consumption. Although *Listeria* infections are relatively uncommon, it is the leading cause of deaths attributed to foodborne illnesses in the United States.

CLINICAL DISEASES

Neonatal Disease

Two forms of neonatal disease have been described: (1) **early-onset disease,** acquired transplacentally in utero, and (2) **late-onset disease,** acquired at or soon after birth (see Table 21.2). Early-onset disease can result in

abortion, stillbirth, or premature birth. **Granulomatosis infantiseptica** is a severe form of early-onset listeriosis characterized by the formation of abscesses and granulomas in multiple organs and a high mortality rate unless treated promptly.

Late-onset disease occurs 2 to 3 weeks after birth in the form of meningitis or meningoencephalitis with septicemia. The clinical signs and symptoms are not unique; thus other causes of neonatal central nervous system disease, such as group B streptococcal disease, must be excluded.

Infections in Pregnant Women

Most infections in pregnant women occur during the third trimester when cellular immunity is most impaired. Infected women typically develop nonspecific influenza-like symptoms that may resolve without treatment. Unless blood cultures are collected in pregnant febrile women without another source of infection (e.g., urinary tract infection), *Listeria* bacteremia and the associated neonatal risk may be unappreciated.

Disease in Healthy Adults

Most *Listeria* infections in healthy adults are asymptomatic or occur in the form of a mild influenza-like illness. An acute self-limited gastroenteritis develops in some patients, characterized by a 1-day incubation period followed by 2 days of symptoms, including watery diarrhea, fever, nausea, headache, myalgias, and arthralgias. In contrast to these self-limited illnesses, listeriosis in elderly patients and those with compromised cellular immunity is more severe.

Meningitis in Adults

Meningitis is the most common form of disseminated *Listeria* infection in adults (Clinical Case 21.1). Although the clinical signs and symptoms of meningitis caused by this organism are not specific, *Listeria* should always be suspected in patients with organ transplants or cancer and in pregnant women in whom meningitis develops. Disease is associated with high mortality (20% to 50%) and significant neurologic sequelae among the survivors.

Primary Bacteremia

Patients with bacteremia may have an unremarkable history of chills and fever (commonly observed in pregnant women) or a more acute presentation with high-grade fever and hypotension. Only severely immunocompromised patients and the infants of pregnant women with sepsis appear to be at risk of death.

LABORATORY DIAGNOSIS

Microscopy

Gram-stain preparations of cerebrospinal fluid (CSF) typically show no organisms because the bacteria are generally present in concentrations (e.g., 10^4 bacteria per milliliter CSF or less) below the limit of detection (10^5 bacteria per milliliter). This is in contrast with most other bacterial pathogens of the central nervous system, which are present in concentrations of 100-fold to 1000-fold higher. If the Gram stain shows organisms, they are intracellular and extracellular gram-positive coccobacilli. Care must be used to distinguish them from other bacteria such as *S. pneumoniae*.

Clinical Case 21.1 *Listeria* Meningitis in Immunocompromised Man

The following patient described by Bowie and associates (*Ann Pharmacother* 38:58–61, 2004) illustrates the clinical presentation of *Listeria* meningitis. A 73-year-old man with refractory rheumatoid arthritis was brought by his family to the local hospital because he had a decreased level of consciousness and a 3-day history of headache, nausea, and vomiting. His current medications were infliximab, methotrexate, and prednisone for his rheumatoid arthritis. On physical examination, the patient had a stiff neck and was febrile, had a pulse of 92 beats/min, and had a blood pressure of 179/72 mm Hg. Because meningitis was suspected, blood and cerebrospinal fluid (CSF) were collected for culture. The Gram stain of the CSF was negative, but *Listeria* grew from both blood and CSF cultures. The patient was treated with vancomycin, the infliximab was discontinued, and he made an uneventful recovery despite using less-than-optimal antimicrobial therapy. Infliximab has been associated with a dose-dependent monocytopenia. Because monocytes are key effectors for clearance of *Listeria,* this immunocompromised patient was specifically at risk for infection with this organism. Failure to detect *Listeria* in CSF by Gram stain is typical of this disease because the bacteria fail to multiply to detectable levels.

Culture

Listeria grows on most conventional laboratory media, with small, round colonies observed on agar media after incubation for 1 to 2 days. It may be necessary to use selective media and **cold enrichment** (storage of the specimen in the refrigerator for a prolonged period) to detect listeriae in specimens contaminated with rapidly growing bacteria. β-Hemolysis on sheep blood agar media can serve to distinguish *Listeria* from morphologically similar bacteria; however, hemolysis is generally weak and may not be observed initially. The characteristic motility of the organism in a liquid medium or semisolid agar is helpful for the preliminary identification of listeriae. All gram-positive rods isolated from blood and CSF should be identified to distinguish between *Corynebacterium* (presumably a skin contaminant) and *Listeria*.

Identification

Selected biochemical tests have been used historically to identify *Listeria*. More recently matrix-assisted laser desorption ionization (MALDI) mass spectrometry has replaced biochemical testing in many laboratories. Serologic and molecular typing methods are used for epidemiologic investigations. A total of 13 serotypes have been described; however, serotypes 1/2a, 1/2b, and 4b are responsible for most infections in neonates and adults, so serotyping is generally not useful in epidemiologic investigations. Pulsed-field gel electrophoresis (PFGE) and more recently whole genome sequence analysis are the most commonly used molecular methods for epidemiologic investigations of suspected outbreaks.

TREATMENT, PREVENTION, AND CONTROL

Because most antibiotics are only bacteriostatic with *L. monocytogenes,* the combination of **gentamicin with either penicillin or ampicillin** is the treatment of choice for serious infections. Listeriae are naturally resistant to cephalosporins, and resistance to macrolides, fluoroquinolones, and tetracyclines has been observed, which can limit the utility of these drugs. Trimethoprim-sulfamethoxazole is bactericidal to *L. monocytogenes* and has been used successfully. Other antibiotics, such as linezolid, daptomycin, and tigecycline, have good in vitro activity but have not been used extensively to treat patients.

Because listeriae are ubiquitous and most infections are sporadic, prevention and control are difficult. People at high risk of infection should avoid eating raw or partially cooked foods of animal origin, soft cheeses, and unwashed raw vegetables. A vaccine is not available, and prophylactic antibiotic therapy for high-risk patients has not been evaluated.

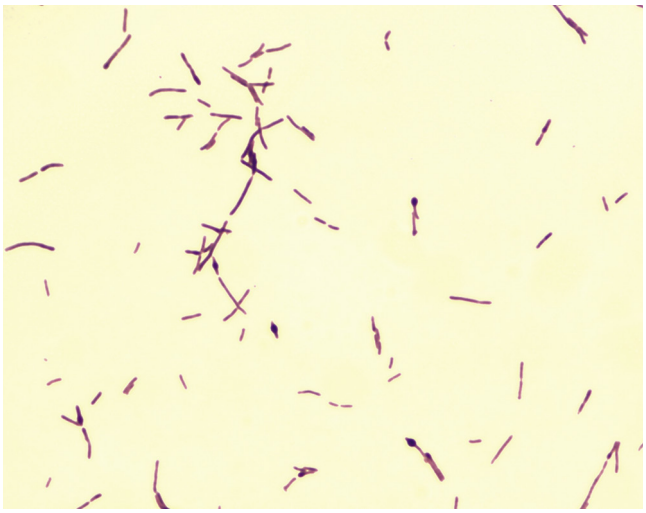

Fig. 21.2 Gram stain of *Erysipelothrix rhusiopathiae* in culture. Note the variable lengths of the rods and the "gram-negative" appearance.

Erysipelothrix rhusiopathiae

PHYSIOLOGY AND STRUCTURE

E. rhusiopathiae is a gram-positive, non–spore-forming rod that is distributed worldwide in wild and domestic animals. The rods are slender (0.2 to 0.5 × 0.8 to 2.5 μm) and sometimes pleomorphic, with a tendency to form "hairlike" filaments as long as 60 μm. They decolorize readily and may appear gram-negative (Fig. 21.2). The organisms are microaerophilic and grow best in an atmosphere of reduced oxygen and supplemented carbon dioxide (5% to 10% CO_2). A mixture of tiny, smooth colonies and larger, rough colonies are observed after 2 to 3 days of incubation. If the rough colonies are absent, then the small smooth colonies may be overlooked unless the culture plates are examined carefully.

PATHOGENESIS

Little is known about specific virulence factors in *Erysipelothrix*. Production of neuraminidase is believed to be important for attachment and penetration into epithelial cells, and a polysaccharide-like capsule protects the bacteria from phagocytosis.

EPIDEMIOLOGY

Erysipelothrix is a ubiquitous organism that is distributed worldwide. It can be recovered on the tonsils or in the digestive tracts of many wild and domestic animals, including mammals, birds, and fish. Colonization is particularly high in **swine** and **turkeys.** Soil rich in organic matter or groundwater contaminated with animal wastes can facilitate spread in an animal population. These bacteria are resistant to drying and can survive in soil for months to years. In addition, *E. rhusiopathiae* is resistant to high concentrations of salt, pickling, and smoking. *Erysipelothrix* disease in humans is **zoonotic** (spread from animals to humans) and primarily occupational. Butchers, meat processors, farmers, poultry workers, fish handlers, and veterinarians are at greatest risk. Cutaneous infections typically develop after the organism is inoculated subcutaneously through an abrasion or puncture wound during the handling of contaminated animal products or soil. The incidence of human disease is unknown because *Erysipelothrix* infection is not a reportable disease.

CLINICAL DISEASES

Animal disease, particularly in swine, is widely recognized, but human disease is less common (see Table 21.2; Clinical Case 21.2). Three primary forms of human infection with *E. rhusiopathiae* have been described: (1) a localized skin infection, **erysipeloid** (not to be confused with streptococcal erysipelas), (2) generalized cutaneous disease, and (3) **septicemia.** Erysipeloid is an inflammatory skin lesion that develops at the site of trauma after 2 to 7 days of incubation. The lesion most commonly presents on the fingers or hands and appears violaceous with a raised edge. It slowly spreads peripherally as the discoloration in the central area fades. The painful lesion is pruritic, and the patient experiences a burning or throbbing sensation. Suppuration is uncommon and is a feature that distinguishes erysipeloid from streptococcal erysipelas. The resolution can be spontaneous but can be hastened with appropriate antibiotic therapy. The diffuse cutaneous infection is characterized by development of lesions either in the general area of the initial lesion or at other skin locations. The systemic signs of fever and arthralgias are common, but blood cultures are typically negative.

The septicemic form of *Erysipelothrix* infections is uncommon, but when present, it is frequently associated with endocarditis. *Erysipelothrix* endocarditis may have an acute onset but is usually subacute. Involvement of previously undamaged heart valves (particularly the aortic valve) is common. Other systemic complications (e.g., abscess formation, meningitis, osteomyelitis) are relatively uncommon.

LABORATORY DIAGNOSIS

The rods are located only in the deep tissue of the lesion. Thus full-thickness biopsy specimens or deep aspirates must

Clinical Case 21.2 *Erysipelothrix* Endocarditis

Endocarditis caused by *Erysipelothrix rhusiopathiae* is an uncommon but well-recognized disease. The following case history reported by Artz and associates (*Eur J Clin Microbiol Infect Dis* 20:587–588, 2001) is typical of this disease. A 46-year-old man who worked as a butcher and had a history of alcoholism was admitted to the hospital with an erythematous rash over his upper body and a complaint of arthralgias of both shoulders. Medical history revealed a 4-week history of night sweats and daily recurring chills, which the patient attributed to his drinking. Physical examination revealed hepatosplenomegaly, a systolic murmur detected on auscultation, and a calcified aortic valve with mild regurgitation but no vegetations on echocardiography. Five blood cultures were collected, and all were positive for *E. rhusiopathiae* after 2 days. The patient was transferred to surgery for valve replacement, and paravalvular abscesses were detected intraoperatively. After surgical repair, the patient was treated with clindamycin and penicillin and made a complete recovery. This case illustrates risk factors (i.e., butcher, alcoholism), a chronic course, and the value of surgery combined with treatment with effective antibiotics (i.e., penicillin, clindamycin).

be collected from the margin of the lesion. A Gram stain of the specimen is typically negative, although the presence of **thin, gram-positive rods** associated with a characteristic lesion and clinical history can be diagnostic. *E. rhusiopathiae* is not fastidious and grows on most conventional laboratory media incubated in the presence of 5% to 10% CO_2; however, growth is slow, and cultures must be incubated for 3 days or longer before being considered negative. The absence of both motility and catalase production distinguishes this organism from *Listeria*. The organism is weakly fermentative and produces hydrogen sulfide on triple-sugar iron agar. Serology is not useful for diagnosis because an antibody response is weak in human infections.

TREATMENT, PREVENTION, AND CONTROL

Erysipelothrix is susceptible to **penicillin,** which is the antibiotic of choice for both localized and systemic diseases. Cephalosporins, carbapenems, fluoroquinolones, and clindamycin are also active in vitro, but the organism has variable susceptibility to macrolides, sulfonamides, and aminoglycosides and is resistant to vancomycin. For patients allergic to penicillin, ciprofloxacin or clindamycin can be used for localized cutaneous infections, and ceftriaxone or imipenem can be considered for disseminated infections. Infections in people at a higher occupational risk are prevented by the use of gloves and other appropriate coverings on exposed skin. Vaccination is used to control disease in swine.

Corynebacterium diphtheriae

The genus *Corynebacterium* is a large, heterogeneous collection of almost 150 species and subspecies that have a cell wall with arabinose, galactose, *meso*-diaminopimelic acid (*meso*-DAP), and (in most species) **short-chain mycolic acids** (22 to 36 carbon atoms). Although organisms with medium- and long-chain mycolic acids stain with acid-fast stains (see Chapter 22), *Corynebacterium* organisms are not acid-fast. Gram stains of these bacteria reveal clumps and short chains of irregularly shaped ("club-shaped") rods (Fig. 21.3). Corynebacteria are aerobic or facultatively anaerobic, nonmotile, and catalase positive. Most (but not all) species ferment carbohydrates, producing lactic acid as a by-product. Many species grow well on common laboratory media; however, some species form small colonies because they require lipid supplemented media for good growth (**lipophilic** strains).

Corynebacteria are ubiquitous in plants and animals, and they normally colonize the skin, upper respiratory tract, gastrointestinal tract, and urogenital tract in humans. Although all species of corynebacteria can function as opportunistic pathogens, relatively few are associated with human disease (see Table 21.2). The most famous of these is *C. diphtheriae,* which is the etiologic agent of **diphtheria.** A number of other genera of coryneform bacteria have been characterized. Three genera associated with human disease (*Arcanobacterium, Rothia,* and *Tropheryma*) are listed in Table 21.2, but these will not be discussed further.

PHYSIOLOGY AND STRUCTURE

C. diphtheriae is an irregularly staining, pleomorphic rod (0.3 to 0.8 × 1.0 to 8.0 μm). After overnight incubation, large 1- to 3-mm colonies are observed on blood agar medium. More selective, differential media can be used to recover this pathogen from specimens with other organisms present, such as pharyngeal specimens. This species is subdivided into four biotypes based on their colonial morphology and biochemical properties: *belfanti, gravis, intermedius,* and *mitis,* with most disease caused by **biotype *mitis*.**

PATHOGENESIS AND IMMUNITY

Diphtheria toxin is the major virulence factor of *C. diphtheriae*. The *tox* gene that codes for the exotoxin is introduced into strains of *C. diphtheriae* by a lysogenic bacteriophage, **β-phage.** Two processing steps are necessary for the active gene product to be secreted: (1) proteolytic cleavage of the leader sequence from the Tox protein during secretion from the bacterial cell and (2) cleavage of the toxin molecule into two polypeptides (A and B) that remain attached by a disulfide bond. This 58,300-Da protein is an example of the classic **A-B exotoxin.**

Three functional regions exist on the toxin molecule: a **catalytic region** on the A subunit and a **receptor-binding region** and a **translocation region** on the B subunit. The receptor for the toxin is **heparin-binding epidermal growth factor,** which is present on the surface of many eukaryotic cells, particularly heart and nerve cells; its presence explains the cardiac and neurologic symptoms observed in patients with severe diphtheria. After the toxin becomes attached to the host cell, the translocation region is inserted into the endosomal

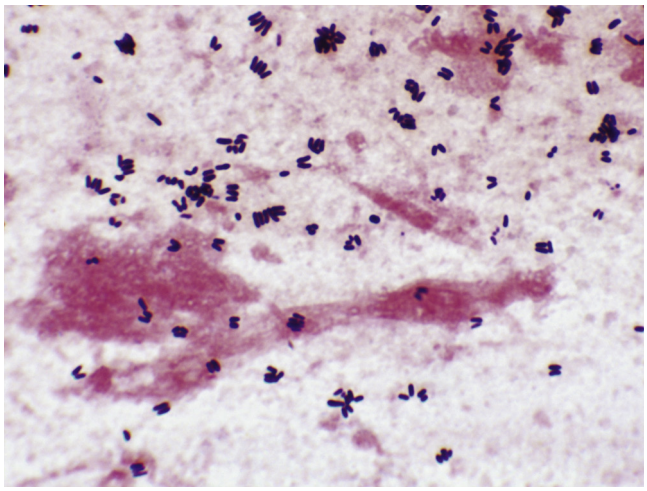

Fig. 21.3 Gram stain of *Corynebacterium* species in sputum specimen.

membrane, facilitating the movement of the catalytic region into the cell cytosol. The A subunit then terminates host cell protein synthesis by inactivating **elongation factor-2 (EF-2),** which is a factor required for the movement of nascent peptide chains on ribosomes. Because the turnover of EF-2 is very slow and approximately only one molecule per ribosome is present in a cell, it has been estimated that one exotoxin molecule can inactivate the entire EF-2 content in a cell, completely terminating host cell protein synthesis. Toxin synthesis is regulated by a chromosomally encoded element, **diphtheria toxin repressor (DTxR).** This protein, activated in the presence of high iron concentrations, can bind to the toxin gene operator and prevent toxin production.

EPIDEMIOLOGY

Diphtheria is a disease found worldwide, particularly in poor urban areas in which there is crowding and the protective level of vaccine-induced immunity is low. The largest outbreak in the latter part of the 20th century occurred in the former Soviet Union, where in 1994 almost 48,000 cases were documented, with 1746 deaths. *C. diphtheriae* is maintained in the population by **asymptomatic carriage** in the oropharynx or on the skin of immune people. Respiratory droplets or skin contact transmits it from person to person. **Humans** are the **only known reservoir** for this organism.

Diphtheria has become uncommon in the United States because of an active immunization program, as shown by the fact that more than 200,000 cases were reported in 1921, but only 2 cases have been reported since 2003. An analysis of *C. diphtheriae* infections in the United Kingdom between 1986 and 2008 identified that the major risk factor for infection was travel of nonimmune individuals to countries with endemic disease (e.g., Indian subcontinent, Africa, Southeast Asia). Diphtheria is primarily a pediatric disease, but the highest incidence has shifted toward older age groups in areas in which there are active immunization programs for children. Skin infection with toxigenic *C. diphtheriae* (cutaneous diphtheria) also occurs, but it is not a reportable disease in the United States, so its incidence is unknown.

CLINICAL DISEASES

The clinical presentation of diphtheria is determined by the (1) site of infection, (2) immune status of the patient, and (3) virulence of the organism. Exposure to *C. diphtheriae* may result in asymptomatic colonization in fully immune people; mild respiratory disease in partially immune patients; or a fulminant, sometimes fatal, disease in nonimmune patients. Diphtheria toxin is produced at the site of the infection and then disseminates through the blood to produce the systemic signs of diphtheria. The organism does not need to enter the blood to produce disease.

Respiratory Diphtheria

The symptoms of diphtheria involving the respiratory tract develop after a 2- to 4-day incubation period (Clinical Case 21.3). Organisms multiply locally on epithelial cells in the pharynx or adjacent surfaces and initially cause localized damage as a result of exotoxin activity. The onset is sudden, with malaise, sore throat, **exudative pharyngitis,** and a low-grade fever. The exudate evolves into a thick **pseudomembrane** composed of bacteria, lymphocytes, plasma cells, fibrin, and dead cells that can cover the tonsils, uvula, and palate and can extend up into the nasopharynx or down into the larynx (Fig. 21.4). The pseudomembrane firmly adheres to the underlying tissue and is difficult to dislodge without making the tissue bleed (unique to diphtheria). As the patient recovers after the approximately 1-week course of the disease, the membrane dislodges and is expectorated. Systemic complications in patients with severe disease primarily involve the heart and nervous system. Evidence of **myocarditis** can be detected in the majority of patients with diphtheria, typically developing 1 to 2 weeks into the illness and at a time when the pharyngeal symptoms are improving. Symptoms can present acutely or gradually, progressing in severe disease to congestive heart failure, cardiac arrhythmias, and death. **Neurotoxicity** is proportional to the severity of the primary disease, which is influenced by the patient's immunity. The majority of patients with severe primary disease develop neuropathy, initially localized to the soft palate and pharynx, later involving oculomotor and ciliary paralysis, with progression to peripheral neuritis.

Cutaneous Diphtheria

Cutaneous diphtheria is acquired through skin contact with other infected persons. The organism colonizes the skin and gains entry into the subcutaneous tissue through breaks in the skin. A papule develops first and then evolves into a **chronic, nonhealing ulcer,** sometimes covered with a grayish membrane. *Staphylococcus aureus* or *S. pyogenes* is also frequently present in the wound.

Laboratory Diagnosis

The initial treatment of a patient with diphtheria is instituted on the basis of the clinical diagnosis, not laboratory results, because definitive results are not available for at least a week.

Clinical Case 21.3 **Respiratory Diphtheria**

Lurie and associates (*JAMA* 291:937–938, 2004) reported the last patient with respiratory diphtheria seen in the United States. An unvaccinated 63-year-old man developed a sore throat while on a week-long trip in rural Haiti. Two days after he returned home to Pennsylvania, he visited a local hospital with complaints of a sore throat and difficulties in swallowing. He was treated with oral antibiotics but returned 2 days later with chills, sweating, difficulty swallowing and breathing, nausea, and vomiting. He had diminished breath sounds in the left lung, and radiographs confirmed pulmonary infiltrates and enlargement of the epiglottis. Laryngoscopy revealed yellow exudates on the tonsils, posterior pharynx, and soft palate. He was admitted to the intensive care unit and treated with azithromycin, ceftriaxone, nafcillin, and steroids, but over the next 4 days he became hypotensive with a low-grade fever. Cultures were negative for *Corynebacterium diphtheriae*. By the eighth day of illness, a chest radiograph showed infiltrates in the right and left lung bases, and a white exudate consistent with *C. diphtheriae* pseudomembrane was observed over the supraglottic structures. Cultures at this time remained negative for *C. diphtheriae,* but polymerase chain reaction testing for the exotoxin gene was positive. Despite aggressive therapy, the patient continued to deteriorate, and on the 17th day of hospitalization he developed cardiac complications and died. This patient illustrates (1) the risk factor of an unimmunized patient traveling to an endemic area, (2) the classic presentation of severe respiratory diphtheria, (3) delays associated with diagnosis of an uncommon disease, and (4) the difficulties most laboratories would now have isolating the organism in culture.

Fig. 21.4 Pharynx of a 39-year-old woman with bacteriologically confirmed diphtheria. The photograph was taken 4 days after the onset of fever, malaise, and sore throat. Hemorrhage caused by removal of the membrane by swabbing appears as a dark area on the left. (From Mandell, G., Bennett, J., Dolin, R., 2015. Principles and Practice of Infectious Diseases, eighth ed. Elsevier, Philadelphia, PA.)

Microscopy

The results of microscopic examination of clinical material are unreliable. Metachromatic granules in bacteria stained with methylene blue have been described, but this appearance is not specific to *C. diphtheriae*.

Culture

Specimens for the recovery of *C. diphtheriae* should be collected from both the nasopharynx and throat and should be inoculated onto a nonselective, enriched blood agar plate and a selective medium (e.g., cysteine-tellurite blood agar [CTBA], Tinsdale medium, colistin-nalidixic agar [CNA]). Tellurite inhibits the growth of most upper respiratory tract bacteria and gram-negative rods and is reduced by *C. diphtheriae,* producing a characteristic gray to black color on agar. Degradation of cysteine by *C. diphtheriae* cysteinase activity produces a brown halo around the colonies. CTBA has a long shelf life (practical for cultures that are infrequently performed) but inhibits some strains of *C. diphtheriae*. Tinsdale medium is the best medium for recovering *C. diphtheriae* in clinical specimens, but it has a short shelf life and requires the addition of horse serum. Because infections caused by *C. diphtheriae* are rarely seen or suspected in nonendemic areas, CTBA and Tinsdale medium are not commonly available in most laboratories. CNA is commonly used for the selective recovery of gram-positive bacteria; therefore this is a practical alternative medium. Regardless of the media used, all isolates resembling *C. diphtheriae* must be identified by biochemical testing and the presence of the diphtheria exotoxin confirmed because nontoxigenic strains occur.

Identification

The presumptive identification of *C. diphtheriae* can be based on the presence of cystinase and absence of pyrazinamidase (two enzyme reactions that can be rapidly determined). More extensive biochemical tests or nucleic acid sequencing of species-specific genes is required for identification at the species level.

Toxigenicity Testing

All isolates of *C. diphtheriae* should be tested for the production of exotoxin. The gold standard for detection of diphtheria toxin is an in vitro immunodiffusion assay **(Elek test).** An alternative method is detection of the exotoxin gene using a **polymerase chain reaction (PCR)–based nucleic acid amplification method.** This test can detect the *tox* gene in clinical isolates and directly in clinical specimens (e.g., swabs from the diphtheritic membrane or biopsy material). Although this test is rapid and specific, strains in which the *tox* gene is not expressed (presumably because the **DTxR** is expressed) can give a positive signal. Nontoxigenic strains of *C. diphtheriae* do not produce classic diphtheria; however, they should not be ignored because these strains have been associated with other significant diseases, including septicemia, endocarditis, septic arthritis, osteomyelitis, and abscess formation.

TREATMENT, PREVENTION, AND CONTROL

The most important aspect of the treatment for diphtheria is early administration of **diphtheria antitoxin** to specifically neutralize the exotoxin before it is bound by the host cell. Once the cell internalizes the toxin, cell death is inevitable. Unfortunately, because diphtheria may not be suspected initially, significant disease progression can occur before the antitoxin is administered. Antibiotic therapy

with **penicillin or erythromycin** is also used to eliminate *C. diphtheriae* and terminate toxin production. Bed rest, isolation to prevent secondary spread, and maintenance of an open airway in patients with respiratory diphtheria are all important. After the patient has recovered, **immunization with toxoid** is required because most patients fail to develop protective antibodies after a natural infection.

Symptomatic diphtheria can be prevented by actively immunizing people with diphtheria toxoid. The nontoxic, immunogenic toxoid is prepared by formalin treatment of the toxin. Initially, children are given five injections of this preparation with pertussis and tetanus antigens **(DPT vaccine)** at ages 2, 4, 6, 15 to 18 months, and 4 to 6 years. After that time, it is recommended that booster vaccinations with diphtheria toxoid combined with tetanus toxoid be given every 10 years. The effectiveness of immunization is well documented, with disease restricted to nonimmune or incompletely immunized individuals.

People in close contact with patients who have documented diphtheria are at risk for acquiring the disease. Nasopharyngeal specimens for culture should be collected from all close contacts and antimicrobial prophylaxis with erythromycin or penicillin started immediately. Any contact who has not completed the series of diphtheria immunizations or who has not received a booster dose within the previous 5 years should receive a booster dose of toxoid. People exposed to cutaneous diphtheria should be managed in the same manner because it is reported that they are more contagious than patients with respiratory diphtheria. If the respiratory or cutaneous infection is caused by a nontoxigenic strain, it is unnecessary to institute prophylaxis in contacts.

Case Study and Questions

A 35-year-old man was hospitalized because of headache, fever, and confusion. He had received a kidney transplant 7 months earlier, after which he had been given immunosuppressive drugs to prevent organ rejection. Cerebrospinal fluid (CSF) was collected, which revealed a white blood cell count of 36 cells/mm^3, with 96% polymorphonuclear leukocytes, a glucose concentration of 40 mg/dl, and a protein concentration of 172 mg/dl. A Gram stain preparation of CSF was negative for organisms, but gram-positive coccobacilli grew in cultures of the blood and CSF.

1. What is the most likely cause of this patient's meningitis?
2. What are the potential sources of this organism?
3. What virulence factors are associated with this organism?
4. How would this disease be treated? Which antibiotics are effective in vitro? Which antibiotics are ineffective?

22 Mycobacterium *and* *Related Acid-Fast Bacteria*

A 47-year-old renal transplant recipient who had been receiving prednisone and azathioprine for 2 years was admitted to the university medical center. Two weeks earlier, the patient had noticed the development of a dry, persistent cough. Five days before admission, the cough became productive and pleuritic chest pain developed. On the day of admission, the patient was in mild respiratory distress, and chest radiographs revealed a patchy right upper lobe infiltrate. Sputum specimens were initially sent for bacterial culture, and the modified acid-fast stain was positive.

1. What genera of bacteria will stain with the modified acid-fast stain?
2. If this patient has no travel history outside the United States, what would be the most likely cause of the respiratory illness?
3. What are the most common diseases caused by the genera of acid-fast bacteria?
4. What characteristic morphologic properties and growth properties will help differentiate the most common acid-fast bacteria?

Answers to these questions are available on Student Consult.com.

Summaries Clinically Significant Organisms

MYCOBACTERIUM TUBERCULOSIS

Trigger Words

Acid-fast, lipid-rich cell wall, intracellular, purified protein derivative (PPD), drug-resistant

Biology and Virulence

- Weakly gram-positive, strongly acid-fast, aerobic rods
- Lipid-rich cell wall, making the organism resistant to traditional stains, disinfectants, detergents, common antibacterial antibiotics, and host immune response
- Capable of intracellular growth in alveolar macrophages
- Disease primarily from host response to infection

Epidemiology

- Worldwide; one-fourth of the world's population is infected with this organism
- A total of 10.4 million new cases each year and 1.6 million deaths
- Disease most common in India, Pakistan, sub-Saharan Africa, South Africa, China, and Eastern Europe
- 9272 new cases in the United States in 2016
- Populations at greatest risk for disease are foreign born or travelers to endemic countries, immunocompromised patients (particularly those with HIV infection), drug or alcohol abusers, homeless persons, and individuals exposed to diseased patients
- Humans are the only natural reservoir
- Person-to-person spread by infectious aerosols

Diseases

- Primary infection is pulmonary
- Dissemination to any body site occurs most commonly in immunocompromised patients

Diagnosis

- Tuberculin skin test and interferon (IFN)-γ release tests are sensitive markers for exposure to the organism
- Microscopy and culture are sensitive and specific
- Nucleic acid amplification tests are important where culture is not available and microscopy is inaccurate for detection of *M. tuberculosis* in clinical specimens
- Identification most commonly made using species-specific molecular probes, sequencing, or mass spectrometry

Treatment, Prevention, and Control

- Prolonged treatment with multiple drugs is required to prevent development of drug-resistant strains
- Isoniazid (INH), ethambutol, pyrazinamide, and rifampin for 2 months followed by 4-6 months of INH and rifampin or alternative combination drugs
- Prophylaxis for exposure to tuberculosis can include INH for 6-9 months or daily rifampin for 4 months; pyrazinamide and ethambutol or levofloxacin are used for 6-12 months after exposure to drug-resistant *M. tuberculosis*
- Immunoprophylaxis with bacillus Calmette-Guérin (BCG) in endemic countries
- Control of disease through active surveillance, prophylactic and therapeutic intervention, and careful case monitoring

MYCOBACTERIUM LEPRAE

Trigger Words

Acid-fast, leprosy, nonculturable, skin test

Biology and Virulence

- Weakly gram-positive, strongly acid-fast rods
- Lipid-rich cell wall
- Unable to be cultured on artificial media
- Disease primarily from host response to infection

Epidemiology

- 200,000 new cases were reported in 2016, with most cases in India, Brazil, and Indonesia
- 178 new cases reported in the United States in 2015
- Lepromatous form of disease, but not the tuberculoid form, is highly infectious
- Person-to-person spread by prolonged exposure to respiratory secretions of an untreated, infected person

Diseases

- Tuberculoid (paucibacillary) and lepromatous (multibacillary) forms of leprosy

Diagnosis

- Microscopy is sensitive for the lepromatous form but not the tuberculoid form
- Skin testing is required to confirm tuberculoid leprosy
- Culture is not useful

Treatment, Prevention, and Control

- Tuberculoid form is treated with rifampicin and dapsone for 6 months; clofazimine is added to this regimen for treatment of the lepromatous form, and therapy is extended to a minimum of 12 months
- Disease is controlled through prompt recognition and treatment of infected people

MYCOBACTERIUM AVIUM COMPLEX

Trigger Words

Acid-fast, pulmonary infections, AIDS, prophylaxis

Biology and Virulence

- Weakly gram-positive, strongly acid-fast aerobic rods
- Lipid-rich cell wall
- Disease primarily from host response to infection

Epidemiology

- Worldwide distribution, but disease is seen most commonly in countries where tuberculosis is less common
- Acquired primarily through ingestion of contaminated water or food; inhalation of infectious aerosols is believed to play a minor role in transmission
- Patients at greatest risk for disease are those who are immunocompromised (particularly patients with acquired immunodeficiency syndrome [AIDS]) and those with long-standing pulmonary disease

Diseases

- Disease includes asymptomatic colonization, chronic localized pulmonary disease, solitary nodule, or disseminated disease, particularly in patients with AIDS

Diagnosis

- Microscopy and culture are sensitive and specific

Treatment, Prevention, and Control

- Infections treated for prolonged period with clarithromycin or azithromycin combined with ethambutol and rifabutin
- Prophylaxis in AIDS patients who have a low CD4 cell count consists of clarithromycin or azithromycin or rifabutin, and such treatment has greatly reduced the incidence of disease

NOCARDIA

Trigger Words

Modified acid-fast, filamentous, bronchopulmonary or cutaneous disease, opportunistic

Biology and Virulence

- Gram-positive, partially acid-fast, filamentous rods; cell wall with mycolic acid
- Strict aerobe capable of growth on most nonselective bacteria, fungal, and mycobacterial media; however, prolonged incubation (2 days or more) may be required
- Virulence associated with ability to avoid intracellular killing
- Catalase and superoxide dismutase inactivate toxic oxygen metabolites (e.g., hydrogen peroxide, superoxide)
- Cord factor prevents intracellular killing in phagocytes by interfering with fusion of phagosomes with lysosomes

Epidemiology

- Worldwide distribution in soil rich with organic matter
- Exogenous infections acquired by inhalation (pulmonary) or traumatic introduction (cutaneous)
- Opportunistic pathogen causing disease most commonly in immunocompromised patients with T-cell deficiencies (transplant recipients, patients with malignancies, patients infected with the human immunodeficiency virus [HIV], patients receiving corticosteroids)

Diseases

- Primary disease most commonly bronchopulmonary (e.g., cavitary disease) or primary cutaneous infections (e.g., mycetoma, lymphocutaneous infection, cellulitis, subcutaneous abscesses)
- Dissemination most commonly to central nervous system (e.g., brain abscesses) or skin

Diagnosis

- Microscopy is sensitive and relatively specific when branching, partially acid-fast organisms are seen
- Culture is slow, requiring incubation for up to 1 week; selective media (e.g., buffered charcoal yeast extract agar) may be required for isolating *Nocardia* in mixed cultures
- Identification at the genus level can be made by the microscopic and macroscopic appearances (branching, weakly acid-fast rods forming colonies with aerial hyphae)
- Identification at the species level requires genomic analysis for most isolates or mass spectrometry

Treatment, Prevention, and Control

- Infections are treated with antibiotics and proper wound care
- Trimethoprim-sulfamethoxazole (TMP-SMX) used as initial empirical therapy for cutaneous infections in immunocompetent patients; therapy for severe infections and cutaneous infections in immunocompromised patients should include TMP-SMX plus amikacin for pulmonary or cutaneous infections and TMP-SMX plus imipenem or a cephalosporin for central nervous system infections; prolonged treatment (up to 12 months) is recommended
- Exposure cannot be avoided because nocardiae are ubiquitous

The genera discussed in this chapter are nonmotile, non–spore-forming, aerobic gram-positive rods that stain **acid-fast** (i.e., resist decolorization with weak to strong acid solutions) because of the presence of medium to long chains of mycolic acids in their cell wall. This staining property is important because only five genera of acid-fast bacteria are medically important (Table 22.1). All acid-fast organisms are relatively slow-growing bacteria, requiring incubation for 2 to 7 days *(Nocardia, Rhodococcus, Gordonia,* and *Tsukamurella)* to as long as 1 month or more *(Mycobacteria)*. Currently, more than 450 species and subspecies of acid-fast bacteria have been described; however, the number associated commonly with human disease is relatively limited (Table 22.2). The spectrum of the infections associated with the acid-fast genera is extensive and includes insignificant colonization, cutaneous infections, pulmonary disease, systemic infections, and opportunistic infections. *Mycobacteria* and *Nocardia* will be the emphasis of this chapter because these are the most common acid-fast bacteria responsible for human disease.

• Physiology and Structure of Mycobacteria

Bacteria are included in the genus *Mycobacterium* on the basis of (1) their acid-fastness, (2) the presence of cell wall **mycolic acids** containing 70 to 90 carbons, and (3) a high (61% to 71% mol) guanine plus cytosine (G + C) content in their deoxyribonucleic acid (DNA). Mycobacteria possess a complex, **lipid-rich cell wall** that is responsible for many of the characteristic properties of the bacteria (e.g., acid-fastness; slow growth; resistance to detergents, common antibacterial antibiotics, and the host immune response; antigenicity). The proteins associated with the cell wall are biologically important antigens, stimulating the patient's cellular immune response. Extracted and partially purified preparations of these proteins **(purified protein derivatives [PPDs])** are used as specific diagnostic skin test reagents to measure exposure to *Mycobacterium tuberculosis.*

Growth properties and colonial morphology are used for the preliminary classification of mycobacteria. *M. tuberculosis* and closely related species in the *M. tuberculosis* complex are slow-growing bacteria. The colonies of these mycobacteria are either nonpigmented or a light tan color (Fig. 22.1). The other mycobacteria, referred to as *nontuberculous mycobacteria* (NTM), were classified originally by Runyon according to their rate of growth (see Table 22.2) and pigmentation. The pigmented mycobacteria produce intensely **yellow carotenoids,** which may be stimulated by exposure to light (photochromogenic organisms; Fig. 22.2) or are produced in the absence of light (scotochromogenic organisms). The **Runyon classification** scheme of NTM consists of four groups: slow-growing photochromogens (e.g., *M. kansasii, M. marinum*), slow-growing scotochromogens

Table 22.1 Important Acid-Fast Bacteria

Organism	Historical Derivation
Mycobacterium	*myces,* a fungus; *bakterion,* a small rod (fungus-like rod)
M. abscessus	*abscessus,* of abscesses (causes abscess formation)
M. avium	*avis,* of birds (causes tuberculosis-like illness in birds)
M. chelonae	*chelone,* a tortoise (initial source)
M. fortuitum	*fortuitum,* casual, accidental (refers to the fact that this is an opportunistic pathogen)
M. haemophilum	*haema,* blood; *philos,* loving (blood loving; refers to requirement for blood or hemin for in vitro growth)
M. intracellulare	*intra,* within; *cella,* small room (within cells; refers to the intracellular location of this and all mycobacteria)
M. kansasii	*kansasii,* of Kansas (where the organism was originally isolated)
M. leprae	*lepra,* of leprosy (the cause of leprosy)
M. marinum	*marinum,* of the sea (bacterium associated with contaminated freshwater and saltwater)
M. tuberculosis	*tuberculum,* a small swelling or tubercle; *osis* (characterized by tubercles; refers to the formation of tubercles in the lungs of infected patients)
Nocardia	Named after the French veterinarian Edmond Nocard
Rhodococcus	*rhodo,* rose or red colored; *coccus,* berry (red-colored coccus)
Gordonia	Named after the American microbiologist Ruth Gordon
Tsukamurella	Honoring the Japanese microbiologist Michio Tsukamura, who first described the original isolate of this genus

(e.g., *M. gordonae,* which is a commonly isolated nonpathogen), slow-growing nonpigmented mycobacteria (e.g., *M. avium, M. intracellulare*), and rapidly growing mycobacteria (e.g., *M. fortuitum, M. chelonae, M. abscessus, M. mucogenicum*). Currently used methods for rapid detection and identification of mycobacteria have made this scheme less important. Nonetheless, a pigmented or rapidly growing *Mycobacterium* should never be mistaken for *M. tuberculosis.*

• *Mycobacterium Tuberculosis*

PATHOGENESIS AND IMMUNITY

M. tuberculosis is an intracellular pathogen that is able to establish lifelong infection. Maintenance of persistent infection without progression to disease involves a delicate balance between growth of the bacteria and immunologic regulation. At the time of exposure, *M. tuberculosis* enters the respiratory airways, and infectious particles penetrate to the alveoli in which they are phagocytized by alveolar macrophages. In contrast with most phagocytized bacteria, *M. tuberculosis* **prevents fusion of the phagosome with lysosomes** (by blocking the specific bridging molecule, early endosomal autoantigen 1 [EEA1]). At the same time, the phagosome is able to fuse with other intracellular vesicles, permitting access to nutrients and facilitating intracellular

Table 22.2 Classification of Selected Acid-Fast Bacteria Pathogenic for Humans

Organism	Pathogenicity	Frequency in United States
***MYCOBACTERIUM TUBERCULOSIS* COMPLEX**		
M. tuberculosis	Strictly pathogenic	Common

Rhodococcus equi	Usually pathogenic	Common
Gordonia spp.	Sometimes pathogenic	Rare
Tsukamurella spp.	Sometimes pathogenic	Rare

replication. Phagocytized bacteria are also able to evade macrophage killing mediated by reactive nitrogen intermediates formed between nitric oxide and superoxide anions by catalytically catabolizing the oxidants that are formed. So in this state, the bacteria are able to evade the immune system and replicate. However, in response to infection with *M. tuberculosis,* macrophages secrete **interleukin (IL)-12** and **tumor necrosis factor (TNF)-α.** These cytokines increase localized inflammation with the recruitment of T

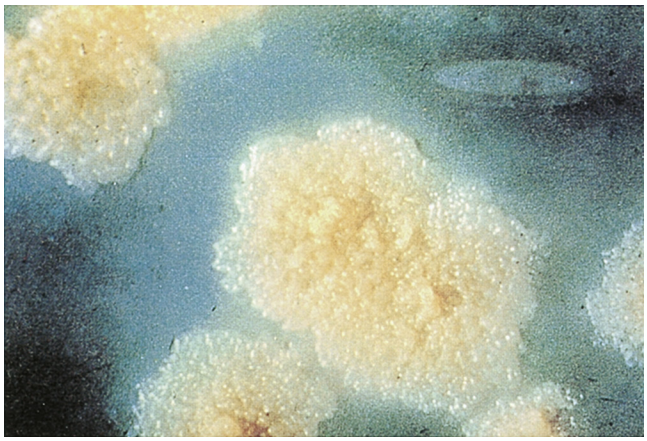

Fig. 22.1 *Mycobacterium tuberculosis* colonies on Löwenstein-Jensen agar after 8 weeks of incubation. (From Baron, E.J., Peterson, L.R., Finegold, S.M., 1994. Bailey and Scott's Diagnostic Microbiology, ninth ed. St Louis, MO: Mosby.)

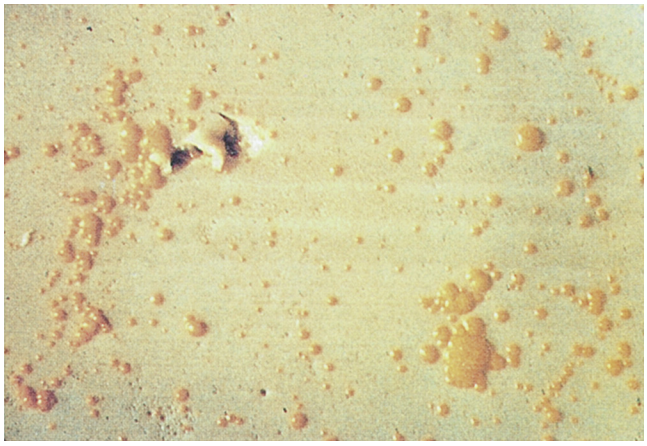

Fig. 22.2 *Mycobacterium kansasii* colonies on Middlebrook agar; yellow pigment develops after brief exposure to light.

cells and natural killer (NK) cells into the area of the infected macrophages, inducing T-cell differentiation into **TH1 cells (T-helper cells),** with subsequent secretion of **interferon (IFN)-γ.** In the presence of IFN-γ, the infected macrophages are activated, leading to increased phagosome-lysosome fusion and intracellular killing. In addition, TNF-α stimulates production of nitric oxide and related reactive nitrogen intermediates, leading to enhanced intracellular killing. Patients with decreased production of IFN-γ or TNF-α, or who have defects in the receptors for these cytokines, are at increased risk for severe progressive mycobacterial infections.

The effectiveness of bacterial elimination is in part related to the size of the focus of infection. Alveolar macrophages, epithelioid cells, and **Langhans giant cells** (fused epithelioid cells) with intracellular mycobacteria form the central core of a necrotic mass that is surrounded by a dense wall of macrophages and CD4, CD8, and NK T cells. This structure, a **granuloma,** prevents further spread of the bacteria. If a small antigenic burden is present at the time the macrophages are stimulated, the granuloma is small and the bacteria are destroyed with minimal tissue damage. However, if many bacteria are present, then the large necrotic or caseous granulomas become encapsulated with fibrin that effectively protects the bacteria from macrophage killing. The bacteria can remain dormant in this stage or can be reactivated years later when the patient's immunologic responsiveness wanes as the result of old age or immunosuppressive disease or therapy. This process is the reason that disease may not develop until late in life in patients exposed to *M. tuberculosis.*

EPIDEMIOLOGY

Although tuberculosis can be established in primates and laboratory animals, such as guinea pigs, **humans are the only natural reservoir.** The disease is spread by close person-to-person contact through the inhalation of infectious aerosols. Large particles are trapped on mucosal surfaces and removed by the ciliary action of the respiratory tree. However, small particles containing one to three tubercle bacilli can reach the alveolar spaces and establish infection.

The World Health Organization (WHO) estimated that one-fourth of the world's population is infected with *M. tuberculosis* and 460,000 developed disease with multidrug resistant strains. In 2016, there were 10.4 million new cases of tuberculosis and 1.6 million deaths. Despite the concerted effort to eliminate tuberculosis, it is the world's leading cause of death. Regions with the highest incidence of disease are India, Pakistan, sub-Saharan Africa, South Africa, Eastern Europe, and China. In the United States, the incidence of tuberculosis has decreased steadily since 1992 (Fig. 22.3). A total of 9272 cases were reported in 2016 (2.9 cases per 100,000 individuals), with almost 70% of the infections in foreign-born persons. Other populations at increased risk for *M. tuberculosis* disease are homeless persons, drug and alcohol abusers, prisoners, and people infected with the human immunodeficiency virus (HIV). Because it is difficult to eradicate disease in these patients, spread of the infection to other populations, including health care workers, poses a significant public health problem. This is particularly true for drug-resistant *M. tuberculosis* because patients who receive inadequate treatment may remain infectious for a long time.

CLINICAL DISEASES

Although tuberculosis can involve any organ, most infections in immunocompetent patients are restricted to the lungs. The initial pulmonary focus is the middle or lower lung fields, in which the tubercle bacilli can multiply freely. The patient's cellular immunity is activated and mycobacterial replication ceases in most patients within 3 to 6 weeks after exposure to the organism. Approximately 5% of patients exposed to *M. tuberculosis* progress to having active disease within 2 years, and another 5% experience disease sometime later in life.

The likelihood that infection will progress to active disease is a function of both the infectious dose and the patient's immune competence. For example, active disease develops within 1 year of exposure in approximately 10% of patients who are infected with HIV and have a low CD4 T-cell count, usually appears before the onset of other opportunistic infections, is twice as likely to spread to extrapulmonary sites, and can progress rapidly to death (Clinical Case 22.1). Indeed, tuberculosis is the leading cause of death in HIV-infected patients. Because these patients have compromised immunity, they commonly present with asymptomatic, subclinical disease and negative chest radiography despite widespread dissemination of the bacteria.

The clinical signs and symptoms of tuberculosis reflect the site of infection, with primary disease usually restricted to the lower respiratory tract. The disease is insidious at

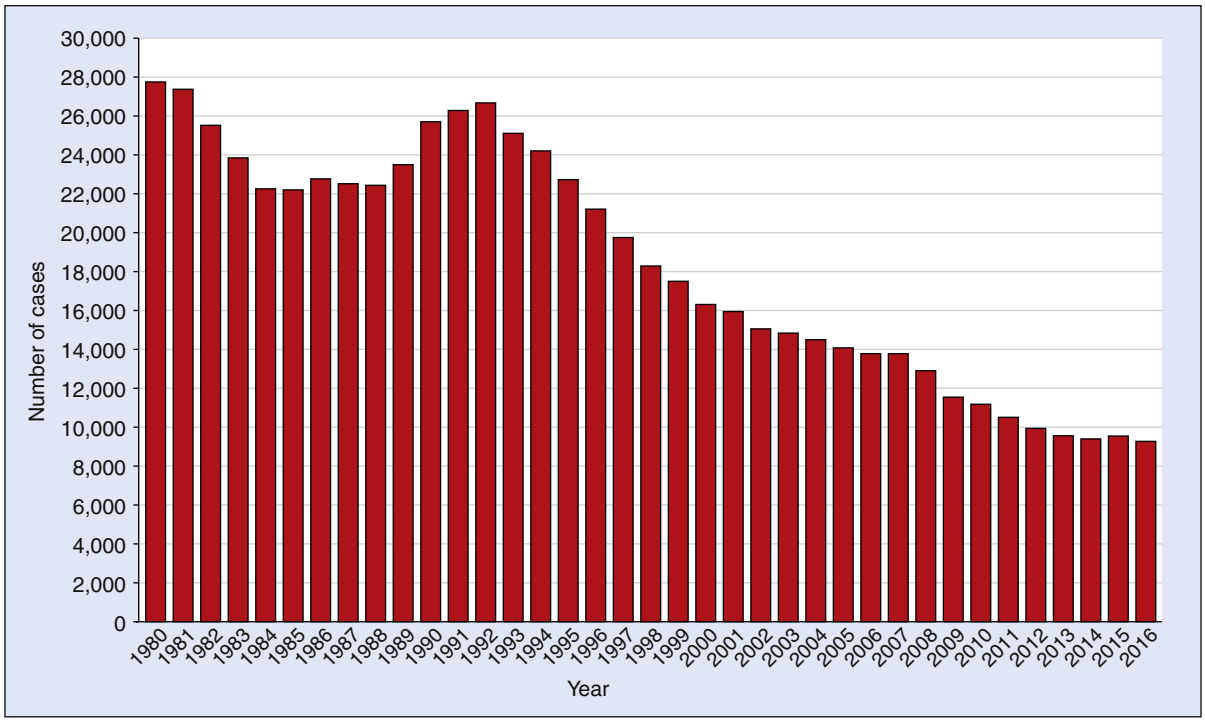

Fig. 22.3 Incidence of *Mycobacterium tuberculosis* infections in the United States from 1980 to 2016.

Clinical Case 22.1 **Drug-Resistant *Mycobacterium Tuberculosis***

The risk of active tuberculosis is significantly increased in HIV-infected individuals. Unfortunately, this problem is complicated by the development of drug-resistant *M. tuberculosis* strains in this population. This was illustrated by the report by Gandhi and associates (*Lancet* 368:1575–1580, 2006) who studied the prevalence of tuberculosis in South Africa from January 2005 to March 2006. They identified 475 patients with culture-confirmed tuberculosis, of whom 39% had MDR TB and 6% had XDR TB. All patients with XDR TB were coinfected with HIV, and 98% of these patients died. The high prevalence of MDR TB and the evolution of XDR TB pose a serious challenge for tuberculosis treatment programs and emphasize the need for rapid diagnostic tests.

HIV, Human immunodeficiency virus; *MDR TB,* multidrug-resistant tuberculosis; *XDR TB,* extensively drug-resistant tuberculosis.

onset. Patients typically have nonspecific complaints of malaise, weight loss, cough, and night sweats. Sputum may be scant or bloody and purulent. Blood-streaked sputum production (hemoptysis) is associated with tissue destruction (e.g., **cavitary disease**). The clinical diagnosis is supported by (1) radiographic evidence of pulmonary disease (Fig. 22.4); (2) positive skin test reactivity; and (3) the laboratory detection of mycobacteria, either with microscopy or in cultures. One or both upper lobes of the lungs are usually involved in patients with active disease that includes either pneumonitis or abscess formation and cavitation.

Extrapulmonary tuberculosis can occur as the result of the hematogenous spread of the bacilli during the initial phase of multiplication. There may be no evidence of pulmonary disease in patients with **disseminated tuberculosis.**

LABORATORY DIAGNOSIS

Immunodiagnosis

The traditional test to assess the patient's response to exposure to *M. tuberculosis* is the **tuberculin skin test** (Box 22.1). Reactivity to an intradermal injection of mycobacterial antigens (PPD) can differentiate between infected and noninfected people, with a positive reaction usually developing 3 to 4 weeks after exposure to *M. tuberculosis*. The only evidence of infection with mycobacteria in most patients is a lifelong positive skin test reaction and radiographic evidence of calcification of granulomas in the lungs or other organs. In this test, a specific amount of the antigen (five tuberculin units of PPD) is inoculated into the intradermal layer of the patient's skin. Skin test reactivity (defined by the diameter of the area of induration) is measured 48 hours later. Patients infected with *M. tuberculosis* may not show a response to the tuberculin skin test if they are anergic (nonreactive to antigens; particularly true of HIV-infected patients); thus control antigens should always be used with tuberculin tests. Additionally, individuals from countries in which vaccination with attenuated *M. bovis* **(bacillus Calmette-Guérin [BCG])** is widespread will have a positive skin test reaction, so this test is not helpful.

In vitro IFN-γ release assays are as an alternative to the PPD skin test. The tests use immunoassays to measure IFN-γ produced by sensitized T cells stimulated by *M. tuberculosis* antigens. If an individual was previously infected with *M. tuberculosis*, exposure of sensitized T cells present in whole blood to *M. tuberculosis*–specific

antigens results in IFN-γ production. The initial assays that used PPD as the stimulating antigen have been replaced with second-generation assays that use more specific antigens (i.e., **early secreted antigenic target-6 [ESAT-6], culture filtrate protein-10 [CFP-10])** and can be used to discriminate between infections with *M. tuberculosis* and BCG vaccination. These tests are sensitive and highly specific.

Microscopy

Microscopic detection of acid-fast bacteria in clinical specimens is the most rapid way to confirm mycobacterial disease. The clinical specimen is stained with carbolfuchsin (**Ziehl-Neelsen** or **Kinyoun** methods) or fluorescent auramine-rhodamine dyes (**Truant fluorochrome** method), decolorized with an acid-alcohol solution, and then counterstained. The specimens are examined with a light microscope or, if fluorescent dyes are used, a fluorescent microscope (Fig. 22.5). The fluorochrome method is the most sensitive microscopic method because the specimen can be scanned rapidly under low magnification for fluorescent areas, and then the presence of acid-fast bacteria can be confirmed with higher magnification.

In approximately half of all culture-positive specimens, acid-fast bacteria are detected by microscopy, although this varies tremendously based on the skill of the microscopist. The sensitivity of this test is high for (1) respiratory specimens (particularly from patients with radiographic evidence of cavitation) and (2) specimens for which many mycobacteria are isolated in culture; thus a positive acid-fast stain reaction corresponds to higher infectivity. The specificity of the test is greater than 95% when it is performed carefully. Despite the excellent analytical performance of acid-fast microscopy, the test is challenging to perform and interpret in many resource-limited countries in which tuberculosis is widespread.

Nucleic Acid–Based Tests

Commercial nucleic acid amplification tests (particularly polymerase chain reaction [PCR] tests) have gained broad acceptance as the diagnostic test of choice for tuberculosis. Despite the high test cost, nongovernment organizations heavily subsidize these tests to bring highly sensitive, rapid diagnostics to countries in greatest need in which microscopy is inaccurate and culture is impractical. Detection of resistance to rifampin and/or isoniazid is incorporated in some tests, so they provide both rapid detection of *M. tuberculosis* and guide antimicrobial therapy.

There is significant effort now to extend nucleic acid diagnostics to whole genome sequencing for the purpose of both rapid detection of *M. tuberculosis* in clinical specimens and a comprehensive detection of antimicrobial resistance genes. The goal of this work is to replace the need to grow *M. tuberculosis* in culture for performing antibiotic susceptibility tests. Currently, this approach is used to avoid treatment with drugs in which resistance is detected and to select a first-line treatment for which no resistance genes are found.

It should be recognized that mycobacterial disease caused by NTM will not be detected with these assays, so supplementary tests must be used in countries in which NTM infections are common (e.g., United States, Western Europe).

Culture

Agar-based or egg-based media
Broth-based media

Identification

Morphologic properties
Biochemical reactions
Analysis of cell wall lipids
Nucleic acid probes
Nucleic acid sequencing Mass spectrometry

Culture

Mycobacteria that cause pulmonary disease, particularly in patients with evidence of cavitation, are abundant in the respiratory secretions (e.g., 10^8 bacilli per milliliter or more). Recovery of the organisms is virtually ensured in patients from whom early morning respiratory specimens are collected for 3 consecutive days; however, it is more difficult to isolate *M. tuberculosis* from other sites in patients with disseminated disease (e.g., genitourinary tract, tissues, cerebrospinal fluid). In such cases, additional specimens must be collected for cultures, and a large volume of fluid or tissue must be processed.

The in vitro growth of mycobacteria is complicated by the fact that most isolates grow slowly and can be obscured by the rapidly growing bacteria that normally colonize people;

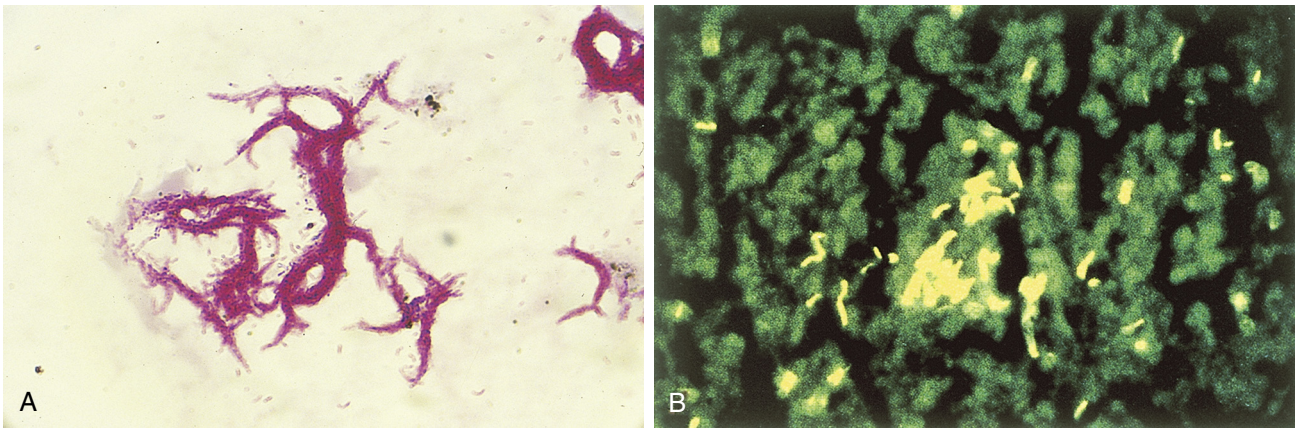

Fig. 22.5 Acid-fast stains of *Mycobacterium tuberculosis.* (A) Stained with carbolfuchsin using the Kinyoun method. (B) Stained with the fluorescent dyes auramine and rhodamine using the Truant fluorochrome method.

thus specimens such as sputum are initially treated with a **decontaminating reagent** (e.g., 2% sodium hydroxide) to eliminate organisms that could confound results. Mycobacteria can tolerate brief alkali treatment that kills the rapidly growing bacteria and permits selective isolation of mycobacteria. Extended decontamination of the specimen kills mycobacteria, so the procedure is not performed when normally sterile specimens are being tested or when few mycobacteria are expected.

Specimens inoculated onto egg-based (e.g., **Löwenstein-Jensen**) and agar-based (e.g., **Middlebrook**) media generally take 4 or more weeks for *M. tuberculosis* to be detected. However, this time has been shortened approximately 2 weeks through the use of specially formulated **broth cultures** that support the rapid growth of most mycobacteria. The ability of *M. tuberculosis* to grow rapidly in broth cultures has also been used for performing rapid susceptibility tests.

Identification

Growth properties and colonial morphology can be used for the preliminary identification of the most common species of mycobacteria. The definitive identification of mycobacteria can be made using a variety of techniques. Biochemical tests were the standard method for identifying mycobacteria; however, the results are not available for at least 3 weeks or more, and many species cannot be differentiated by this approach. Species-specific molecular probes, amplification of species-specific target genes (e.g., *16S rRNA* gene, *SecA* gene), and mass spectrometry are used now for mycobacterial identification. It is likely that mass spectrometry will become the identification test of choice because of the rapid time to results (<1 hour), low cost, and ability to identify virtually all species of acid-fast organisms.

TREATMENT, PREVENTION, AND CONTROL

Treatment

Treatment of *M. tuberculosis* infections, unlike those for most other bacterial infections, is complex. Slow-growing mycobacteria are resistant to most antibiotics used to treat other bacterial infections, and in general, patients must take multiple antibiotics for an extended period (e.g., minimum of 6 to 9 months) or else antibiotic-resistant strains will develop.

In 1990, the first outbreaks of **multidrug-resistant *M. tuberculosis* (MDR TB);** resistant to at least isoniazid and rifampin) were observed in patients with acquired immunodeficiency syndrome (AIDS) and in homeless persons in New York City and Miami. Although there has been a reduction in the United States of infections with these resistant strains, they are increasing dramatically in prevalence in resource-limited countries. In addition, strains of highly resistant *M. tuberculosis* called **extensively drug-resistant (XDR) TB** have emerged in most regions of the world. These strains, defined as MDR TB, which are resistant to fluoroquinolones and at least one of the second-line drugs (e.g., kanamycin, amikacin, capreomycin), are potentially untreatable.

The various treatment regimens that have been developed for drug-susceptible and drug-resistant tuberculosis are too complex to review here comprehensively (refer to the reference citations, the Centers for Disease Control and Prevention [CDC] website www.cdc.gov/tb/ and the WHO website https://www.who.int/tb/publications/2018/rapid_communications_MDR/en/). Most treatment regimens begin with 2 months of isoniazid (isonicotinyl hydrazine [INH]), ethambutol, pyrazinamide, and rifampin, followed by 4 to 6 months of INH and rifampin or alternative combination drugs. Modifications to this treatment scheme are dictated by the drug susceptibility of the isolate and the patient population.

Chemoprophylaxis

The American Thoracic Society and the CDC have examined a number of prophylactic regimens for use in patients (HIV positive and HIV negative) exposed to *M. tuberculosis.* The regimens that have been recommended include daily or twice weekly INH for 6 to 9 months, or daily rifampin for 4 months. Patients who have been exposed to drug-resistant *M. tuberculosis* should receive prophylaxis with pyrazinamide and either ethambutol or levofloxacin for 6 to 12 months.

Immunoprophylaxis

Vaccination with attenuated *M. bovis* **(BCG)** is commonly used in countries in which tuberculosis is endemic and is responsible for significant morbidity and mortality. This practice can lead to a significant reduction in the incidence

of tuberculosis if BCG is administered to people when they are young (it is less effective in adults). Unfortunately, BCG immunization cannot be used in immunocompromised patients (e.g., those with HIV infection); thus it is unlikely to be useful in countries with a high prevalence of HIV infections (e.g., Africa) or to control the spread of drug-resistant tuberculosis. An additional problem with BCG immunization is that positive skin test reactivity develops in all patients and may persist for a prolonged time. However, skin test reactivity is generally low, so a strongly reactive skin test (e.g., >20 mm of induration) is generally significant for recent exposure to *M. tuberculosis*. The second-generation IFN-γ release assays are not affected by BCG immunization, so they can be used for screening this population. BCG immunization is not widely used in the United States or in other countries in which the incidence of tuberculosis is low.

Control

Because one-fourth of the world's population is infected with *M. tuberculosis,* elimination of this disease is highly unlikely. Disease can be controlled, however, with a combination of active surveillance, prophylactic and therapeutic intervention, and careful case monitoring.

• Other Slow-Growing Mycobacteria

Leprosy (also called **Hansen disease**) is caused by ***Mycobacterium leprae.*** Leprosy was first described in 600 BC and was recognized in the ancient civilizations of China, Egypt, and India. The global **prevalence of leprosy has fallen dramatically** with widespread use of effective therapy. More than 5 million cases were documented in 1985 and 200,000 cases in 2016. Currently, the highest number of new diagnoses is in India, Brazil, and Indonesia. In the United States, leprosy is uncommon, with 178 new cases reported in 2015 primarily in immigrants from endemic countries. Interestingly, leprosy is endemic in **armadillos** found in Texas and Louisiana, producing a disease similar to the highly infectious lepromatous form of leprosy in humans. Thus these armadillos represent a potential endemic focus in this country.

Leprosy is spread by person-to-person contact; however, it is not considered highly contagious. Prolonged contact with an untreated, infected person is required. Although the most important route of infection is unknown, it is believed that *M. leprae* is spread either through the inhalation of infectious aerosols or through skin contact with respiratory secretions and wound exudates. Because the bacteria multiply very slowly, the incubation period is prolonged, with symptoms developing as long as 20 years after infection. The clinical presentation of leprosy ranges from the tuberculoid form to the lepromatous form (Table 22.3). Patients with **tuberculoid leprosy** (also called **paucibacillary Hansen disease**) have a strong cellular immune reaction to the bacteria, with the induction of cytokine production that mediates macrophage activation, phagocytosis, and bacillary clearance. The tuberculoid form (Fig. 22.6) is characterized by hypopigmented skin macules and diagnosed by reactive skins tests to mycobacterial antigen (lepromin); acid-fast stains are generally negative. *M. leprae* cannot grow in cell-free cultures. Patients with **lepromatous leprosy (multibacillary Hansen disease)** have a strong antibody response but a specific defect in the cellular response to *M. leprae* antigens. Thus an abundance of bacteria are typically observed in dermal macrophages and the Schwann cells of the peripheral nerves. As would be expected, this is the most infectious form of leprosy. The lepromatous form (Fig. 22.7) is associated with disfiguring skin lesions, nodules, plaques, thickened dermis, and involvement of the nasal mucosa.

In the last decade, treatment of leprosy has successfully reduced the overall incidence of disease. The treatment regimens advanced by the WHO (https://WHO.int/lep) have distinguished between patients with the tuberculoid (paucibacillary) form and the lepromatous (multibacillary) form. The paucibacillary form should be treated with rifampicin and dapsone for a minimum of 6 months, whereas the multibacillary form should have clofazimine added to the regimen, and treatment should be extended to 12 months. It should be noted that many investigators believe much longer therapy is required for optimum management of patients. Single-drug treatment should not be used for either form.

Members of the *Mycobacterium avium* complex (MAC) are among the most common pathogenic acid-fast species, particularly in immunocompromised patients. The taxonomy of these mycobacteria is in a state of flux with a number of subspecies identified. Although some subspecies do not cause human disease, representatives of the two most common MAC species, *M. avium* and *M. intracellulare*, are human pathogens.

Both species in the MAC produce disease in immunocompetent patients. Pulmonary disease in immunocompetent patients presents in one of three forms. Most commonly, disease is seen in middle-age or older men with a history of smoking and **underlying pulmonary disease.** These patients typically have a slowly evolving cavitary disease that resembles tuberculosis on chest radiography. The second form of MAC infection is observed in elderly female nonsmokers. These patients have lingular or middle lobe infiltrates with a patchy, nodular appearance on radiography and associated bronchiectasis (chronically dilated bronchi). This form of disease is indolent and has been associated with significant morbidity and mortality. It has been postulated that this disease is seen primarily in fastidious elderly women who chronically suppress their cough reflex, leading to nonspecific inflammatory changes in the lungs and predisposing them to superinfection with MAC. This specific disease has been called **Lady Windermere syndrome** after the name of the principle character in an Oscar Wilde play. The third form of MAC disease is the formation of a **solitary pulmonary nodule.** MAC is the most common mycobacterial species that causes solitary the pulmonary nodules.

A different spectrum of disease develops in **patients with AIDS.** In contrast to disease in other groups of patients, MAC infection in patients with AIDS is primarily caused by *M. avium* and is typically disseminated, with virtually no organ spared (Clinical Case 22.2). The magnitude of these infections is remarkable; the tissues of some patients are literally filled with the mycobacteria (Fig. 22.8), and there

Table 22.3 Clinical and Immunologic Manifestations of Leprosy

Features	Tuberculoid Leprosy	Lepromatous Leprosy
Skin lesions	Few erythematous or hypopigmented plaques with flat centers and raised, demarcated borders; peripheral nerve damage with complete sensory loss; visible enlargement of nerves	Many erythematous macules, papules, or nodules; extensive tissue destruction (e.g., nasal cartilage, bones, ears); diffuse nerve involvement with patchy sensory loss; lack of nerve enlargement
Histopathology	Infiltration of lymphocytes around center of epithelial cells; presence of Langhans cells; few or no acid-fast rods observed	Predominantly "foamy" macrophages with few lymphocytes; lack of Langhans cells; numerous acid-fast rods in skin lesions and internal organs
Infectivity	Low	High
Immune response	Delayed hypersensitivity reactivity to lepromin	Nonreactivity to lepromin
Immunoglobulin levels	Normal	Hypergammaglobulinemia
Erythema nodosum	Absent	Usually present

Fig. 22.6 Tuberculoid leprosy. Early tuberculoid lesions are characterized by anesthetic macules with hypopigmentation. (From Cohen, J., Powderly, W.G., Opal, S.M., 2010. Infectious Diseases, third ed. Philadelphia, PA: Mosby.)

Fig. 22.7 Lepromatous leprosy. Diffuse infiltration of the skin by multiple nodules of varying size, each with many bacteria. (From Cohen, J., Powderly, W.G., Opal, S.M., 2010. Infectious Diseases, third ed. Philadelphia, PA: Mosby.)

are hundreds to thousands of bacteria per milliliter of blood. Overwhelming disseminated infections with *M. avium* are particularly common in patients who are in the terminal stages of their immune disorder, when their CD4 T-lymphocyte counts fall to less than 50 cells/ul. Fortunately, with more effective antiretroviral therapy and the routine use of prophylactic antibiotics, *M. avium* disease infection in HIV-infected patients has become much less common. Although some patients with AIDS develop *M. avium* disease after pulmonary exposure (e.g., infectious aerosols of contaminated water), most infections are believed to develop after ingestion of the bacteria. Person-to-person transmission has not been demonstrated. After exposure to the mycobacteria, replication is initiated in localized lymph nodes followed by systemic spread. The clinical manifestations of disease are not observed until the mass of replicating bacteria impairs normal organ function.

MAC and many other slow-growing mycobacteria are resistant to common antimycobacterial agents. One regimen recommended currently for MAC infections is clarithromycin or azithromycin, combined with ethambutol and rifampin. The duration of treatment and final selection of drugs for these species and other slow-growing mycobacteria are determined (1) by the response to therapy and (2) by interactions among these drugs and other drugs the patient is receiving (e.g., toxic and pharmacokinetic interactions of these drugs with protease inhibitors used to treat HIV infection). Refer to the publication by Griffith and associates cited in the bibliography for additional information about treating MAC and other NTM infections. Because MAC intracellular infections are common in patients with AIDS, chemoprophylaxis is recommended for patients whose CD4 T-cell counts fall to less than 50 cells/μl. Prophylaxis with clarithromycin or azithromycin is recommended. Combinations of these drugs with rifabutin have been used, but they are generally more toxic and no more effective than the single agent.

Many **other slow-growing mycobacteria** can cause human disease and new species continue to be reported as better diagnostic test methods are developed. The spectrum of diseases produced by these mycobacteria also continues to expand, in large part because diseases such as AIDS, malignancies, and organ transplantation

with concomitant use of immunosuppressive drugs have created a population of patients who are highly susceptible to organisms with relatively low virulence potential. Some mycobacteria produce disease identical to pulmonary tuberculosis (e.g., *M. bovis, M. kansasii*), other species commonly cause infections localized to lymphatic tissue *(M. scrofulaceum)*, and others that grow optimally at cool temperatures primarily produce cutaneous infections *(M. ulcerans, M. marinum,* and *M. haemophilum)*. However, disseminated disease can be observed in patients with AIDS who are infected with these same species, as well as with relatively uncommon mycobacteria (e.g., *M. genavense, M. simiae*). With the exception of *M. bovis* and other mycobacteria closely related to *M. tuberculosis,* person-to-person spread of these mycobacteria does not occur.

Clinical Case 22.2 *Mycobacterium avium* Infections

Woods and Goldsmith (*Chest* 95:1355–1357, 1989) described a patient with advanced AIDS who died of disseminated *M. avium* infection. The patient was a 27-year-old man who initially presented in October 1985 with a 2-week history of progressive dyspnea and a nonproductive cough. *Pneumocystis* was detected in a bronchoalveolar lavage, and serology confirmed the patient had an HIV infection. The patient was successfully treated with TMP-SMX and discharged. The patient remained stable until May 1987, when he presented with persistent fever and dyspnea. Over the next week, he developed severe substernal chest pain and a pericardial friction rub. Echocardiogram revealed a small effusion. The patient left the hospital against medical advice but returned 1 week later with a persistent cough, fever, and pain in the chest and left arm. A diagnostic pericardiocentesis was performed, and 220 ml of fluid was aspirated. Tuberculous pericarditis was suspected, and appropriate antimycobacterial therapy was initiated. However, over the next 3 weeks, the patient developed progressive cardiac failure and died. *M. avium* was recovered from the pericardial fluid, as well as autopsy cultures of the pericardium, spleen, liver, adrenal glands, kidneys, small intestine, lymph nodes, and pituitary gland. Although *M. avium* pericarditis was unusual, the extensive dissemination of the mycobacteria in patients with advanced AIDS was common before azithromycin prophylaxis became widely used.

• Rapidly Growing Mycobacteria

As discussed previously, NTM can be subdivided into slow-growing species and rapidly growing species (growth in <7 days). This distinction is important because the rapidly growing species have a relatively low virulence potential, stain irregularly with traditional mycobacterial stains, and are more susceptible to "conventional" antibacterial antibiotics than to drugs used to treat other mycobacterial infections. The most common species associated with disease are *M. fortuitum, M. chelonae, M. abscessus,* and *M. mucogenicum*.

The rapidly growing mycobacteria rarely cause disseminated infections; rather, they are most commonly associated with disease occurring after bacteria are introduced into the deep subcutaneous tissues by **trauma or iatrogenic infections** (e.g., infections associated with an intravenous catheter, contaminated wound dressing, prosthetic device such as a heart valve, peritoneal dialysis, or bronchoscopy). Unfortunately, the incidence of infections with these organisms is increasing as more invasive procedures are performed in hospitalized patients and advanced medical care lengthens the life expectancy of immunocompromised patients. Opportunistic infections in immunocompetent patients are also becoming commonplace (Clinical Case 22.3).

Unlike the slow-growing mycobacteria, the rapidly growing species are resistant to most commonly used antimycobacterial agents but are susceptible to antibiotics such as clarithromycin, imipenem, amikacin, cefoxitin, and the sulfonamides. The specific activity of these agents must be determined with in vitro tests. Removal of prosthetic devices are generally required for successful treatment of these infections.

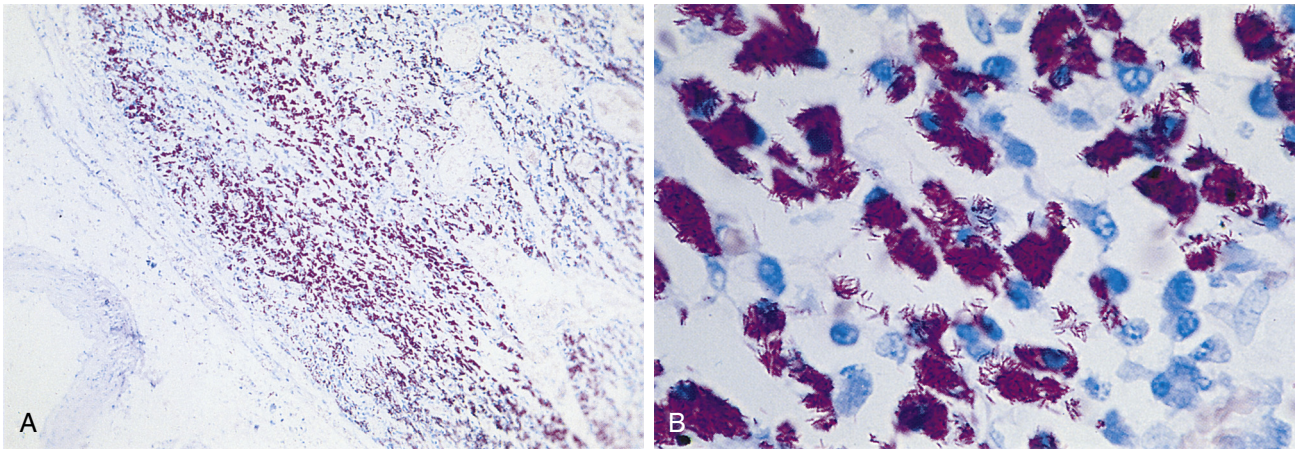

Fig. 22.8 Tissue from a patient with acquired immunodeficiency syndrome AIDS who is infected with *Mycobacterium avium* complex, photographed under (A) low and (B) high magnification.

• *Nocardia*

PHYSIOLOGY AND STRUCTURE

Nocardiae are strict aerobic rods that form branched filaments in tissues and culture. These filaments resemble the hyphae formed by molds, and at one time *Nocardia* was thought to be a fungus; however, the organisms have a gram-positive cell wall and other cellular structures that are characteristic of bacteria. Most isolates stain poorly with the Gram stain and appear to be gram-negative, with intracellular gram-positive beads (Fig. 22.9). The reason for this staining property is that nocardiae have a cell wall structure with branched-chain fatty acids (e.g., **tuberculostearic acid,** *meso*-diaminopimelic acid [*meso*-DAP], mycolic acids). The length of the mycolic acids in nocardiae (50 to 62 carbon atoms) is shorter than in mycobacteria (70 to 90 carbon atoms). This difference may explain why even though both genera stain acid-fast, *Nocardia* is described as **"weakly acid-fast";** that is, a weak decolorizing solution of hydrochloric acid must be used to demonstrate the acid-fast property of nocardiae (Fig. 22.10). This acid-fastness is also a helpful characteristic for distinguishing *Nocardia* organisms from morphologically similar organisms, such as *Actinomyces*.

Nocardia species can grow on most nonselective laboratory media used for the isolation of bacteria, mycobacteria, and fungi. However, their growth is slow, requiring 3 to 5 days of incubation before colonies may be observed on the culture plates, so the laboratory should be notified that a *Nocardia* infection is suspected so the cultures can be incubated beyond the normal 1 to 2 days. The colonies initially appear white but can be quite variable (e.g., dry to waxy, white to orange; Fig. 22.11). Aerial hyphae (hyphae that protrude upward from the surface of a colony) are usually observed when the colonies are viewed with a dissecting microscope (Fig. 22.12). The combination of both **presence of aerial hyphae and acid-fastness is unique** to the genus *Nocardia* and can be used as a rapid test for identification of the genus.

The taxonomic classification of this genus is, simply stated, a mess, with most of the organisms described in the literature now recognized as incorrectly identified. Historically, these organisms were classified by their ability to use carbohydrates oxidatively and decompose a variety of substrates, as well as their antimicrobial susceptibility patterns. The true taxonomic relationships among the members of the genus were appreciated recently through the use of gene sequencing. Currently, more than 100 species have been identified, far more than what is identified by biochemical testing. Fortunately, most infections are caused by a relatively few species, and identification of this group of organisms at the genus level combined with in vitro susceptibility testing is sufficient for the management of most patients (Table 22.4).

PATHOGENESIS AND IMMUNITY

Although toxins and hemolysins have been described for nocardiae, the role these factors play in disease has not been defined. It would appear that the primary factor associated with virulence is the ability of pathogenic strains to **avoid phagocytic killing.** When phagocytes contact microbes, an oxidative burst occurs, with release of toxic oxygen metabolites (i.e., hydrogen peroxide, superoxide).

Clinical Case 22.3 Mycobacterial Infections Associated with Nail Salons

In September 2000 (Winthrop KL et al: *N Engl J Med* 346:1366–1371, 2002) a physician reported to the California Department of Health four female patients who developed lower extremity furunculosis. Each patient presented with small erythematous papules that became large, tender, fluctuant, violaceous boils over several weeks. Bacterial cultures of the lesions were negative, and the patients failed empirical antibacterial therapy. All of the patients had visited the same nail salon before the furuncles developed. As a result of the investigation of the nail salon, a total of 110 patients with furunculosis were identified. *Mycobacterium fortuitum* was cultured from the lesions from 32 patients, as well as from the footbaths used by the patients before their pedicures. Shaving the legs was identified as a risk factor for disease. Similar outbreaks have been reported in the literature, which illustrates the risks associated with contamination of waters with rapidly growing mycobacteria; the difficulties of confirming these infections by routine bacterial cultures, which are typically incubated for only 1 to 2 days; and the need for effective antibiotic therapy.

Pathogenic strains of nocardiae are protected from these metabolites by their secretion of **catalase** and **superoxide dismutase.** Surface-associated superoxide dismutase also protects the bacteria. Nocardiae are also able to survive and **replicate in macrophages** by (1) preventing fusion of the phagosome-lysosome (mediated by **cord factor**), (2) preventing acidification of the phagosome, and (3) avoiding acid phosphatase–mediated killing by metabolic utilization of the enzyme as a carbon source.

EPIDEMIOLOGY

Nocardia infections are **exogenous** (i.e., caused by organisms not normally part of the normal human bacterial population). The ubiquitous presence of the organism in soil rich with organic matter and the increasing numbers of immunocompromised individuals have led to dramatic increases in disease caused by this organism. The increase is particularly noticeable in high-risk populations, such as ambulatory patients who are infected with HIV or have other T-cell deficiencies; patients receiving immunosuppressive therapy for bone marrow or solid organ transplants; and immunocompetent patients with pulmonary function compromised by bronchitis, emphysema, asthma, bronchiectasis, and alveolar proteinosis. Bronchopulmonary disease develops after the initial colonization of the upper respiratory tract by inhalation and then aspiration of oral secretions into the lower airways. Primary cutaneous nocardiosis develops after traumatic introduction of organisms into subcutaneous tissues, and secondary cutaneous involvement typically follows dissemination from a pulmonary site.

CLINICAL DISEASES

Bronchopulmonary disease caused by *Nocardia* species cannot be distinguished from infections caused by other pyogenic organisms, although *Nocardia* infections tend

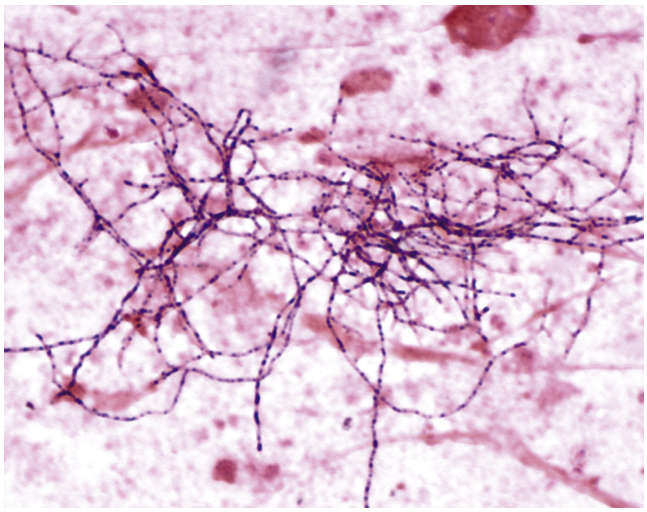

Fig. 22.9 Gram stain of *Nocardia* in expectorated sputum. Note the delicate beaded filaments.

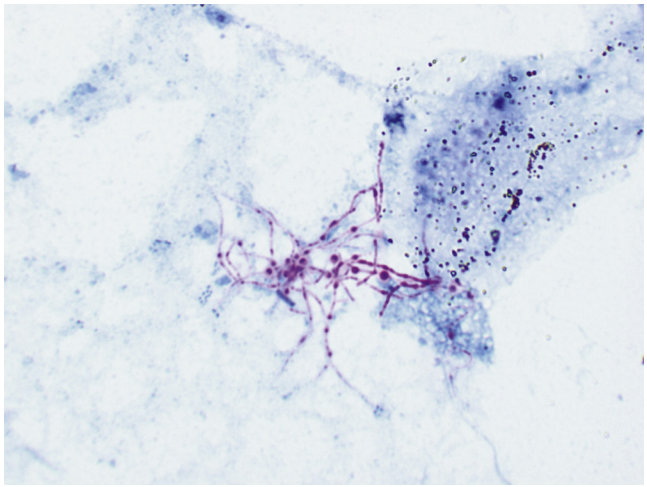

Fig. 22.10 Acid-fast stain of *Nocardia* species in expectorated sputum. In contrast with the mycobacteria, members of the genus *Nocardia* do not uniformly retain the stain ("partially acid-fast").

to develop more slowly, and primary pulmonary disease caused by *Nocardia* occurs almost always in immunocompromised patients (Box 22.2). Signs such as cough, dyspnea, and fever are usually present but are not diagnostic. Cavitation and spread into the pleura are common. Although the clinical picture is not specific for *Nocardia,* these organisms should be considered when immunocompromised patients experience pneumonia with cavitation, particularly if there is evidence of dissemination to the central nervous system (CNS) or subcutaneous tissues. If a pulmonary or disseminated *Nocardia* infection is diagnosed in an individual with no underlying disease, then a comprehensive immunologic workup is indicated.

Cutaneous infections may be primary infections (e.g., mycetoma, lymphocutaneous infections, cellulitis, subcutaneous abscesses) or from the result of the secondary spread of organisms from a primary pulmonary infection. **Mycetoma** is a painless, chronic infection primarily of the feet, characterized by localized subcutaneous swelling with involvement of the underlying tissues, muscle, and

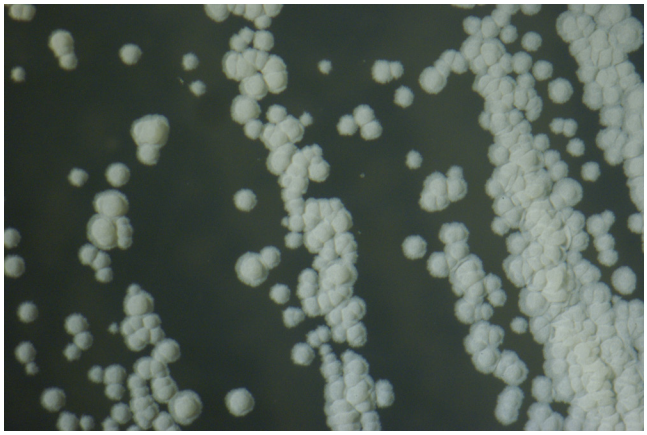

Fig. 22.11 Colonies of *Nocardia*.

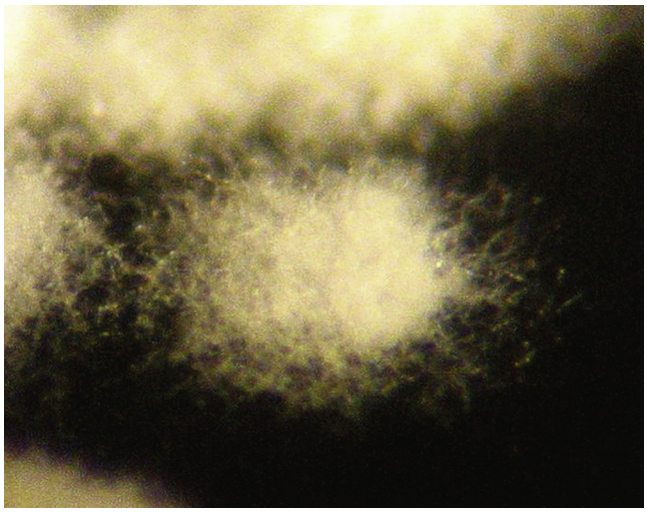

Fig. 22.12 Aerial hyphae of *Nocardia.*

bone; suppuration; and the formation of multiple sinus tracts (narrow path from the focus of infection to the skin surface). A variety of bacterial and fungal organisms can cause mycetoma, although *N. brasiliensis* is the most common cause in North America, Central America, and South America. **Lymphocutaneous infections** can manifest as cutaneous nodules and ulcerations along the lymphatics and regional lymph node involvement. These infections resemble cutaneous infections caused by some species of mycobacteria and by the fungus *Sporothrix schenckii. Nocardia* can also cause **chronic ulcerative lesions, subcutaneous abscesses,** and **cellulitis** (Fig. 22.13).

As many as one-third of all patients with *Nocardia* infections have dissemination to the brain, most commonly involving the formation of single or multiple **brain abscesses.** The disease can present initially as chronic meningitis (Clinical Case 22.4).

LABORATORY DIAGNOSIS

Multiple sputum specimens should be collected from patients with pulmonary disease. Because nocardiae are usually distributed throughout the tissue and abscess material, it is relatively easy to detect them by microscopy and to recover them in culture of specimens from patients

Table 22.4 Diseases of Selected Pathogenic Actinomycetes

Organism	Diseases	Frequency
Nocardia	Pulmonary diseases (bronchitis, pneumonia, lung abscesses); primary or secondary cutaneous infections (e.g., mycetoma, lymphocutaneous infections, cellulitis, subcutaneous abscesses); secondary central nervous system infections (e.g., meningitis, brain abscesses)	Common
Rhodococcus	Pulmonary diseases (pneumonia, lung abscesses); disseminated diseases (e.g., meningitis, pericarditis); opportunistic infections (e.g., wound infections, peritonitis, traumatic endophthalmitis)	Uncommon
Gordonia	Opportunistic infections	Rare
Tsukamurella	Opportunistic infections	Rare

Clinical Case 22.4 Disseminated Nocardiosis

Shin and associates (*Transplant Infect Dis* 8:222–225, 2006) described a 63-year-old man who received a liver transplant for liver cirrhosis caused by hepatitis C. The patient was treated with immunosuppressive drugs, including tacrolimus and prednisone for 4 months, at which time he returned to the hospital with fever and lower leg pain. Although the chest radiograph was normal, ultrasound revealed an abscess in the soleus muscle. Poorly staining gram-positive rods were observed in the Gram stain of the pus aspirated from the abscess, and *Nocardia* grew after 3 days of incubation. Treatment with imipenem was started; however, the patient developed convulsions 10 days later and partial left-sided paralysis. Brain imaging studies revealed three lesions. Treatment was switched to ceftriaxone and amikacin. The subcutaneous abscess and brain lesions gradually improved, and the patient was discharged after 55 days of hospitalization. This patient illustrates the propensity of *Nocardia* to infect immunocompromised patients and disseminate to the brain, the slow rate of growth of the organism in culture, and the related need for prolonged treatment.

BOX 22.2 Nocardiosis: Clinical Summaries

Bronchopulmonary disease: indolent pulmonary disease with necrosis and abscess formation; dissemination to central nervous system or skin is common

Mycetoma: chronic destructive progressive disease, generally of extremities, characterized by suppurative granulomas, progressive fibrosis and necrosis, and sinus tract formation

Lymphocutaneous disease: primary infection or secondary spread to cutaneous site, characterized by chronic granuloma formation and erythematous subcutaneous nodules, with eventual ulcer formation

Cellulitis and subcutaneous abscesses: granulomatous ulcer formation with surrounding erythema but minimal or no involvement of the draining lymph nodes

Brain abscess: chronic infection with fever, headache, and focal deficits related to the location of the slowly developing abscess(es)

with pulmonary, cutaneous, or CNS disease. The delicate hyphae of *Nocardia* in tissues cause them to resemble *Actinomyces* organisms (see Chapter 31); however, in contrast with *Actinomyces*, nocardiae are typically weakly acid-fast (see Fig. 22.10).

The organisms grow on most laboratory media incubated in an atmosphere of 5% to 10% carbon dioxide, but the presence of these slow-growing organisms may be obscured by more rapidly growing commensal bacteria. If a specimen is potentially contaminated with other bacteria (e.g., oral bacteria in sputum), selective media should be inoculated. Success has been achieved with the medium used for the isolation of *Legionella* species **(buffered charcoal yeast extract [BCYE] agar).** Indeed, this medium can be used to recover both *Nocardia* and *Legionella* from pulmonary specimens. *Nocardia* occasionally grows on media used for the isolation of mycobacteria and fungi; however, this method is less reliable than the use of special bacterial media. As mentioned previously, it is important to notify the laboratory if nocardiosis is suspected so the culture plates are held for additional days.

The preliminary identification of *Nocardia* is uncomplicated. Members of the genus can be classified initially on the basis of the presence of **filamentous, weakly acid-fast bacilli** and **aerial hyphae** on the colony surface. Definitive identification at the species level is more difficult because most species cannot be identified accurately by biochemical tests, although many laboratories continue to use these tests. Accurate identification of *Nocardia* requires molecular analysis of ribosomal ribonucleic acid (RNA) genes and "housekeeping" genes (e.g., heat shock protein gene) or use of mass spectrometry. Although mass spectrometry has only recently been introduced into diagnostic microbiology laboratories, this is rapidly becoming the method of choice for identification of these organisms.

TREATMENT, PREVENTION, AND CONTROL

Antibiotics with activity against *Nocardia* include trimethoprim-sulfamethoxazole (TMP-SMX), amikacin, imipenem, and broad-spectrum cephalosporins (e.g., ceftriaxone, cefotaxime). Because antibiotic susceptibility can vary among individual isolates, antimicrobial susceptibility tests should be performed to guide specific therapy. TMP-SMX can be used as initial empirical therapy for cutaneous infections in immunocompetent patients. Antibiotic therapy for severe infections and cutaneous infections in immunocompromised patients should include two or three antibiotics, such as TMP-SMX plus amikacin for pulmonary or cutaneous infections and TMP-SMX plus imipenem or a cephalosporin for CNS infections. Because *Nocardia* grows slowly and is associated with therapeutic relapses, prolonged treatment (up to 12 months) is recommended. Whereas the clinical response is favorable in patients with localized

Fig. 22.13 Cutaneous lesion caused by *Nocardia.* (From Cohen, J., Powderly, W.G., Opal, S.M., 2010. Infectious Diseases, third ed. Philadelphia, PA: Mosby.)

infections, the prognosis is poor for immunocompromised patients with disseminated disease.

Nocardiae are ubiquitous, so it is impossible to avoid exposure to them. However, bronchopulmonary disease caused by nocardiae is uncommon in immunocompetent persons, and primary cutaneous infections can be prevented with proper wound care. The complications associated with disseminated disease can be minimized if nocardiosis is considered in the differential diagnosis for immunocompromised patients with cavitary pulmonary disease and promptly treated.

• Other Weakly Acid-Fast Bacteria

The genus *Rhodococcus* consists of gram-positive acid-fast bacteria that initially appear rodlike and then revert to coccoid forms (Fig. 22.14). Rudimentary branching may be present, but the delicate, branching, filamentous forms commonly seen with nocardiae are not observed with rhodococci. Of the species currently recognized, ***Rhodococcus equi*** is the most important human pathogen. Originally, *R. equi* (formerly *Corynebacterium equi*) was considered a veterinary pathogen, particularly in herbivores, which occasionally caused occupational disease in farmers and veterinarians. However, this organism has become an increasingly more common **pathogen of immunocompromised patients** (e.g., patients infected with HIV, transplant recipients). Interestingly, most infected patients do not have a history of contact with grazing animals or of exposure to soil contaminated with herbivore manure. The rise in the incidence of human infection is most likely related to the increase in the number of patients with immunosuppressive diseases, particularly AIDS, and to the enhanced awareness of the organism. It is likely that many isolates were ignored previously or were misidentified as insignificant coryneform bacteria.

Similar to *Nocardia, R. equi* is a facultative, intracellular organism that survives in macrophages and causes granulomatous inflammation that leads to **abscess formation.** Although numerous putative virulence factors have been identified, the precise pathophysiology of the infection is incompletely understood. Individuals with depressed production of IFN-γ appear to be unable to clear bacteria from lung infections.

Immunocompromised patients most typically present with **invasive pulmonary disease** (e.g., pulmonary nodules, consolidation, lung abscesses), and evidence of dissemination in the blood to distal sites (lymph nodes, meninges, pericardium, and skin) is commonly observed. Rhodococci usually cause **opportunistic infections in immunocompetent patients** (e.g., posttraumatic cutaneous infections, peritonitis in patients undergoing long-term dialysis, traumatic endophthalmitis).

Rhodococci grow on nonselective media incubated aerobically, but the characteristic salmon-pink pigment may not be obvious for at least 4 days. Colonies are typically **mucoid,** although dry forms may also be seen. The organisms can be identified initially by their slow growth, macroscopic and microscopic morphology, and ability to weakly retain the **acid-fast** stain (acid-fastness observed primarily when organisms are grown on media for mycobacteria). Definitive identification at the species level is problematic; organisms are relatively inert, so biochemical tests are not useful. Similar to *Nocardia,* accurate identification at the species level requires either gene sequencing or protein profiling by mass spectrometry.

Rhodococcus infections are difficult to treat. Although in vitro tests and tests in animal models have identified specific combinations of effective drugs, only limited success has been realized in the treatment of human infections, particularly in immunocompromised patients with low CD4 cell counts (50% mortality) compared with immunocompetent patients (20% mortality). The current recommendation for treating localized infections in immunocompetent patients is to use either an extended-spectrum macrolide (e.g., azithromycin, clarithromycin) or fluoroquinolone (e.g., levofloxacin). Disseminated infections and infections in immunocompromised patients should be managed with combinations of two or more antibiotics, with at least one with excellent penetration into macrophages (e.g., vancomycin, imipenem, aminoglycosides, levofloxacin, rifampin, ciprofloxacin). Penicillins and cephalosporins should not be used because resistance to these agents is common in rhodococci, and the effectiveness of any antibiotic must be confirmed by in vitro testing.

Gordonia and ***Tsukamurella*** were previously classified with *Rhodococcus* because they are morphologically similar, contain mycolic acids, and are **partially acid-fast.** The organisms are present in soil and are rare opportunistic pathogens in humans. *Gordonia* has been associated with pulmonary and cutaneous infections, as well as nosocomial infections, such as those resulting from contaminated intravascular catheters. *Tsukamurella* has been associated with catheter infections. The significance of isolating either organism in clinical specimens must be evaluated carefully.

For a case study and question see StudentConsult.com.

Case Study and Questions

A 35-year-old man with a history of intravenous drug use entered the local health clinic with complaints of a dry persistent cough, fever, malaise, and anorexia. Over the preceding 4 weeks, he had lost 15 pounds and experienced chills and sweats. A chest radiograph revealed patchy infiltrates throughout the lung fields. Because the patient had a nonproductive cough, sputum was induced and submitted for bacterial, fungal, and mycobacterial cultures, as well as examination for *Pneumocystis* organisms. Blood cultures and serologic tests for HIV infection were performed. The patient was found to be HIV positive. The results of all cultures were negative after 2 days of incubation; however, sputum cultures were positive for *M. tuberculosis* after an additional week of incubation.

1. What is unique about the cell wall of mycobacteria, and what biological effects can be attributed to the cell wall structure?

2. Why is *M. tuberculosis* more virulent in patients with HIV infection than in non–HIV-infected patients?

3. What are the two clinical presentations of *M. leprae* infections? How do the diagnostic tests differ for these two presentations?

4. Why do mycobacterial infections have to be treated with multiple drugs for 6 months or more?

23 Neisseria *and Related Genera*

A 22-year-old woman was admitted to the hospital with a 1-day history of high fever, chills, headache, and an erythematous maculopapular rash over her chest, arms, and legs. She had an elevated leukocyte count and sedimentation rate. Blood cultures drawn at the time of admission were positive 10 hours later with gram-negative diplococci. This patient most likely has an infection with either *Neisseria gonorrhoeae* or *Neisseria meningitidis* because no other gram-negative bacteria in this clinical setting will look like this. Additional tests will be required to determine which bacterium is responsible for this infection.

1. *N. gonorrhoeae* and *N. meningitidis* are the most important members of the genus *Neisseria.* How is this genus differentiated from other bacteria, and what growth properties distinguish these two species from other members of the genus?
2. What are the major virulence factors for each organism?
3. Why does a vaccine exist for *N. meningitidis* but not *N. gonorrhoeae?* What serogroup is not covered by the *N. meningitidis* vaccine, and why is this important?

Answers to these questions are available on Student Consult.com.

Summaries Clinically Significant Organisms

NEISSERIA GONORRHOEAE

Trigger Words

Diplococci, gonorrhea, arthritis, ophthalmia

Biology and Virulence

- Gram-negative diplococci with fastidious growth requirements
- Growth best at 35° C-37° C in a humid atmosphere supplemented with CO_2
- Oxidase and catalase positive; acid produced from glucose oxidatively
- Outer surface with multiple antigens: pili protein; Por proteins; Opa proteins; Rmp protein; protein receptors for transferrin, lactoferrin, and hemoglobin; lipooligosaccharide; immunoglobulin protease; β-lactamase
- Refer to Table 23.2 for summary of virulence factors

Epidemiology

- Humans are the only natural hosts
- Carriage can be asymptomatic in women
- Transmission is primarily by sexual contact
- Almost 555,608 cases reported in United States in 2017 (true incidence of disease believed to be at least twice that); estimated 78 million new cases worldwide
- Disease most common in blacks, people aged 15-24 years, residents of southeastern United States, people who have multiple sexual encounters
- Higher risk of disseminated disease in patients with deficiencies in late components of complement

Diseases

- Refer to Box 23.1 for summary of clinical diseases

Diagnosis

- Gram stain of urethral specimens is accurate for symptomatic males only
- Culture is sensitive and specific but has been replaced with nucleic acid tests in most laboratories

Treatment, Prevention, and Control

- Ceftriaxone with azithromycin is currently the treatment of choice, although high-level resistance to cephalosporins and azithromycin has been observed
- For neonates, prophylaxis with 1% silver nitrate; ophthalmia neonatorum is treated with ceftriaxone
- Prevention consists of patient education, use of condoms or spermicides with nonoxynol-9 (only partially effective), and aggressive follow-up of sexual partners of infected patients
- Effective vaccines are not available

NEISSERIA MENINGITIDIS

Trigger Words

Diplococci, meningitis, meningococcemia, pneumonia, vaccine

Biology and Virulence

- Gram-negative diplococci with fastidious growth requirements
- Grows best at 35° C-37° C in a humid atmosphere
- Oxidase and catalase positive; acid produced from carbohydrates oxidatively
- Outer surface antigens include polysaccharide capsule, pili, and lipooligosaccharides
- Capsule protects bacteria from antibody-mediated phagocytosis
- Specific receptors for meningococcal pili allow colonization of nasopharynx and replication; posttranslational modification of the pili enhances host cell penetration and person-to-person spread
- Bacteria can survive intracellular killing in the absence of humoral immunity
- Endotoxin mediates most clinical manifestations

Epidemiology

- Humans are the only natural hosts
- Person-to-person spread occurs via aerosolization of respiratory tract secretions
- Highest incidence of disease is in children younger than 1 year old, institutionalized people, and patients with late complement deficiencies
- Endemic and epidemic disease most commonly caused by serogroups A, B, C, W135, X, and Y; pneumonia most commonly caused by serogroups Y and W135; serogroups A and W135 associated with disease in underdeveloped countries
- Disease occurs worldwide, most commonly in the dry, cold months of the year

Continued

Summaries Clinically Significant Organisms—cont'd

Diseases

- Refer to Box 23.1 for summary of clinical diseases

Diagnosis

- Gram stain of cerebrospinal fluid is sensitive and specific but is of limited value for blood specimens (too few organisms are generally present, except in overwhelming sepsis)
- Culture is definitive, but organism is fastidious and dies rapidly when exposed to cold or dry conditions
- Tests to detect meningococcal antigens are insensitive and nonspecific

Treatment, Prevention, and Control

- Breast-feeding infants have passive immunity (first 6 months)
- Empirical treatment of patients with suspected meningitis or bacteremia should be initiated with ceftriaxone; if the isolate is penicillin susceptible, treatment can be changed to penicillin G
- Chemoprophylaxis for contact with persons with the disease is with rifampin, ciprofloxacin, or ceftriaxone
- For immunoprophylaxis, vaccination is an adjunct to chemoprophylaxis; it is used only for serogroups A, C, Y, and W135; no effective vaccine is available for serogroup B; vaccination for serogroup A has been introduced in Africa

TABLE 23.1 Important Neisseriaceae

Organism	Historical Derivation
Neisseria	Named after the German physician Albert Neisser, who originally described the organism responsible for gonorrhea
N. gonorrhoeae	*gone,* seed; *rhoia,* a flow (a flow of seeds; reference to the disease gonorrhea)
N. meningitidis	*meningis,* the covering of the brain; *itis,* inflammation (inflammation of the meninges as in meningitis)
Eikenella	Named after M. Eiken, who first named the type species in this genus
E. corrodens	*corrodens,* gnawing or eating (reference to the observation that colonies of this species pit [eat into] the agar)
Kingella	Named after the American bacteriologist Elizabeth King

BOX 23.1 **Neisseriaceae: Clinical Summaries**

Neisseria gonorrhoeae

Gonorrhea: characterized by purulent discharge for involved site (e.g., urethra, cervix, epididymis, prostate, rectum) after a 2- to 5-day incubation period

Disseminated infections: spread of infection from genitourinary tract through blood to skin or joints; characterized by pustular rash with erythematous base and suppurative arthritis in involved joints

Ophthalmia neonatorum: purulent ocular infection acquired by neonate at birth

Neisseria meningitidis

Meningitis: purulent inflammation of meninges associated with headache, meningeal signs, and fever; high mortality rate unless promptly treated with effective antibiotics

Meningococcemia: disseminated infection characterized by thrombosis of small blood vessels and multiorgan involvement; small petechial skin lesions coalesce into larger hemorrhagic lesions

Pneumonia: milder form of meningococcal disease characterized by bronchopneumonia in patients with underlying pulmonary disease

Eikenella corrodens

Human bite wounds: infection associated with traumatic (e.g., bite, fistfight injury) introduction of oral organisms into deep tissue

Subacute endocarditis: infection of endocardium characterized by gradual onset of low-grade fevers, night sweats, and chills

Kingella kingae

Subacute endocarditis: as with *E. corrodens*

Three genera of medically important bacteria are in the family Neisseriaceae: ***Neisseria, Eikenella,*** and ***Kingella*** (Table 23.1). Other genera in the family are rarely associated with human disease and will not be discussed in this chapter. The genus *Neisseria* consists of 35 species and subspecies with two species, ***Neisseria gonorrhoeae*** and ***Neisseria meningitidis,*** strictly human pathogens. Additional species are commonly present on mucosal surfaces of the oropharynx and nasopharynx and occasionally colonize the anogenital mucosal membranes. Diseases caused by *N. gonorrhoeae* and *N. meningitidis* are well known; the other *Neisseria* species have limited virulence and generally produce opportunistic infections (Box 23.1). ***Eikenella corrodens*** and ***Kingella kingae*** colonize the human oropharynx and are also opportunistic pathogens.

Neisseria gonorrhoeae and *Neisseria meningitidis*

Infections caused by *N. gonorrhoeae,* particularly the sexually transmitted disease gonorrhea, have been recognized for centuries. Despite effective antibiotic therapy, gonorrhea is still one of the most common sexually transmitted diseases in the United States. The presence of *N. gonorrhoeae* in a clinical specimen is always considered significant. In contrast, strains of *N. meningitidis* can colonize the nasopharynx of healthy people without producing disease or can cause community-acquired meningitis, overwhelming and rapidly fatal sepsis, or bronchopneumonia. The swift progression from good health to life-threatening disease produces fear and panic in communities, unlike the reaction to almost any other pathogen.

PHYSIOLOGY AND STRUCTURE

Neisseria species are aerobic **gram-negative** bacteria, typically coccoid shaped (0.6 to 1.0 μm in diameter) and arranged in pairs **(diplococci)** with adjacent sides flattened together (resembling coffee beans [Fig. 23.1]). All species are oxidase positive and most produce catalase, which are

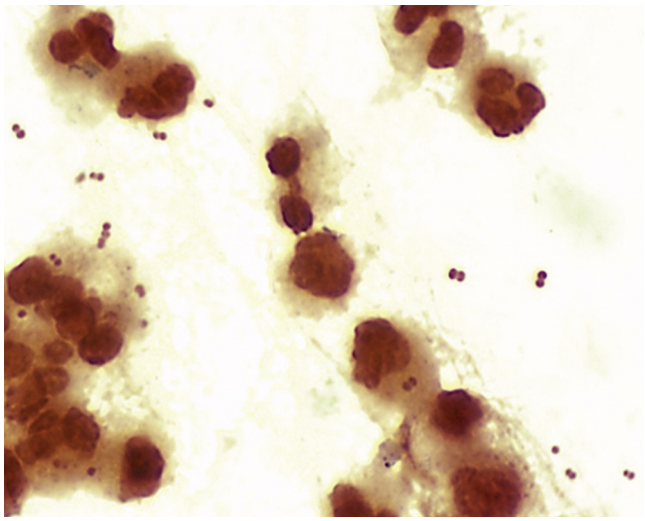

Fig. 23.1 *Neisseria meningitidis* in cerebrospinal fluid. Note the spatial arrangement of the pairs of cocci with sides pressed together, which is characteristic of this genus.

properties that combined with the Gram stain morphology allow a rapid, presumptive identification of a clinical isolate. Acid is produced by oxidation of carbohydrates (not by fermentation), a property that was historically used to differentiate *Neisseria* species. More rapid methods such as mass spectrometry are now used to identify these bacteria.

Pathogenic and nonpathogenic species of *Neisseria* can also be differentiated by their growth on blood agar and nutrient agar. Nonpathogenic strains grow on both media, *N. meningitidis* grows on blood agar and has variable growth on nutrient agar, and *N. gonorrhoeae* typically do not grow on either media. Strains of *N. gonorrhoeae* require cystine and an energy source (e.g., glucose, pyruvate, lactate) for growth, and many strains require supplementation of media with amino acids, purines, pyrimidines, and vitamins. Soluble starch is added to the media to neutralize the toxic effect of the fatty acids. Thus *N. gonorrhoeae* only grows on enriched **chocolate agar** and other supplemented media. The optimum growth temperature is **35° C to 37° C**, with poor survival of the organism at cooler temperatures. A humid atmosphere supplemented with **5% carbon dioxide** is either required or enhances growth of *N. gonorrhoeae.* These growth properties have practical importance: unless the specimen is processed on appropriate enriched media, *N. gonorrhoeae* will not be recovered. Although the fastidious nature of this organism makes recovery from clinical specimens difficult, it is nevertheless easy for the organism to be transmitted sexually from person to person.

The cell wall structure of *N. gonorrhoeae* and *N. meningitidis* is typical of gram-negative bacteria, with the thin peptidoglycan layer sandwiched between the inner cytoplasmic membrane and the outer membrane. The major virulence factor for *N. meningitidis* is the polysaccharide capsule. Although the outer surface of *N. gonorrhoeae* is not covered with a true carbohydrate capsule, the cell surface of *N. gonorrhoeae* has a capsule-like negative charge. Antigenic differences in the **polysaccharide capsule** of *N. meningitidis* are the basis for serogrouping these bacteria in vitro and play a prominent role in determining whether an individual strain will cause disease. Thirteen serogroups are currently recognized, with six serogroups (A, B, C, W135, X, and Y) associated with endemic and epidemic disease.

Pathogenic and nonpathogenic strains of *Neisseria* have **pili** that extend from the cytoplasmic membrane through the outer membrane. Pili mediate a number of functions, including attachment to host cells, transfer of genetic material, and motility, and the presence of pili in *N. gonorrhoeae* and *N. meningitidis* appears to be important for pathogenesis, in part because the pili mediate attachment to nonciliated epithelial cells and provide resistance to killing by neutrophils. The pili are composed of repeating protein subunits **(pilins)** that have a conserved region at one end and a highly variable region at the exposed carboxyl terminus. The lack of immunity to reinfection with *N. gonorrhoeae* results partially from the antigenic variation among the pilin proteins and partially from the phase variation in pilin expression, which are factors that complicate attempts to develop effective vaccines for gonorrhea.

Other prominent families of proteins are present in the outer membrane. The **porin proteins** are integral outer membrane proteins that form pores or channels for nutrients to pass into the cell and waste products to exit. *N. gonorrhoeae* and *N. meningitidis* have two porin genes, *porA* and *porB.* The gene products, **PorA and PorB proteins,** are both expressed in *N. meningitidis,* but the *porA* gene is silent in *N. gonorrhoeae.* Thus not only is PorB the major outer membrane protein in *N. gonorrhoeae* (an estimated 60% of the gonococcal outer membrane proteins), but it must also be functionally active for *N. gonorrhoeae* to survive. This would seem to be a logical target for a vaccine; however, PorB is expressed as two distinct classes of antigens, PorB1A and PorB1B, with many distinct serologic variants. Thus, although the PorB protein is expressed in all gonococci, the large number of antigens and antigenic variation of this protein make it a poor target for vaccine development.

PorB is important for the virulence of *N. gonorrhoeae* because these proteins can interfere with degranulation of neutrophils (i.e., phagolysosome fusion that would lead to killing of intracellular bacteria) and presumably protect the bacteria from the host's inflammatory response. Additionally, PorB with other adhesins facilitates the bacterial invasion into epithelial cells. Finally, expression of some PorB antigens makes the bacteria resistant to complement-mediated serum killing.

Opa proteins (opacity proteins) are a family of membrane proteins that mediate intimate binding to epithelial and phagocytic cells and are important for cell-to-cell signaling. Multiple alleles of these proteins can be expressed by individual isolates. *N. gonorrhoeae* expressing the Opa proteins appear opaque when grown in culture (thus the source of the name). Opaque colonies are recovered most commonly in patients with localized disease (i.e., endocervicitis, urethritis, pharyngitis, proctitis), whereas transparent colonies are more commonly associated with pelvic inflammatory disease (PID) and disseminated infections.

The third group of proteins in the outer membrane is the highly conserved **Rmp proteins** (reduction-modifiable proteins). These proteins stimulate antibodies that interfere with the serum bactericidal activity against pathogenic neisseriae.

Iron is essential for the growth and metabolism of *N. gonorrhoeae* and *N. meningitidis.* These pathogenic neisseriae are able to compete with their human hosts for iron by **binding host cell transferrin** to specific bacterial surface receptors. The specificity of this binding for human transferrin is likely the reason these bacteria are strict human pathogens. The presence of this receptor is fundamentally different from most bacteria that synthesize siderophores to scavenge iron. The gonococci also have a variety of additional surface receptors for other host iron complexes, such as lactoferrin and hemoglobin.

Another major antigen in the cell wall is **LOS.** This antigen is composed of lipid A and a core oligosaccharide but lacks the O-antigen polysaccharide found in lipopolysaccharide (LPS) in most gram-negative rods. The lipid A moiety possesses endotoxin activity. Both *N. gonorrhoeae* and *N. meningitidis* spontaneously release **outer membrane blebs** during rapid cell growth. These blebs contain LOS and surface proteins and may act to both enhance endotoxin-mediated toxicity and protect replicating bacteria by binding protein-directed antibodies.

N. gonorrhoeae and *N. meningitidis* produce **immunoglobulin (Ig)A1 protease,** which cleaves the hinge region in IgA1. This action creates immunologically inactive Fc and Fab fragments. Some strains of *N. gonorrhoeae* also produce **β-lactamase** that can degrade penicillin.

PATHOGENESIS AND IMMUNITY

Gonococci attach to mucosal cells, penetrate into the cells and multiply, and then pass through the cells into the subepithelial space in which infection is established (Table 23.2). Pili, PorB, and Opa proteins mediate attachment and penetration into host cells. The gonococcal LOS stimulates release of the proinflammatory cytokine **TNF-α,** which causes most of the symptoms associated with gonococcal disease.

TABLE 23.2 Virulence Factors in *Neisseria gonorrhoeae*

Virulence Factor	Biological Effect
Pilin	Protein that mediates initial attachment to nonciliated human cells (e.g., epithelium of vagina, fallopian tube, and buccal cavity); interferes with neutrophil killing
Por protein	Porin protein: promotes intracellular survival by preventing phagolysosome fusion in neutrophils
Opa protein	Opacity protein: mediates firm attachment to eukaryotic cells
Rmp protein	Reduction-modifiable protein: protects other surface antigens (Por protein, lipooligosaccharide) from bactericidal antibodies
Transferrin-, lactoferrin-, and hemoglobin-binding proteins	Mediate acquisition of iron for bacterial metabolism
LOS	Lipooligosaccharide: has endotoxin activity
IgA1 protease	Destroys immunoglobulin A1 (role in virulence is unknown)
β-Lactamase	Hydrolyzes the β-lactam ring in penicillin

IgG3 is the predominant IgG antibody formed in response to gonococcal infection. Although the antibody response to PorB is minimal, serum antibodies to pilin, Opa protein, and LOS are readily detected. Antibodies to LOS can activate complement, releasing complement component C5a, which has a chemotactic effect on neutrophils; however, IgG and secretory IgA1 antibodies directed against Rmp protein can block this bactericidal antibody response.

Experiments with nasopharyngeal tissue organ cultures have shown that meningococci attach selectively to specific receptors on nonciliated columnar cells of the nasopharynx. Presence of the capsule interferes with epithelial cell attachment, so synthesis is downregulated before attachment. After attachment, meningococci are able to multiply, forming large aggregates of bacteria anchored to the host cells. Within a few hours of attachment, the pili undergo posttranslational modification, leading to destabilization of the aggregates. This results in the enhanced ability of the bacteria to both penetrate into the host cells and release into the airways, thus person-to-person spread is potentially increased.

Meningococcal disease occurs in patients who lack specific antibodies directed against the polysaccharide capsule and other expressed bacterial antigens. Infants are initially afforded protection by the passive transfer of maternal antibodies. When the infant has reached age 6 months, however, this protective immunity has waned, which is a finding consistent with the observation that the incidence of disease is greatest in children younger than 2 years. Immunity can be stimulated by colonization with *N. meningitidis* or other bacteria with cross-reactive antigens (e.g., colonization with nonencapsulated *Neisseria* species; exposure to *Escherichia coli* K1 antigen that cross-reacts with the group B capsular polysaccharide). Bactericidal activity also requires the existence of complement. Patients with **deficiencies in C5, C6, C7, or C8** of the complement system are estimated to be at a 6000-fold greater risk for meningococcal disease. Although immunity is mediated primarily by the humoral immune response, lymphocyte responsiveness to meningococcal antigens is markedly depressed in patients with acute disease.

Similar to *N. gonorrhoeae,* meningococci are internalized into phagocytic vacuoles and are able to avoid intracellular death, replicate, and then migrate to the subepithelial spaces. The polysaccharide capsule protects *N. meningitidis* from phagocytic destruction. The diffuse vascular damage associated with meningococcal infections (e.g., endothelial damage, inflammation of vessel walls, thrombosis, disseminated intravascular coagulation [DIC]) is largely attributed to the action of the **LOS endotoxin** present in the outer membrane.

EPIDEMIOLOGY

Gonorrhea occurs naturally only in humans; it has no other known reservoir. It is second only to chlamydia as the most commonly reported sexually transmitted disease in the United States. Infection rates are the same in males and females, are disproportionately higher in blacks than in Hispanic Americans and whites, and are highest in the southeastern United States. The peak incidence of the disease is in the age group 15 to 24 years. The incidence of

disease generally declined after 1978, but the decrease slowed around 1996, and gonococcal infections have increased since 2010. In 2017, 555,608 new infections were reported in the United States, the highest number of infections in more than 25 years. However, even this large number is an underestimation of the true incidence of disease because diagnosis and reporting of infections are incomplete. Public health officials believe new infections may be twice the number reported. The American experience also pales in comparison with the WHO 2012 estimate of 78 million new cases of gonorrhea worldwide.

N. gonorrhoeae is transmitted primarily by sexual contact. Women have a 50% risk of acquiring the infection as the result of a single exposure to an infected man, whereas men have a risk of approximately 20% as the result of a single exposure to an infected woman. The risk of infection rises as the person has more sexual encounters with infected partners. Newborns are also at risk of developing infection when the mother is infected.

The major reservoir for gonococci is the asymptomatically infected person. Asymptomatic carriage is more common in women than in men. As many as half of all infected women have mild or asymptomatic infections, whereas most men are initially symptomatic. The symptoms generally clear within a few weeks in individuals with untreated disease, and asymptomatic carriage may then become established. The site of infection also determines whether carriage occurs, with rectal and pharyngeal infections more commonly asymptomatic than genital infections.

Endemic meningococcal disease occurs worldwide, and epidemics are common in developing countries. Epidemic spread of disease results from the introduction of a new virulent strain into an immunologically naive population. Endemic disease and pandemics have been uncommon in developed countries since World War II. For example, in the United States, rates of meningococcal disease have been declining since the late 1990s, with only about 370 cases reported in 2016. In contrast, outbreaks occur every 5 to 12 years in sub-Saharan Africa in which the attack rate can reach 1% of the population. Of the 13 serogroups, almost all infections are caused by serogroups A, B, C, W135, X, and Y. In Europe and the Americas, serogroups B, C, and Y predominate in meningitis or meningococcemia; serogroup A is responsible for 80% to 85% of disease in the 26 countries comprising the sub-Saharan African meningitis belt (stretching from Senegal to Ethiopia); and W135 is responsible for an ongoing outbreak of meningitis in Chile. Serogroups Y and W135 are most commonly associated with meningococcal pneumonia.

N. meningitidis is transmitted by respiratory droplets among people in prolonged close contact, such as family members living in the same household and soldiers living together in military barracks. Classmates in schools and hospital employees are not considered close contacts and are not at significantly higher risk of acquiring the disease unless they are in direct contact with the respiratory secretions of an infected person.

Humans are the only natural carriers for *N. meningitidis.* Studies of asymptomatic carriage of *N. meningitidis* have shown tremendous variation in its prevalence, from less than 1% to almost 40%. The oral and nasopharyngeal carriage rates are highest for school-age children and young adults; are higher in lower socioeconomic populations (caused by person-to-person spread in crowded areas); and do not vary with the seasons, even though disease is most common during the dry, cold months of the year. Carriage is typically transient, with clearance occurring after specific antibodies develop. Disease is most common in children younger than 1 year old with a second peak in adolescence. People who are immunocompromised, the elderly, or those who live in closed populations (e.g., military barracks, prisons) are prone to infection during epidemics.

CLINICAL DISEASES

Neisseria gonorrhoeae

Gonorrhea. Genital infection in men is primarily restricted to the **urethra** (see Box 23.1). A purulent urethral discharge (Fig. 23.2) and dysuria develop after a 2- to 5-day incubation period. Virtually all infected men have acute symptoms. Although complications are rare, epididymitis, prostatitis, and periurethral abscesses may occur. The primary site of infection in women is the cervix because the bacteria infect the endocervical columnar epithelial cells. The organism cannot infect the squamous epithelial cells that line the vagina of postpubescent women. Symptomatic patients commonly experience vaginal discharge, dysuria, and abdominal pain. Ascending genital infections, including salpingitis, tuboovarian abscesses, and PID, are observed in 10% to 20% of women. Although the initial infection in many women is asymptomatic, they are at increased risk of PID, ectopic pregnancies, infertility, destructive arthritis, and disseminated infections.

Gonococcemia. Disseminated infections with **septicemia** and **infection of skin and joints** occur in 1% to 3% of infected women and in a much lower percentage of infected men (Clinical Case 23.1). The greater proportion of disseminated infections in women is caused by the numerous untreated asymptomatic infections in this population. The clinical manifestations of disseminated disease include fever; migratory arthralgias; suppurative arthritis in the wrists, knees, and ankles; and a pustular rash on an erythematous base (Fig. 23.3) over the extremities but not

Fig. 23.2 Purulent urethral discharge in man with urethritis. (From Morse, S.A., Ballard, R.C., Holmes, K.K., et al., 2010. Atlas of Sexually Transmitted Diseases and AIDS, fourth ed. London, UK: Saunders.)

Clinical Case 23.1 **Gonococcal Arthritis**

Gonococcal arthritis is a common presentation of disseminated *Neisseria gonorrhoeae* infection. Fam and associates (*Can Med Assoc J* 108:319–325, 1973) described six patients with this disease, including the following patient, who has a typical presentation. A 17-year-old girl was admitted to the hospital with a 4-day history of fever, chills, malaise, sore throat, skin rash, and polyarthralgia. She reported being sexually active and having a 5-week history of a profuse yellowish vaginal discharge that was untreated. On presentation, she had erythematous maculopapular skin lesions over her forearm, thigh, and ankle, and her metacarpophalangeal joint, wrist, knee, ankle, and midtarsal joints were acutely inflamed. She had an elevated leukocyte count and sedimentation rate. Cultures of her cervix were positive for *N. gonorrhoeae*, but blood specimens, exudates for the skin lesions, and synovial fluid were all sterile. The diagnosis of disseminated gonorrhea with polyarthritis was made, and she was successfully treated with penicillin G for 2 weeks. This case illustrates the limitations of culture in disseminated infections and the value of a careful history.

Fig. 23.3 Skin lesions of disseminated gonococcal infection. Classic large lesions with a necrotic, grayish central lesion on an erythematous base. (From Morse, S.A., Ballard, R.C., Holmes, K.K., et al., 2010. Atlas of Sexually Transmitted Diseases and AIDS, fourth ed. London, UK: Saunders.)

on the head and trunk. *N. gonorrhoeae* is a leading cause of **purulent arthritis** in adults.

Other *Neisseria gonorrhoeae* Syndromes. Other diseases associated with *N. gonorrhoeae* are perihepatitis **(Fitz-Hugh–Curtis syndrome);** purulent conjunctivitis (Fig. 23.4), particularly in newborns infected during vaginal delivery (ophthalmia neonatorum); anorectal gonorrhea in homosexual men; and pharyngitis.

Neisseria meningitidis

Meningitis. The disease usually begins abruptly with headache, meningeal signs, and fever; however, very young children may have only nonspecific signs such as fever and vomiting. Mortality approaches 100% in untreated patients but is less than 10% in patients in whom appropriate antibiotic therapy is instituted promptly. The incidence of neurologic sequelae is low, with hearing deficits, learning disabilities, and arthritis most common.

Fig. 23.4 Gonococcal ophthalmia neonatorum. Lid edema, erythema, and marked purulent discharge are seen. A Gram-stained smear would reveal abundant organisms and inflammatory cells. (From Morse, S.A., Ballard, R.C., Holmes, K.K., et al., 2010. Atlas of Sexually Transmitted Diseases and AIDS, fourth ed. London, UK: Saunders.)

Meningococcemia. Septicemia (meningococcemia) with or without meningitis is a life-threatening disease (Clinical Case 23.2). Thrombosis of small blood vessels and multiorgan involvement are the characteristic clinical features. Small, petechial skin lesions on the trunk and lower extremities are common and may coalesce to form larger hemorrhagic lesions (Fig. 23.5). Overwhelming DIC with shock, together with bilateral destruction of the adrenal glands **(Waterhouse-Friderichsen syndrome),** may ensue. A milder, chronic septicemia has also been observed. Bacteremia can persist for days or weeks, and the only signs of infection are a low-grade fever, arthritis, and petechial skin lesions. The response to antibiotic therapy in patients with this form of the disease is generally excellent.

Other *Neisseria meningitidis* Syndromes. Additional infections caused by *N. meningitidis* are pneumonia, arthritis, and urethritis. Meningococcal pneumonia is usually preceded by a respiratory tract infection. Symptoms include cough, chest pain, rales, fever, and chills. Evidence of pharyngitis is observed in most affected patients. The prognosis in patients with meningococcal pneumonia is good.

LABORATORY DIAGNOSIS

Microscopy

Gram stain is very sensitive (>90%) and specific (98%) in detecting gonococcal infection in men with purulent urethritis. However, its sensitivity in detecting infection in asymptomatic men is 60% or less. The test is also relatively insensitive in detecting gonococcal cervicitis in both symptomatic and asymptomatic women, although a positive result is considered reliable when an experienced microscopist sees gram-negative diplococci within

Clinical Case 23.2 **Meningococcal Disease**

Gardner (*N Engl J Med* 355:1466–1473, 2006) described a previously healthy 18-year-old man who presented to a local emergency department with the acute onset of fever and headache. His temperature was elevated (40° C), and he was tachycardic (pulse of 140 beats/min) and hypotensive (blood pressure 70/40 mm Hg). Petechiae were noted over his chest. Although the result of a cerebrospinal fluid culture was not reported, *Neisseria meningitidis* was recovered in the patient's blood cultures. Despite prompt administration of antibiotics and other support measures, the patient's condition rapidly deteriorated, and he died 12 hours after arrival in the hospital. This patient illustrates the rapid progression of meningococcal disease, even in healthy young adults.

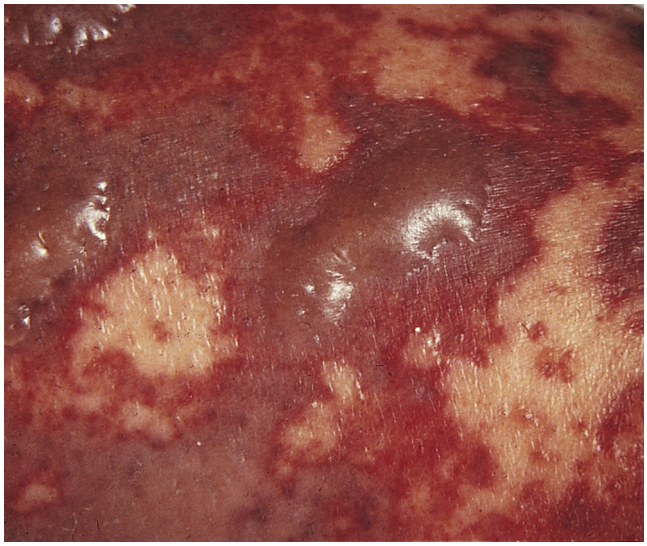

Fig. 23.5 Skin lesions in a patient with meningococcemia. Note that the petechial lesions have coalesced and formed hemorrhagic bullae.

polymorphonuclear leukocytes. Thus all negative Gram stain results in women and asymptomatic men must be confirmed.

The Gram stain is also useful for early diagnosis of purulent arthritis but is insensitive and nonspecific for detection of *N. gonorrhoeae* in patients with skin lesions, anorectal infections, or pharyngitis. Commensal *Neisseria* species in the oropharynx and morphologically similar bacteria in the gastrointestinal tract can be confused with *N. gonorrhoeae.*

N. meningitidis can be readily seen in the cerebrospinal fluid (CSF) of patients with meningitis (see Fig. 23.1) unless the patient has received antimicrobial therapy before the clinical specimen is collected. Most patients with bacteremia caused by other organisms have so few organisms present in their blood that the Gram stain has no value; however, patients with overwhelming meningococcal disease commonly have large numbers of organisms in their blood, which can be seen when the peripheral blood leukocytes are Gram stained.

Antigen Detection

Antigen testing for the detection of *N. gonorrhoeae* is less sensitive than culture or nucleic acid amplification tests (NAATs) and is not recommended unless confirmatory tests are performed on negative specimens. Commercial tests to detect *N. meningitidis* capsular antigens in CSF, blood, and urine (where the antigens are excreted) were widely used in the past but have fallen into disfavor in recent years because the tests are less sensitive than the Gram stain and false-positive reactions, particularly with urine specimens, can occur.

Nucleic Acid–Based Tests

NAATs specific for *N. gonorrhoeae* were one of the first molecular tests introduced in clinical laboratories and currently represent the diagnostic gold standard. Combination NAATs for both *N. gonorrhoeae* and *Chlamydia* organisms are available and have replaced culture or other diagnostic tests in most laboratories. Tests using the current assays are rapid (results are available in 1 to 2 hours), sensitive, and generally specific. Very rapid (less than 10 minutes) point-of-care NAATs are currently in development and should be introduced within the next few years. When this happens, it will dramatically alter the diagnosis and treatment of sexually transmitted diseases. The primary problem with NAATs is that they cannot be used to monitor antibiotic resistance of the identified pathogens.

Culture

N. gonorrhoeae can be readily isolated from genital specimens if care is taken in collecting and processing the specimens (Fig. 23.6). Because other commensal organisms normally colonize mucosal surfaces, all genital, rectal, and pharyngeal specimens must be inoculated onto both **nonselective media** (e.g., chocolate blood agar) and **selective media** that suppress the growth of contaminating organisms (e.g., modified Thayer-Martin medium). A nonselective medium should be used because some gonococcal strains are inhibited by the vancomycin present in most selective media. The organisms are also inhibited by the fatty acids and trace metals present in the peptone hydrolysates and agar in other common laboratory media (e.g., blood agar, nutrient agar). Gonococci die rapidly if specimens are allowed to dry, so drying and cold temperatures should be avoided by directly inoculating the specimen onto prewarmed media at the time of collection.

The endocervix must be properly exposed to ensure that an adequate specimen is collected. Although bacteria can be recovered in endocervical exudate present in the vagina, a vaginal specimen is inadequate from asymptomatic women. Although the endocervix is the most common site of infection in women, rectal cultures may be the only positive specimens in women who have asymptomatic infections, as well as in homosexual and bisexual men. Blood culture results are generally positive for gonococci only during the first week of the infection in patients with disseminated disease. In addition, special handling of blood specimens is required to ensure adequate recovery of gonococci because supplements present in the blood culture media can be toxic to *Neisseria.* Cultures of specimens from

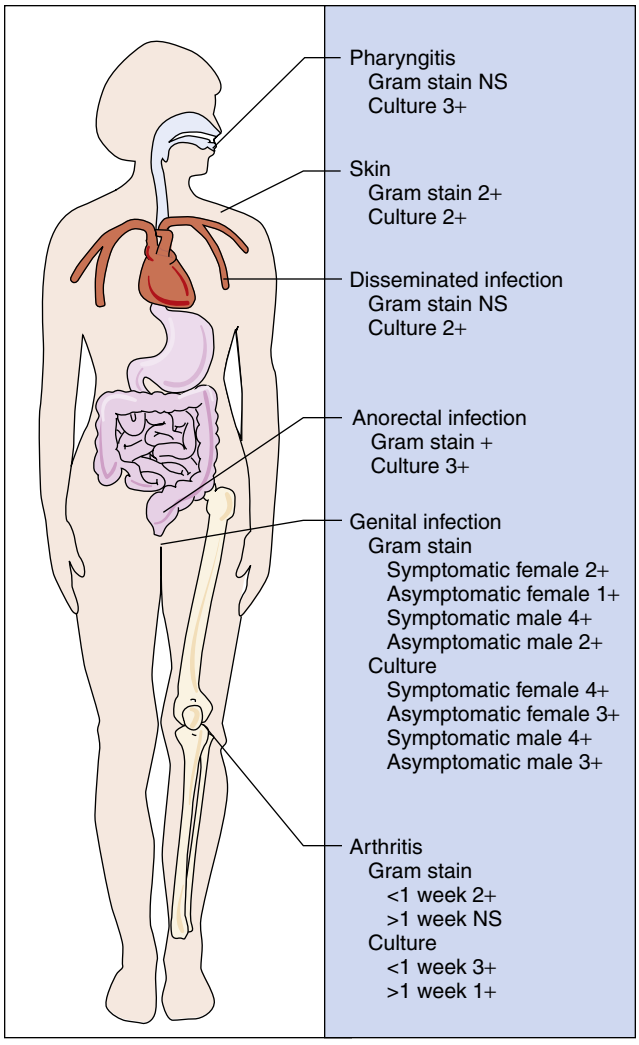

Fig. 23.6 Laboratory detection of *Neisseria gonorrhoeae. NS,* Not specific or sensitive.

infected joints are positive for the organism if the specimens are collected at the time the arthritis develops, but cultures of skin specimens are usually negative.

N. meningitidis is generally present in large numbers in CSF, blood, and sputum. Although the organism is inhibited by toxic factors in media and by the anticoagulant in blood cultures, this appears to be less of a problem than with *N. gonorrhoeae.* Care should be used in processing CSF and blood specimens because bacterial strains responsible for disseminated disease are more virulent and pose a safety risk for laboratory technologists.

Identification

Pathogenic *Neisseria* species are identified preliminarily on the basis of the isolation of oxidase-positive, gram-negative diplococci that grow on chocolate blood agar or on media that are selective for pathogenic *Neisseria* species. Definitive identification is guided by the pattern of oxidation of carbohydrates or other tests such as matrix-assisted laser desorption ionization (MALDI) mass spectrometry.

TREATMENT, PREVENTION, AND CONTROL

Penicillin was historically the antibiotic of choice for treatment of gonorrhea; however, penicillin is not used today because the concentration of drug required to kill "susceptible" strains has steadily increased and frank resistance has become common. Resistance to tetracycline and ciprofloxacin has also become prevalent, and neither antibiotic is recommended for treatment. Currently the Centers for Disease Control and Prevention (CDC) recommends dual therapy with **ceftriaxone** and azithromycin. Resistance to each of these antibiotics is observed globally; however, the combination still remains effective, although it is unclear how long this will be the case.

Major efforts to stem the epidemic of gonorrhea encompass education, aggressive detection, and follow-up screening of sexual contacts. It is important to realize that gonorrhea is a significant disease. Chronic infections can lead to sterility, and asymptomatic infections perpetuate the reservoir of disease and lead to a higher incidence of disseminated infections. Chemoprophylaxis with 1% silver nitrate, 1% tetracycline, or 0.5% erythromycin eye ointment is routinely used to protect newborns against gonococcal eye infections (ophthalmia neonatorum); however, prophylactic use of antibiotics to prevent genital disease is ineffective and not recommended. Although there is interest in developing a vaccine against ***N. gonorrhoeae,*** an **effective vaccine is not yet available.** Immunity to infection with *N. gonorrhoeae* is poorly understood. Antibodies to pili antigens, Por proteins, and LOS can be detected; however, multiple infections are common in sexually promiscuous people. This lack of protective immunity is explained in part by the antigenic diversity of gonococcal strains. The variable region at the carboxyl terminus of the pilin proteins is the immunodominant portion of the molecule. Antibodies developed against this region protect against reinfection with a homologous strain, but cross-protection against heterologous strains is incomplete. This antigenic diversity also explains the ineffectiveness of vaccines developed against pilin proteins.

Cefotaxime or ceftriaxone should be used initially to treat *N. meningitidis* infections. If the organism is demonstrated to be penicillin susceptible, treatment can be changed to penicillin G. Chemoprophylaxis is recommended for contacts with significant exposure to patients with meningococcal disease (defined as individuals with direct exposure to respiratory secretions or >8 hours of close contact with the patient). Currently, rifampin, ciprofloxacin, or ceftriaxone is recommended for prophylaxis.

Antibiotic eradication of *N. meningitidis* in healthy carriers is ineffective, so disease prevention has focused on enhancement of immunity through the use of vaccines directed against the serogroups most commonly associated with disease. Two tetravalent vaccines effective against serogroups A, C, Y, and W135 are currently licensed in the United States: a polysaccharide vaccine and a polysaccharide-protein conjugate vaccine. The conjugate vaccine is recommended for all adolescents aged 11 or 12 years, with a booster dose given at age 16. Other adults at increased risk for meningococcal disease should be vaccinated with either tetravalent vaccine. Unfortunately, the group B polysaccharide is a weak immunogen and is antigenically related to a polysaccharide in human neurologic tissues. Efforts to develop group B protein

vaccines are ongoing. In December 2010, a new meningococcal A conjugate vaccine was introduced successfully in Africa, and a decreased incidence of meningitis was observed in the regions in which the vaccine was used. By 2016 the vaccine was introduced into 16 of the targeted 26 countries in the African meningitis belt, with the elimination of serogroup A meningococcal epidemics. Currently epidemics in these countries are primarily caused by serogroups C and W.

Other *Neisseria* Species

Neisseria species such as *N. sicca* and *N. mucosa* are commensal organisms in the oropharynx. These organisms have been implicated in isolated cases of meningitis, osteomyelitis, endocarditis, bronchopulmonary infections, acute otitis media, and acute sinusitis. The true incidence of respiratory tract infections caused by these organisms is not known because most specimens are contaminated with oral secretions. However, the observation of many gram-negative diplococci associated with inflammatory cells in a well-collected respiratory specimen would support the etiologic role of these organisms. Most isolates of *N. sicca* and *N. mucosa* are susceptible to penicillin, although low-level resistance caused by altered penicillin-binding protein (i.e., PBP2) has been observed.

EIKENELLA CORRODENS

In the early 1960s, a collection of small, fastidious, gram-negative rods were classified by workers at the CDC as members of the HB group (named after the patient infected with the original isolate). The organisms were subsequently subdivided into subgroup HB-1 (now known as *E. corrodens*), subgroup HB-2 (*Aggregatibacter [Haemophilus] aphrophilus*), and subgroups HB-3 and HB-4 (*A. [Actinobacillus] actinomycetemcomitans;* see Chapter 24). In addition to being morphologically similar, these organisms colonize the human oropharynx and, in the setting of preexisting heart disease, can cause subacute bacterial endocarditis.

E. corrodens is a moderate-sized (0.2 × 2.0 μm), nonmotile, non–spore-forming, facultatively anaerobic, gram-negative rod. The organism is named after Eiken, who characterized the bacterium and observed the ability of the organism to pit or "corrode" agar. *E. corrodens* is a normal inhabitant of the human upper respiratory tract, but because of its fastidious growth requirements it is difficult to detect unless specific selective culture media are used. It is an opportunistic pathogen that causes infections in patients who are immunocompromised or have diseases or trauma of the oral cavity. *E. corrodens* is most commonly isolated in the settings of a **human bite wound** or fistfight injury. Other infections are endocarditis, sinusitis, meningitis, brain abscesses, pneumonia, and lung abscesses. Because most infections originate from the oropharynx, polymicrobial mixtures of aerobic and anaerobic bacteria are often present in cultures.

A slow-growing, fastidious organism, *E. corrodens* requires 5% to 10% carbon dioxide to grow. Small (0.5- to 1.0-mm) colonies are observed after 48 hours of incubation on blood or chocolate agar, but the organism grows poorly or not at all on selective media for gram-negative rods. Pitting in agar is a useful differential characteristic, but fewer than half of all isolates exhibit pitting. The organism also produces a characteristic bleachlike odor. Thus if a slow-growing gram-negative rod is found to pit blood agar and produce a bleachlike odor, a preliminary identification of the organism can be made. *E. corrodens* is susceptible to penicillin (unusual for a gram-negative bacterium), ampicillin, extended-spectrum cephalosporins, tetracyclines, and fluoroquinolones, but it is resistant to oxacillin, first-generation cephalosporins, clindamycin, erythromycin, and the aminoglycosides. Thus *E. corrodens* is resistant to many antibiotics that are selected empirically to treat bite-wound infections.

KINGELLA KINGAE

Kingella species are small gram-negative coccobacilli that morphologically resemble *Neisseria* species and reside in the human oropharynx. The bacteria are facultatively anaerobic, ferment carbohydrates, and have fastidious growth requirements. *K. kingae,* the most commonly isolated species, has been primarily responsible for septic arthritis in children and endocarditis in patients of all ages. Because the organism grows slowly, it may take 3 or more days of incubation for the organism to be detected in clinical specimens. Most strains are susceptible to β-lactam antibiotics, including penicillin, tetracyclines, erythromycin, fluoroquinolones, and aminoglycosides.

Case Study and Questions

A 22-year-old female schoolteacher was brought to the emergency room after a 2-day history of headache and fever. On the day of admission, the patient had failed to come to school and could not be reached by telephone. When notified of this fact, the patient's mother went to her daughter's apartment, where she found her daughter in bed, confused and highly agitated. The patient was rushed to the local hospital, where she was comatose on arrival. Purpuric skin lesions were present on her trunk and arms. Analysis of her CSF revealed the presence of 380 cells/mm^3 (93% polymorphonuclear leukocytes), a protein concentration of 220 mg/dl, and a glucose concentration of 32 mg/dl. Gram staining of CSF showed many gram-negative diplococci, and the same organisms were isolated from blood and CSF. The patient died despite prompt initiation of therapy with penicillin.

1. What is the most likely organism responsible for this fulminant disease? What is the most likely source of this organism?

2. Chemoprophylaxis should be administered to which people? What are the criteria for administering chemoprophylaxis?

3. What other diseases does this organism cause?

4. What virulence factors have been associated with other bacterial species in this genus?

24 Haemophilus *and Related Bacteria*

A 10-year-old boy was catching and throwing a baseball with a friend. When he missed catching the ball, he ran into a neighbor's yard to retrieve the ball. His motion surprised a sleeping dog who then barked and bit the boy in the leg. The bite broke the skin but otherwise did not hurt the boy. He ran back to his friend and continued tossing the ball, not terribly concerned by the bite. Two days later the bite wound became erythematous and painful, and a serous discharge was present. His mother took the boy to the local emergency clinic, where cultures were performed and antibiotics started. The next day the laboratory reported that it had isolated a gram-negative rod that was subsequently identified as Pasteurella multocida. This organism is a member of the family Pasteurellaceae, which is a heterogeneous collection of small gram-negative rods.

1. What are the most common infections associated with *Haemophilus influenzae* type b, *Aggregatibacter*, and *Pasteurella?*
2. Why is disease with *H. influenzae* type b uncommon in the United States?
3. Why is detection of the capsular polysaccharide (i.e., polyribitol phosphate [PRP]) in *H. influenzae* of limited value?
4. What is the treatment of choice for *Pasteurella* infections?

Answers to these questions are available on Student Consult.com.

Summaries Clinically Significant Organisms

HAEMOPHILUS

Trigger Words

Coccobacilli, type b, PRP, meningitis, chancroid, vaccine

Biology and Virulence

- Small, pleomorphic, gram-negative rods or coccobacilli
- Facultative anaerobes, fermentative
- Most species require X and/or V factor for growth
- *Haemophilus influenzae* subdivided serologically (types a to f) and biochemically (biotypes I to VIII)
- *H. influenzae* type b is clinically most virulent (with PRP in capsule)
- *Haemophilus* adhere to host cells via pili and nonpilus structures

Epidemiology

- *Haemophilus* species commonly colonized in humans, although encapsulated *Haemophilus* species, particularly *H. influenzae* type b, are uncommon members of normal flora
- Disease caused by *H. influenzae* type b was primarily a pediatric problem; eliminated in immunized populations
- *H. ducreyi* disease is uncommon in the United States
- With the exception of *H. ducreyi,* which is spread by sexual contact, most *Haemophilus* infections are caused by the patient's oropharyngeal flora (endogenous infections)
- Patients at greatest risk for disease are those with inadequate levels of protective antibodies, those with depleted complement, and those who have undergone splenectomy

Diseases

- Refer to Table 24.2 for a summary of diseases

Diagnosis

- Microscopy is a sensitive test for detecting *H. influenzae* in cerebrospinal fluid, synovial fluid, and lower respiratory specimens but not from other sites
- Culture is performed using chocolate agar
- Antigen tests are specific for *H. influenzae* type b; therefore these tests are nonreactive for infections caused by other organisms

Treatment, Prevention, and Control

- *Haemophilus* infections are treated with broad-spectrum cephalosporins, amoxicillin, azithromycin, doxycycline, or fluoroquinolones; susceptibility to amoxicillin should be documented
- Active immunization with conjugated PRP vaccines prevents most *H. influenzae* type b infections

PRP, Polyribitol phosphate.

The three most important genera in the family Pasteurellaceae are ***Haemophilus, Aggregatibacter,*** and ***Pasteurella*** (Table 24.1), and they are responsible for a broad spectrum of diseases (Box 24.1). The members of this family are small (0.2 to 0.3 × 1.0 to 2.0 μm), facultative anaerobic, gram-negative rods. Most have fastidious properties, requiring enriched media for isolation. Members of the genus *Haemophilus,* particularly *H. influenzae,* are the most common pathogens in this family and will be the main focus of this chapter (Table 24.2).

Haemophilus

Haemophilae are small, sometimes pleomorphic, gram-negative rods present on the mucous membranes of

humans (Fig. 24.1). ***H. influenzae*** is the species most commonly associated with disease, although introduction of the *H. influenzae* type b vaccine has dramatically reduced the incidence of disease, particularly in the pediatric population. ***H. aegyptius*** is an important cause of acute purulent conjunctivitis. ***H. ducreyi*** is recognized as the etiologic agent of the sexually transmitted disease **soft chancre** or **chancroid.** The other members of the genus are commonly isolated in clinical specimens (e.g., *H. parainfluenzae* is the most common species in the mouth) but are rarely pathogenic, and are responsible primarily for opportunistic infections.

PHYSIOLOGY AND STRUCTURE

The growth of most species of *Haemophilus* requires supplementation of media with one or both of the following growth-stimulating factors: (1) **hemin** (also called **X factor** for "unknown factor") and (2) **nicotinamide adenine dinucleotide** (**NAD;** also called **V factor** for "vitamin"). Although both factors are present in blood-enriched media, sheep blood agar must be gently heated to destroy the inhibitors of V factor. For this reason, heated blood ("chocolate") agar is used for the isolation of *Haemophilus* in culture.

The cell wall structure of *Haemophilus* is typical of other gram-negative rods. Lipopolysaccharide with endotoxin activity is present in the cell wall, and strain-specific and species-specific proteins are found in the outer membrane. Analysis of these strain-specific proteins is valuable in epidemiologic investigations. The surface of many, but not all, strains of *H. influenzae* are covered with a **polysaccharide capsule,** and six antigenic serotypes (a through f) have been identified. Before the introduction of the *H. influenzae* type b vaccine, ***H. influenzae* serotype** b was responsible for more than 95% of all invasive *Haemophilus* infections. After introduction of the vaccine, most disease caused by this serotype disappeared in vaccinated populations, and more than half of all invasive disease is now caused by nonencapsulated (nontypeable) strains. The incidence of *Haemophilus* serotype b disease has not increased since 2000, whereas disease caused by other serotypes or nontypeable strains has slowly increased in the United States.

In addition to the serologic differentiation of *H. influenzae,* the species is subdivided into eight **biotypes** (I through VIII) as determined by three biochemical reactions: indole production, urease activity, and ornithine decarboxylase activity. The separation of these biotypes is useful for epidemiologic purposes.

TABLE 24.1 Important Pasteurellaceae

Organism	Historical Derivation
Haemophilus	*haemo,* blood; *hilos,* lover ("blood lover"; requires blood for growth on agar media)
H. influenzae	Originally thought to be the cause of influenza
H. aegyptius	*aegyptius,* Egyptian (observed by Robert Koch in 1883 in exudates from Egyptians with conjunctivitis)
H. ducreyi	Named after the bacteriologist Ducrey, who first isolated this organism
Aggregatibacter	*aggregare,* to come together; *bacter,* bacterial rod; rod-shaped bacteria that aggregate or clump together
A. actinomycetemcomitans	*comitans,* accompanying ("accompanying an actinomycete"; isolates are frequently associated with *Actinomyces*)
A. aphrophilus	*aphros,* foam; *philos,* loving ("foam loving")
Pasteurella	Named after Louis Pasteur
P. multocida	*multus,* many; *cidus,* to kill ("many-killing"; pathogenic for many species of animals)
P. canis	*canis,* dogs (isolated from the mouths of dogs)

PATHOGENESIS AND IMMUNITY

Haemophilus species, particularly *H. parainfluenzae* and nonencapsulated *H. influenzae,* colonize the upper respiratory tract in virtually all people within the first few months of life. These organisms can spread locally and cause disease in the ears (otitis media), sinuses (sinusitis), and lower respiratory tract (bronchitis, pneumonia). Disseminated disease, however, is relatively uncommon. In contrast, encapsulated *H. influenzae* (particularly serotype b [biotype I]) is uncommon in the upper respiratory tract or is present in only very small numbers, but it is a common cause of disease in unvaccinated children (i.e., meningitis,

BOX 24.1 Pasteurellaceae: Clinical Summaries

Haemophilus influenzae

Meningitis: a disease primarily of unimmunized children characterized by fever, severe headache, and systemic signs

Epiglottitis: a disease primarily of unimmunized children characterized by initial pharyngitis, fever, and difficulty breathing, and progressing to cellulitis and swelling of the supraglottic tissues, with obstruction of the airways possible

Pneumonia: inflammation and consolidation of the lungs observed primarily in the elderly with underlying chronic pulmonary disease; typically caused by nontypeable strains

Haemophilus aegyptius

Conjunctivitis: an acute purulent conjunctivitis ("pink eye")

Haemophilus ducreyi

Chancroid: sexually transmitted disease characterized by a tender papule with an erythematous base that progresses to painful ulceration with associated lymphadenopathy

Aggregatibacter actinomycetemcomitans

Endocarditis: responsible for subacute form of endocarditis in patients with underlying damage to the heart valve

Aggregatibacter aphrophilus

Endocarditis: as with *A. actinomycetemcomitans*

Pasteurella multocida

Bite wound: most common manifestation is infected cat or dog bite wound; particularly common with cat bites because the wounds are deep and difficult to disinfect

TABLE 24.2 *Haemophilus* Species Associated with Human Disease

Species	Primary Diseases	Frequency
Haemophilus influenzae	Pneumonia, sinusitis, otitis, meningitis, epiglottitis, cellulitis, bacteremia	Common worldwide; uncommon in United States
H. aegyptius	Conjunctivitis	Uncommon
H. ducreyi	Chancroid	Uncommon in United States
H. parainfluenzae	Bacteremia, endocarditis, opportunistic infections	Rare

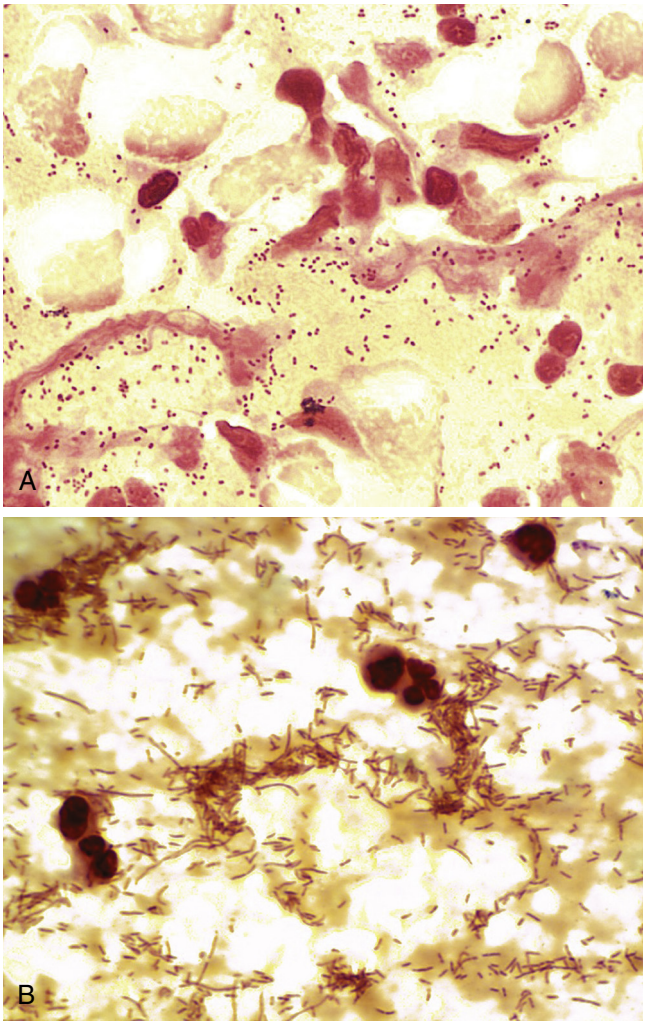

Fig. 24.1 Gram stains of *Haemophilus influenzae.* (A) Small coccobacilli forms seen in sputum from patient with pneumonia. (B) Thin pleomorphic forms seen in a 1-year-old unvaccinated child in Africa with overwhelming meningitis and exposed to initial dose of ampicillin.

epiglottitis [obstructive laryngitis], cellulitis). Pili and nonpilus adhesins mediate colonization of the oropharynx with *H. influenzae.* Cell wall components of the bacteria (e.g., lipopolysaccharide and a low-molecular-weight glycopeptide) impair ciliary function, leading to damage of the respiratory epithelium. The bacteria can then be translocated across both epithelial and endothelial cells and can enter the blood. In the absence of specific opsonic antibodies directed against the polysaccharide capsule, high-grade bacteremia can develop with dissemination to the meninges or other distal foci.

The major virulence factor in *H. influenzae* type b is the antiphagocytic polysaccharide capsule, which contains ribose, ribitol, and phosphate (commonly referred to as **polyribitol phosphate [PRP]**). Antibodies directed against the capsule greatly stimulate bacterial phagocytosis and complement-mediated bactericidal activity. These antibodies develop because of natural infection, vaccination with purified PRP, or the passive transfer of maternal antibodies. The severity of systemic disease is inversely related to the rate of clearance of bacteria from the blood. The risk of meningitis and epiglottitis is significantly greater in patients with no anti-PRP antibodies, those with depletion of complement, and those who have undergone splenectomy. The lipopolysaccharide **lipid A** component induces meningeal inflammation in an animal model and may be responsible for initiating this response in humans. Immunoglobulin **(Ig)A1 proteases** are produced by *H. influenzae* (both encapsulated and nonencapsulated strains) and may facilitate colonization of the organisms on mucosal surfaces by interfering with humoral immunity.

EPIDEMIOLOGY

Haemophilus species are present in almost all individuals, primarily colonizing the mucosal membranes of the respiratory tract. *H. parainfluenzae* is the predominant *Haemophilus* species in the mouth. Nonencapsulated strains of *H. influenzae* are also commonly found in the upper respiratory tract; however, encapsulated strains are detectable only in small numbers and only when highly selective culture methods are used. Before the introduction of the *H. influenzae* vaccine, even though *H. influenzae* type b was the most common serotype that caused systemic disease, it was rarely isolated in healthy children (a fact that emphasizes the virulence of this bacterium).

The epidemiology of *Haemophilus* disease has changed dramatically. Before the introduction of **conjugated *H. influenzae* type b vaccines,** an estimated 20,000 cases of invasive *H. influenzae* type b disease occurred annually in children younger than age 5 years in the United States. The first polysaccharide vaccines for *H. influenzae* type b were not protective for children younger than 18 months (the population at greatest risk for disease) because there is a natural delay in the maturation of the immune response to polysaccharide antigens. When vaccines containing purified PRP antigens conjugated to protein carriers (i.e., diphtheria toxoid, tetanus toxoid, meningococcal outer membrane protein) were introduced in December 1987, a protective antibody response in infants aged 2 months and older was produced, and systemic disease in children younger than age 5 was virtually eliminated in the United States, with only 29 cases reported in

2015. Most of the *H. influenzae* type b infections now occur in children who are not immune (because of incomplete vaccination or a poor response to the vaccine) and in elderly adults with waning immunity. In addition, invasive *H. influenzae* disease caused by other serotypes of encapsulated bacteria and by nonencapsulated strains has now become proportionally more common than that resulting from serotype b. It should be noted that successful elimination of *H. influenzae* type b disease in the United States has not been seen in many developing countries in which vaccination programs have been difficult to implement. Thus *H. influenzae* type b remains the most significant pediatric pathogen in many countries of the world. It is estimated that 3 million cases of serious disease and up to 700,000 fatalities occur in children each year worldwide, which is a tragedy considering that vaccination could eliminate virtually all disease. The epidemiology of disease caused by nonencapsulated *H. influenzae* and other *Haemophilus* species is distinct. Ear and sinus infections caused by these organisms are primarily pediatric diseases but can occur in adults. Pulmonary disease most commonly affects elderly people, particularly those with a history of underlying chronic obstructive pulmonary disease (COPD) or conditions predisposing to aspiration (e.g., alcoholism, altered mental state).

H. ducreyi is an important cause of genital ulcers (chancroid) in Africa and Asia but is less common in Europe and North America. The incidence of disease in the United States is cyclic. A peak incidence of more than 5000 cases was reported in 1988, which decreased to 7 cases in 2016. Despite this favorable trend, the Centers for Disease Control and Prevention has documented that the disease is significantly unrecognized and underreported, making the true incidence unknown.

CLINICAL DISEASES

The clinical syndromes seen in patients with *H. influenzae* infections are represented in Fig. 24.2. The diseases caused by all *Haemophilus* species are described in the following sections (see Table 24.2).

Meningitis

H. influenzae type b was the most common cause of pediatric meningitis, but this situation changed rapidly when the conjugated vaccines became widely used. Disease in nonimmune patients results from bacteremic spread of the organisms from the nasopharynx and cannot be differentiated clinically from other causes of bacterial meningitis. The initial presentation is a 1- to 3-day history of mild upper respiratory disease, after which the typical signs and symptoms of meningitis appear. Mortality is less than 10% in patients who receive prompt therapy, and carefully designed studies have documented a low incidence of serious neurologic sequelae (in contrast with the 50% incidence of severe residual damage reported in nonimmune children seen in early studies). Person-to-person spread in a nonimmune population is well documented, so appropriate epidemiologic precautions must be used.

Epiglottitis

Epiglottitis, characterized by cellulitis and the swelling of the supraglottic tissues, represents a life-threatening emergency. Although epiglottitis is a pediatric disease, the peak incidence of this disease during the prevaccine era occurred in children 2 to 4 years of age; in contrast, the peak incidence of meningitis was seen in children 3 to 18 months of age. Children with epiglottitis have pharyngitis, fever, and difficulty breathing, which can progress rapidly to obstruction of the airway and death. Since the introduction of the vaccine, the incidence of this disease has also decreased dramatically in children and remains relatively rare in adults.

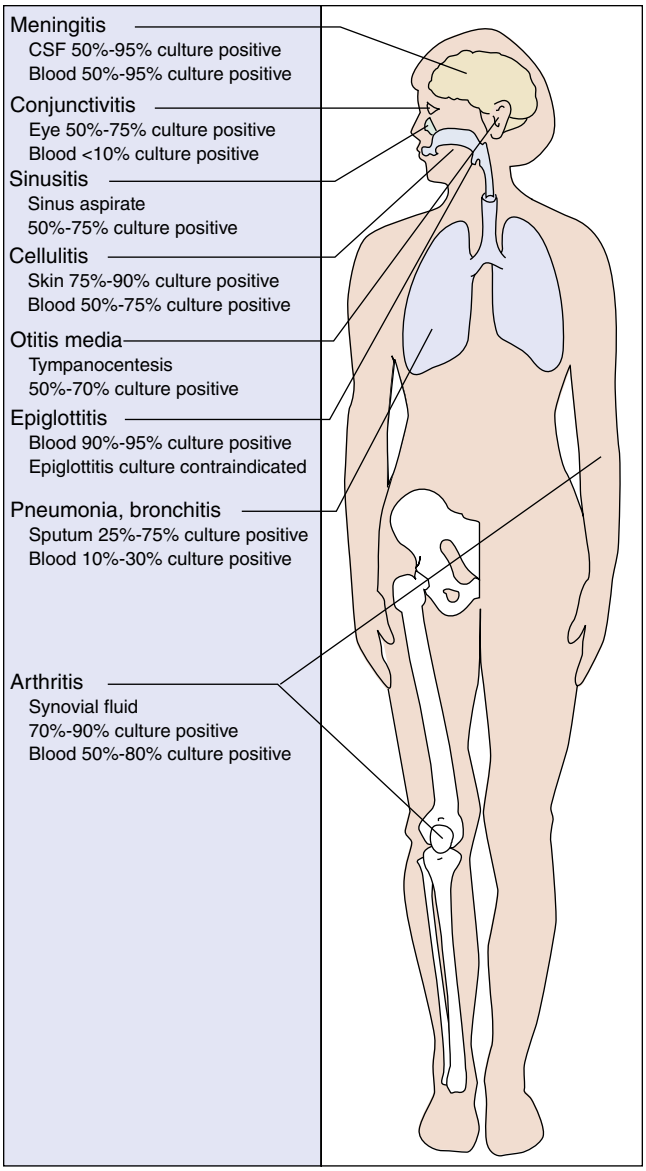

Fig. 24.2 Infections caused by *Haemophilus influenzae.* With the advent of the conjugated vaccine, most infections in adults involve areas contiguous with the oropharynx (i.e., lower respiratory tract, sinuses, ears). Serious systemic infections (e.g., meningitis, epiglottitis) can occur in nonimmune patients. *CSF,* Cerebrospinal fluid.

Cellulitis

Like meningitis and epiglottitis, cellulitis is a pediatric *H. influenzae* disease that has largely been eliminated by vaccination. When it is observed, patients have fever and cellulitis characterized by the development of reddish-blue patches on the cheeks or periorbital areas. The diagnosis is strongly suggested by the typical clinical presentation, cellulitis proximal to the oral mucosa, and lack of documented vaccination in the child.

Arthritis

Before the advent of conjugated vaccines, the most common form of arthritis in children younger than 2 years was an infection of a single, large joint secondary to bacteremic spread of *H. influenzae* type b. Disease does occur in older children and adults, but it is very uncommon and generally affects immunocompromised patients and patients with previously damaged joints.

Otitis, Sinusitis, and Lower Respiratory Tract Disease

Nonencapsulated strains of *H. influenzae* are opportunistic pathogens that can cause infections of the upper and lower airways. Most studies have shown that *H. influenzae* and *Streptococcus pneumoniae* are the two most common causes of acute and chronic otitis and sinusitis. Primary pneumonia is uncommon in children and adults who have normal pulmonary function. These organisms commonly colonize patients who have chronic pulmonary disease (including cystic fibrosis), and are frequently associated with exacerbation of bronchitis and frank pneumonia (Clinical Case 24.1).

Conjunctivitis

H. aegyptius, also called the **Koch-Weeks bacillus,** causes an acute purulent conjunctivitis. This contagious organism is associated with epidemics, particularly during the warm months of the year.

Chancroid

Chancroid, caused by H. ducreyi, is a sexually transmitted disease that is most commonly diagnosed in men, presumably because women can have asymptomatic or inapparent disease. Approximately 5 to 7 days after exposure, a tender papule with an erythematous base develops on the genitalia or perianal area. Within 2 days the lesion ulcerates and becomes **painful,** and inguinal **lymphadenopathy** is commonly present. Other causes of genital ulcers, such as syphilis and herpes simplex disease, must be excluded to confirm the diagnosis of chancroid.

Other Infections

Other species of *Haemophilus* can cause opportunistic infections such as otitis media, conjunctivitis, sinusitis, endocarditis, meningitis, and dental abscesses.

Clinical Case 24.1 **Pneumonia Caused by *Haemophilus influenzae***

Holmes and Kozinn (*J Clin Microbiol* 18:730–732, 1983) described a 61-year-old woman with pneumonia caused by *Haemophilus influenzae* serotype d. The patient had a long history of smoking, chronic obstructive lung disease, diabetes mellitus, and congestive heart failure. She presented with left upper lobe pneumonia, producing purulent sputum with many gram-negative coccobacilli. Both sputum and blood cultures were positive for *H. influenzae* serotype d. The organism was susceptible to ampicillin, to which the patient responded. This case illustrates the susceptibility of patients with chronic underlying pulmonary disease to infections with non–serotype b strains of *H. influenzae*.

LABORATORY DIAGNOSIS

Specimen Collection and Transport

Because most *Haemophilus* infections in vaccinated individuals originate from the oropharynx and are restricted to the upper and lower respiratory tract, contamination of the specimen with oral secretions should be avoided. Direct needle aspiration should be used for the microbiological diagnosis of sinusitis or otitis, and sputum produced from the lower airways is used for the diagnosis of pneumonia. Culture of blood for patients with pneumonia may be useful but would be predictably negative in patients with upper respiratory infections. Both blood and cerebrospinal fluid (CSF) should be collected from patients with the diagnosis of meningitis. Because there are approximately 10^7 bacteria per milliliter of CSF in patients with untreated meningitis, 1 to 2 ml of fluid is generally adequate for microscopy, culture, and antigen-detection tests. Microscopy and culture are less sensitive if the patient has been exposed to antibiotics before the CSF is collected. Blood cultures should also be collected for the diagnosis of epiglottitis, cellulitis, and arthritis. Specimens should not be collected from the posterior pharynx in patients with suspected epiglottitis because the procedure may stimulate coughing and obstruct the airway. Specimens for the detection of *H. ducreyi* should be collected with a moistened swab from the base or margin of the ulcer. Culture of pus collected by aspiration from an enlarged lymph node can be performed but is generally less sensitive than culture of the ulcer. The laboratory should be notified that *H. ducreyi* is suspected because special culture techniques must be used for recovery of the organism.

Microscopy

If microscopy is performed carefully, the detection of *Haemophilus* species in clinical specimens is both sensitive and specific. Gram-negative rods ranging in shape from coccobacilli to long, pleomorphic filaments can be detected in more than 80% of CSF specimens from patients with untreated *Haemophilus* meningitis (see Fig. 24.1). Microscopic examination of Gram-stained specimens is also useful for the rapid diagnosis of the organism in arthritis and lower respiratory tract disease.

Antigen Detection

The immunologic detection of *H. influenzae* antigen, specifically the PRP capsular antigen, is a rapid and sensitive way to diagnose *H. influenzae* type b disease. PRP can be detected with the particle agglutination test, which can detect less than 1 ng/ml of PRP in a clinical specimen. In this test, antibody-coated latex particles are mixed with the clinical specimen; agglutination occurs if PRP is present. Antigen can be detected in CSF and urine (in which the antigen is eliminated intact). However, this test has limited use because it can detect only *H. influenzae* type b, which is now uncommon in the United States and other countries with an established vaccine program. Other capsular serotypes and nonencapsulated strains do not give a positive reaction.

Culture

It is relatively easy to isolate *H. influenzae* from clinical specimens inoculated onto media supplemented with the appropriate growth factors. Chocolate agar is used in most

laboratories. However, if chocolate agar is overheated during preparation, V factor is destroyed, and *Haemophilus* species requiring this growth factor (e.g., *H. influenzae, H. aegyptius, H. parainfluenzae*) will not grow. The bacteria appear as 1- to 2-mm, smooth, opaque colonies after 24 hours of incubation. They can also be detected growing around colonies of *Staphylococcus aureus* on unheated blood agar (**satellite phenomenon** [Fig. 24.3]). The staphylococci provide the requisite growth factors by lysing the erythrocytes in the medium and releasing intracellular heme (X factor) and excreting NAD (V factor). The colonies of *H. influenzae* in these cultures are much smaller than they are on chocolate agar because the V factor inhibitors present in blood are not inactivated.

The growth of *Haemophilus* in blood cultures is generally delayed because most commercially prepared blood culture broths are not supplemented with optimum concentrations of X and V factors and inhibitors of V factor. Furthermore, the growth factors are released only when the blood cells lyse. Isolates of *H. influenzae* often grow better in anaerobically incubated blood cultures because, under these conditions, the organisms do not require X factor for growth.

H. aegyptius and *H. ducreyi* are fastidious and require specialized growth conditions. *H. aegyptius* grows best on chocolate agar supplemented with 1% IsoVitaleX (mixture of chemically defined supplements), with growth detected after incubation in a carbon dioxide atmosphere for 2 to 4 days. Culture for *H. ducreyi* is relatively insensitive (<85% of cultures yield organisms under optimal conditions) but reportedly is best on gonococcal (GC) agar supplemented with 1% to 2% hemoglobin, 5% fetal bovine serum, IsoVitaleX enrichment, and vancomycin (3 μg/ml). Cultures should be incubated at 33° C in 5% to 10% carbon dioxide for 7 days or more. Because the media and incubation conditions are not used for other bacterial cultures, success in recovering *H. ducreyi* requires that the microbiologist look specifically for this organism.

Identification

A presumptive identification of *H. influenzae* can be made by the Gram stain morphology and demonstration of a requirement for both X and V factors. Further subgrouping of *H. influenzae* can be done with biotyping, electrophoretic characterization of the membrane protein antigens, and analysis of the strain-specific nucleic acid sequences. Biochemical tests, nucleic acid analysis, or mass spectrometry is used to identify other species in this genus.

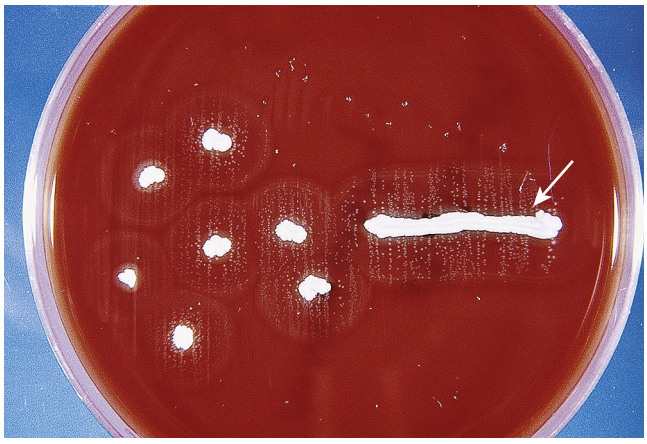

Fig. 24.3 Satellite phenomenon. *Staphylococcus aureus* excretes nicotinamide adenine dinucleotide (NAD, or V factor) into the medium, providing a growth factor required for *Haemophilus influenzae* (small colonies surrounding *S. aureus* colonies *[arrow]*).

TREATMENT, PREVENTION, AND CONTROL

Patients with systemic *H. influenzae* infections require prompt antimicrobial therapy because the mortality rate in patients with untreated meningitis or epiglottitis approaches 100%. Serious infections are treated with **broad-spectrum cephalosporins.** Less severe infections, such as sinusitis and otitis, can be treated with amoxicillin (if susceptible; approximately 30% of strains are resistant), an active cephalosporin, azithromycin, doxycycline, or a fluoroquinolone. Most isolates of *H. ducreyi* are susceptible to **erythromycin,** which is the drug recommended for treatment.

The primary approach to preventing *H. influenzae* type b disease is through active immunization with purified capsular PRP. As discussed previously, the use of conjugated vaccines has been remarkably successful in reducing the incidences of *H. influenzae* type b disease and colonization. Currently, it is recommended that children receive two or three doses of vaccine against *H. influenzae* type b disease before the age of 6 months, followed by a booster dose at age 12 to 15 months.

Antibiotic chemoprophylaxis is used to eliminate the carriage of *H. influenzae* type b in children at high risk for disease (e.g., children <2 years in a family or day-care center in which systemic disease is documented). Rifampin prophylaxis has been used in these settings.

Aggregatibacter

Two members of this genus are important human pathogens: ***A. actinomycetemcomitans*** and ***A. aphrophilus*** (Table 24.3). Both species colonize the human mouth and can spread from the mouth into the blood and then stick to a previously damaged heart valve or artificial valve, leading to the development of endocarditis. **Endocarditis** caused by these bacteria is particularly difficult to diagnose because clinical signs and symptoms develop slowly **(subacute endocarditis)** and the bacteria grow slowly in blood cultures. (Clinical Case 24.2) Both species form adherent colonies that can be observed on the glass surface of blood culture bottles and on agar media. The treatment of choice for endocarditis caused by these organisms is a cephalosporin such as ceftriaxone.

Pasteurella

Pasteurella are small, facultatively anaerobic, fermentative coccobacilli (Fig. 24.4) commonly found as commensals in the oropharynx of healthy animals. Most human infections result from animal contact (e.g., animal bites, scratches, shared food). ***P. multocida*** (the most common isolate) and ***P. canis*** are human pathogens; the other *Pasteurella* species are rarely associated with human infections (Table 24.4). The following three general forms of disease are reported: (1) localized **cellulitis** and **lymphadenitis** that occur after an animal bite or scratch (*P. multocida* from contact with cats or dogs; *P. canis* from dogs); (2) an exacerbation of chronic **respiratory disease** in patients with underlying pulmonary dysfunction (presumably related to colonization of the patient's oropharynx followed by the aspiration of oral secretions); and (3) a **systemic infection in immunocompromised patients,** particularly those with underlying hepatic disease. Production of a polysaccharide capsule composed of hyaluronic acid is an important

TABLE 24.3 *Aggregatibacter* and *Pasteurella* Species Associated with Human Disease

Species	Primary Diseases	Frequency
Aggregatibacter actinomycetemcomitans	Periodontitis, endocarditis, bite wound infections	Common
A. aphrophilus	Endocarditis, opportunistic infections	Uncommon
Pasteurella multocida	Bite wound infections, chronic pulmonary disease, bacteremia, meningitis	Common
P. canis	Bite wound infections	Uncommon

TABLE 24.4 *Pasteurella* Species Associated with Human Disease

Species	Primary Disease	Frequency
P. multocida	Bite wound infections, chronic pulmonary disease, bacteremia, meningitis	Common
P. canis	Bite wound infections	Uncommon
P. bettyae	Opportunistic infections (abscesses, bite wound infections, urogenital infections, bacteremia)	Rare
P. dagmatis	Bite wound infections	Rare
P. stomatis	Bite wound infections	Rare

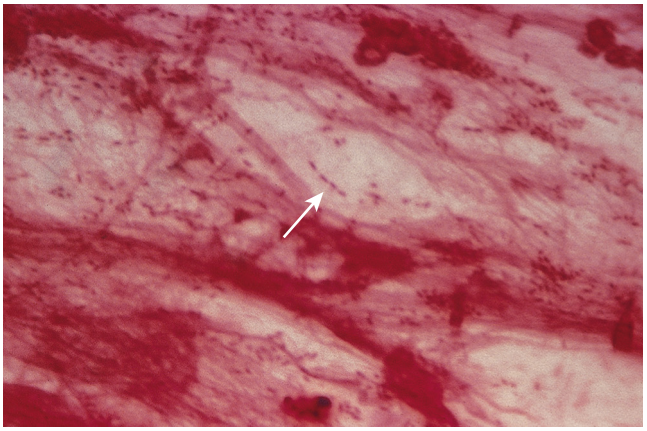

Fig. 24.4 *Pasteurella multocida* in respiratory specimen from patient with pneumonia *(arrow)*.

Clinical Case 24.2 **Endocarditis Caused by *Aggregatibacter actinomycetemcomitans***

Steitz and associates (*Clin Infect Dis* 27:224–225, 1998) described a 54-year-old woman who was admitted to their hospital with a history of fever, night sweats, and fatigue. Physical examination revealed a tricuspid systolic murmur and splenomegaly, and echocardiography revealed vegetation on the tricuspid valve. Cultures of blood collected on admission were positive after 5 days of incubation for *Aggregatibacter (Actinobacillus) actinomycetemcomitans*. Her clinical history was incomplete because it was not known how chronic her course was; however, this case illustrates the slow growth of the organism in routine culture.

virulence factor in *Pasteurella* strains responsible for animal diseases and is likely to be important in human infections (Clinical Case 24.3).

P. multocida grows well on blood and chocolate agars but poorly on MacConkey agar and other media typically selective for gram-negative rods. After overnight incubation on blood agar, large buttery colonies (resulting from the polysaccharide capsule) with a characteristic musty odor caused by the production of indole are present. *P. multocida* is susceptible to a variety of antibiotics. **Penicillin** is the antibiotic of choice, and expanded-spectrum cephalosporins, macrolides, tetracyclines, or fluoroquinolones are acceptable alternatives. Semisynthetic penicillins (e.g., oxacillin), first-generation cephalosporins, and aminoglycosides have poor activity.

Clinical Case 24.3 **Fatal *Pasteurella multocida* Infection**

Chang and associates (*Scan J Infect Dis* 39:167–192, 2007) described a fatal case of *Pasteurella multocida* bacteremia and necrotizing fasciitis. The 58-year-old man had a history of chronic renal insufficiency, gouty arthritis, and Cushing syndrome treated with steroids. On admission to the hospital, his left hand was erythematous, warm, and tender with reddish to purplish macules over the surface. Over a 2-day period, bullae developed and extended rapidly to the left arm, left calf, and right foot, and the patient had systemic signs of shock and gastrointestinal bleeding. Blood cultures collected at the time of admission were positive for *P. multocida*. Despite aggressive antibiotic and surgical treatment, the lesions progressed rapidly and the patient eventually expired. A careful history at the time of admission revealed that the patient allowed his pet dog to lick his open wounds. This was the likely source of the bacteria, and the steroid treatments allowed the organism to invade the wound and rapidly spread in the tissues.

Case Study and Questions

A 78-year-old man confined to a nursing home awoke with a severe headache and stiff neck. Because he had a high fever and signs of meningitis, the nursing home staff took him to a local emergency department. The CSF specimen was cloudy. Analysis revealed 400 white blood cells/mm^3 (95% polymorphonuclear neutrophils), a protein concentration of 75 mg/dl, and a glucose concentration of 20 mg/dl. Small gram-negative rods were seen on Gram stain of the CSF, and cultures of CSF and blood were positive for *H. influenzae.*

1. Discuss the epidemiology of *H. influenzae* meningitis, and compare it with the epidemiology of meningitis caused by *S. pneumoniae* and *Neisseria* meningitidis.

2. Compare the biology of the *H. influenzae* strain that is likely to be the cause of this patient's disease with that of the strains that historically caused pediatric diseases (before vaccination).

3. What other diseases does this organism cause? What other *Haemophilus* species cause disease, and what are the diseases?

4. Why is chocolate agar needed for the isolation of *Haemophilus* organisms?

5. What diseases are caused by *Aggregatibacter actinomycetemcomitans*? What is the source of this organism?

6. What diseases are caused by *P. multocida*? What is the source of this organism?

25 Enterobacteriaceae

This chapter covers the largest family of clinically important bacteria. This is a heterogeneous collection of organisms responsible for virtually all types of infections that would be seen in a clinical practice.

1. Many of the members of the Enterobacteriaceae family are part of the normal population of bacteria that colonize the human body. Give three examples of organisms that are normal flora in healthy individuals and an example of disease caused by each organism. What condition leads to disease with each?
2. Some Enterobacteriaceae are normally found in animals but cause disease when humans are exposed. Give three examples and the diseases they cause.
3. Some Enterobacteriaceae are strict human pathogens. Give two examples and the diseases they cause.

Answers to these questions are available on Student Consult.com.

Summaries Clinically Significant Organisms

ESCHERICHIA COLI

Trigger Words

Gastroenteritis, EAEC, EIEC, EPEC, ETEC, STEC, neonatal meningitis, urinary tract infection

Biology and Virulence

- Gram-negative, facultative anaerobic rods
- Fermenter; oxidase negative
- Lipopolysaccharide consists of outer somatic O polysaccharide, core polysaccharide (common antigen), and lipid A (endotoxin)
- Virulence: refer to Box 25.2 and Table 25.2

Epidemiology

- Most common aerobic gram-negative rods in the gastrointestinal tract
- Most infections are endogenous (patient's microbial flora), although strains causing gastroenteritis are generally acquired exogenously

Diseases

- At least five different pathogenic groups cause gastroenteritis: EAEC, EIEC, EPEC, ETEC, and STEC
- Most cause diseases in developing countries, although STEC is an important cause of hemorrhagic colitis and hemolytic uremic syndrome in the United States
- Extraintestinal disease includes bacteremia, neonatal meningitis, urinary tract infections, and intraabdominal infections

Diagnosis

- Organisms grow rapidly on most culture media
- Enteric multiplex NAATs considered gold standard diagnostic

Treatment, Prevention, and Control

- Enteric pathogens are treated symptomatically unless disseminated disease occurs
- Antibiotic therapy is guided by in vitro susceptibility tests; increased resistance to penicillins and cephalosporins mediated by ESBLs
- Appropriate infection-control practices are used to reduce the risk of nosocomial infections (e.g., restricting use of antibiotics, avoiding unnecessary use of urinary tract catheters)
- Maintenance of high hygienic standards to reduce the risk of exposure to gastroenteritis strains
- Proper cooking of beef products to reduce risk of STEC infections

SALMONELLA

Trigger Words

Gastroenteritis, enteric fever, antibiotic treatment

Biology and Virulence

- Gram-negative, facultative anaerobic rods
- Fermenter; oxidase negative
- Lipopolysaccharide consists of outer somatic O polysaccharide, core polysaccharide (common antigen), and lipid A (endotoxin)
- More than 2500 O serotypes
- Virulence: refer to Box 25.2; tolerant of acids in phagocytic vesicles
- Can survive in macrophages and spread from the intestine to other body sites

Epidemiology

- Most infections are acquired by eating contaminated food products (poultry, eggs, and dairy products are the most common sources of infection)
- Direct fecal-oral spread in children
- *Salmonella* Typhi and *Salmonella* Paratyphi are strict human pathogens (no other reservoirs); these infections are passed person to person; asymptomatic long-term colonization occurs commonly
- Individuals at risk for infection include those who eat improperly cooked poultry or eggs, patients with reduced gastric acid levels, and immunocompromised patients
- Infections occur worldwide, particularly in the warm months of the year

Diseases

- Diseases: enteritis (fever, nausea, vomiting, bloody or nonbloody diarrhea, abdominal cramps); enteric fever (typhoid fever, paratyphoid fever); bacteremia (most commonly seen with *Salmonella* serotype Typhi, *Salmonella* serotype Paratyphi, *Salmonella* serotype Choleraesuis); asymptomatic colonization (primarily with *Salmonella* Typhi and *Salmonella* Paratyphi)

Diagnosis

- Isolation from stool specimens requires use of selective media
- Enteric multiplex NAATs considered gold standard diagnostic

Treatment, Prevention, and Control

- Antibiotic treatment not recommended for enteritis because this may prolong the duration of disease
- Infections with *Salmonella* Typhi and *Salmonella* Paratyphi or disseminated infections with other organisms should be treated with an effective antibiotic (selected by in vitro susceptibility tests); fluoroquinolones (e.g., ciprofloxacin), chloramphenicol, trimethoprim-sulfamethoxazole, or a broad-spectrum cephalosporin may be used
- Most infections can be controlled by proper preparation of poultry and eggs (completely cooked) and avoidance of contamination of other foods with uncooked poultry products
- Carriers of *Salmonella* Typhi and *Salmonella* Paratyphi should be identified and treated
- Vaccination against *Salmonella* Typhi can reduce the risk of disease for travelers into endemic areas

Continued

Summaries Clinically Significant Organisms—cont'd

SHIGELLA

Trigger Words

Gastroenteritis, dysentery, Shiga toxin

Biology and Virulence

- Gram-negative, facultatively anaerobic rods
- Fermenter; oxidase negative
- Lipopolysaccharide consists of somatic O polysaccharide, core polysaccharide (common antigen), and lipid A (endotoxin)
- Four species recognized: *S. sonnei* responsible for most infections in developed countries, *S. flexneri* for infections in developing countries, *S. dysenteriae* for the most severe infections, and *S. boydii* not commonly isolated
- Virulence: refer to Box 25.2; exotoxin (Shiga toxin) produced by *S. dysenteriae* disrupts protein synthesis and produces endothelial damage

Epidemiology

- Humans are the only reservoir for these bacteria
- Disease spread person to person by fecal-oral route
- Patients at highest risk for disease are young children in day-care centers, nurseries, and custodial institutions; siblings and parents of these children; male homosexuals
- Relatively few organisms can produce disease (highly infectious)
- Disease occurs worldwide with no seasonal incidence (consistent with person-to-person spread involving a low inoculum)

Diseases

- Disease: most common form of disease is gastroenteritis (shigellosis), an initial watery diarrhea progressing within 1 to 2 days to abdominal cramps and tenesmus (with or without bloody stools); severe form of disease is caused by *S. dysenteriae* (bacterial dysentery); asymptomatic carriage develops in a small number of patients (reservoir for future infections)

Diagnosis

- Isolation from stool specimens requires use of selective media
- Enteric multiplex NAATs considered gold standard diagnostic

Treatment, Prevention, and Control

- Antibiotic therapy shortens the course of symptomatic disease and fecal shedding
- Treatment should be guided by in vitro susceptibility tests
- Empirical therapy can be initiated with a fluoroquinolone or trimethoprim-sulfamethoxazole
- Appropriate infection control measures should be instituted to prevent spread of the organism, including hand washing and proper disposal of soiled linens

YERSINIA

Trigger Words

Bubonic plague, pneumonic plague, gastroenteritis, transfusion sepsis

Biology and Virulence

- Gram-negative, facultatively anaerobic rods
- Fermenter; oxidase negative
- Lipopolysaccharide consists of somatic O polysaccharide, core polysaccharide (common antigen), and lipid A (endotoxin)
- *Y. pestis* is covered with a protein capsule
- Some species (e.g., *Y. enterocolitica*) can grow at cold temperatures (e.g., can grow to high numbers in contaminated refrigerated food or blood products)
- Virulence: refer to Box 25.2; capsule on *Y. pestis* is antiphagocytic; *Y. pestis* is resistant to serum killing; *Yersinia* with genes for adherence, cytotoxic activity, inhibition of phagocytic migration and engulfment, and inhibition of platelet aggregation

Epidemiology

- *Y. pestis* is a zoonotic infection, with humans the accidental host; natural reservoirs include rats, squirrels, rabbits, and domestic animals
- Disease is spread by flea bites or direct contact with infected tissues or person to person by inhalation of infectious aerosols from a patient with pulmonary disease
- Other *Yersinia* infections are spread through exposure to contaminated food products or blood products *(Y. enterocolitica)*
- Colonization with other *Yersinia* species can occur

Diseases

Y. pestis causes bubonic plague (most common) and pulmonary plague, both having a high mortality rate; other *Yersinia* species cause gastroenteritis (acute watery diarrhea or chronic diarrhea) and transfusion-related sepsis; enteric disease in children may manifest as enlarged mesenteric lymph nodes and mimic acute appendicitis

Diagnosis

- Organisms grow on most culture media; prolonged storage at 4° C can selectively enhance isolation

Treatment, Prevention, and Control

- *Y. pestis* infections are treated with streptomycin; tetracyclines, chloramphenicol, or trimethoprim-sulfamethoxazole can be administered as alternative therapy
- Enteric infections with other *Yersinia* species are usually self-limited; if antibiotic therapy is indicated, most organisms are susceptible to broad-spectrum cephalosporins, aminoglycosides, chloramphenicol, tetracyclines, and trimethoprim-sulfamethoxazole
- Plague is controlled by reduction of the rodent population and vaccination of individuals at risk
- Other *Yersinia* infections are controlled by proper preparation of food products

EAEC, Enteroaggregative *E. coli*; *EIEC,* enteroinvasive *E. coli*; *EPEC,* enteropathogenic *E. coli*; ESBL, extended-spectrum β-lactamase; *ETEC,* enterotoxigenic *E. coli*; *NAAT,* nucleic acid amplification test; *STEC,* Shiga toxin–producing *E. coli*.

The family Enterobacteriaceae is the largest, most heterogeneous collection of medically important gram-negative rods. More than 50 genera and hundreds of species and subspecies have been described (Table 25.1). These genera have been classified based on biochemical properties, antigenic structure, and molecular analysis of their genomes by gene sequencing and protein composition by mass spectrometry. Despite the complexity of this family, most human infections are caused by relatively few genera and species (Box 25.1).

Enterobacteriaceae are **ubiquitous** organisms found worldwide in soil, water, and vegetation and are part of the normal intestinal flora of most animals, including humans. These bacteria cause a variety of human diseases, including one-quarter to one-third of all bacteremias, more than 70% of urinary tract infections (UTIs), and many intestinal infections. Some organisms (e.g., *Salmonella* serotype Typhi, *Shigella* species, *Yersinia pestis*) are **always associated with human disease** when present in clinical specimens, whereas others (e.g., *Escherichia coli, Klebsiella pneumoniae, Proteus mirabilis*) are members of the normal commensal flora that can cause **opportunistic infections.** A third group of Enterobacteriaceae exists: those normally commensal organisms that become pathogenic when they acquire virulence genes present on plasmids, bacteriophages, or pathogenicity

TABLE 25.1 Important Enterobacteriaceae

Organism	Historical Derivation
Escherichia coli	*escherichia,* named after Escherich; *coli,* of the colon
Salmonella enterica	*salmonella,* named after Salmon; *enteron*, gut; pertaining to the gut
Salmonella Typhi	*typhi,* of typhoid; disease is typhoid fever
Salmonella Paratyphi	*paratyphi,* of a typhoid-like infection
Salmonella Choleraesuis	*cholera,* cholera; *sus,* hog; cholera of a hog
Salmonella Typhimurium	*typhi,* of typhoid; *murium,* of mice; *typhimurium,* typhoid of mice
Salmonella Enteritidis	*enteris,* gut; *idis,* inflammation
Shigella dysenteriae	*shigella,* named after Shiga; *dysenteriae,* dysentery
S. flexneri	*flexneri,* named after Flexner
S. boydii	*boydii,* named after Boyd
S. sonnei	*sonnei,* named after Sonne
Yersinia pestis	*yersinia,* named after Yersin; *pestis,* plague
Y. enterocolitica	*enterocolitica,* pertaining to the intestine and colon
Y. pseudotuberculosis	*tuberculum,* a small swelling; *pseudotuberculosis,* false swelling
Klebsiella pneumoniae	*klebsiella,* named after Klebs; *pneumoniae,* inflammation of the lungs
K. oxytoca	*oxus,* acid; *tokos,* producing; acid producing (refers to biochemical properties)
Proteus mirabilis	*proteus,* a god able to change himself into different shapes; *mirabilis,* surprising; refers to pleomorphic colony forms
Citrobacter freundii	*citrus,* lemon; *bacter,* a rod; citrate-utilizing rod; *freundii,* named after Freund
Citrobacter koseri	*koseri,* named after Koser
E. Enterobacter cloacae	enteron, intestine; bacter, a small rod; *cloacae,* of a sewer; originally isolated in sewage
Serratia marcescens	*serratia,* named after Serrati; *marcescens,* becoming weak, fading away; originally believed not virulent

BOX 25.1 Common Medically Important Enterobacteriaceae

Citrobacter freundii, C. koseri
Enterobacter cloacae
Escherichia coli
Klebsiella pneumoniae, K. oxytoca
Morganella morganii
Proteus mirabilis
Salmonella serotype Typhi, Salmonella nontyphoidal serotypes
Serratia marcescens
Shigella sonnei, S. flexneri
Yersinia pestis, Y. enterocolitica, Y. pseudotuberculosis

islands (e.g., *E. coli*). Infections with the Enterobacteriaceae can originate from an animal reservoir (e.g., most *Salmonella* species, *Yersinia* species), from a human carrier (e.g., *Shigella* species, *Salmonella* Typhi), or through the endogenous spread of organisms (e.g., spread of *E. coli* from the intestine to the peritoneal cavity after perforation of the intestine).

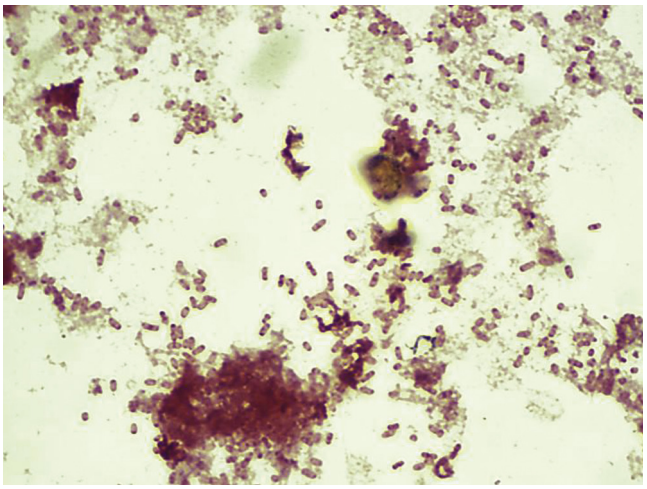

Fig. 25.1 Gram stain of *Salmonella* Typhi from a positive blood culture. Note the intense staining at the ends of the bacteria. This "bipolar staining" is characteristic of the Enterobacteriaceae.

General Properties

PHYSIOLOGY AND STRUCTURE

Members of the family Enterobacteriaceae are moderate-sized (0.3 to 1.0 × 1.0 to 6.0 μm), non–spore-forming, gram-negative rods (Fig. 25.1) that share a common antigen **(enterobacterial common antigen).** All members can grow rapidly, aerobically and anaerobically **(facultative anaerobes),** on a variety of nonselective (e.g., blood agar) and selective (e.g., MacConkey agar) media. The Enterobacteriaceae have simple nutritional requirements, ferment glucose, reduce nitrate, and are catalase positive and oxidase negative. The absence of cytochrome oxidase activity is an important characteristic, because it can be measured rapidly with a simple test and is used to distinguish the Enterobacteriaceae from many other fermentative (e.g., *Vibrio*) and nonfermentative (e.g., *Pseudomonas*) gram-negative rods.

The appearance of the bacteria on culture media is used to differentiate common members of the Enterobacteriaceae. For example, **fermentation of lactose** (detected by color changes in lactose-containing media such as the commonly used MacConkey agar) is used to differentiate some enteric pathogens that do not ferment lactose or do so slowly (e.g., *Salmonella, Shigella,* and *Yersinia* spp., which are colorless colonies on MacConkey agar) from lactose-fermenting species (e.g., *Escherichia, Klebsiella, Enterobacter, Citrobacter,* and *Serratia,* which are pink-purple colonies on MacConkey agar). **Resistance to bile salts** in some selective media has also been used to separate enteric pathogens (e.g., *Shigella, Salmonella*) from commensal organisms that are inhibited by bile salts (e.g., gram-positive and some gram-negative bacteria present in the gastrointestinal [GI] tract). In this way, use of culture media that assess lactose fermentation and resistance to bile salts is a rapid screening test for enteric pathogens that would be otherwise difficult

to detect in diarrheal stool specimens, in which many different organisms may be present. Some Enterobacteriaceae such as *Klebsiella* are also characteristically mucoid (wet, heaped, viscous colonies with prominent **capsules,** whereas a loose-fitting, diffusible slime layer surrounds other strains.

The heat-stable **lipopolysaccharide (LPS)** is the major cell wall antigen and consists of three components: the outermost somatic **O polysaccharide,** a **core polysaccharide** common to all Enterobacteriaceae (enterobacterial common antigen mentioned earlier), and **lipid A** (Fig. 25.2). The core polysaccharide is important for classifying an organism as a member of the Enterobacteriaceae; the O polysaccharide is important for the epidemiologic classification of strains within a species; and the lipid A component of LPS is responsible for endotoxin activity, which is an important virulence factor.

The epidemiologic (serologic) classification of the Enterobacteriaceae is based on three major groups of antigens: **somatic O polysaccharides, K antigens** in the capsule (type-specific polysaccharides), and **H proteins** in the bacterial flagella. Strain-specific O antigens are present in each genus and species, although cross-reactions between closely related genera are common (e.g., *Salmonella* with *Citrobacter, Escherichia* with *Shigella*). The K antigens are not commonly used for strain typing, but they are important because they may interfere with detection of the O antigens. The H antigens are heat-labile flagellin proteins. Detection of these various antigens has important clinical significance beyond epidemiologic investigations: some pathogenic species of bacteria are associated with specific O and H serotypes (e.g., *E. coli* O157:H7 is associated with diarrhea and hemorrhagic colitis).

Most Enterobacteriaceae are motile, with the exception of some common genera (e.g., *Klebsiella, Shigella, Yersinia*). The motile strains are coated with **flagella** (peritrichous). Many Enterobacteriaceae also possess fimbriae (also referred to as *pili*), which have been subdivided into two general classes:

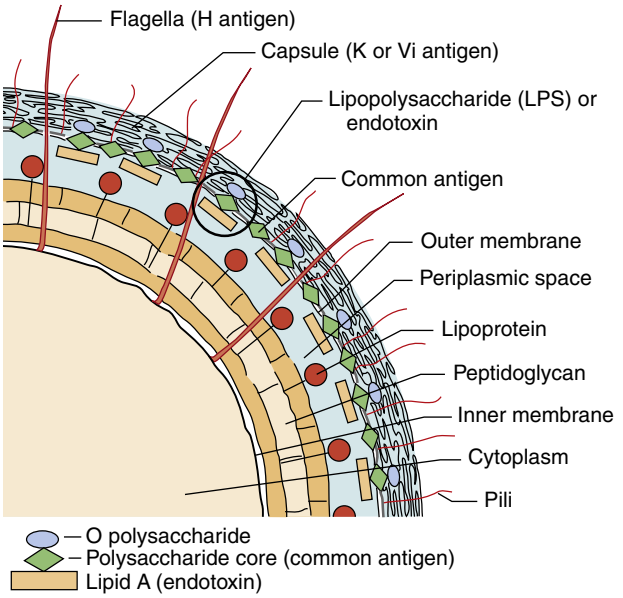

Fig. 25.2 Antigenic structure of Enterobacteriaceae cell wall.

chromosomally mediated common fimbriae and plasmid-encoded sex pili. The **common fimbriae** are important for the ability of bacteria to adhere to specific host cell receptors, whereas the **sex** or **conjugative pili** facilitate genetic transfer between bacteria.

PATHOGENESIS AND IMMUNITY

Numerous virulence factors have been identified in the members of the family Enterobacteriaceae. Some are common to all genera (Box 25.2), and others are unique to specific virulent strains.

Endotoxin

Endotoxin is a virulence factor shared among aerobic and some anaerobic gram-negative bacteria. The activity of this toxin depends on the **lipid A** component of LPS, which is released at cell lysis. Many of the systemic manifestations of gram-negative bacterial infections are initiated by endotoxin: activation of complement, release of cytokines, leukocytosis, thrombocytopenia, disseminated intravascular coagulation, fever, decreased peripheral circulation, shock, and death.

Capsule

Encapsulated Enterobacteriaceae are protected from phagocytosis by the hydrophilic capsular antigens, which repel the hydrophobic phagocytic cell surface. These antigens interfere with the binding of antibodies to the bacteria and are poor immunogens or activators of complement. The protective role of the capsule is diminished, however, if the patient develops specific anticapsular antibodies.

Antigenic Phase Variation

The expression of the somatic O antigens, capsular K antigens, and flagellar H antigens is under the genetic control of the organism. Each of these antigens can be alternately expressed or not expressed (phase variation), which is a feature that protects the bacteria from antibody-mediated cell death.

Type III Secretion Systems

A variety of bacteria (e.g., *Yersinia, Salmonella, Shigella,* enteropathogenic *Escherichia, Pseudomonas, Chlamydia*) have a common effector system for delivering their virulence factors into targeted eukaryotic cells. Think of the **type III secretion system** as a molecular syringe consisting of approximately 20 proteins that facilitate transfer of bacterial virulence factors into the targeted host cells. Although

BOX 25.2 Common Virulence Factors Associated with Enterobacteriaceae

Endotoxin
Capsule
Antigenic phase variation
Type III secretion systems
Sequestration of growth factors
Resistance to serum killing
Antimicrobial resistance

the virulence factors and their effects differ among the various gram-negative rods, the general mechanism by which the virulence factors are introduced is the same. In the absence of the type III secretion system, the bacteria have diminished virulence.

Sequestration of Growth Factors

Nutrients are provided to the organisms in enriched culture media, but the bacteria must become nutritional scavengers when growing in vivo. Iron is an important growth factor required by bacteria, but it is bound in **heme proteins** (e.g., hemoglobin, myoglobin) or in **iron-chelating proteins** (e.g., transferrin, lactoferrin). The bacteria counteract the binding by producing their own competitive **siderophores** or iron-chelating compounds (e.g., **enterobactin, aerobactin**). Iron can also be released from host cells by hemolysins produced by the bacteria.

Resistance to Serum Killing

Whereas many bacteria can be rapidly cleared from blood, virulent organisms capable of producing systemic infections are often resistant to serum killing. The bacterial capsule can protect the organism from serum killing and other factors that prevent the binding of complement components to the bacteria and subsequent complement-mediated clearance.

Antimicrobial Resistance

As rapidly as new antibiotics are introduced, organisms can develop resistance to them. This resistance can be encoded on transferable plasmids and exchanged among species, genera, and even families of bacteria. In recent years, acquisition of resistance genes has created some Enterobacteriaceae, particularly *Klebsiella*, resistant to all classes of antibiotics.

Escherichia coli

E. coli is the most common and important member of the genus *Escherichia*. This organism is associated with a variety of diseases, including gastroenteritis and extraintestinal infections such as UTIs, meningitis, and sepsis. A multitude of strains are capable of causing disease, with some serotypes associated with greater virulence (e.g., *E. coli* O157 is the most common cause of hemorrhagic colitis and hemolytic uremic syndrome [HUS]).

PATHOGENESIS AND IMMUNITY

E. coli possesses a broad range of virulence factors (Table 25.2). In addition to the general factors possessed by all members of the family Enterobacteriaceae, *Escherichia* strains possess specialized virulence factors that can be placed into two general categories: adhesins and exotoxins. The function of these factors will be discussed in greater detail in the following sections.

EPIDEMIOLOGY

Large numbers of *E. coli* are present in the GI tract. Although these organisms can be opportunistic pathogens when the intestines are perforated and the bacteria enter the peritoneal cavity, most *E. coli* that cause GI and extraintestinal disease do so because they have acquired specific virulence factors encoded on plasmids or in bacteriophage deoxyribonucleic acid (DNA). The effectiveness of *E. coli* as a pathogen is illustrated by the fact that the bacteria are (1) the most common gram-negative rods isolated from patients with sepsis (Fig. 25.3), (2) responsible for causing more than 80% of all community-acquired UTIs and many hospital-acquired infections, and (3) a prominent cause of gastroenteritis. Most infections (with the exception of gastroenteritis and neonatal meningitis) are endogenous; that is, the *E. coli* that are part of the patient's normal microbial flora are able to establish infection when the patient's defenses are compromised (e.g., through trauma or immune suppression).

TABLE 25.2 Specialized Virulence Factors Associated with *Escherichia coli*

Bacteria	Adhesins	Exotoxins
ETEC	Colonization factor antigens (CFA/I, CFA/II, CFA/III)	Heat-labile toxin (LT-1); heat-stable toxin (STa)
EPEC	BFP; intimin	—
EAEC	Aggregative adherence fimbriae (AAF/I, AAF/II, AAF/III)	Enteroaggregative heat-stable toxin; plasmid-encoded toxin
STEC	BFP; intimin	Shiga toxins (Stx1, Stx2)
EIEC	Invasive plasmid antigen	Hemolysin (HlyA)
Uropathogens	P pili; Dr fimbriae	—

BFP, Bundle-forming pili; *EAEC*, enteroaggregative *E. coli*; *EIEC*, enteroinvasive *E. coli*; *EPEC*, enteropathogenic *E. coli*; *ETEC*, enterotoxigenic *E. coli*; *STEC*, Shiga toxin–producing *E. coli*.

CLINICAL DISEASES

Gastroenteritis

The strains of *E. coli* that cause gastroenteritis are subdivided into a number of groups. Five of these groups will be the focus of this chapter: enterotoxigenic, enteropathogenic, enteroaggregative, Shiga toxin–producing, and enteroinvasive *E. coli* (EIEC) (Table 25.3). The first three groups primarily cause a secretory diarrhea involving the small intestine, and the last two groups primarily involve the large intestine.

TABLE 25.3 Gastroenteritis Caused by *Escherichia coli*

Organism	Site of Action	Disease	Pathogenesis	Diagnosis
ETEC	Small intestine	Traveler's diarrhea; infant diarrhea in developing countries; watery diarrhea, vomiting, cramps, nausea, low-grade fever	Plasmid-mediated, ST and LT enterotoxins that stimulate hypersecretion of fluids and electrolytes	Most U.S. outbreaks caused by ST-producing strains; commercial immunoassays available for detecting ST in clinical specimens and cultures; PCR assays used with clinical specimens
EPEC	Small intestine	Infant diarrhea in developing countries; watery diarrhea and vomiting, nonbloody stools; believed to be rare in United States	Plasmid-mediated A/E histopathology, with disruption of normal microvillus structure resulting in malabsorption and diarrhea	Characteristic adherence to HEp-2 or HeLa cells; probes and amplification assays developed for the plasmid-encoded bundle-forming pili and gene targets on the "locus of enterocyte effacement" pathogenicity island
EAEC	Small intestine	Infant diarrhea in developing and probably developed countries; traveler's diarrhea; persistent watery diarrhea with vomiting, dehydration, and low-grade fever	Plasmid-mediated aggregative adherence of rods ("stacked bricks") with shortening of microvilli, mononuclear infiltration, and hemorrhage; decreased fluid absorption	Characteristic adherence to HEp-2 cells; DNA probe and amplification assays developed for conserved plasmid
STEC	Large intestine	Initial watery diarrhea followed by grossly bloody diarrhea (hemorrhagic colitis) with abdominal cramps; little or no fever; may progress to hemolytic uremic syndrome	STEC evolved from EPEC; A/E lesions with destruction of intestinal microvilli, resulting in decreased absorption; pathology mediated by cytotoxic Shiga toxins (Stx1, Stx2), which disrupt protein synthesis	Screen for O157:H7 with sorbitol-MacConkey agar; confirm by serotyping; immunoassays (ELISA, latex agglutination) for detection of the Stx toxins in stool specimens and cultured bacteria; DNA amplification assays developed for Stx genes
EIEC	Large intestine	Rare in developing and developed countries; fever, cramping, watery diarrhea; may progress to dysentery with scant bloody stools	Plasmid-mediated invasion and destruction of epithelial cells lining colon	Sereny (guinea pig keratoconjunctivitis) test; plaque assay in HeLa cells; probes and amplification assays for genes regulating invasion (cannot discriminate between EIEC and *Shigella*)

A/E, Attachment/effacement; *DNA,* deoxyribonucleic acid; *EAEC,* enteroaggregative *E. coli*; *EIEC,* enteroinvasive *E. coli*; *ELISA,* enzyme-linked immunosorbent assay; *EPEC,* enteropathogenic *E. coli*; *ETEC,* enterotoxigenic *E. coli*; *LT,* labile toxin; *PCR,* polymerase chain reaction; *ST,* stable toxin; *STEC,* Shiga toxin–producing *E. coli*.

Enterotoxigenic *E. coli*

Enterotoxigenic *E. coli* (ETEC) is one of the most common causes of bacterial diarrheal disease in developing countries (estimated 840 million cases annually) and in an estimated 30% of travelers to these countries with diarrheal disease. Because the inoculum for disease is high, infections are primarily **acquired through consumption of fecally contaminated food or water.** Person-to-person spread does not occur. **Secretory diarrhea** caused by ETEC develops after a 1- to 2-day incubation period and persists for an average of 3 to 5 days. The symptoms (watery, nonbloody diarrhea and abdominal cramps; less commonly nausea and vomiting) are similar to those of cholera but are usually milder, although mortality is high in malnourished individuals and in those with underlying diseases, particularly children and the elderly.

Disease requires bacterial attachment to the small bowel epithelium by bacterial surface proteins (colonization factors [CFs]) and elaboration of heat-stable and heat-labile enterotoxins. The genes for the CFs and enterotoxins are encoded on a transmissible plasmid. The CFs are subdivided into families (CFA/I, CFA/II, and CFA/IV are the most common) and further subdivided by their antigenic properties (coli surface antigens [CSs]). More than 20 CS CFs have been described, and host specificity is defined by their affinity for receptors on host cells.

ETEC produce two classes of enterotoxins: **heat-stable toxins (STa and STb)** and **heat-labile toxins (LT-I, LT-II).** Heat-stable toxin STa but not STb is associated with human disease; it is found in 75% to 80% of ETEC, either alone or associated with LT, and is responsible more commonly for severe disease than LT-only ETEC strains. STa is a small monomeric peptide that binds to the transmembrane guanylate cyclase C receptor on the intestinal epithelium, leading to an **increase in cyclic guanosine monophosphate (cGMP)** and subsequent hypersecretion of fluids well as inhibition of fluid absorption. Of the heat-labile toxins, LT-I is more commonly associated with human disease. LT-I is functionally and structurally similar to cholera toxin (80% homology) and consists of one A subunit and five identical B subunits. The B subunits bind to the same receptor as cholera toxin (GM_1 gangliosides) and other surface glycoproteins on epithelial cells in the small intestine. After endocytosis, the A subunit moves across the membrane of the vacuole and interacts with a membrane protein (Gs) that regulates adenylate cyclase. The net effect of this interaction is an **increase in cyclic adenosine monophosphate (cAMP)** levels, resulting in enhanced secretion of chloride and decreased absorption of sodium and chloride. These changes are manifested in a watery diarrhea. Exposure to the toxin also stimulates prostaglandin secretion and production of inflammatory cytokines, resulting in further fluid loss.

Enteropathogenic *E. coli*. Two groups of *E. coli* responsible for enteric disease (enteropathogenic *E. coli* [EPEC] and some Shiga toxin–producing *E. coli* [STEC]) possess a

cluster of virulence genes located on a chromosomal pathogenicity island called the **locus of enterocyte effacement (LEE).** Bacteria in the heterogeneous EPEC group were the first *E. coli* strains associated with outbreaks of diarrheal disease reported in the 1940s and 1950s. They were originally characterized by the specific serotypes responsible for each outbreak but are now defined by the (1) presence of LEE and (2) absence of Shiga toxin. EPEC are further subdivided into typical and atypical strains based on the presence or absence of the ***E. coli* adherence factor (EAF) plasmid**. Sporadic disease and outbreaks are relatively uncommon in developed countries and are now reported only sporadically in impoverished countries, with disease primarily in infants and most commonly associated with the atypical strains. Disease is transmitted by fecal-oral exposure to contaminated surfaces or food products. Humans are the only source of typical strains, whereas both humans and a variety of animal hosts are reservoirs of atypical strains.

Infection is initiated by bacterial attachment to epithelial cells of the small intestine, with subsequent effacement (destruction) of the microvillus **(attachment/effacement [A/E] histopathology).** The initial aggregation of typical EPEC leading to the formation of microcolonies on the epithelial cell surface is mediated by plasmid-encoded **bundle-forming pili (BFP);** however, this plasmid is not present in atypical EPEC. The subsequent stages of attachment are regulated by genes encoded on the **LEE pathogenicity island.** This island of more than 40 genes is responsible for attachment and destruction of the host cell surface. After the loose attachment, active secretion of bacterial proteins into the host epithelial cell occurs by the bacterial type III secretion system. One protein, **translocated intimin receptor (Tir),** is inserted into the epithelial cell membrane and functions as a receptor for an outer membrane bacterial adhesin, **intimin.** Binding of intimin to Tir results in polymerization of actin, accumulation of cytoskeletal elements beneath the attached bacteria, loss of cell-surface integrity, and eventual cell death.

Disease occurs primarily in children younger than 2 years and is characterized by **watery diarrhea** that may be severe and protracted and is often accompanied by fever and vomiting. The onset of disease may be as rapid as a few hours after ingestion of EPEC, and although most infections resolve after a few days, persistent diarrhea requiring hospitalization can occur.

Enteroaggregative *E. coli*. Enteroaggregative *E. coli* (EAEC) are a heterogeneous collection of strains characterized by their autoagglutination in a "stacked-brick" arrangement over the epithelium of the small intestine and, in some cases, the colon. The prevalence of disease caused by EAEC is unclear because a single molecular marker for these bacteria has not been discovered. Genes encoding adhesins, toxins including Shiga toxin, and other virulence proteins are highly variable among EAEC. However, comprehensive analyses of outbreaks in both developed and developing countries have demonstrated these bacteria are common. Outbreaks of gastroenteritis caused by EAEC have also been reported in the United States, Europe, and Japan and are likely an important cause of childhood diarrhea in developed countries. These are one of the few bacteria associated with **chronic diarrhea and growth retardation** in children. Characteristically, after adherence to the epithelium, cytokine release is stimulated, which results in neutrophil recruitment and progression to an inflammatory diarrhea. Disease is characterized by a watery secretory diarrhea, often with inflammatory cells and accompanied by fever, nausea, vomiting, and abdominal pain. This process can either be acute or can progress to a persistent diarrhea, particularly in children and human immunodeficiency virus (HIV)-infected patients.

Shiga Toxin–Producing *E. coli*. Nomenclature for this group of *E. coli* is confusing, referring to them as **STEC**, verocytotoxin-producing *E. coli* (VTEC), and enterohemorrhagic *E. coli* (EHEC). To provide some clarity, consider VTEC an outdated name and EHEC a subset of STEC. All members of this group are defined by the presence of Shiga toxin 1 (Stx1) or 2 (Stx2). Some but not all EHEC strains are LEE positive and form A/E cytopathology, resembling EPEC strains. Classification of STEC is further complicated because the most common serotype associated with human disease is O157:H7, and initial efforts to diagnose disease were made to determine if the suspected pathogen was this serotype. It is now appreciated that although O157:H7 is the most common serotype associated with severe human disease, it represents less than 50% of the responsible serotypes. Additionally, the prevalent serotypes will vary geographically. Thus diagnosis of STEC disease is now based on detection of the Shiga toxins rather than serotyping suspected isolates (Clinical Case 25.1).

Various national programs have been established in the United States, Canada, Europe, and Australia to monitor foodborne diseases and have documented widespread prevalence of STEC disease in these countries, as well as in other countries in which outbreaks have been documented. It is estimated that these bacteria cause 73,000 infections and 60 deaths each year in the United States, although awareness of these pathogens is now associated with an overall decrease in prevalence. STEC disease is most common in the warm months, and the highest incidence is in children

Clinical Case 25.1 **Multistate Outbreak of Shiga Toxin–Producing *Escherichia coli* Infections**

In 2006, *E. coli* O157 was responsible for a large multistate outbreak of gastroenteritis. The outbreak was linked to contamination of spinach, with a total of 173 cases reported in 25 states, primarily over an 18-day period. The outbreak resulted in hospitalization of more than 50% of the patients with documented disease, a 16% rate of hemolytic uremic syndrome, and one death. Despite the wide distribution of the contaminated spinach, publication of the outbreak and the rapid determination that spinach was responsible resulted in prompt removal of spinach from grocery stores and termination of the outbreak. This outbreak illustrates how contamination of a food product, even with small numbers of organisms, can lead to a widespread outbreak with a particularly virulent organism, such as strains of STEC.

younger than 5 years. Most infections are attributed to the consumption of undercooked ground beef or other meat products, water, unpasteurized milk or fruit juices (e.g., cider made from apples contaminated with feces from cattle), uncooked vegetables such as spinach, and fruits. **Ingestion of fewer than 100 bacteria can produce disease,** and person-to-person spread occurs.

Disease caused by STEC ranges from mild uncomplicated diarrhea to **hemorrhagic colitis** with severe abdominal pain and bloody diarrhea. Severe disease is more commonly associated with STEC O157:H7. Initially, diarrhea with abdominal pain develops in patients after 3 to 4 days of incubation. Vomiting is observed in approximately half the patients, but a high fever is generally absent. Within 2 days of onset, disease in 30% to 65% of patients progresses to a bloody diarrhea with severe abdominal pain. Complete resolution of symptoms typically occurs after 4 to 10 days in most untreated patients. **HUS,** a disorder characterized by acute renal failure, thrombocytopenia, and microangiopathic hemolytic anemia, is a complication in 5% to 10% of infected children younger than 10 years. Resolution of symptoms occurs in uncomplicated disease after 4 to 10 days in most untreated patients; however, death can occur in 3% to 5% of patients with HUS, and severe sequelae (e.g., renal impairment, hypertension, central nervous system [CNS] manifestations) can occur in as many as 30% of HUS patients.

Stx1 is essentially identical to the Shiga toxin produced by *S. dysenteriae* (thus the source of the name); Stx2 has a 60% homology. Both toxins are acquired by lysogenic bacteriophages. Both have one A subunit and five B subunits, with the B subunits binding to a specific glycolipid on the host cell (globotriaosylceramide [Gb3]). A high concentration of Gb3 receptors is found in the intestinal villi and renal endothelial cells. After the A subunit is internalized, it is cleaved into two molecules, and the A_1 fragment binds to 28S rRNA and causes a cessation of protein synthesis. STEC strains with both Shiga toxins and A/E activity are more pathogenic than strains producing only one Shiga toxin.

HUS has been preferentially associated with the production of Stx2, which has been shown to destroy glomerular endothelial cells. Damage to the endothelial cells leads to platelet activation and thrombin deposition, which results in decreased glomerular filtration and acute renal failure. The Shiga toxins also stimulate expression of inflammatory cytokines (e.g., tumor necrosis factor [TNF]-γ, interleukin [IL]-6), enhancing expression of the B subunit receptor Gb3.

Enteroinvasive *E. coli*. EIEC strains are rare in both developed and developing countries. Pathogenic strains are primarily associated with a few restricted O serotypes: O124, O143, and O164. The strains are closely related by phenotypic and pathogenic properties to *Shigella.* The bacteria are able to invade and destroy the colonic epithelium, producing a disease characterized initially by **watery diarrhea.** A minority of patients progress to the dysenteric form of disease, consisting of fever, abdominal cramps, and blood and leukocytes in stool specimens.

A series of genes on a plasmid mediate bacterial invasion **(*pInv* genes)** into the colonic epithelium. The bacteria then lyse the phagocytic vacuole and replicate in the cell cytoplasm. Movement within the cytoplasm and into adjacent epithelial cells is regulated by formation of actin tails (similar to that observed with *Listeria*). This process of epithelial cell destruction with inflammatory infiltration can progress to colonic ulceration.

Extraintestinal Infections

Urinary Tract Infection. Most gram-negative rods that produce UTIs originate in the colon, contaminate the urethra, ascend into the bladder, and may migrate to the kidney or prostate. Although most strains of *E. coli* can produce UTIs, disease is more common with certain specific serogroups. These bacteria are particularly virulent because of their ability to produce **adhesins** (primarily P pili, AAF/I, AAF/III, and Dr) that bind to cells lining the bladder and upper urinary tract (preventing elimination of the bacteria in voided urine) and **hemolysin HlyA,** which lyses erythrocytes and other cell types (leading to cytokine release and stimulation of an inflammatory response).

Neonatal Meningitis. *E. coli* and group B streptococci cause the majority of CNS infections in infants younger than 1 month. Approximately 75% of the *E. coli* strains possess the **K1 capsular antigen.** This serogroup is also commonly present in the GI tracts of pregnant women and newborn infants. However, the reason this serogroup has a predilection for crossing the blood-brain barrier and causing meningitis in newborns is not understood.

Septicemia. Typically, septicemia caused by gram-negative rods, such as *E. coli,* most commonly originates from infections in the urinary or GI tract (e.g., intestinal leakage leading to an intraabdominal infection). The mortality associated with *E. coli* septicemia is high for patients in whom immunity is compromised or the primary infection is in the abdomen or CNS.

Salmonella

The taxonomic classification of the genus *Salmonella* is problematic. DNA homology studies have revealed that most clinically significant isolates belong to the species *S. enterica*. More than 2500 unique serotypes have been described for this single species; however, these serotypes are commonly listed as individual species (e.g., *S. typhi, S. choleraesuis, S. typhimurium, S. enteritidis*). These designations are incorrect; for example, the correct nomenclature is *S. enterica,* serovar Typhi. In an effort to prevent confusion and still retain the historical terms, individual serotypes are now commonly written with the serotype name capitalized and not in italics. For example, *S. enterica*, serovar Typhi is commonly designated as *Salmonella* Typhi. For the sake of consistency, this nomenclature will be used in this chapter.

PATHOGENESIS AND IMMUNITY

After ingestion and passage through the stomach, salmonellae attach to the mucosa of the **small intestine** and invade into the **M (microfold) cells** located in Peyer patches, as

well as into enterocytes. The bacteria remain in endocytic vacuoles, in which they replicate. The bacteria can also be transported across the cytoplasm and released into the blood or lymphatic circulation. Regulation of attachment, engulfment, and replication is controlled primarily by two large clusters of genes **(pathogenicity island I and II)** on the bacterial chromosome. Pathogenicity island I encodes **salmonella-secreted invasion proteins (Ssps)** and a **type III secretion system** that injects the proteins into the host cell. Pathogenicity island II contains genes that allow the bacteria to evade the host's immune response and encodes a second type III secretion system for this function. The inflammatory response confines the infection to the GI tract, mediates the release of prostaglandins, and stimulates cAMP and active fluid secretion.

EPIDEMIOLOGY

Salmonella can colonize virtually all animals, including poultry, reptiles, livestock, rodents, domestic animals, birds, and humans. Animal-to-animal spread and the use of *Salmonella*-contaminated animal feeds maintain an **animal reservoir.** Serotypes such as *Salmonella* Typhi and *Salmonella* Paratyphi are highly **adapted to humans** and do not cause disease in nonhuman hosts. Other *Salmonella* serotypes (e.g., *Salmonella* Choleraesuis) are adapted to animals and, when they infect humans, can cause severe disease. In addition, in contrast with other *Salmonella* serotypes, strains that are highly adapted to humans (i.e., *Salmonella* Typhi, *Salmonella* Paratyphi) can survive in the gallbladder and establish chronic carriage. Finally, many *Salmonella* strains have no host specificity and cause disease in both human and nonhuman hosts.

Most infections result from **ingestion** of contaminated food products and, in children, from direct fecal-oral spread. The incidence of disease is greatest in children younger than 5 years and adults older than 60 years, who are infected during the summer and autumn months when contaminated foods are consumed at outdoor social gatherings. The most common sources of human infections are **poultry, eggs, dairy products,** and foods prepared on contaminated work surfaces (e.g., cutting boards on which uncooked poultry was prepared). Approximately 50,000 cases of nontyphoidal *Salmonella* infections are reported annually in the United States, although it has been estimated that 1.2 million infections and 400 deaths occur each year. *Salmonella* Typhi infections occur when food or water contaminated by infected food handlers is ingested. There is no animal reservoir. An average of 400 to 500 *Salmonella* Typhi infections are reported annually in the United States, most of which are acquired during foreign travel. In contrast, it is estimated that 27 million *Salmonella* Typhi and *Salmonella* Paratyphi infections and more than 200,000 deaths occur each year worldwide. The risk of disease is highest in children living in poverty in developing countries.

The infectious dose for *Salmonella* Typhi infections is low, so person-to-person spread is common. In contrast, a large inoculum (e.g., 10^6 to 10^8 bacteria) is required for symptomatic disease to develop with most other *Salmonella* serotypes. The organisms can multiply to this high density if contaminated food products are improperly stored (e.g., left at room temperature). The infectious dose is lower for people at high risk for disease because of age, immunosuppression or underlying disease (leukemia, lymphoma, sickle cell disease), or reduced gastric acidity.

CLINICAL DISEASES

The following four forms of *Salmonella* infection exist: gastroenteritis, septicemia, enteric fever, and asymptomatic colonization.

Gastroenteritis

Gastroenteritis is the **most common form of salmonellosis** in the United States. Symptoms generally appear 6 to 48 hours after the consumption of contaminated food or water, with the initial presentation consisting of **nausea, vomiting, and nonbloody diarrhea.** Fever, abdominal cramps, myalgias, and headache are also common. Colonic involvement can be demonstrated in the acute form of the disease. Symptoms can persist for 2 to 7 days before spontaneous resolution.

Septicemia

All *Salmonella* species can cause bacteremia, although infections with *Salmonella* Typhi, *Salmonella* Paratyphi, and *Salmonella* Choleraesuis more commonly lead to a bacteremic phase. The risk for *Salmonella* bacteremia is higher in pediatric and geriatric patients and in immunocompromised patients (e.g., those with HIV infections, sickle cell disease, congenital immunodeficiencies). The clinical presentation of *Salmonella* bacteremia is like that of other gram-negative bacteremias; however, localized suppurative infections (e.g., osteomyelitis, endocarditis, arthritis) can occur in as many as 10% of patients.

Enteric Fever

Salmonella Typhi produces a febrile illness called **typhoid fever.** A milder form of this disease, referred to as **paratyphoid fever,** is produced by *Salmonella* Paratyphi A, *Salmonella* Schottmuelleri (formerly *Salmonella* Paratyphi B), and *Salmonella* Hirschfeldii (formerly *Salmonella* Paratyphi C). Other *Salmonella* serotypes can rarely produce a similar syndrome. The bacteria responsible for enteric fever pass through the cells lining the intestines and are engulfed by macrophages. They replicate after being transported to the liver, spleen, and bone marrow. Ten to 14 days after ingestion of the bacteria, patients experience gradually increasing fever, with nonspecific complaints of headache, myalgias, malaise, and anorexia. These symptoms persist for 1 week or longer and are followed by GI symptoms. This cycle corresponds to an initial bacteremic phase that is followed by colonization of the gallbladder and reinfection of the intestines. Enteric fever is a serious clinical disease and must be suspected in febrile patients who have recently traveled to developing countries where disease is endemic (Clinical Case 25.2).

Asymptomatic Colonization

The strains of *Salmonella* responsible for causing typhoid and paratyphoid fevers are maintained by human colonization. **Chronic colonization** for more than 1 year after symptomatic disease develops in 1% to 5% of patients, with

Clinical Case 25.2 *Salmonella* Typhi Infection

Scully and associates (*N Engl J Med* 345:201–205, 2007) described a 25-year-old woman who was admitted to a Boston hospital with a history of persistent fever that did not respond to amoxicillin or acetaminophen or ibuprofen. She was a resident of the Philippines who had been traveling in the United States for the previous 11 days. On physical examination, she was febrile and had an enlarged liver, abdominal pain, and an abnormal urinalysis. Blood cultures were collected on admission to the hospital and were positive the next day with *Salmonella* Typhi. Because the organism was susceptible to fluoroquinolones, this therapy was selected. Within 4 days, she had defervesced and was discharged to return home to the Philippines. Although typhoid fever can be a very serious life-threatening illness, it can initially present with nonspecific symptoms, as was seen in this woman.

the gallbladder being the reservoir in most patients. Chronic colonization with other species of *Salmonella* occurs in less than 1% of patients and does not represent an important source of human infection.

Shigella

The commonly used taxonomic classification of *Shigella* is simple, although technically incorrect. Four species consisting of almost 50 O-antigen–based serogroups have been described: *S. dysenteriae, S. flexneri, S. boydii,* and *S. sonnei.* However, analysis of DNA has determined that these four species are actually biogroups within the species *E. coli.* Because it would be confusing to refer to these bacteria as *E. coli,* their historical names have been retained.

PATHOGENESIS AND IMMUNITY

Shigellae cause disease by invading and replicating in cells lining the **colon.** Structural gene proteins mediate the adherence of the organisms to the cells, as well as their invasion, intracellular replication, and cell-to-cell spread. These genes are carried on a large virulence plasmid but are regulated by chromosomal genes. Thus the presence of the plasmid does not ensure functional gene activity.

Shigella species appear unable to attach to differentiated mucosal cells; rather, they first attach to and invade the M cells located in Peyer patches. The **type III secretion system** mediates secretion of four proteins **(IpaA, IpaB, IpaC,** and **IpaD)** into epithelial cells and macrophages. These proteins induce membrane ruffling on the target cell, leading to engulfment of the bacteria. Shigellae lyse the phagocytic vacuole and replicate in the host cell cytoplasm (unlike *Salmonella,* which replicate in the vacuole). With the rearrangement of actin filaments in the host cells, the bacteria are propelled through the cytoplasm to adjacent cells, in which **cell-to-cell passage** occurs. In this way, *Shigella* organisms are protected from immune-mediated clearance. Shigellae survive phagocytosis by inducing programmed cell death **(apoptosis).** This process also leads to the release of IL-1β, resulting in the attraction of polymorphonuclear leukocytes into the infected tissues. This, in turn, destabilizes the integrity of the intestinal wall and allows the bacteria to reach the deeper epithelial cells.

S. dysenteriae strains produce an exotoxin, **Shiga toxin.** Similar to Shiga toxin produced by STEC, this toxin has one A subunit and five B subunits. The B subunits bind to a host cell glycolipid (Gb3) and facilitate transfer of the A subunit into the cell. The A subunit cleaves the 28S rRNA in the 60S ribosomal subunit, preventing the binding of aminoacyl-transfer RNA and disrupting protein synthesis. The primary manifestation of toxin activity is damage to the intestinal epithelium; however, in a small subset of patients, the Shiga toxin can mediate damage to the glomerular endothelial cells, resulting in renal failure (HUS).

EPIDEMIOLOGY

Humans are the only reservoir for *Shigella*. It is estimated that almost 500,000 cases of *Shigella* infections occur each year in the United States. This figure pales in comparison with the estimated 90 million cases that occur annually worldwide. ***S. sonnei*** is responsible for almost 85% of U.S. infections, whereas ***S. flexneri*** predominates in developing countries. Epidemics of ***S. dysenteriae*** infections occur periodically, most recently in West Africa and Central America, and are associated with case fatality rates of 5% to 15%.

Shigellosis is primarily a pediatric disease, with 60% of all infections occurring in children younger than 10 years. Endemic disease in adults is common in male homosexuals and in household contacts of infected children. Epidemic outbreaks of disease occur in day-care centers, nurseries, and custodial institutions. (Clinical Case 25.3) Shigellosis is **transmitted person to person** by the fecal-oral route, primarily by people with contaminated hands and less commonly in water or food. Because as few as 100 to 200 bacteria can establish disease, shigellosis spreads rapidly in communities in which sanitary standards and the level of personal hygiene are low.

Clinical Case 25.3 *Shigella* Infections in Day-Care Centers

In 2005, three states reported outbreaks of multidrug-resistant *Shigella* infections in day-care centers. A total of 532 infections were reported in the Kansas City area, with the median age of patients 6 years old (Centers for Disease Control and Prevention: *MMWR* 55:1068–1071, 2006). The predominant pathogen was a multidrug-resistant strain of *S. sonnei,* with 89% of the isolates resistant to ampicillin and trimethoprim-sulfamethoxazole. Shigellosis spreads easily in day-care centers because of the increased risk of fecal contamination and the low infectious dose responsible for disease. Parents and teachers, as well as classmates, are at significant risk for disease.

CLINICAL DISEASES

Shigellosis is characterized by **abdominal cramps, diarrhea, fever,** and **bloody stools.** The clinical signs and symptoms of the disease appear 1 to 3 days after the bacteria are ingested. Shigellae initially colonize the small intestine and begin to multiply within the first 12 hours. The first sign of infection (profuse watery diarrhea without histologic evidence of mucosal invasion) is mediated by an enterotoxin. However, the cardinal feature of shigellosis is lower abdominal cramps and tenesmus (straining to defecate), with abundant pus and blood in the stool. It results from invasion of the colonic mucosa by the bacteria. Abundant neutrophils, erythrocytes, and mucus are found in the stool. Infection is generally self-limited, although antibiotic treatment is recommended to reduce the risk of secondary spread to family members and other contacts. Asymptomatic colonization of the organism in the colon develops in a small number of patients and represents a persistent reservoir for infection.

Yersinia

The best known human pathogens within the genus *Yersinia* are ***Y. pestis, Y. enterocolitica,*** and ***Y. pseudotuberculosis.*** *Y. pestis* is a highly virulent pathogen that causes the potentially fatal systemic disease known as **plague;** *Y. enterocolitica* and *Y. pseudotuberculosis* are primarily enteric pathogens that are relatively uncommon and rarely cultured from blood.

PATHOGENESIS AND IMMUNITY

A common characteristic of the pathogenic *Yersinia* species is their ability to **resist phagocytic killing.** The type III secretion system mediates this property. On contact with phagocytic cells, the bacteria secrete proteins into the phagocyte that dephosphorylate several proteins required for phagocytosis (YopH gene product), induce cytotoxicity by disrupting actin filaments (YopE gene product), and initiate apoptosis in macrophages (YopJ/P gene product). The type III secretion system also suppresses cytokine production, in turn diminishing the inflammatory immune response to infection.

Y. pestis has two plasmids that encode virulence genes: (1) fraction 1 *(f1)* gene, which codes for an antiphagocytic **protein capsule,** and (2) **plasminogen activator *(pla)* protease** gene, which degrades complement components C3b and C5a, preventing opsonization and phagocytic migration, respectively. The *pla* gene also degrades fibrin clots, permitting *Y. pestis* to spread rapidly. Other virulence factors specifically associated with *Y. pestis* are serum resistance and the ability of the organism to absorb organic iron as a result of a siderophore-independent mechanism.

EPIDEMIOLOGY

All *Yersinia* infections are **zoonotic,** with humans the accidental hosts. There are two forms of *Y. pestis* infection: **urban plague,** for which rats are the natural reservoirs, and **sylvatic plague,** which causes infections in squirrels, rabbits, field rats, and domestic cats. Pigs, rodents, livestock, and rabbits are the natural reservoirs for *Y. enterocolitica,* whereas rodents, wild animals, and game birds are the natural reservoirs for *Y. pseudotuberculosis.*

Plague, caused by *Y. pestis,* was one of the most devastating diseases in history. Epidemics of the plague were recorded in the Old Testament. The first of three major pandemics (urban plague) started in Egypt in AD 541 and spread throughout North Africa, Europe, central and southern Asia, and Arabia. By the time this pandemic ended in the mid-700s, a major proportion of the population in these countries had died from the plague. The second pandemic, which started in the 1320s, resulted (over a 5-year period) in more than 25 million deaths in Europe alone (30% to 40% of the population). The third pandemic began in China in the 1860s and spread to Africa, Europe, and the Americas. Epidemic and sporadic cases of the disease continue to this day. In recent years, fewer than 10 cases are reported annually in the United States, with disease primarily sylvatic plague and present in western states.

Urban plague is maintained in rat populations and is spread among **rats** or between rats and humans by infected **fleas.** Fleas become infected during a blood meal from a bacteremic rat. After the bacteria replicate in the flea gut, the organisms can be transferred to another rodent or to humans. Urban plague has been eliminated from most communities by the effective control of rats and better hygiene. In contrast, **sylvatic plague** is difficult or impossible to eliminate because the **mammalian reservoirs** and **flea vectors** are widespread. *Y. pestis* produces a fatal infection in the animal reservoir, so cyclic patterns of human disease occur as the number of infected reservoir hosts increases or decreases. Infections can also be acquired through ingestion of contaminated animals or handling of contaminated animal tissues. Although the organism is highly infectious, human-to-human spread is uncommon unless the patient has pulmonary involvement.

Y. enterocolitica is a common cause of enterocolitis in Scandinavian and other northern European countries and in the colder areas of North America. In the United States, approximately one culture-confirmed infection occurs per 100,000 persons each year, with 90% of the infections being associated with the consumption of contaminated meat, milk, or water. Most studies show that infections are more common during the cold months. Virulence with this organism is associated with specific serogroups. The most common serogroups found in Europe, Africa, Japan, and Canada are O3 and O9. Serogroup O8 has been identified in the United States. *Y. pseudotuberculosis* is a relatively uncommon cause of human disease.

CLINICAL DISEASES

The two clinical manifestations of *Y. pestis* infection are bubonic plague and pneumonic plague. **Bubonic plague** is characterized by an incubation period of no more than 7 days after a person has been bitten by an infected flea. Patients have a high fever and a painful **bubo** (inflammatory swelling of the lymph nodes) in the groin or axilla. Bacteremia develops rapidly if patients are not treated, and as many as 75% die. (Clinical Case 25.4) The incubation

Clinical Case 25.4 **Human Plague in the United States**

In 2006, a total of 13 human plague cases were reported in the United States: seven in New Mexico, three in Colorado, two in California, and one in Texas (Centers for Disease Control and Prevention: *MMWR* 55:940–943, 2006). The following is a description of a 30-year-old man with a classic presentation of bubonic plague. On July 9, the man presented to his local hospital with a 3-day history of fever, nausea, vomiting, and right inguinal lymphadenopathy. He was discharged without treatment. Three days later, he returned to the hospital and was admitted with sepsis and bilateral pulmonary infiltrates. He was placed on respiratory isolation and treated with gentamicin, to which he responded. Cultures of his blood and enlarged lymph node were positive for *Yersinia pestis*. These bacteria were also recovered in fleas collected near the patient's home. Typically the reservoirs for sylvatic plague are small mammals, and the vectors are fleas. When the mammals die off, the fleas will seek human hosts.

period (2 to 3 days) is shorter in patients with **pneumonic plague.** Initially these patients experience fever and malaise, and pulmonary signs develop within 1 day. The patients are highly infectious; person-to-person spread occurs by aerosols. The mortality rate in untreated patients with pneumonic plague exceeds 90%.

Approximately two thirds of all *Y. enterocolitica* infections are **enterocolitis,** as the name implies. The gastroenteritis is typically associated with ingestion of contaminated food products or water. After an incubation period of 1 to 10 days (average, 4 to 6 days), the patient experiences disease characterized by diarrhea, fever, and abdominal pain that last as long as 1 to 2 weeks. A chronic form of the disease can also develop and persist for months. Disease involves the terminal ileum and, if the mesenteric lymph nodes become enlarged, can mimic acute appendicitis. *Y. enterocolitica* infection is most common in children, with **pseudoappendicitis** posing a particular problem in this age group. *Y. pseudotuberculosis* can also produce an enteric disease with the same clinical features. Other manifestations seen in adults are septicemia, arthritis, intraabdominal abscess, hepatitis, and osteomyelitis.

In 1987, *Y. enterocolitica* was first reported to cause **blood transfusion–related bacteremia** and endotoxic shock. Because *Yersinia* organisms **can grow at 4° C,** this organism can multiply to high concentrations in nutritionally rich blood products that are stored in a refrigerator.

Other Enterobacteriaceae

KLEBSIELLA

Members of the genus *Klebsiella* have a prominent capsule that is responsible for the mucoid appearance of isolated colonies and the enhanced virulence of the organisms in vivo. Additionally, strains of *Klebsiella* resistant to all β-lactam antibiotics including the carbapenems, as well as most other classes of antibiotics, are becoming increasingly common globally. The management of patients with *Klebsiella* infections is a major clinical challenge.

The most commonly isolated members of the genus are ***K. pneumoniae*** and ***K. oxytoca*,** which can cause community-acquired or hospital-acquired primary **lobar pneumonia.** Pneumonia caused by *Klebsiella* species frequently involves necrotic destruction of alveolar spaces, formation of cavities, and the production of blood-tinged sputum. These bacteria also cause wound and soft-tissue infections and UTIs.

The organism, formerly called *Donovania granulomatis* and then *Calymmatobacterium granulomatis,* has been reclassified as ***K. granulomatis*.** *K. granulomatis* is the etiologic agent of **granuloma inguinale,** which is a granulomatous disease affecting the genitalia and inguinal area (Figs. 25.4 and 25.5). Unfortunately, this disease is commonly called **donovanosis** in reference to the historical origin of the genus name. Granuloma inguinale is a rare disease in

Fig. 25.4 Penile ulcer caused by *Klebsiella granulomatis.* This can mimic the chancre of syphilis. (From Morse, S.A., Ballard, R.C., Holmes, K.K., et al., 2010. Atlas of Sexually Transmitted Diseases and AIDS, fourth ed. London, Saunders.)

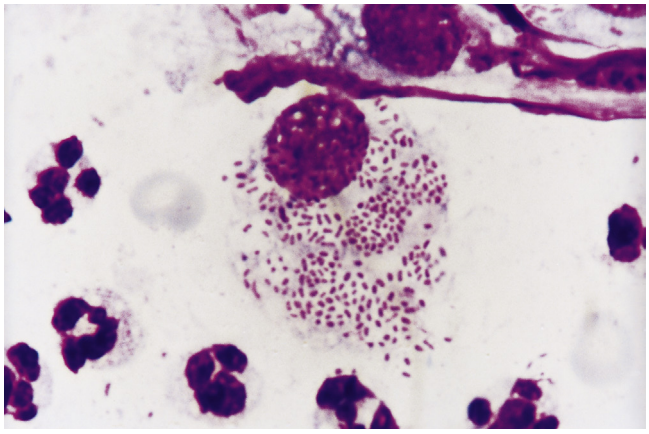

Fig. 25.5 Light microscopy of impression smear of granulation tissue from genital lesion of patient infected with *Klebsiella granulomatis.* Note the numerous bacteria in the cytoplasmic vacuole of the mononuclear cell (modified Giemsa stain). (From Morse, S.A., Ballard, R.C., Holmes, K.K., et al., 2010. Atlas of Sexually Transmitted Diseases and AIDS, fourth ed. London, Saunders.)

the United States, but it is endemic in parts of Papua New Guinea, the Caribbean, South America, India, southern Africa, Vietnam, and Australia. It can be transmitted after repeated exposure through sexual intercourse or nonsexual trauma to the genitalia. After a prolonged incubation of weeks to months, subcutaneous nodules appear on the genitalia or in the inguinal area. The nodules subsequently break down, revealing one or more painless granulomatous lesions that can extend and coalesce into ulcers resembling syphilitic lesions.

Two other *Klebsiella* species of clinical importance are ***K. rhinoscleromatis,*** which is the cause of a granulomatous disease of the nose, and ***K. ozaenae,*** which is the cause of chronic atrophic rhinitis. Both diseases are relatively uncommon in the United States.

PROTEUS

P. mirabilis, the most common member of this genus, primarily produces infections of the urinary tract (e.g., bladder infection or cystitis; kidney infection or pyelonephritis). *P. mirabilis* produces large quantities of urease, which splits urea into carbon dioxide and ammonia. This process raises the urine pH, precipitating magnesium and calcium in the form of struvite and apatite crystals, respectively, and results in the formation of **renal (kidney) stones.** The increased alkalinity of the urine is also toxic to the uroepithelium.

ENTEROBACTER, CITROBACTER, MORGANELLA, AND *SERRATIA*

Primary infections caused by *Enterobacter, Citrobacter, Morganella,* and *Serratia* are rare in immunocompetent patients. They are more common causes of hospital-acquired infections in neonates and immunocompromised patients. For example, ***Citrobacter koseri*** has been recognized to have a predilection for causing meningitis and brain abscesses in neonates.

Other General Properties

LABORATORY DIAGNOSIS

Culture

Members of the family Enterobacteriaceae grow readily on culture media. Specimens of normally sterile material, such as spinal fluid and tissue collected at surgery, can be inoculated onto nonselective blood agar media. Selective media (e.g., MacConkey agar, eosin-methylene blue [EMB] agar) are used for the culture of specimens normally contaminated with other organisms (e.g., sputum, feces). Use of these selective differential agars enables the separation of lactose-fermenting Enterobacteriaceae genera (e.g., *Escherichia, Klebsiella, Enterobacter*) from nonfermenting genera (e.g., *Salmonella, Shigella*). Another example of a selective differential agar is **sorbitol-containing MacConkey agar** (S-MAC), which is used to screen stool specimens for sorbitol-negative (colorless), gram-negative bacteria such as *E. coli* O157. Highly selective or organism-specific media are useful for the recovery of organisms such as *Salmonella* and *Shigella* in stool specimens, in which an abundance of normal flora can obscure the presence of these important pathogens.

It is difficult to recover *Y. enterocolitica* because this organism grows slowly at traditional incubation temperatures and prefers cooler temperatures, at which it is more active metabolically. Clinical laboratories have exploited this property, however, by mixing the fecal specimen with saline and then storing the specimen at 4° C for 2 weeks or more before subculturing it to agar media. This **cold enrichment** permits the growth of *Yersinia* but inhibits or kills other organisms in the specimen. Although use of the cold enrichment method does not aid in the initial management of a patient with *Yersinia* gastroenteritis, it has helped elucidate the role of this organism in chronic intestinal disease.

Biochemical Identification

There are many diverse species in the family Enterobacteriaceae. The citations listed in the Bibliography at the end of this chapter provide additional information about their biochemical identification. Biochemical test systems have become increasingly sophisticated, and the most common members of the family can be identified accurately in less than 24 hours with one of the many commercially available identification systems. Sequencing of species-specific genes (e.g., 16S rRNA gene) or detection of characteristic protein profiles by mass spectrometry is used to identify most species of Enterobacteriaceae.

Serologic Classification

Serologic testing is very useful for determining the clinical significance of an isolate (e.g., serotyping specific pathogenic strains such as *E. coli* O157 or *Y. enterocolitica* O8) and for classifying isolates for epidemiologic purposes. The usefulness of this procedure is limited, however, by cross-reactions with antigenically related Enterobacteriaceae and with organisms from other bacterial families.

Nucleic Acid Amplification Tests

In the last decade, commercial multiplex nucleic acid amplification tests (NAATs) have become widely used for specific diseases, such as respiratory or GI infections. The advantage of these tests is that a large selection of enteric pathogens (e.g., *Salmonella, Shigella, E. coli, Campylobacter*, as well as common enteric viruses and parasites) are identified simultaneously with a single test.

TREATMENT, PREVENTION, AND CONTROL

Antibiotic therapy for infections with Enterobacteriaceae must be guided by in vitro susceptibility test results and clinical experience. Some organisms, such as *E. coli* and *P. mirabilis,* are susceptible to many antibiotics, but others can be highly resistant. Production of enzymes that inactivate all the penicillins and cephalosporins (e.g., ESBLs) is now widespread in *E. coli, Klebsiella,* and *Proteus*. Additionally, use of carbapenems (e.g., imipenem, meropenem, ertapenem) was once a mainstay of treatment; however, the recent recovery of carbapenemase-producing bacteria has limited the empirical use of carbapenems and all other β-lactam antibiotics for many regions of the world. In general, **antibiotic resistance**

is more common in hospital-acquired infections than in community-acquired infections. Antibiotic therapy is not recommended for some infections. For example, symptomatic relief but not antibiotic treatment is usually recommended for patients with STEC and *Salmonella* gastroenteritis because antibiotics can prolong the fecal carriage of these organisms or increase the risk of secondary complications (e.g., HUS with STEC infections in children). Treatment of *Salmonella* Typhi infections or other systemic *Salmonella* infections is indicated; however, increasing resistance to antibiotics, such as the fluoroquinolones, has complicated therapy.

It is difficult to prevent infections with Enterobacteriaceae because these organisms are a major part of the endogenous microbial population. However, some risk factors for the infections should be avoided. These include the unrestricted use of antibiotics that can select for resistant bacteria, performance of procedures that traumatize mucosal barriers without prophylactic antibiotic coverage, and use of urinary catheters. Unfortunately, many of these factors are present in patients at greatest risk for infection (e.g., immunocompromised patients confined to the hospital for extended periods).

Exogenous infection with Enterobacteriaceae is theoretically easier to control. For example, the source of infections with organisms such as *Salmonella* is well defined. However, these bacteria are ubiquitous in poultry and eggs. Unless care is taken in the preparation and refrigeration of such foods, little can be done to control these infections. *Shigella* organisms are predominantly transmitted in young children, but it is difficult to interrupt the fecal-hand-mouth transmission responsible for spreading the infection in this population. Outbreaks of these infections can be effectively prevented and controlled only through education and the introduction of appropriate infection-control procedures (e.g., handwashing, proper disposal of soiled diapers and linens) in the settings in which these infections typically occur.

A vaccine for *Y. pestis* is no longer available, although this is likely to change in light of the concern that this organism can be used by bioterrorists. Two vaccines for *Salmonella* Typhi are available: an oral, live, attenuated vaccine and a Vi capsular polysaccharide vaccine. Both vaccines protect 40% to 70% of the recipients. Vaccination is recommended for travelers to endemic areas of the world (e.g., Africa, Asia, Latin America). The Vi capsular vaccine can be administered in a single dose, but the attenuated live vaccine must be administered in four doses over a 1-week period. Refer to the Centers for Disease Control and Prevention website (www.cdc.gov) for current recommendations.

Case Study and Questions

A 25-year-old previously healthy woman came to the emergency room for evaluation of bloody diarrhea and diffuse abdominal pain of 24 hours' duration. She complained of nausea and had vomited twice. She reported no history of inflammatory bowel disease, previous diarrhea, or contact with other people with diarrhea. The symptoms began 24 hours after she had eaten an undercooked hamburger at a local fast food restaurant. Rectal examination revealed watery stool with gross blood. Sigmoidoscopy showed diffuse mucosal erythema and petechiae with a modest exudation but no ulceration or pseudomembranes.

1. Name four genera of Enterobacteriaceae that can cause gastrointestinal (GI) disease. Name two genera that can cause hemorrhagic colitis.
2. What virulence factor mediates this disease?
3. Name the five groups of *E. coli* that can cause gastroenteritis. What is characteristic of each group of organisms?
4. What are the four forms of *Salmonella* infection?
5. Differentiate between disease caused by *Salmonella* Typhi and that caused by *S. sonnei.*
6. Describe the epidemiology of the two forms of disease caused by *Y. pestis.*

26 Vibrio *and Related Bacteria*

A 67-year-old woman living in Louisiana developed massive watery diarrhea 2 days after she ate crabs. She was admitted to the local hospital's intensive care unit with hypotension and bradycardia. She was resuscitated after a large volume of fluid (≈22 liters of fluids over 24 hours) was administered. Stool cultures grew *Vibrio cholerae* 01 biotype El Tor, serotype Inaba, and treatment with intravenous doxycycline was initiated. Over the next week her diarrhea resolved, and her recovery was uneventful.

1. *Vibrio* and *Aeromonas* are important gram-negative rods that cause significant enteric disease and wound infections. What properties do these genera share with the Enterobacteriaceae, and how would they be differentiated from this family?
2. How do certain strains of *Vibrio cholerae* produce cholera, and what other organism has a similar virulence factor?
3. What disease does *V. vulnificus* produce, and who is at greatest risk for serious disease?
4. What diseases are associated with *Aeromonas*?

Answers to these questions are available on Student Consult.com.

Summaries Clinically Significant Organisms

VIBRIO CHOLERAE

Trigger Words

Serogroup O1, cholera, cholera toxin, shellfish, gastroenteritis

Biology and Virulence

- Curved gram-negative rods
- Fermentative, facultative anaerobic; require salt for growth
- Strains subdivided into more than 200 serogroups (O–cell wall antigens)
- *V. cholerae* serogroup O1 is further subdivided into serotypes (Inaba, Ogawa, and Hikojima) and biotypes (Classical and El Tor)
- Disease mediated by cholera toxin (complex A-B toxin) and toxin coregulated pilus

Epidemiology

- Serotype O1 is responsible for major pandemics (worldwide epidemics), with significant mortality in developing countries; O139 can cause similar diseases
- Organism found in estuarine and marine environments worldwide (including along the coast of the United States); associated with chitinous shellfish
- Organism can multiply freely in water
- Bacterial levels in contaminated waters increase during the warm months
- Most commonly spread by consumption of freshly contaminated water
- Direct person-to-person spread is rare because the infectious dose is high; the infectious dose is high because most organisms are killed by stomach acids

Diseases

- Infection can range from asymptomatic colonization or mild diarrhea to severe, rapidly fatal diarrhea

Diagnosis

- Microscopic examination of stool can be useful in acute infections in the setting of an epidemic but rapidly becomes negative as the disease progresses
- Immunoassays for cholera toxin or O1 and O139 lipopolysaccharides can be useful, although the analytical performance of the assays is quite variable
- Multiplex nucleic acid amplification tests can be used to detect many enteric pathogens (bacteria, viruses, and parasites) and are the diagnostic test of choice
- Culture should be performed early in course of disease with fresh stool specimens maintained in a neutral to alkaline pH

Treatment, Prevention, and Control

- Fluid and electrolyte replacement are crucial
- Antibiotics (e.g., azithromycin) reduce the bacterial burden and exotoxin production, as well as duration of diarrhea
- Improved hygiene is critical for control
- Combination inactivated whole cell and cholera toxin B subunit vaccines provide limited protection and herd immunity

VIBRIO PARAHAEMOLYTICUS

Trigger Words

Kanagawa hemolysin, shellfish, gastroenteritis

Biology and Virulence

- Curved gram-negative rods
- Fermentative, facultative anaerobic; require salt for growth
- Production of thermostable direct hemolysin (Kanagawa hemolysin) associated with pathogenic strains

Epidemiology

- Organism found in estuarine and marine environments worldwide
- Associated with consumption of contaminated raw shellfish
- Most common cause of bacterial gastroenteritis in Japan and Southeast Asia
- Most common cause of seafood-associated gastroenteritis in United States

Diseases

- Most symptomatic infections are self-limited diarrhea

Diagnosis

- Culture should be performed as with *V. cholerae*

Treatment, Prevention, and Control

- Self-limited disease, although antibiotics can shorten length of symptoms and fluid loss
- Disease prevented by proper cooking of shellfish
- No vaccine is available

VIBRIO VULNIFICUS

Trigger Words

Septicemia, wound infections, hepatic disease

Biology and Virulence

- Curved gram-negative rods
- Fermentative, facultative anaerobic; require salt for growth
- Virulence associated with presence of polysaccharide capsule and hydrolytic enzymes

Continued

Summaries Clinically Significant Organisms—cont'd

Epidemiology
- Infection associated with exposure of a wound to contaminated salt water or ingestion of improperly prepared shellfish

Diseases
- High mortality associated with primary septicemia and wound infections, particularly in patients with underlying hepatic disease

Diagnosis
- Culture wounds and blood

Treatment, Prevention, and Control
- Life-threatening illnesses that must be promptly treated with antibiotics
- Minocycline or doxycycline combined with a ceftriaxone or cefotaxime is the treatment of choice
- No vaccine is available

TABLE 26.1 Important *Vibrio* and *Aeromonas* Species

Organism	Historical Derivation
Vibrio	*vibrio,* move rapidly or vibrate (rapid movement caused by polar flagella)
V. cholerae	*cholera,* cholera or an intestinal disease
V. parahaemolyticus	*para,* by the side of; *haema,* blood; *lyticus,* dissolving (dissolving blood; Kanagawa toxin–positive strains are hemolytic)
V. vulnificus	*vulnificus,* inflicting wounds (associated with prominent wound infections)
Aeromonas	*aero,* gas or air; *monas,* unit or monad (gas-producing bacteria)
A. caviae	*cavia,* guinea pig (first isolated in guinea pigs)
A. hydrophila	*hydro,* water; *phila,* loving (water loving)
A. veronii	*veron,* named after the bacteriologist Veron

The second major group of gram-negative, facultatively anaerobic, fermentative rods are the genera *Vibrio* and *Aeromonas.* These organisms were at one time classified together in the family Vibrionaceae and were separated from the Enterobacteriaceae on the basis of a positive oxidase reaction and the presence of polar flagella. These organisms were also classified together because they are primarily found in water and are able to cause gastrointestinal disease. However, deoxyribonucleic acid (DNA) sequencing has established that these genera are only distantly related and belong in separate families: *Vibrio* and *Aeromonas* are now classified in the families Vibrionaceae and Aeromonadaceae, respectively (Table 26.1). Despite this taxonomic reorganization, it is appropriate to consider these bacteria together because their epidemiology and range of diseases are similar.

Vibrio

The genus *Vibrio* has undergone numerous changes in recent years, with a number of less common species described or reclassified. Currently the genus is composed of more than 150 species and subspecies of **curved rods.** Three species are particularly important human pathogens (Table 26.2): ***V. cholerae, V. parahaemolyticus,*** and ***V. vulnificus.***

TABLE 26.2 *Vibrio* Species Most Commonly Associated with Human Disease

Species	Source of Infection	Clinical Disease
Vibrio cholerae	Water, food	Gastroenteritis, bacteremia
V. parahaemolyticus	Shellfish, seawater	Gastroenteritis, wound infection, bacteremia
V. vulnificus	Shellfish, seawater	Bacteremia, wound infection

PHYSIOLOGY AND STRUCTURE

Vibrio species can grow on a variety of simple media within a broad temperature range (from 14° C to 40° C). All species of *Vibrio* **require sodium chloride (NaCl)** for growth. *V. cholerae* can grow on most media without additional salt, but most other halophilic ("salt-loving") species require supplementation with NaCl. Vibrios tolerate a wide range of pH (e.g., pH of 6.5 to 9.0) but are **susceptible to stomach acids.** Generally, exposure to a large inoculum of organisms is required for disease, but if gastric acid production is reduced or neutralized, patients are more susceptible to *Vibrio* infections.

Most vibrios have **polar flagella** (important for motility) and various pili that are important for virulence (e.g., **toxin coregulated pilus** [TCP] in epidemic strains of *V. cholera*). The cell wall structure of vibrios is also important. All strains possess **lipopolysaccharides** consisting of lipid A (endotoxin), core polysaccharide, and an O polysaccharide side chain. The O polysaccharide is used to subdivide *Vibrio* species into **serogroups:** there are more than 200 serogroups of *V. cholerae* plus multiple serogroups of *V. vulnificus* and *V. parahaemolyticus.* The interest in this classification scheme is more than academic; ***V. cholerae* O1 and O139** produce **cholera toxin** and are associated with epidemics of cholera. Other strains of *V. cholerae* generally do not produce cholera toxin and do not cause epidemic disease. *V. cholerae* serogroup O1 is further subdivided into serotypes **(Inaba, Ogawa,** and **Hikojima)** and biotypes **(Classical** and **El Tor).** Strains can shift between serotype Inaba and serotype Ogawa, with Hikojima a transitional state in which both Inaba and Ogawa antigens are expressed. Seven worldwide pandemics of *V. cholerae* infections have been documented since 1817. *V. cholerae* strains responsible for the sixth worldwide pandemic of cholera were of the

TABLE 26.3 Virulence Factors of *Vibrio* Species

Species	Virulence Factor	Biological Effect
Vibrio cholerae	Cholera toxin	Hypersecretion of electrolytes and water
	Toxin coregulated pilus	Surface binding site receptor for bacteriophage CTXΦ; mediates bacterial adherence to intestinal mucosal cells
	Chemotaxis protein	Adhesin factor
	Accessory cholera enterotoxin	Increases intestinal fluid secretion
	Zonula occludens toxin	Increases intestinal permeability
	Neuraminidase	Modifies cell surface to increase GM_1 binding sites for cholera toxin
V. parahaemolyticus	Kanagawa hemolysin	Enterotoxin that induces chloride ion secretion (watery diarrhea)
V. vulnificus	Polysaccharide capsule	Antiphagocytic
	Cytolysins, proteases, collagenase	Mediates tissue destruction

Classical biotype, whereas strains responsible for the current seventh pandemic are of the El Tor biotype.

V. vulnificus and non-O1 *V. cholerae* produce acidic **polysaccharide capsules** that are important for disseminated infections. *V. cholerae* O1 does not produce a capsule, so infections with this organism do not spread beyond the confines of the intestine.

V. cholerae and *V. parahaemolyticus* possess two circular chromosomes, each of which carries essential genes for these bacteria. Plasmids, including those encoding antimicrobial resistance, are also commonly found in *Vibrio* species.

PATHOGENESIS AND IMMUNITY

Virulence of *V. cholerae* involved acquisition of a sequence of genes including **TCP** on what is termed the **Vibrio Pathogenicity Island (VPI-1),** followed by infection with the **bacteriophage CTXΦ**, which encodes the genes for the two subunits of **cholera toxin** (*ctxA* and *ctxB*) (Table 26.3). TCP serves as the cell-surface receptor for the bacteriophage, permitting it to move into the bacterial cell, in which it becomes integrated into the *V. cholerae* genome. The lysogenic bacteriophage chromosomal locus also contains other virulence factors, including the *ace* gene (**accessory cholera enterotoxin**), *zot* gene (**zonula occludens toxin**), and *cep* gene (**chemotaxis proteins**). Multiple copies of these genes are found in *V. cholerae* O1 and O139, and their expression is coordinated by regulatory genes.

The cholera toxin is a **complex A-B toxin** that is structurally and functionally similar to the heat-labile enterotoxin of enterotoxigenic *Escherichia coli* (ETEC). A ring of five identical B subunits of cholera toxin binds to the ganglioside GM_1 receptors on the intestinal epithelial cells. The active portion of the A subunit is internalized and interacts with G proteins that control adenylate cyclase, leading to the catabolic conversion of adenosine triphosphate (ATP) to cyclic adenosine monophosphate (cAMP). This results in a hypersecretion of water and electrolytes. Severely infected patients can lose as much as 1 liter of fluid per hour during the height of the disease. Such a tremendous loss of fluid would normally flush the organisms out of the gastrointestinal tract; however, *V. cholerae* are able to **adhere to the mucosal cell layer** by means of (1) the **TCP** encoded by the *tcp* gene complex, and (2) the *cep*-encoded **chemotaxis proteins.** Nonadherent strains are unable to establish infection.

In the absence of cholera toxin, *V. cholerae* O1 can still produce significant diarrhea through the action of the **accessory cholera enterotoxin** and **zonula occludens toxin.** The enterotoxin produces increased fluid secretion, and the zonula occludens toxin loosens the tight junctions (zonula occludens) of the small intestine mucosa, leading to increased intestinal permeability.

Unlike other non-O1 serotypes, *V. cholerae* O139 possesses the same virulence complex as the O1 strains. Thus the ability of the O139 strains to adhere to the intestinal mucosa and produce cholera toxin is the reason these strains can produce a watery diarrhea similar to cholera.

The means by which other *Vibrio* species cause disease is less clearly understood, although a variety of potential virulence factors have been identified. Most virulent strains of *V. parahaemolyticus* produce adhesins, a thermostable direct hemolysin (TDH; also called **Kanagawa hemolysin**), and type III secretion systems that mediate bacterial survival and expression of virulence factors. TDH is an enterotoxin that induces chloride ion secretion in epithelial cells by increasing intracellular calcium. An important method for classifying virulent strains of *V. parahaemolyticus* is detection of this hemolysin, which produces β-hemolytic colonies on agar media with human blood but not sheep blood. These virulent strains are referred to as **Kanagawa positive.**

In the presence of gastric acids, *V. vulnificus* rapidly degrades lysine, producing alkaline by-products that neutralize the acids. In addition, the bacteria are able to evade the host immune response by inducing macrophage apoptosis and to avoid phagocytosis by expression of a polysaccharide capsule. *V. vulnificus* also possesses surface proteins that mediate attachment to host cells and secretes cytolytic toxins leading to tissue necrosis.

EPIDEMIOLOGY

Halophilic *Vibrio* species, including *V. cholerae,* grow naturally in **estuarine and marine environments** worldwide. All *Vibrio* species are able to survive and replicate in contaminated waters with increased salinity. Pathogenic vibrios can also flourish in waters with chitinous **shellfish** (e.g., oysters, clams, mussels); hence the association between *Vibrio* infections and the consumption of shellfish. Asymptomatically infected humans can also be an important reservoir for this organism in areas in which *V. cholerae* disease is endemic.

Seven major pandemics of cholera have occurred since 1817, resulting in thousands of deaths and major socioeconomic changes. Sporadic disease and epidemics occurred before this time, but worldwide spread of the disease

became possible with intercontinental travel resulting from increased commerce and wars.

The seventh pandemic, which was caused by ***V. cholerae* O1 biotype El Tor,** began in Asia in 1961 and spread to Africa, Europe, and Oceania in the 1970s and 1980s. In 1991, the pandemic strain spread to Peru and subsequently has caused disease in most countries in South and Central America, as well as in the United States and Canada. A second epidemic strain emerged in 1992 in India and rapidly spread across Asia but now remains primarily restricted to this area. This strain, ***V. cholerae* O139 Bengal,** produces the cholera toxin and shares other traits with *V. cholerae* O1. This is the first non-O1 strain capable of causing epidemic disease, and it is capable of producing disease in adults who were previously infected with the O1 strain (showing that no protective immunity is conferred).

It is estimated that 3 to 5 million cases of cholera and 120,000 deaths occur worldwide each year. The most recent epidemics occurred in 2004 in Bangladesh after flooding, in 2008 to 2009 in Zimbabwe, and in 2010 in Haiti after the devastating earthquake. Cholera is spread by **contaminated water and food** rather than direct person-to-person spread because a high inoculum (e.g., $>10^8$ organisms) is required to establish infection in a person with normal gastric acidity. In a person with achlorhydria or hypochlorhydria, the infectious dose can be as low as 10^3 to 10^5 organisms. Strains shed from patients are 10- to 100-fold more infectious than environmental strains, although this hyperinfectivity is lost within 24 hours of shedding. Thus cholera is usually seen in communities with **poor sanitation.** Indeed, one outcome from the cholera pandemics was recognition of the role of contaminated water in the spread of disease and the need to improve community sanitation systems so that the disease could be controlled. Thus it is not surprising to observe cholera outbreaks when natural disasters, such as the earthquake in Haiti, compromise the control of sanitary wastes. DNA sequencing of the genomes of epidemic strains has helped us to understand how epidemics develop and are maintained. *V. cholerae* strains in contaminated waters are typically polyclonal. In contrast, epidemic strains are monoclonal, which means they are able to initiate disease by specific virulence properties. Thus exposure to *V. cholerae* whose concentration in water may fluctuate during the seasons or after a natural disaster is not sufficient to maintain an epidemic. Exposure must be with the specific clone responsible for disease.

Infections caused by *V. parahaemolyticus, V. vulnificus,* and other pathogenic vibrios result from consumption of improperly cooked seafood, particularly oysters, or exposure to contaminated seawater. ***V. parahaemolyticus*** is the most common cause of bacterial gastroenteritis in Japan and Southeast Asia and is the most common *Vibrio* species responsible for gastroenteritis in the United States. ***V. vulnificus*** is not frequently isolated but is responsible for severe wound infections and a high incidence of fatal outcomes. *V. vulnificus* is the most common cause of *Vibrio* septicemia. Gastroenteritis caused by vibrios occurs throughout the year because oysters are typically contaminated with abundant organisms year-round. In contrast, septicemia and wound infections with *Vibrio* occur during the warm months, when the organisms in seawater can multiply to high numbers.

BOX 26.1 *Vibrio* Clinical Summaries

Vibrio cholerae

Cholera: it begins with an abrupt onset of watery diarrhea and vomiting and can progress to severe dehydration, metabolic acidosis and hypokalemia, and hypovolemic shock.

Gastroenteritis: milder forms of diarrheal disease can occur in toxin-negative strains of *V. cholerae* O1 and in non-O1 serotypes.

Vibrio parahaemolyticus

Gastroenteritis: it is generally self-limited, with an explosive onset of watery diarrhea and nausea, vomiting, abdominal cramps, headache, and low-grade fever.

Wound infection: it is associated with exposure to contaminated water.

Vibrio vulnificus

Wound infection: severe, potentially fatal infections characterized by erythema, pain, bullae formation, tissue necrosis, and septicemia.

CLINICAL DISEASES

Vibrio cholerae

The majority of individuals exposed to toxigenic ***V. cholerae* O1** have asymptomatic infections or self-limited diarrhea; however, some individuals develop severe, rapidly fatal diarrhea (Box 26.1). The clinical manifestations of cholera begin an average of 2 to 3 days after ingestion of the bacteria (can be <12 hours), with the abrupt onset of watery diarrhea and vomiting. Fever is rare and may be indicative of a secondary infection. As more fluid is lost, the feces-streaked stool specimens become colorless and odorless, free of protein, and speckled with mucus **("rice-water" stools).** The resulting severe fluid and electrolyte loss can lead to dehydration, painful muscle cramps, metabolic acidosis (bicarbonate loss), and hypokalemia and hypovolemic shock (potassium loss), with cardiac arrhythmia and renal failure. The mortality rate is as high as 70% in untreated patients but less than 1% in patients who are promptly treated with replacement of lost fluids and electrolytes. (Clinical Case 26.1) Disease caused by ***V. cholerae* O139** can be as severe as disease caused by *V. cholerae* O1. Other serotypes of *V. cholerae* (commonly called ***V. cholerae* non-O1**) do not produce cholera toxin and are usually responsible for mild watery diarrhea. These strains can also cause extraintestinal infections such as septicemia, particularly in patients with liver disease or hematologic malignancies.

Vibrio parahaemolyticus

The severity of gastroenteritis caused by *V. parahaemolyticus* can range from a self-limited diarrhea to a mild, cholera-like illness. In general, the disease develops after a 5- to 72-hour incubation period (mean, 24 hours), with explosive **watery diarrhea.** No grossly evident blood or mucus is found in stool specimens except in severe cases. Headache, abdominal cramps, nausea, vomiting, and low-grade fever may persist for 72 hours or more. The patient usually experiences an uneventful recovery. (Clinical Case 26.2) Wound infections with this organism can occur in people exposed to contaminated seawater.

Clinical Case 26.1 **Cholera Caused by *Vibrio cholerae***

Although cholera is widespread in Africa, Asia, and Latin America, toxigenic *V. cholerae* O1 is also endemic along the U.S. Gulf Coast. Most disease reported in the United States occurs in travelers to countries with an active cholera outbreak in the community; however, after Hurricane Katrina and Hurricane Rita, unsanitary conditions in coastal communities along the Gulf increased the risk of cholera, as illustrated by the following report (Centers for Disease Control and Prevention, *MMWR* 55:31–32, 2006). Three weeks after extensive damage to their southeastern Louisiana community by Hurricane Rita, a 43-year-old man and his 46-year-old wife developed diarrhea. Whereas the woman had only mild diarrhea, the man was hospitalized the next day with low-grade fever, muscle pains, nausea, vomiting, abdominal cramps, and severe diarrhea and dehydration. He rapidly progressed to complete loss of renal function and respiratory and cardiac failure. With antibiotic therapy and aggressive rehydration therapy, he eventually recovered to his previous state of health. Toxigenic *V. cholerae* O1, serotype Inaba, biotype El Tor, was isolated at the hospital from stool specimens of the two patients. The isolates were indistinguishable from each other and from other isolates previously associated with the Gulf Coast by use of pulsed-field gel electrophoresis. This case illustrates the rapid progression of cholera resulting from severe diarrhea and dehydration, the need for aggressive rehydration therapy, and the association with deterioration of the public health infrastructure after a natural disaster.

Clinical Case 26.2 ***Vibrio parahaemolyticus* Disease**

One of the largest known outbreaks of *V. parahaemolyticus* in the United States was reported in 2005 by McLaughlin and associates (*N Engl J Med* 353:1463–1470, 2005). On July 19, the Nevada Office of Epidemiology reported isolation of *V. parahaemolyticus* from a person who developed gastroenteritis 1 day after eating raw oysters served on an Alaskan cruise ship. Epidemiologic investigations determined that 62 individuals (29% attack rate) developed gastroenteritis after consumption of as few as one raw oyster. In addition to watery diarrhea, the ill individuals reported abdominal cramping (82%), chills (44%), myalgias (36%), headache (32%), and vomiting (29%), with symptoms lasting a median of 5 days. None of the persons required hospitalization. All of the oysters were harvested from a single farm in which the water temperatures in July and August were recorded at 16.6° C and 17.4° C. Water temperatures above 15° C are considered favorable for growth of *V. parahaemolyticus*. Since 1997, the mean water temperatures at the oyster farm have increased 0.21° C per year, and they now remain consistently above 15° C. Thus this seasonal warming has extended the range of *V. parahaemolyticus* and the associated gastrointestinal disease. This outbreak illustrates the role of contaminated shellfish in *V. parahaemolyticus* disease and the clinical symptoms typically observed.

Clinical Case 26.3 ***Vibrio vulnificus* Septicemia**

Septicemia and wound infections are well-known complications after exposure to *V. vulnificus*. The following clinical case published in *Morbidity and Mortality Weekly Report* (*MMWR* 45:621–624, 1996) illustrates typical features of these diseases. A 38-year-old man with a history of alcoholism and insulin-dependent diabetes developed fever, chills, nausea, and myalgia 3 days after eating raw oysters. He was admitted to the local hospital the next day with high fevers and two necrotic lesions on his left leg. The clinical diagnosis of sepsis was made, and the patient was transferred to the intensive care unit. Antibiotic therapy was initiated, and on the second hospital day *V. vulnificus* was isolated from blood specimens collected at the time of admission. Despite aggressive medical management, the patient continued to deteriorate and died on the third day of hospitalization. This case illustrates the rapid, often fatal progression of *V. vulnificus* disease and the risk factor of eating raw shellfish, particularly for individuals with liver disease. A similar progression of disease could have been observed if this individual had been exposed to *V. vulnificus* through a contaminated superficial wound.

Vibrio vulnificus

V. vulnificus is a particularly virulent species of *Vibrio* responsible for more than 90% of the *Vibrio*-related deaths in the United States. The most common presentations are **primary septicemia** after consumption of contaminated raw oysters or rapidly progressive **wound infection** after exposure to contaminated seawater. Patients with primary septicemia present with a sudden onset of fever and chills, vomiting, diarrhea, and abdominal pain. Secondary skin lesions with tissue necrosis are often present. The mortality in patients with *V. vulnificus* septicemia can be as high as 50%. (Clinical Case 26.3) The wound infections are characterized by initial swelling, erythema, and pain at the wound site, followed by the development of vesicles or bullae and eventual tissue necrosis together with systemic signs of fever and chills. Mortality associated with wound infections ranges from 20% to 30%. *V. vulnificus* infections are most severe in patients with hepatic disease, hematopoietic disease, or chronic renal failure and in those receiving immunosuppressive drugs.

LABORATORY DIAGNOSIS

Microscopy

Vibrio species are small (0.5 to 1.5 to 3 μm), curved, gram-negative rods. Large numbers of organisms are typically present in the stools of patients at the onset of cholera, so the direct microscopic examination of stool specimens can provide a rapid, presumptive diagnosis in cholera outbreaks; however, as disease progresses the organisms are diluted with massive fluid loss, and microscopy is less useful. Examination of Gram-stained wound specimens may also be useful in a setting suggestive of *V. vulnificus* infection (e.g., exposure of susceptible individual to seafood or seawater).

Immunoassays

Immunoassays for the detection of cholera toxin or the O1 and O139 lipopolysaccharides are used for the diagnosis of cholera in endemic areas. These tests have variable sensitivity (as high as 97%) and specificity and have decreasing value as the disease progresses because fewer organisms are present in the clinical specimens.

Nucleic Acid Amplification Tests

Commercial nucleic acid amplification tests are now widely used for diagnosis of enteric infections because they are rapid and have high sensitivity compared with alternative tests. Most of these tests are multiplex tests, allowing detection of multiple bacterial, viral, and parasitic enteric pathogens. These are rapidly becoming the standard of diagnosis for enteric infections.

Culture

Vibrio organisms survive poorly in an acidic or dry environment. Specimens must be collected early in the disease and inoculated promptly onto culture media. If culture will be delayed, the specimen should be mixed in a Cary-Blair transport medium and refrigerated. Vibrios have low survival rates in buffered glycerol-saline, which is the transport medium used for most enteric pathogens.

Vibrios grow on most media used in clinical laboratories for stool and wound cultures, including blood agar and MacConkey agar. Special selective agar for vibrios (e.g., thiosulfate citrate bile salts sucrose **[TCBS]** agar), as well as an enrichment broth (e.g., **alkaline peptone broth,** pH 8.6), can also be used to recover vibrios in specimens with a mixture of organisms (e.g., stools). Isolates are identified with selective biochemical tests and serotyped using polyvalent antisera. In tests performed to identify halophilic vibrios, the media for biochemical testing must be supplemented with 1% NaCl.

TREATMENT, PREVENTION, AND CONTROL

Patients with cholera must be promptly treated with **fluid and electrolyte replacement** before the resultant massive fluid loss leads to hypovolemic shock. Antibiotic therapy, although of secondary value, can reduce toxin production and clinical symptoms and decrease transmission by the more rapid elimination of the organism. A single dose of **azithromycin** is currently the drug of choice for children and adults because macrolide resistance is relatively uncommon. A single dose of doxycycline or ciprofloxacin in nonpregnant adults can be used as alternative therapy if demonstrated to be active in vitro; however, resistance to the tetracycline and fluoroquinolones is relatively common.

V. parahaemolyticus gastroenteritis is usually a self-limited disease, although antibiotic therapy can be used in addition to fluid and electrolyte therapy in patients with severe infections. *V. vulnificus* wound infections and septicemia must be promptly treated with antibiotic therapy. The combination of minocycline or doxycycline with ceftriaxone or cefotaxime appears to be the most effective treatment.

People infected with *V. cholerae* can shed bacteria for the first few days of acute illness and represent important sources of new infections. Although long-term carriage of *V. cholerae* does not occur, vibrios are free living in estuarine and marine reservoirs. Only improvements in sanitation can lead to effective control of the disease. This involves adequate sewage management, use of purification systems to eliminate contamination of the water supply, and implementation of appropriate steps to prevent contamination of food.

Although no oral cholera vaccine is available in the United States, a variety of killed oral **vaccines** are available outside the United States; however, none of the vaccines provide long-term protection. A killed vaccine consisting of whole cells of *V. cholerae* O1 plus recombinant cholera toxin B subunit or a bivalent killed vaccine of whole cells of *V. cholerae* O1 and O139 is recommended for short-term protection of travelers in high-risk settings (e.g., exposure to untreated water or care of ill patients) and endemic regions of the world. Antibiotic prophylaxis of contacts to household patients with cholera can limit the spread but is generally ineffective in communities in which disease occurs.

Aeromonas

Aeromonas is a **gram-negative, facultative anaerobic, fermentative rod** that morphologically resembles members of the family Enterobacteriaceae. As with *Vibrio,* extensive reorganization of the taxonomy of these bacteria has occurred. Almost 50 species and subspecies of *Aeromonas* have been described, many of which are associated with human disease. The most important pathogens are ***A. hydrophila, A. caviae,*** and ***A. veronii*** biovar sobria. The organisms are ubiquitous in fresh and brackish water.

Aeromonas species cause three forms of disease: (1) **diarrheal disease** in otherwise healthy people, (2) **wound infections,** and (3) **opportunistic systemic disease** in immunocompromised patients (particularly those with hepatobiliary disease or an underlying malignancy). Intestinal disease can present as acute watery diarrhea, dysenteric diarrhea characterized by severe abdominal pain and blood and leukocytes in the stools, or a chronic illness with intermittent diarrhea. Gastrointestinal carriage has been observed in individuals, with the highest carriage in the warm months. Thus the significance of isolating *Aeromonas* in enteric specimens must be determined by the clinical presentation of the patient. Gastroenteritis typically occurs after the ingestion of contaminated water or food (e.g., fresh produce, meats, dairy products), whereas wound infections most commonly result from a traumatic injury associated with exposure to contaminated water. One unusual form of *Aeromonas* wound infections is associated with the use of medicinal leeches whose gut is colonized with *A. veronii* biovar sobria (Clinical Case 26.4).

Although numerous potential virulence factors (e.g., endotoxin, hemolysins, heat-labile and heat-stable enterotoxins) have been identified for *Aeromonas,* their precise role in disease is unknown.

Acute diarrheal disease is self-limited, and only supportive care is indicated in affected patients. Antimicrobial therapy is necessary in patients with chronic diarrheal disease, wound infections, or systemic disease. *Aeromonas* species are resistant to penicillins, most cephalosporins,

Clinical Case 26.4 ***Aeromonas* Wound Infections**

Medicinal leeches *(Hiruda medicinalis)* are sometimes used in plastic surgery to stimulate blood flow in surgical skin grafts. Leeches remove stagnant blood and stimulate oozing of blood into the skin graft for up to 48 hours after removal of the leech. This bleeding is mediated by an inhibitor of thrombin, hirudin (source of the genus name), which is present in the saliva of leeches. *Aeromonas* is present in the leech gut and produces proteolytic enzymes used by the leech to digest blood. One complication of using leeches is wound infections with *Aeromonas,* as illustrated by the patient described by Snower and associates (*J Clin Microbiol* 27:1421–1422, 1989). A 62-year-old woman had basal cell epitheliomas removed from her forehead, with the surgical site covered with skin grafts. Medicinal leeches were used to relieve swelling at the graft site. The leeches were removed from a leech tank and applied to the wound for 1 hour on four separate occasions. Eleven days after the initial surgery, the graft appeared infected and was removed. Cultures of this graft, and leeches and water from the leech tank, were positive for *Aeromonas*. The patient was treated with parenteral antibiotics, and regrafting without the use of leeches was successful.

and erythromycin. Fluoroquinolones (e.g., levofloxacin, ciprofloxacin) are almost uniformly active against *Aeromonas* strains isolated in the United States and Europe; however, resistance has been reported in strains recovered in Asia. Thus the long-term effectiveness of fluoroquinolones remains to be seen. A fluoroquinolone can be used initially for empirical therapy, but activity should be confirmed with in vitro susceptibility tests.

Case Study and Questions

A 57-year-old man was hospitalized in New York with a 2-day history of severe watery diarrhea. The illness had begun 1 day after his return from Ecuador. The patient was dehydrated and suffering from an electrolyte imbalance (acidosis, hypokalemia). He made an uneventful recovery after fluid and electrolyte replacement was instituted to compensate for the losses resulting from the watery diarrhea. Stool cultures were positive for *Vibrio cholerae.*

1. What are the characteristic clinical symptoms of cholera?
2. What is the most important virulence factor in this disease? What other virulence factors have been described? What are the modes of their action?
3. How did this patient acquire this infection? How does this situation differ from the acquisition of infections caused by *V. parahaemolyticus* or *V. vulnificus*?
4. How can cholera be controlled in areas in which infection is endemic?

27 Pseudomonas *and Related Bacteria*

A 70-year-old man who had been admitted 7 days previously to the intensive care unit for acute shortness of breath and a temperature of 39°C developed a new productive cough and associated pleuritic chest pain. Examination of his chest revealed crackles at the bases of both lungs, with rhonchi present in both upper lobes; the chest radiograph indicated bilateral opacities consistent with bronchopneumonia. Sputum and blood cultures were performed, and 24 hours later the laboratory reported isolation of *Pseudomonas aeruginosa*. *Pseudomonas* and the other nonfermentative rods discussed in this chapter are primarily opportunistic pathogens responsible for infections in hospitalized patients, in patients with innate immunity defects (e.g., compromised pulmonary function), or after trauma (e.g., contamination of a wound).

1. *Pseudomonas, Burkholderia,* and *Stenotrophomonas* share what epidemiologic factors?
2. What is the most important virulence factor in *P. aeruginosa*, and how does it function?
3. What patient population is at risk for infections with *B. cepacia*? What is the infection in these patients?
4. Which antibiotics are generally effective against *Pseudomonas* but not *Stenotrophomonas*, and against *S. maltophilia* but not *P. aeruginosa*?

Answers to these questions are available on Student Consult.com.

Summaries Clinically Significant Organisms

PSEUDOMONAS AERUGINOSA

Trigger Words

Capsule, exotoxin A, opportunistic, nosocomial infections

Biology and Virulence

- Small gram-negative rods typically arranged in pairs
- Obligate aerobe; glucose oxidizer; simple nutritional needs
- Mucoid polysaccharide capsule
- Multiple virulence factors, including adhesins (e.g., flagella, pili, lipopolysaccharide, alginate capsule), secreted toxins and enzymes (e.g., exotoxin A, pyocyanin, pyoverdin, elastases, proteases, phospholipase C, exoenzymes S and T), and antimicrobial resistance (intrinsic, acquired, and adaptive)

Epidemiology

- Ubiquitous in nature and moist environmental hospital sites (e.g., flowers, sinks, toilets, mechanical ventilation, and dialysis equipment)
- No seasonal incidence of disease
- Can transiently colonize the respiratory and gastrointestinal tracts of hospitalized patients, particularly those treated with broad-spectrum antibiotics, exposed to respiratory therapy equipment, or hospitalized for extended periods
- Patients at high risk for developing infections include neutropenic or immunocompromised patients, cystic fibrosis patients, and burn patients

Diseases

- Diseases include infections of the respiratory tract, urinary tract, skin and soft tissues, ears, and eyes, as well as bacteremia and endocarditis

Diagnosis

- Grows rapidly on common laboratory media
- Identified by colonial characteristics (e.g., β-hemolysis, green pigment, grape-like odor) and simple biochemical tests (e.g., positive oxidase reaction, oxidative utilization of carbohydrates)

Treatment, Prevention, and Control

- Combined use of effective antibiotics (e.g., aminoglycoside and β-lactam antibiotics) frequently required; monotherapy is generally ineffective and can select for resistant strains
- Hospital infection-control efforts should concentrate on preventing contamination of sterile medical equipment and nosocomial transmission; unnecessary use of broad-spectrum antibiotics can select for resistant organisms

Pseudomonas and related nonfermentative rods are opportunistic pathogens of plants, animals, and humans. To complicate our understanding of these organisms, their taxonomic classification has undergone numerous changes in recent years. Despite the many genera, most clinically significant isolates are members of five genera: *Pseudomonas, Burkholderia, Stenotrophomonas, Acinetobacter,* and *Moraxella* (Table 27.1). These organisms will be the focus of this chapter.

Pseudomonas

The genus *Pseudomonas* originally consisted of a large heterogeneous collection of nonfermentative bacteria that were grouped together because of their morphologic similarity. They were referred to as pseudomonads because they are commonly arranged in pairs of cells that resemble a single cell (Fig. 27.1). In 1992, this genus was subdivided into a number of new genera (including *Burkholderia* and *Stenotrophomonas*); however, there are still more than 250 species in *Pseudomonas*. ***P. aeruginosa*** is the most important species and the one discussed in this chapter.

Members of the genus are found in soil, decaying organic matter, vegetation, and water. Unfortunately, they are also found throughout the hospital environment in moist reservoirs such as food, cut flowers, sinks, toilets, floor mops, respiratory therapy and dialysis equipment, and even disinfectant solutions. It is uncommon for carriage to persist in humans as part of the normal microbial flora, except in hospitalized patients and ambulatory, immunocompromised hosts.

TABLE 27.1 Important Nonfermentative Gram-Negative Rods

Organism	Historical Derivation
Acinetobacter	*akinetos,* unable to move; *bactrum,* rod (nonmotile rods)
A. baumannii	*baumannii,* named after the microbiologist Baumann
Burkholderia	*Burkholderia,* named after the microbiologist Burkholder
B. cepacia	*cepacia,* like an onion (original strains isolated from rotten onions)
B. mallei	*mallei,* the disease glanders
B. pseudomallei	*pseudes,* false; *mallei* (refers to the fact this species closely resembles *B. mallei*)
Moraxella	*Moraxella,* named after the Swiss ophthalmologist Morax, who first recognized the species
M. catarrhalis	*catarrhus,* downflowing or catarrh (refers to inflammation of the respiratory tract mucus membranes)
Pseudomonas	*pseudes,* false; *monas,* a unit (refers to Gram-stain appearance of pairs of organisms that resemble a single cell)
P. aeruginosa	*aeruginosa,* full of copper rust or green (refers to blue and yellow pigments produced by this species that appear green)
Stenotrophomonas	*stenos,* narrow; *trophos,* one who feeds; *monas,* unit (refers to observation that these are narrow bacteria that require few substrates for growth)
S. maltophilia	*malt,* malt; *philia,* friend (friend of malt)

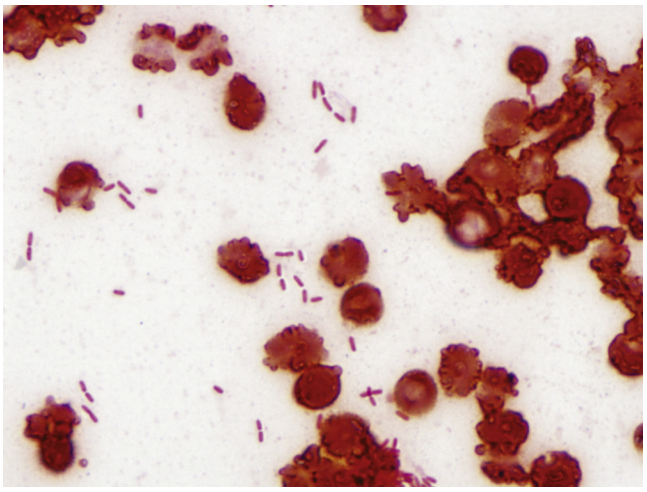

Fig. 27.1 Gram stain of *Pseudomonas aeruginosa* with cells arranged singly and in pairs.

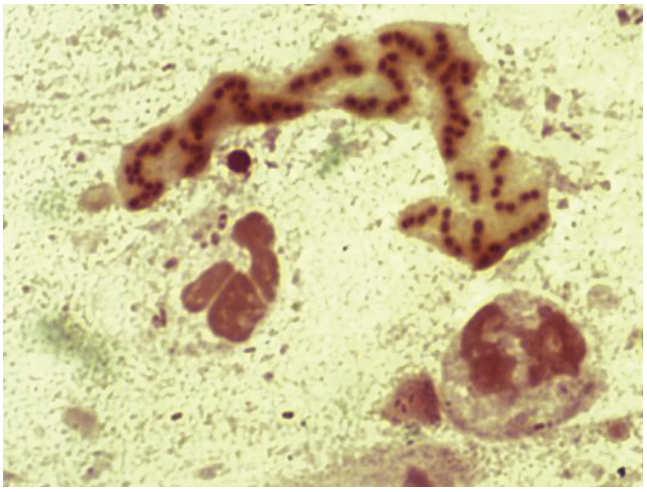

Fig. 27.2 Gram stain of *Pseudomonas aeruginosa* surrounded by mucoid capsular material in cystic fibrosis patient.

The broad environmental distribution of *Pseudomonas* is made possible by their simple growth requirements and nutritional versatility. They are capable of using many organic compounds as sources of carbon and nitrogen, and some strains can even grow in distilled water by using trace nutrients. These organisms also possess many structural factors, enzymes, and toxins that enhance their virulence and render them resistant to most commonly used antibiotics. Indeed, it is surprising that they are not more common pathogens, considering their ubiquitous presence, ability to grow in virtually any environment, virulence properties, and resistance to many antibiotics. Fortunately, *Pseudomonas* infections are **primarily opportunistic** (i.e., restricted to patients receiving broad-spectrum antibiotics that suppress the normal intestinal bacterial population or patients with compromised host defenses). Additionally, expression of virulence traits is regulated by complex cell-density signaling (quorum sensing) systems that in turn are influenced by host factors such as the presence of serum and cytokines.

PHYSIOLOGY AND STRUCTURE

Pseudomonas species are usually motile, straight or slightly curved, gram-negative rods (0.5 to 1.0 × 1.5 to 5.0 μm) typically **arranged in pairs** (see Fig. 27.1). The organisms utilize carbohydrates through **aerobic respiration,** with oxygen the terminal electron acceptor. Although described as obligate aerobes, they can grow anaerobically using nitrate or arginine as an alternate electron acceptor. The presence of **cytochrome oxidase** (detected in a rapid 5-minute test) in *Pseudomonas* species is used to differentiate them from the Enterobacteriaceae and *Stenotrophomonas*. Some strains appear **mucoid** because of the abundance of a polysaccharide capsule (Fig. 27.2); these strains are particularly common in patients with cystic fibrosis (CF). Some species produce **diffusible pigments** (e.g., pyocyanin [blue], pyoverdin [yellow-green], pyorubin [reddish-brown]) that give them a characteristic appearance in culture and simplify the preliminary identification.

P. aeruginosa has one of the largest bacterial genomes, encoding 5567 genes including 468 regulatory genes. This is important for the understanding that *P. aeruginosa* is highly adaptable, and is capable of growth in a wide range of environmental conditions and in the presence of antimicrobials.

PATHOGENESIS AND IMMUNITY

P. aeruginosa has many virulence factors, including adhesins, toxins, and enzymes. In addition, the delivery system

used by *Pseudomonas*, the type III secretion system, is particularly effective in injecting toxins into the host cell. Despite the diversity of virulence factors, most experts believe that multiple factors must work together for *P. aeruginosa* to cause disease.

Adhesins

As with many bacteria, adherence to host cells is critical for establishing infection. At least four surface components of *P. aeruginosa* facilitate this adherence: (1) flagella, (2) pili, (3) lipopolysaccharide (LPS), and (4) alginate. Flagella and pili also mediate motility in *P. aeruginosa,* and the lipid A component of LPS is responsible for endotoxin activity. Alginate is a mucoid exopolysaccharide that forms a prominent **capsule** on the bacterial surface and protects the organism from phagocytosis and antibiotic killing. Production of this mucoid polysaccharide is under complex regulation. The genes controlling production of the alginate polysaccharide can be activated in patients such as those with CF or other chronic respiratory diseases, who are predisposed to long-term colonization with these mucoid strains of *P. aeruginosa.*

Secreted Toxins and Enzymes

Exotoxin A (ETA) is believed to be one of the most important virulence factors produced by pathogenic strains of *P. aeruginosa.* This toxin **disrupts protein synthesis** by blocking peptide chain elongation in eukaryotic cells, much like the diphtheria toxin produced by *Corynebacterium diphtheriae.* However, the toxins produced by these two organisms are structurally and immunologically different, and ETA is less potent than diphtheria toxin. ETA most likely contributes to the dermatonecrosis that occurs in burn wounds, corneal damage in ocular infections, and tissue damage in chronic pulmonary infections.

A blue pigment, **pyocyanin,** produced by *P. aeruginosa,* catalyzes the production of superoxide and hydrogen peroxide, which are toxic forms of oxygen. This pigment also stimulates interleukin (IL)-8 release, leading to enhanced attraction of neutrophils. A yellow-green pigment, **pyoverdin,** is a siderophore that binds iron for use in metabolism. This pigment also regulates secretion of other virulence factors including ETA.

Two elastases, LasA **(serine protease)** and LasB **(zinc metalloprotease),** act synergistically to degrade elastin, resulting in damage to elastin-containing tissues and producing the lung parenchymal damage and hemorrhagic lesions **(ecthyma gangrenosum)** associated with disseminated *P. aeruginosa* infections. These enzymes can also degrade complement components and inhibit neutrophil chemotaxis and function, leading to further spread and tissue damage in acute infections. Chronic *Pseudomonas* infections are characterized by the formation of antibodies to LasA and LasB, with the deposition of immune complexes in the infected tissues. Similar to the elastases, **alkaline protease** contributes to tissue destruction and spread of *P. aeruginosa.* It also interferes with the host immune response.

Phospholipase C is a heat-labile hemolysin that breaks down lipids and lecithin, facilitating tissue destruction. The exact role of this enzyme in respiratory and urinary tract infections (UTIs) is unclear, although an important association between hemolysin production and disease has been recognized.

Exoenzymes S and **T** are extracellular toxins produced by *P. aeruginosa.* When the type III secretion system introduces the proteins into their target eukaryotic cells, epithelial cell damage occurs, facilitating bacterial spread, tissue invasion, and necrosis. This cytotoxicity is mediated by actin rearrangement.

Antibiotic Resistance

P. aeruginosa is intrinsically **resistant to many antibiotics** and can acquire resistance to additional antibiotics through horizontal transfer of resistance genes and mutations. The main mechanisms responsible for **intrinsic resistance** are the low rate of movement of antibiotics through the outer membrane pores into the bacterial cell, combined with the rapid efflux of antibiotics caused by intrinsic regulation of efflux pumps. Resistance to additional antibiotics such as aminoglycosides and β-lactams can be acquired **(acquired resistance)** through horizontal transfer of resistance genes on plasmids and other genetic elements or mutations of genes that increase expression of resistance. A third form of resistance, **adaptive resistance,** is induced when *Pseudomonas* is exposed to environmental stimuli or specific antibiotics. For example, biofilm formation, such as in the lungs of a CF patient or on the surface of catheters, can trigger bacterial regulatory genes that permit expression of resistance. In the same way, exposure to some β-lactam antibiotics (e.g., ceftazidime) triggers the expression of the ampC gene in *Pseudomonas* that results in inactivation of many β-lactam antibiotics. It is important to recognize that in vitro susceptibility tests can identify resistance caused by intrinsic and acquired mechanisms but likely would not be able to predict adaptive resistance, underlying the limitations of these lab tests.

EPIDEMIOLOGY

Pseudomonas is an opportunistic pathogen present in a variety of environments. The ability to isolate this organism from moist surfaces may be limited only by the efforts to look for the organism. *Pseudomonas* has minimal nutritional requirements, tolerates a wide range of temperatures (4° C to 42° C), and is resistant to many antibiotics and disinfectants. Indeed, the recovery of *Pseudomonas* from an environmental source (e.g., hospital sink or floor) means very little unless there is epidemiologic evidence that the contaminated site is a reservoir for infection.

Furthermore, isolation of *Pseudomonas* from a hospitalized patient is worrisome but does not normally justify therapeutic intervention unless there is evidence of disease. The recovery of *Pseudomonas,* particularly species other than *P. aeruginosa,* from a clinical specimen may represent transient colonization of the patient or environmental contamination of the specimen during collection or laboratory processing. Patients at high risk for developing infections with *P. aeruginosa* include neutropenic or immunocompromised patients, CF patients, burn patients, and individuals receiving broad-spectrum antibiotics. It is estimated that *P. aeruginosa* is responsible for more than 50,000 healthcare associated infections annually in the United States and approximately 440 deaths.

BOX 27.1 Clinical Summaries for Nonfermentative Gram-Negative Rods

Pseudomonas aeruginosa

Pulmonary infections: range from mild irritation of the bronchi (tracheobronchitis) to necrosis of the lung parenchyma (necrotizing bronchopneumonia)
Primary skin infections: opportunistic infections of existing wounds (e.g., burns) to localized infections of hair follicles (e.g., associated with immersion in contaminated waters such as hot tubs)
Urinary tract infections: opportunistic infections in patients with indwelling urinary catheters and after exposure to broad-spectrum antibiotics (selects for these antibiotic-resistant bacteria)
Ear infections: can range from mild irritation of external ear ("swimmer's ear") to invasive destruction of cranial bones adjacent to the infected ear
Eye infections: opportunistic infections of mildly damaged corneas
Bacteremia: dissemination of bacteria from primary infection (e.g., pulmonary) to other organs and tissues; can be characterized by necrotic skin lesions (ecthyma gangrenosum)

***Burkholderia cepacia* Complex**

Pulmonary infections: most worrisome infections are in patients with chronic granulomatous disease or cystic fibrosis, in whom infections can progress to significant destruction of pulmonary tissue
Opportunistic infections: urinary tract infections in catheterized patients; bacteremia in immunocompromised patients with contaminated intravascular catheters

Burkholderia pseudomallei

Pulmonary infections: can range from asymptomatic colonization to abscess formation (melioidosis)

Stenotrophomonas maltophilia

Opportunistic infections: a variety of infections (most commonly bacteremia and pneumonia) in immunocompromised patients previously exposed to broad-spectrum antimicrobial therapy

***Acinetobacter* Species**

Pulmonary infections: opportunistic pathogen in patients receiving respiratory therapy
Wound infections: traumatic (e.g., resulting from military conflicts) and nosocomial wounds

Moraxella catarrhalis

Pulmonary infections: tracheobronchitis or bronchopneumonia in patients with chronic pulmonary diseases

CLINICAL DISEASES

Pulmonary Infections

P. aeruginosa infections of the lower respiratory tract can range in severity from **asymptomatic colonization** or benign inflammation of the bronchials **(tracheobronchitis)** to severe **necrotizing bronchopneumonia** (Box 27.1). Colonization is seen in patients with CF, other chronic lung diseases, or neutropenia. Infections in patients with CF have been associated with exacerbation of the underlying disease and invasive pulmonary disease. Mucoid strains are commonly isolated from these patients and are difficult to eradicate because chronic infections with these bacteria are associated with progressive increase in acquired antibiotic resistance and expression of adaptive resistance (see earlier discussion).

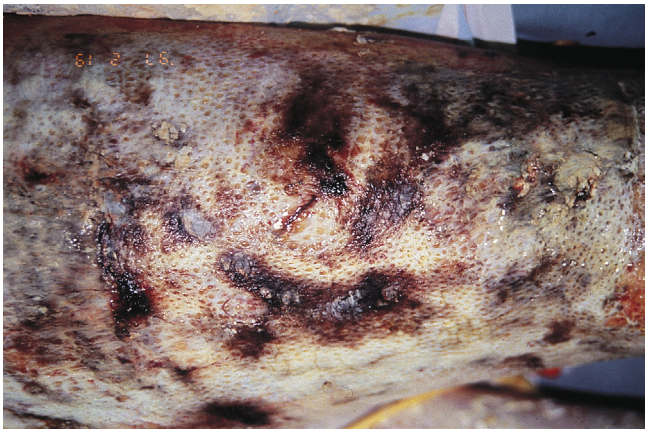

Fig. 27.3 *Pseudomonas* infection of burn wound. (From Cohen, J., Powderly, W.B., 2004. Infectious Diseases, second ed. St Louis, Mosby.)

Conditions that predispose immunocompromised patients to infections with *Pseudomonas* include (1) previous therapy with broad-spectrum antibiotics that eliminate the normal, protective bacterial population and (2) use of mechanical ventilation equipment, which may introduce the organism to the lower airways. Invasive disease in this population is characterized by a diffuse, typically bilateral bronchopneumonia with microabscess formation and tissue necrosis. The mortality rate is as high as 70%.

Primary Skin and Soft-Tissue Infections

P. aeruginosa can cause a variety of primary skin infections. The most recognized are infections of **burn wounds** (Fig. 27.3). Colonization of a burn wound, followed by localized vascular damage, tissue necrosis, and ultimately bacteremia, is common in patients with severe burns. The moist surface of the burn and inability of neutrophils to penetrate into the wounds predispose patients to such infections. Wound management with topical antibiotic creams has had only limited success in controlling these infections.

Folliculitis (Fig. 27.4; Clinical Case 27.1) is another common infection caused by *Pseudomonas,* resulting from immersion in contaminated water (e.g., hot tubs, whirlpools, swimming pools). Secondary infections with *Pseudomonas* also occur in people who have acne or who depilate their legs. Finally, *P. aeruginosa* can cause fingernail infections in people whose hands are frequently exposed to water or who frequent "nail salons."

P. aeruginosa is also the most common cause of **osteochondritis** (inflammation of bone and cartilage) of the foot after a penetrating injury (e.g., associated with stepping on a nail).

Urinary Tract Infections

Infection of the urinary tract is seen primarily in patients with long-term **indwelling urinary catheters.** Typically, such patients are treated with multiple courses of antibiotics, which tend to select for the more resistant strains of bacteria, such as *Pseudomonas.*

Fig. 27.4 *Pseudomonas* folliculitis. (From Cohen, J., Powderly, W.B., 2004. Infectious Diseases, second ed. St Louis, Mosby.)

Clinical Case 27.1 *Pseudomonas* Folliculitis

Ratnam and associates (*J Clin Microbiol* 23:655–659, 1986) described an outbreak of folliculitis caused by *P. aeruginosa* in guests of a Canadian hotel. A number of guests complained of a skin rash that began as pruritic erythematous papules and progressed to erythematous pustules distributed in the axilla and over the abdomen and buttocks. For most patients, the rash resolved spontaneously over a 5-day period. The local health department investigated the outbreak and determined the source was a whirlpool contaminated with a high concentration of *P. aeruginosa*. The outbreak was terminated when the whirlpool was drained, cleaned, and superchlorinated. Skin infections such as this are common in individuals with extensive exposure to contaminated water.

Ear Infections

External otitis is frequently caused by *P. aeruginosa*, with swimming an important risk factor **("swimmer's ear").** This localized infection can be managed with topical antibiotics and drying agents. **Malignant external otitis** is a virulent form of disease seen primarily in persons with diabetes and elderly patients. It can invade the underlying tissues, damage the cranial nerves and bones, and be life-threatening. Aggressive antimicrobial and surgical intervention is required for patients with the latter disease. *P. aeruginosa* is also associated with **chronic otitis media.**

Eye Infections

Infections of the eye occur after initial trauma to the cornea (e.g., abrasion from contact lens, scratch on the eye surface) and then exposure to *P. aeruginosa* in contaminated water. **Corneal ulcers** develop and can progress to rapidly progressive, eye-threatening disease unless prompt treatment is initiated.

Bacteremia and Endocarditis

Bacteremia caused by *P. aeruginosa* is clinically indistinguishable from that caused by other gram-negative bacteria. However, the mortality rate in affected patients is higher with *P. aeruginosa* bacteremia because of (1) the predilection of the organism for immunocompromised patients, (2) difficulty in treating antibiotic-resistant strains, and (3) the inherent virulence of *Pseudomonas.* Bacteremia occurs most often in patients with neutropenia, diabetes mellitus, extensive burns, and hematologic malignancies. Most bacteremias originate from infections of the lower respiratory tract, urinary tract, and skin and soft tissue (particularly burn wound infections). Although seen in a minority of bacteremic patients, characteristic skin lesions **(ecthyma gangrenosum)** may develop. The lesions manifest as erythematous vesicles that become hemorrhagic, necrotic, and ulcerated. Microscopic examination of the lesion shows abundant organisms, vascular destruction (which explains the hemorrhagic nature of the lesions), and an absence of neutrophils, as would be expected in neutropenic patients.

Pseudomonas **endocarditis** is uncommon and is primarily seen in intravenous drug abusers. These patients acquire the infection from the use of drug paraphernalia contaminated with the waterborne organisms. The tricuspid valve is often involved, and the infection is associated with a chronic course but with a more favorable prognosis than that in patients who have infections of the aortic or mitral valve.

Other Infections

P. aeruginosa is also the cause of a variety of other infections, including those localized in the gastrointestinal tract, central nervous system, and musculoskeletal system. The underlying conditions required for most infections are (1) the presence of the organism in a moist reservoir and (2) compromised host defenses (e.g., cutaneous trauma, elimination of normal microbial flora as a result of antibiotic usage, neutropenia).

LABORATORY DIAGNOSIS

Microscopy

Observation of thin gram-negative rods arranged singly and in pairs is suggestive of *Pseudomonas* but not definitive; *Burkholderia, Stenotrophomonas,* and other pseudomonads have a similar morphology.

Culture

Because *Pseudomonas* has simple nutritional requirements, the bacteria are readily recovered on common isolation media such as blood agar and MacConkey agar. They do require aerobic incubation (unless nitrate is available), so their growth in broth is generally confined to the broth–air interface, in which the oxygen concentration is the highest.

Identification

The colonial morphology (Fig. 27.5), odor, and results of selected rapid biochemical tests (e.g., positive **oxidase** reaction)

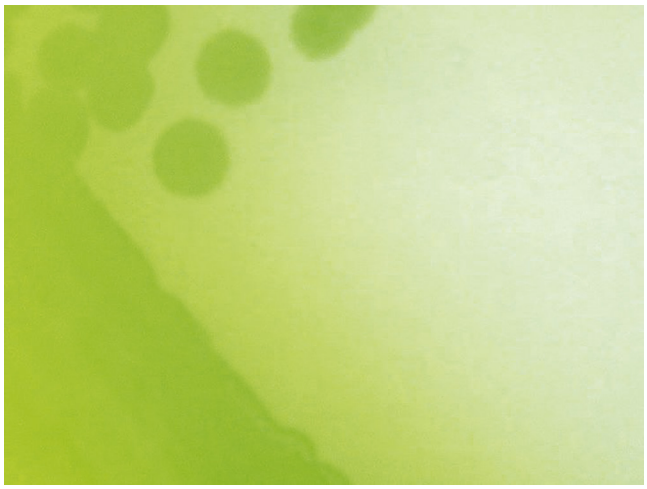

Fig. 27.5 Colonial morphology of *Pseudomonas aeruginosa;* note the green pigmentation that results from the production of two water-soluble dyes: blue pyocyanin and yellow fluorescein.

are sufficient for the preliminary identification of these isolates. For example, *P. aeruginosa* grows rapidly and has flat colonies with a spreading border, **β-hemolysis,** a **green pigmentation** caused by the production of the blue (pyocyanin) and yellow-green (pyoverdin) pigments, and a characteristic sweet, **grapelike odor.** Although definitive identification of *P. aeruginosa* is relatively easy, an extensive battery of physiologic tests may be required to identify other *Pseudomonas* species.

TREATMENT, PREVENTION, AND CONTROL

The antimicrobial therapy for *Pseudomonas* infections is frustrating because (1) the bacteria are typically resistant to most antibiotics, and (2) the infected patient with compromised host defenses cannot augment the antibiotic activity. A **combination of active antibiotics** is generally required for therapy to be successful in patients with serious infections. This is challenging because many strains of *P. aeruginosa* are now resistant to all β-lactam antibiotics including the carbapenems, aminoglycosides, and colistin.

Attempts to eliminate *Pseudomonas* from the hospital environment are practically useless given the ubiquitous presence of the organism in water supplies. Effective infection-control practices should concentrate on **preventing the contamination of sterile equipment,** such as mechanical ventilation equipment and dialysis machines, and the cross-contamination of patients by medical personnel. Inappropriate use of broad-spectrum antibiotics should also be avoided because such use can suppress the normal microbial flora and permit overgrowth of resistant strains of *Pseudomonas*.

Burkholderia

In 1992, seven species formerly classified as *Pseudomonas* were reclassified as members of the new genus *Burkholderia.* It was subsequently appreciated that the most common species, *B. cepacia,* was actually a complex of 17 species. Because most laboratories cannot identify the individual species, the collection is commonly referred to as *B. cepacia* complex. ***B. cepacia* complex** and ***B. pseudomallei*** are important human pathogens in this genus (see Box 27.1); other species (e.g., *B. mallei*) are less commonly associated with human disease.

Clinical Case 27.2 ***Burkholderia* Granulomatous Disease**

Mclean-Tooke and associates (*BMC Clin Pathol* 7:1–5, 2007) described a 21-year-old man with granulomatous lymphadenitis. The man presented with a history of weight loss, fevers, hepatosplenomegaly, and cervical lymphadenopathy. During the preceding 3 years he had presented on two occasions with enlarged lymph nodes that were biopsied, and histologic examination revealed granulomatous lymphadenitis. A clinical diagnosis of sarcoidosis was made, and the man was discharged on 20 mg prednisolone. Over the next 24 months, the patient remained clinically well; however, he developed pancytopenia, and granulomas were observed on a bone marrow biopsy. During the current hospitalization, the patient developed a cough. Chest radiograph revealed consolidation in the base of the lungs. A lung biopsy and bronchoalveolar lavage was submitted for culture, and *B. cepacia* was isolated from both specimens. A subsequent immunologic evaluation of the patient confirmed that he had a genetic disease, chronic granulomatous disease (CGD). This case illustrates the susceptibility of CGD patients to infections with *Burkholderia*.

Like *P. aeruginosa, Burkholderia* species can colonize a variety of moist environmental surfaces and are **opportunistic pathogens**. Patients particularly susceptible to pulmonary infections with *B. cepacia* complex are those with CF or chronic granulomatous disease (CGD; a primary immunodeficiency in which white blood cells have defective intracellular microbicidal activity). (Clinical Case 27.2) Colonization of the respiratory tract of CF patients with *B. cepacia* complex has such a poor prognosis that this is a contraindication for lung transplantation. *B. cepacia* complex is also responsible for UTIs in catheterized patients, septicemia (particularly in patients with contaminated intravascular catheters), and other opportunistic infections. With the exception of pulmonary infections, *B. cepacia* complex has a relatively low level of virulence, and infections with the organism do not commonly result in death.

B. pseudomallei is a saprophyte found in soil, water, and vegetation. It is endemic in Southeast Asia, India, Africa, and Australia. Infections are acquired by either inhalation or less commonly by percutaneous inoculation. Most persons exposed to *B. pseudomallei* remain asymptomatic; however, alcoholics, diabetics, and individuals with chronic renal or lung disease are susceptible to opportunistic infections caused by this organism. Infections are called **melioidosis** (*melis,* distemper; *eidos,* resemblance; *osis,* condition: disease resembling equine distemper or glanders caused by *B. mallei*). Exposure by the percutaneous route presents as a localized, suppurative **cutaneous infection** accompanied by regional lymphadenitis, fever, and malaise. This form of disease can resolve without incident or can progress rapidly to overwhelming sepsis. **Pulmonary disease** that develops after respiratory exposure may range in severity from a mild bronchitis to necrotizing pneumonia. Cavitation

Clinical Case 27.3 **Disseminated *Stenotrophomonas* Infection in a Neutropenic Patient**

Wan-Yee and associates (*Ann Acad Med Singapore* 35:897–900, 2006) described an 8-year-old Chinese girl with acute myeloid leukemia and a complex history of recurrent fungal and bacterial infections during treatment of her leukemia. Infections included pulmonary aspergillosis and septicemia with *Klebsiella, Enterobacter, Staphylococcus, Streptococcus,* and *Bacillus*. While receiving treatment with meropenem (a carbapenem antibiotic) and amikacin (an aminoglycoside), and during a period of severe neutropenia, she became bacteremic with *Stenotrophomonas maltophilia* that was sensitive to trimethoprim-sulfamethoxazole (TMP-SMX). Over the next few days, she developed painful, erythematous, nodular skin lesions. *S. maltophilia* was isolated from a biopsy of one of the lesions. Treatment with intravenous TMP-SMX led to gradual resolution of the skin lesions. This case illustrates the predilection for *Stenotrophomonas* to cause disease in immunocompromised patients receiving a carbapenem antibiotic. Characteristically, *Stenotrophomonas* is one of the few gram-negative bacteria that is inherently resistant to carbapenems and aminoglycoside and susceptible to TMP-SMX.

progressing to overwhelming sepsis and death can develop if appropriate antimicrobial therapy is not instituted. *B. pseudomallei* has been used in biological weapons programs, so work with this organism is restricted to appropriately licensed laboratories and its recovery from a patient justifies intervention by the public health department. Isolation of *B. pseudomallei* for diagnostic purposes should be approached carefully because the organism is highly infectious, similar to respiratory pathogens such as *Mycobacterium tuberculosis*.

Burkholderia species are susceptible to **trimethoprim-sulfamethoxazole (TMP-SMX),** which distinguishes them from *P. aeruginosa,* which is uniformly resistant. Although the organisms appear to be susceptible in vitro to piperacillin, broad-spectrum cephalosporins, and ciprofloxacin, the clinical response is generally poor.

Stenotrophomonas maltophilia

S. maltophilia was originally classified in the genus *Pseudomonas,* moved to the genus *Xanthomonas,* and then transferred to the genus *Stenotrophomonas.* Despite the confusion created by these taxonomic changes, the clinical importance of this opportunistic pathogen is well known. It is responsible for infections in debilitated patients with impaired host defense mechanisms. Also, because *S. maltophilia* is resistant to most commonly used β-lactam and aminoglycoside antibiotics, patients receiving long-term antibiotic therapy with these drugs are particularly at risk for acquiring infections.

The most common nosocomial infections caused by *S. maltophilia* are bacteremia and pneumonia, with both associated with a high incidence of complications and death (Clinical Case 27.3). Hospital infections with this organism have been traced to contaminated intravenous catheters, disinfectant solutions, mechanical ventilation equipment, and ice machines.

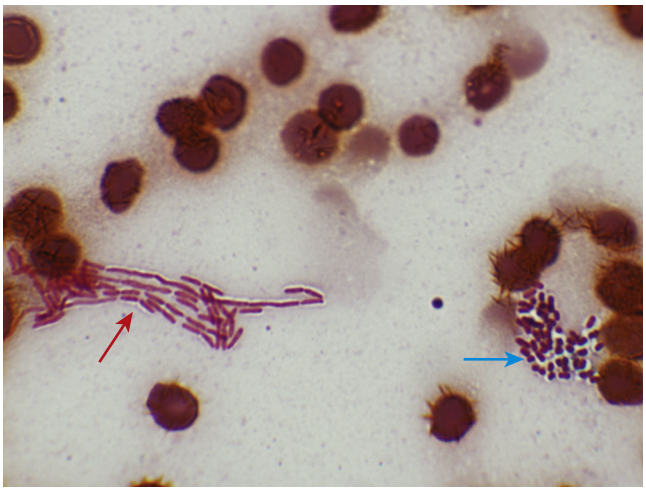

Fig. 27.6 Gram stain of *Acinetobacter baumannii (blue arrow)* and *Pseudomonas aeruginosa (red arrow).*

Antimicrobial therapy is complicated because the organism is resistant to many commonly used drugs. In contrast with most gram-negative rods, *Stenotrophomonas* is uniformly **resistant to carbapenems** (e.g., imipenem, meropenem, ertapenem, doripenem) and typically susceptible to **TMP-SMX,** although increased resistance has been reported in some studies. Treatment is usually effective with TMP-SMX (if susceptible) or with ciprofloxacin combined with ticarcillin-clavulanate or ceftazidime.

Acinetobacter

Acinetobacters are strictly aerobic, oxidase-negative, plump gram-negative coccobacilli (Fig. 27.6). They are saprophytes, recovered in nature and in the hospital and able to survive on both moist surfaces, such as mechanical ventilation equipment, and on dry surfaces, such as human skin (the latter feature is unusual for gram-negative rods). These bacteria are also part of the normal oropharyngeal flora of a small number of healthy people and can proliferate to large numbers during hospitalization. The genus *Acinetobacter* is subdivided into two groups: glucose-oxidizing species (***A. baumannii*** is the most common) and glucose nonoxidizing species (***A. lwoffii*** and ***A. haemolyticus*** are the most common). Most human infections are caused by *A. baumannii*.

Acinetobacters are **opportunistic pathogens** (see Box 27.1) that cause infections in the respiratory tract, urinary tract, and wounds; they also cause septicemia. Patients at risk for *Acinetobacter* infections are those receiving broad-spectrum antibiotics, recovering from surgery, or on respiratory ventilation. Nosocomial wound and pulmonary infections in hospitalized patients have become a significant problem because many of the infections are caused by strains resistant to most antibiotics, including the carbapenems. Specific therapy must be guided by in vitro susceptibility tests. Care must be taken when carbapenems or

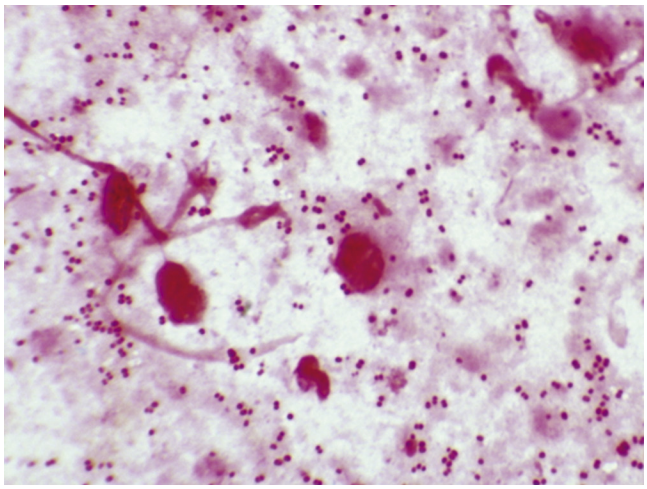

Fig. 27.7 Gram stain of *Moraxella catarrhalis*.

colistin are selected because in vitro tests may not reliably detect heteroresistant strains (i.e., a highly resistant subpopulation of organisms).

Moraxella

Like other genera discussed in this chapter, the genus *Moraxella* was reorganized on the basis of nucleic acid analysis. Although the species classified in this genus continue to change, *M. catarrhalis* is the most important pathogen. ***M. catarrhalis*** is a strictly aerobic, oxidase-positive, gram-negative diplococci (Fig. 27.7). This organism is a common cause of bronchitis and bronchopneumonia (in elderly patients with chronic pulmonary disease), sinusitis, and otitis (see Box 27.1). The latter two infections occur most commonly in previously healthy people. Most isolates produce β-lactamases and are **resistant to penicillins;** however, these bacteria are uniformly susceptible to most other antibiotics, including cephalosporins, erythromycin, tetracycline, TMP-SMX, and the combination of penicillins with a β-lactamase inhibitor (e.g., clavulanic acid).

Case Study and Questions

A 63-year-old man has been hospitalized for 21 days for the management of newly diagnosed leukemia. Three days after he entered the hospital, a UTI with *Escherichia coli* developed. He was treated for 14 days with broad-spectrum antibiotics. On day 21 of his hospital stay, the patient experienced fever and shaking chills. Within 24 hours he became hypotensive, and ecthymic skin lesions appeared. Despite aggressive therapy with antibiotics, the patient died. Multiple blood cultures were positive for *P. aeruginosa.*

1. What factors put this man at increased risk for infection with *P. aeruginosa?*
2. What virulence factors possessed by the organism make it a particularly serious pathogen? What are the biological effects of these factors?
3. What three mechanisms are responsible for the antibiotic resistance found in *P. aeruginosa?*
4. What diseases are caused by *B. cepacia* complex? *S. maltophilia? A. baumannii? M. catarrhalis?* What antibiotics can be used to treat these infections?

28 Campylobacter *and* Helicobacter

A 26-year-old woman was admitted to the hospital with a 48-hour history of colicky lower abdominal pain associated with about 20 watery stools per day, which contained mucus and blood. She was afebrile and had diffuse abdominal tenderness. No pathogens were isolated on routine stool culture, but specimens were also inoculated on a *Campylobacter*-selective medium and incubated microaerophilically at 40°C. Examination of the plates after 42 hours revealed the presence of flat, nonhemolytic, mucoid colonies that were subsequently identified as *C. jejuni*.

***Campylobacter* and *Helicobacter* are now widely recognized as significant human pathogens; however, they were unrecognized for many years.**

1. What properties of *Campylobacter* and *Helicobacter* led to their delayed discovery?
2. *Campylobacter* is associated with what two immune disorders?
3. How does *H. pylori* survive in the stomach?

Answers to these questions are available on Student Consult.com.

Summaries Clinically Significant Organisms

CAMPYLOBACTER

Trigger Words

Curved rods, gastroenteritis, Guillain-Barré syndrome

Biology and Virulence

- Thin, curved, gram-negative rods
- Factors that regulate adhesion, motility, and invasion into intestinal mucosa are poorly defined

Epidemiology

- Zoonotic infection; improperly prepared poultry is a common source of human infections
- Infections acquired by ingestion of contaminated food, unpasteurized milk, or contaminated water
- Person-to-person spread is unusual
- Dose required to establish disease is high unless the gastric acids are neutralized or absent
- Worldwide distribution with enteric infections seen throughout the year

Diseases

- Most common disease is acute enteritis with diarrhea, malaise, fever, and abdominal pain
- Guillain-Barré syndrome is believed to be an autoimmune disease caused by antigenic cross-reactivity between oligosaccharides in the bacterial capsule and glycosphingolipids on the surface of neural tissues
- Most infections are self-limited but can persist for a week or more
- *C. fetus* is associated with septicemia and is disseminated to multiple organs

Diagnosis

- Microscopic detection of thin, S-shaped, gram-negative rods in stool specimens is specific but insensitive
- Commercial multiplex nucleic acid amplification assays are highly sensitive and specific for enteric pathogens and particularly useful for detection of *C. jejuni* and *C. coli* infections
- Culture requires use of specialized media incubated with reduced oxygen, increased carbon dioxide, and (for thermophilic species) elevated temperatures; requires incubation for 2 or more days and is relatively insensitive unless fresh media are used
- Detection of *Campylobacter* antigens in stool specimens is moderately sensitive and very specific compared with culture

Treatment, Prevention, and Control

- For gastroenteritis, infection is self-limited and is managed by fluid and electrolyte replacement
- Severe gastroenteritis and septicemia are treated with erythromycin or azithromycin
- Gastroenteritis is prevented by proper preparation of food and consumption of pasteurized milk; preventing contamination of water supplies also controls infection
- Experimental vaccines targeting the outer capsular polysaccharides are promising for control of infections in animal reservoirs

*H*ELICOBACTER PYLORI

Trigger Words

Gastritis, peptic ulcers, gastric cancer, lymphoid tissue lymphoma, urease

Biology and Virulence

- Curved gram-negative rods
- Urease production at very high levels is typical of gastric helicobacters (e.g., *H. pylori;* important diagnostic test for *H. pylori*) and uncommon in intestinal helicobacters
- Multiple factors contribute to gastric colonization, inflammation, alteration of gastric acid production, and tissue destruction

Epidemiology

- Infections are common, particularly in people in a low socioeconomic class or in developing nations
- Humans are the primary reservoir
- Person-to-person spread is important (typically fecal-oral)
- Ubiquitous and worldwide, with no seasonal incidence of disease

Diseases

- *H. pylori* is an important cause of acute and chronic gastritis, peptic ulcers, gastric adenocarcinoma, and mucosa-associated lymphoid tissue lymphoma

Diagnosis

- Microscopy: histologic examination of biopsy specimens is sensitive and specific
- Urease test relatively sensitive and highly specific; urea breath test is a noninvasive test
- *H. pylori* antigen test is sensitive and specific; performed with stool specimens
- Culture requires incubation in microaerophilic conditions; growth is slow; relatively insensitive unless multiple biopsies are cultured
- Serology useful for demonstrating exposure to *H. pylori*

Treatment, Prevention, and Control

- Multiple regimens have been evaluated for treatment of *H. pylori* infections. Combined therapy with a proton pump inhibitor (e.g., omeprazole), a macrolide (e.g., clarithromycin), and a β-lactam (e.g., amoxicillin) for 2 weeks has had a high success rate
- Prophylactic treatment of colonized individuals has not been useful and potentially has adverse effects, such as predisposing patients to adenocarcinomas of the lower esophagus
- Human vaccines are not currently available

TABLE 28.1 Important *Campylobacter* and *Helicobacter* Species

Organism	Historical Derivation
Campylobacter	*kampylos,* curved; *bacter,* rod (a curved rod)
C. jejuni	*jejuni,* of the jejunum
C. coli	*coli,* of the colon
C. fetus	*fetus,* refers to the initial observation that these bacteria caused fetal infections
C. upsaliensis	*upsaliensis,* original isolates recovered from the feces of dogs at an animal clinic in Uppsala, Sweden
Helicobacter	*helix,* spiral; *bacter,* rod (a spiral rod)
H. pylori	*pylorus,* lower part of the stomach
H. cinaedi	*cinaedi,* of a homosexual (the organism was first isolated from homosexuals with gastroenteritis)
H. fennelliae	*fennelliae,* named after C. Fennell, who first isolated the organism

There are two families of related spiral-shaped gram-negative bacteria of clinical importance: **Campylobacteraceae,** which includes *Campylobacter* and **Helicobacteraceae,** which includes *Helicobacter* (Table 28.1). Members of these families share two important properties that contribute to problems with recovering the organisms in culture and identification by traditional biochemical testing: (1) microaerophilic growth requirements (i.e., growth only in the presence of reduced oxygen and increased carbon dioxide) and (2) inability to ferment or oxidize carbohydrates.

Campylobacter

The genus *Campylobacter* consists of small (0.2 to 0.5 μm wide and 0.5 to 5.0 μm long), motile, **comma-shaped, gram-negative rods** (Fig. 28.1). Bacteria in older colonies may appear coccoid rather than rodlike. More than 50 species and subspecies are recognized, many of which are associated with human disease, but only four species are common human pathogens (Table 28.2).

The primary diseases caused by campylobacters are gastroenteritis and septicemia. *Campylobacter* is the most common cause of bacterial gastroenteritis in both developed and developing countries, with ***C. jejuni*** responsible for most infections and ***C. coli*** associated with a minority of cases of *Campylobacter* gastroenteritis in the United States (more commonly observed in developing countries). The incidence of gastroenteritis caused by ***C. upsaliensis*** is unknown because the organism is inhibited by the antibiotics used in most isolation media for other campylobacters; however, some have estimated that 10% of *Campylobacter* gastroenteritis is caused by this bacterium. Unlike other *Campylobacter* species, ***C. fetus*** is primarily responsible for causing systemic infections such as bacteremia, septic thrombophlebitis, arthritis, septic abortion, and meningitis.

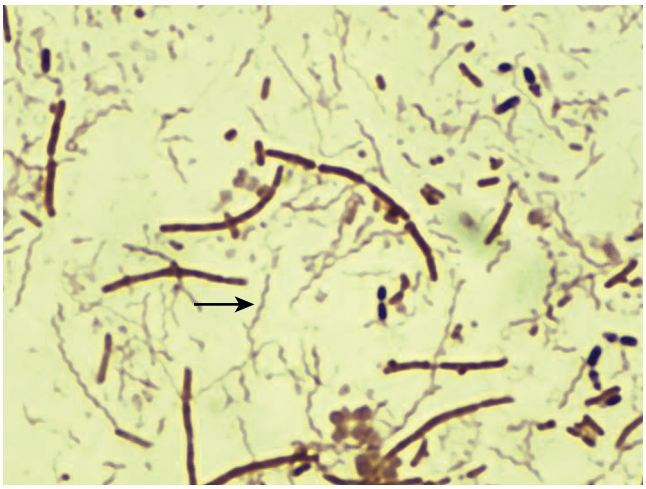

Fig. 28.1 Mixed culture of bacteria from a fecal specimen. *Campylobacter jejuni* is the thin, curved, gram-negative bacteria *(arrow).*

TABLE 28.2 Common *Campylobacter* Species Associated with Human Disease

Species	Common Reservoir Hosts	Human Disease
Campylobacter jejuni	**Poultry,** cattle, sheep	**Gastroenteritis,** extraintestinal infections, **Guillain-Barré syndrome, reactive arthritis**
C. coli	**Pigs,** poultry, sheep, birds	**Gastroenteritis,** extraintestinal infections
C. fetus	**Cattle, sheep**	**Vascular infections** (e.g., septicemia, septic thrombophlebitis, endocarditis), meningoencephalitis, gastroenteritis
C. upsaliensis	**Dogs,** cats	**Gastroenteritis,** extraintestinal infections, Guillain-Barré syndrome

Bold type signifies the most common hosts and diseases.

PHYSIOLOGY AND STRUCTURE

Recognition of the role of campylobacters in gastrointestinal (GI) disease was delayed because the organisms grow best in an atmosphere of reduced oxygen (5% to 7%) and increased carbon dioxide (5% to 10%). These are not the typical incubation conditions used for bacterial cultures. In addition, ***C. jejuni* grows better at 42°C** than at 37°C. These properties have been exploited for the selective isolation of pathogenic campylobacters in stool specimens. The **small size** of the organisms (0.2 to 0.5 μm in diameter) also has been used to recover the bacteria by filtration of stool specimens. Campylobacters pass through 0.45-μm filters, whereas other bacteria are retained. Although this property led to the initial discovery of campylobacters (stools were filtered looking for viruses), filtration of stool specimens is a cumbersome procedure and is not used in clinical laboratories. Campylobacters have a gram-negative cell wall structure with an outer polysaccharide capsule. Instead of cell wall lipopolysaccharides (LPS) with endotoxin activity found in other gram-negative bacteria, they express

lipooligosaccharides. The capsular polysaccharides contribute to the virulence of the bacteria and are the targets of vaccine development.

PATHOGENESIS AND IMMUNITY

Although adhesins, cytotoxic enzymes, and enterotoxins have been detected in *C. jejuni,* their specific role in disease remains poorly defined. It is clear that the risk of disease is influenced by the infectious dose. The organisms are killed when exposed to gastric acids, so conditions that decrease or neutralize gastric acid secretion favor disease. The patient's immune status also affects the severity of disease. People living in a population of high endemic disease develop measurable levels of specific serum and secretory antibodies and have less severe disease. As would be expected, patients with hypogammaglobulinemia have prolonged severe disease with *C. jejuni*.

C. jejuni GI disease characteristically produces **histologic damage to the mucosal surfaces of the jejunum** (as implied by the name of the species), ileum, and colon. The mucosal surface appears ulcerated, edematous, and bloody, with crypt abscesses in the epithelial glands and infiltration of the lamina propria with neutrophils, mononuclear cells, and eosinophils. This inflammatory process is consistent with invasion of the organisms into the intestinal tissue. However, the precise roles of cytopathic toxins, enterotoxins, and endotoxic activity that have been detected in *C. jejuni* isolates have not been defined. For example, strains lacking enterotoxin activity are still fully virulent.

C. jejuni and *C. upsaliensis* have been associated with **Guillain-Barré syndrome,** which is an autoimmune disorder of the peripheral nervous system characterized by development of symmetric weakness over several days and recovery requiring months or longer. Although this is an uncommon complication of *Campylobacter* disease (≈1 in 1000 diagnosed infections), the syndrome has been associated with specific serotypes (primarily *C. jejuni* serotype O:19). It is believed that the pathogenesis of this disease is related to **antigenic cross-reactivity** between the surface lipooligosaccharides of some strains of *Campylobacter* and peripheral nerve gangliosides. Thus antibodies directed against specific strains of *Campylobacter* can damage neural tissue in the peripheral nervous system. Another immune-related late complication of *Campylobacter* infections is **reactive arthritis,** which is a condition characterized by joint pain and swelling involving the hands, ankles, and knees and persisting from 1 week to several months. Reactive arthritis is unrelated to the severity of the diarrheal disease but is more common in patients who have the HLA-B27 phenotype.

C. jejuni and *C. coli* rarely cause bacteremia (1.5 cases per 1000 intestinal infections); however, *C. fetus* has a propensity to spread from the GI tract to the blood and distal foci. In vitro studies provide an explanation for this observation: *C. fetus* is resistant to complement- and antibody-mediated serum killing, and *C. jejuni* and most other *Campylobacter* species are killed rapidly. *C. fetus* is covered with a heat-stable, capsule-like protein **(S protein)** that prevents C3b binding to the bacteria and subsequent complement-mediated killing in serum. *C. fetus* loses its virulence if this protein layer is removed. Bacteremia is particularly common in debilitated and immunocompromised patients, such as those with liver disease, diabetes mellitus, chronic alcoholism, or malignancies.

EPIDEMIOLOGY

Campylobacter infections are **zoonotic,** with a variety of animals serving as reservoirs (see Table 28.2). Humans acquire the infections with *C. jejuni* and *C. coli* after consumption of contaminated food, milk, or water; **contaminated poultry** is responsible for more than half of the *Campylobacter* infections in developed countries. Food products that neutralize gastric acids (e.g., milk) effectively reduce the infectious dose. Fecal-oral transmission from person-to-person contact may also occur, but it is **uncommon for the disease to be transmitted by food handlers.** *C. upsaliensis* infections are acquired primarily after contact with domestic dogs (either healthy carriers or pets with diarrheal disease).

Campylobacter infections are the most common bacterial diarrheal illness in the United States with an estimated annual incidence of 1.3 million illnesses, more than 13,000 hospitalizations, and 119 deaths with a cost of approximately $1.7 billion in medical care and lost productivity. The number of *Campylobacter* infections is likely to be even higher because many laboratories do not routinely culture for these pathogens, and *C. upsaliensis* is not isolated by commonly used techniques. Additionally, the increasing adoption of molecular diagnostics for enteric diseases have identified the poor sensitivity of culture.

Disease occurs sporadically through the year, with a peak incidence during the summer months. Disease is most commonly observed in **infants and young children,** with a second peak of disease in 20- to 40-year-old adults. The incidence of disease is higher in developing countries, with symptomatic disease in infants and young children and asymptomatic carriage frequently observed in adults.

C. fetus infections are relatively uncommon, with fewer than 250 cases reported in the United States annually. Unlike *C. jejuni, C. fetus* primarily infects immunocompromised or elderly people.

CLINICAL DISEASES

GI infections with *C. jejuni, C. coli,* and *C. upsaliensis* present most commonly as **acute enteritis** with diarrhea, fever, and severe abdominal pain. Affected patients can have 10 or more bowel movements per day during the peak of disease, and stools may be bloody on gross examination. The disease is generally self-limited, although symptoms may last for a week or longer. The range of clinical manifestations includes acute colitis, **abdominal pain mimicking acute appendicitis,** and chronic enteric infections that develop most commonly in immunocompromised patients (e.g., patients with acquired immunodeficiency syndrome [AIDS]). Various extraintestinal infections are reported but are relatively uncommon. **Guillain-Barré syndrome** and **reactive arthritis** are well-recognized complications of *Campylobacter* infections.(Clinical Case 28.1) *C. fetus* differs from other *Campylobacter* species in that this species is primarily responsible for **intravascular** (e.g., septicemia, endocarditis, septic thrombophlebitis) and **extraintestinal** (e.g., meningoencephalitis, abscesses) **infections.**

Clinical Case 28.1 ***Campylobacter jejuni* Enteritis and Guillain-Barré Syndrome**

Scully and associates (*N Engl J Med* 341:1996–2003, 1999) described the clinical history of a 74-year-old woman who developed Guillain-Barré syndrome after an episode of *C. jejuni* enteritis. After 1 week of fever, watery diarrhea, nausea, abdominal pain, weakness, and fatigue, the patient's speech was noted to be severely slurred. She was taken to the hospital, where it was noted she was unable to speak, although she was oriented and able to write coherently. She had perioral numbness, bilateral ptosis and facial weakness were noted, and her pupils were nonreactive. Neurologic examination revealed bilateral muscle weakness in her arms and chest. On the second hospital day, the muscle weakness extended to her upper legs. On the third hospital day, the patient's mental status remained normal, but she could only move her thumb minimally and could not lift her legs. Sensation to light touch was normal, but deep-tendon reflexes were absent. *C. jejuni* was recovered from this patient's stool culture, collected at the time of admission, and the clinical diagnosis of Guillain-Barré syndrome was made. Despite aggressive medical treatment, the patient had significant neurologic deficits 3 months after discharge to a rehabilitation facility. This woman illustrates one of the significant complications of *Campylobacter* enteritis.

LABORATORY DIAGNOSIS

Microscopy

Campylobacters are thin and not easily seen when specimens are Gram stained. Despite the low sensitivity of a Gram stain, observation of the characteristic **thin, S-shaped organisms** in a stool specimen (see Fig. 28.1) is useful for a presumptive confirmation of *Campylobacter* infection.

Antigen Detection

Commercial immunoassays for detection of *C. jejuni* and *C. coli* are available. When compared with culture, the tests have a sensitivity of 80% to 90% and a specificity of greater than 95%. Some strains of *C. upsaliensis* are also reactive in these tests.

Nucleic Acid–Based Tests

Commercial multiplex nucleic acid amplification tests for enteric pathogens are rapidly gaining acceptance because they can detect a comprehensive spectrum of bacterial, viral, and parasitic pathogens with a sensitivity superior to culture. This is particularly true for *Campylobacter* infections, although these molecular assays are generally restricted to detection of *C. jejuni* and *C. coli* and not the other *Campylobacter* species.

Culture

C. jejuni, C. coli, and *C. upsaliensis* went unrecognized for many years because their isolation requires growth in a **microaerophilic atmosphere** (i.e., 5% to 7% oxygen, 5% to 10% carbon dioxide), at an **elevated incubation temperature** (i.e., 42° C), and on selective agar media to suppress nonpathogenic enteric bacteria. The appropriate atmosphere for growing campylobacters can be produced by disposable commercial gas generator systems that are added to an incubation jar with the inoculated culture media. The selective media must contain blood or charcoal to remove toxic oxygen radicals, and antibiotics are added to inhibit the growth of contaminating organisms. Unfortunately, the antibiotics used in most *Campylobacter* media may inhibit some species (e.g., *C. upsaliensis*). Campylobacters are **slow-growing** organisms, usually requiring incubation for 48 hours or longer. *C. fetus* is not thermophilic and cannot grow at 42° C; however, its isolation requires a microaerophilic atmosphere.

Identification

A presumptive identification of isolates is based on growth under selective conditions, typical microscopic morphology, and positive oxidase and catalase tests. Mass spectrometry can be used for definitive species identification.

Antibody Detection

Serologic testing for immunoglobulin (Ig)M and IgG is useful for epidemiologic surveys but is not used for diagnosis in an individual patient.

TREATMENT, PREVENTION, AND CONTROL

Campylobacter gastroenteritis is typically a self-limited infection managed by the replacement of lost fluids and electrolytes. Antibiotic therapy may be used in patients with severe infections or septicemia. Campylobacters are susceptible to a variety of antibiotics, including macrolides (i.e., erythromycin, azithromycin, clarithromycin), tetracyclines, aminoglycosides, chloramphenicol, fluoroquinolones, clindamycin, amoxicillin/clavulanic acid, and imipenem. Most isolates are resistant to penicillins, cephalosporins, and sulfonamide antibiotics. **Erythromycin** or **azithromycin** are the antibiotics of choice for the treatment of enteritis, with tetracycline or fluoroquinolones used as secondary antibiotics. Resistance to fluoroquinolones has increased, so these drugs may be less effective. Amoxicillin/clavulanic acid can be used in place of tetracycline, which is contraindicated in young children. Systemic infections are treated with an aminoglycoside, chloramphenicol, or imipenem.

Exposure to enteric campylobacters is prevented by proper food preparation (particularly poultry), avoidance of unpasteurized dairy products, and implementation of safeguards to prevent contamination of water supplies. Almost 50 capsular serotypes of *C. jejuni* are recognized, although the majority of strains associated with disease are restricted to a limited number of serotypes. Preliminary studies demonstrate these are attractive targets for vaccines and potentially could reduce the colonization rate in food animals such as chickens and turkeys.

Helicobacter

In 1983, **spiral gram-negative rods** resembling campylobacters were found in patients with type B gastritis (chronic inflammation of the stomach antrum [pyloric end]). The organisms were originally classified as *Campylobacter* but

TABLE 28.3 *Helicobacter* Species Associated with Human Disease

Species	Common Reservoir Hosts	Human Disease
Helicobacter pylori	**Humans,** primates, pigs	**Gastritis, peptic ulcers, gastric adenocarcinoma,** mucosa-associated lymphoid tissue B-cell lymphomas
H. cinaedi	**Humans,** hamster	**Gastroenteritis,** septicemia, proctocolitis
H. fennelliae	**Humans**	**Gastroenteritis,** septicemia, proctocolitis

Bold type signifies the most common hosts and diseases.

were subsequently reclassified as a new genus, *Helicobacter*. Helicobacters were subsequently subdivided into species that primarily colonize the stomach **(gastric helicobacters)** and those that colonize the intestines **(enterohepatic helicobacters).** The most important species is ***H. pylori*,** which is a gastric helicobacter associated with **gastritis, peptic ulcers**, **gastric adenocarcinoma,** and **gastric mucosa-associated lymphoid tissue (MALT) B-cell lymphomas** (Table 28.3). The most important enterohepatic helicobacters associated with **gastroenteritis** and **bacteremia** are ***H. cinaedi*** and ***H. fennelliae*,** which have been isolated most commonly in immunocompromised patients (e.g., homosexual men with human immunodeficiency virus [HIV] infections).

PHYSIOLOGY AND STRUCTURE

Helicobacter species are characterized according to sequence analysis of their 16S rRNA genes, their cellular fatty acids, and the presence of polar flagella. Currently, more than 40 species have been characterized, but this taxonomy is changing rapidly. Helicobacters have a bacillary or **spiral shape** in young cultures (0.5 to 1.0 μm wide × 2 to 4 μm long) and, like campylobacters, can assume coccoid forms in older cultures (Fig. 28.2).

All gastric helicobacters, including *H. pylori,* are highly **motile** (corkscrew motility) and produce an abundance of **urease.** These properties are believed to be important for survival in gastric acids and rapid movement through the viscous mucus layer toward a neutral pH environment. Most helicobacters are catalase- and oxidase-positive and do not ferment or oxidize carbohydrates, although they can metabolize amino acids by fermentative pathways. LPS, consisting of lipid A, core oligosaccharide, and an O side chain, is present in the outer membrane. *H. pylori* lipid A has low endotoxin activity compared with other gram-negative bacteria, and the O side chain is antigenically similar to the Lewis blood group antigens, which may protect the bacteria from immune clearance.

Growth of *H. pylori* and other helicobacters requires a complex medium supplemented with blood, serum, charcoal, starch, or egg yolk in microaerophilic conditions (decreased oxygen and increased carbon dioxide) and in a temperature range between 30° C and 37° C. Because helicobacters are relatively difficult to isolate in culture and identify by biochemical testing, most diseases caused by *H. pylori* are confirmed by nonculture techniques.

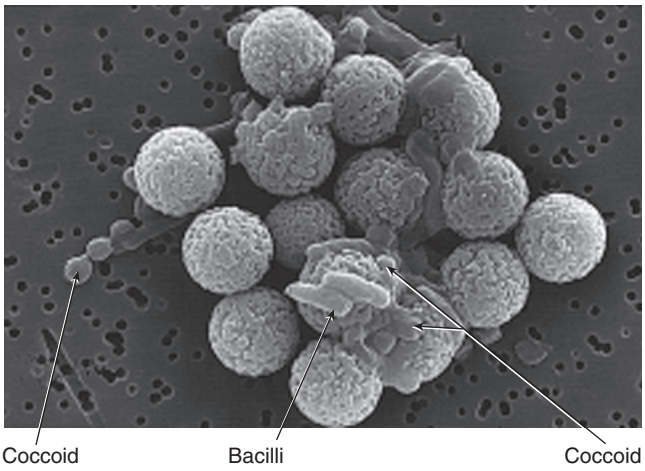

Fig. 28.2 Scanning electron micrograph of *Helicobacter pylori* in a 7-day culture. Bacillary and coccoid forms are bound to paramagnetic beads used in immunomagnetic separation. (Courtesy Dr. L. Engstrand, Uppsala, Sweden.)

PATHOGENESIS AND IMMUNITY

H. pylori is a remarkable bacterium in its ability to establish lifelong colonization in the stomach of untreated humans. Most research into the virulence factors in helicobacters has focused on *H. pylori.* Multiple factors contribute to the gastric colonization, inflammation, alteration of gastric acid production, and tissue destruction that are characteristic of *H. pylori* disease. Initial colonization is facilitated by (1) blockage of acid production by a bacterial acid–inhibitory protein and (2) neutralization of gastric acids with the ammonia produced by bacterial urease activity. The actively motile helicobacters can then pass through the gastric mucus and adhere to the gastric epithelial cells by multiple surface adhesion proteins. Surface proteins can also bind host proteins and help the bacteria evade the immune system. Localized tissue damage is mediated by **urease by-products**, **mucinase, phospholipases,** and the activity of **vacuolating cytotoxin A (VacA),** which is a protein that after penetration into epithelial cells damages the cells by producing vacuoles. Another important virulence factor of *H. pylori* is the **cytotoxin-associated gene *(cagA)*** that resides on a pathogenicity island containing approximately 30 genes. These genes encode a structure (type VI secretion system) that acts like a syringe to inject the CagA protein into the host epithelial cells, which interferes with the normal cytoskeletal structure of the epithelial cells. The *cag p*hosphoribosyl-*a*nthranilate *i*somerase (PAI) genes also induce **interleukin (IL)-8 production,** which attracts neutrophils. Release of proteases and reactive oxygen molecules by these neutrophils is believed to contribute to gastritis and gastric ulcers.

EPIDEMIOLOGY

An enormous amount of information about the prevalence of *H. pylori* has been collected since 1984 when the organism was first isolated in culture. The highest incidence of carriage is found in developing countries, in which 70% to 90% of the population is colonized, most before the age of 10 years. The prevalence of *H. pylori* in industrial countries such as the United States is less than 40% and is decreasing because

of improved hygiene and active treatment of colonized individuals. These studies have also demonstrated that 70% to 100% of patients with gastritis, gastric ulcers, or duodenal ulcers are infected with *H. pylori.* **Humans are the primary reservoir for *H. pylori*,** and colonization is believed to persist for life unless the host is specifically treated. Transmission is most likely via the **fecal-oral route.**

An interesting observation about *H. pylori* colonization has been made. This organism is clearly associated with diseases such as gastritis, gastric ulcers, gastric adenocarcinoma, and gastric MALT lymphomas. It is anticipated that treatment of colonized or infected individuals will lead to a reduction of these diseases. However, colonization with *H. pylori* appears to offer protection from gastroesophageal reflux disease and adenocarcinomas of the lower esophagus and gastric cardia. Thus it may be unwise to eliminate *H. pylori* in patients without symptomatic disease. Certainly, the complex relationship between *H. pylori* and its host continues to be defined.

CLINICAL DISEASES

Disease caused by helicobacters is directly related to their site of colonization. For example, *H. pylori* is associated with gastritis, whereas the enterohepatic species cause gastroenteritis. Colonization with *H. pylori* invariably leads to histologic evidence of **gastritis** (i.e., infiltration of neutrophils and mononuclear cells into the gastric mucosa). The acute phase of gastritis is characterized by a feeling of fullness, nausea, vomiting, and hypochlorhydria (decreased acid production in the stomach). This can evolve into chronic gastritis, with disease confined to the gastric antrum (in which few acid-secreting parietal cells are present) in individuals with normal acid secretion, or involve the entire stomach (pangastritis) if acid secretion is suppressed. Approximately 10% to 15% of patients with chronic gastritis will progress to develop peptic ulcers. The ulcers develop at the sites of intense inflammation, commonly involving the junction between the corpus and antrum **(gastric ulcer)** or the proximal duodenum **(duodenal ulcer).** *H. pylori* is responsible for 85% of the gastric ulcers and 95% of the duodenal ulcers. Recognition of the role of *H. pylori* has dramatically changed the treatment and prognosis of peptic ulcer disease (Clinical Case 28.2).

Chronic gastritis eventually leads to replacement of the normal gastric mucosa with fibrosis and proliferation of intestinal-type epithelium. This process increases the patient's risk for **gastric cancer** by almost 100-fold. This risk is influenced by the strain of *H. pylori* and the host's response (*cagA*-positive strains and high levels of IL-1 production are associated with a higher risk for cancer). Infection with *H. pylori* is also associated with infiltration of lymphoid tissue into the gastric mucosa. In a small number of patients, a monoclonal population of B cells may develop and evolve into a **MALT lymphoma.**

Clinical Case 28.2 **The Discovery of *Helicobacter pylori***

In 1984, Australian physicians Marshall and Warren reported a discovery that completely changed the approach to treatment of gastritis and peptic ulcer disease, as well as set the foundation for understanding the cause of gastric adenocarcinomas and mucosa-associated lymphoid tissue lymphomas (*Lancet* i:1311–1315, 1984). In an analysis of gastric biopsy specimens from 100 consecutive patients presenting for gastroscopy, they demonstrated curved gram-negative rods resembling *Campylobacter* in 58 patients. The bacteria were observed in most patients with active gastritis, gastric ulcers, and duodenal ulcers. Although similar organisms were observed associated with gastric tissues 45 years earlier, this report stimulated resurgence in investigations of the role of this "new" organism in gastric diseases. Despite the skepticism that greeted their initial report, the significance of their work with *Campylobacter* was recognized in 2005 when Marshall and Warren received the Nobel Prize in Medicine.

LABORATORY DIAGNOSIS

Microscopy

H. pylori is detected by histologic examination of gastric biopsy specimens. Although the organism can be seen in specimens stained with hematoxylin-eosin or Gram stain, the Warthin-Starry silver stain is the most sensitive. When an adequate specimen is collected and examined by an experienced microscopist, the test sensitivity and specificity approaches 100% and is considered diagnostic. Because this is an invasive test, alternative test procedures are preferred for routine diagnosis. The microscopic examination of stool specimens for helicobacters is not reliable because the organisms are difficult to see and nonpathogenic helicobacters may be present.

Antigen Detection

Biopsy specimens can also be tested for the presence of bacterial urease activity. The abundance of urease produced by *H. pylori* permits detection of the alkaline by-product in less than 2 hours. The sensitivity of the direct test with biopsy specimens varies from 75% to 95%; however, the specificity approaches 100%. Thus a positive reaction is compelling evidence of an active infection. As with microscopy, the limitation of this method is the requirement for a biopsy specimen. Noninvasive urease testing of human breath (urea breath test) after consumption of an isotopically labeled urea solution has excellent sensitivity and specificity. Unfortunately, this assay is relatively expensive because of the cost of the detection instruments.

A number of polyclonal and monoclonal immunoassays for *H. pylori* antigens excreted in stool have been developed and demonstrated to have sensitivities and specificities exceeding 95%. These tests are easy to perform, inexpensive, and able to be used on stool specimens rather than biopsies. These assays are now widely recommended for both detection of *H. pylori* infections and confirmation of cure after antibiotic treatment.

Nucleic Acid–Based Tests

Currently, nucleic acid–based amplification tests for *H. pylori* and enterohepatic helicobacters are restricted to research laboratories and not used in clinical laboratories.

Culture

H. pylori adheres to gastric mucosa and is not recovered in stool or blood specimens. The bacteria can be isolated in culture if the specimen is inoculated onto an enriched medium supplemented with blood, hemin, or charcoal and incubated in a microaerophilic atmosphere for up to

2 weeks. However, diagnosis of *H. pylori* infections is most commonly done by noninvasive methods (e.g., immunoassay), with culture reserved for antibiotic susceptibility tests.

Identification

Presumptive identification of isolates is based on their growth characteristics under selective conditions; typical microscopic morphologic findings; and detection of oxidase, catalase, and urease activity. Mass spectrometry can be used for definitive species identification.

Antibody Detection

Serology is an important screening test for the diagnosis of *H. pylori,* with a variety of commercial tests available. Although IgM antibodies disappear rapidly, IgA and IgG antibodies can persist for months to years. Because the **antibody titers persist** for many years, the test cannot be used to discriminate between past and current infection. Furthermore, the titer of antibodies measured does not correlate with the severity of disease or the response to therapy. However, the tests are useful for documenting exposure to the bacteria, either for epidemiologic studies or for the initial evaluation of a symptomatic patient.

TREATMENT, PREVENTION, AND CONTROL

Numerous antibiotic regimens have been evaluated for treating *H. pylori* infections. Use of a single antibiotic or an antibiotic combined with bismuth is ineffective. The greatest success in curing gastritis or peptic ulcer disease has been accomplished with the combination of a **proton pump inhibitor** (e.g., omeprazole), a **macrolide** (e.g., clarithromycin), and a β**-lactam** (e.g., amoxicillin), with administration for 7 to 10 days initially. Treatment failure is most commonly associated with clarithromycin resistance. Susceptibility testing should be performed if the patient does not respond to therapy. Metronidazole can also be used in combination therapy, but resistance is commonplace.

Infection with *H. pylori* stimulates a strong TH1 cell–mediated inflammatory response. Use of *H. pylori* antigens in experimental vaccines that stimulate TH1 cells leads to enhanced inflammation. In contrast, use of antigens in combination with mucosal adjuvants that induce a TH2 cell response is protective in an animal model and can eradicate existing infections. The effectiveness of these vaccines in humans remains to be demonstrated.

For a case study and questions see StudentConsult.com.

Case Study and Questions

A mother and her 4-year-old son came to the local emergency room with a 1-day history of diarrhea and abdominal cramping. Both patients had low-grade fevers, and blood was grossly evident in the child's stool specimen. The symptoms had developed 18 hours after the patients had consumed a dinner consisting of mixed green salad, chicken, corn, bread, and apple pie. Culture of blood samples was negative for organisms, but *C. jejuni* was isolated from stool specimens of both the mother and the child.

1. Which food that they consumed is most likely responsible for these infections? What measures should be used to prevent these infections?
2. Name three *Campylobacter* species that have been associated with gastroenteritis. Name the species of *Campylobacter* most commonly associated with septicemia.
3. What diseases have been associated with Helicobacter pylori? *H. cinaedi*? *H. fennelliae*?
4. *H. pylori* has multiple virulence factors. Which factors are responsible for interfering with gastric acid secretion? For adhering to the gastric epithelium? For disrupting the gastric mucus? For interfering with phagocytic killing?

29 Miscellaneous Gram-Negative Rods

The gram-negative rods discussed in this chapter are a miscellaneous collection of clinically important bacteria.

1. Which *Bartonella* species are associated with disease in immunocompromised patients, and how do these infections present?
2. What is the epidemiologic source of *Bordetella pertussis* infections?
3. Why is culture not a good diagnostic test for *B. pertussis?*
4. What is the most common source of human infections with *Francisella* and *Brucella?*
5. What disease is produced by *Cardiobacterium* species?
6. Why had *Legionella* not been recognized before the 1976 outbreak in Philadelphia at the American Legion convention?

Answers to these questions are available on Student Consult.com.

Summaries Clinically Significant Organisms

BORDETELLA PERTUSSIS

Trigger Words

Slow growing, whooping cough, pertussis toxin, person to person, vaccination

Biology and Virulence

- Very small gram-negative coccobacilli
- Nonfermentative but can oxidize amino acids as an energy source
- Strict aerobe
- Growth in vitro requires prolonged incubation in media supplemented with charcoal, starch, blood, or albumin
- Adherence to eukaryotic cells mediated by pertactin, filamentous hemagglutinin, and fimbria; localized tissue destruction mediated by dermonecrotic toxin and tracheal cytotoxin; systemic toxicity produced by pertussis toxin

Epidemiology

- Pertussis is a human disease with no known animal or environmental reservoir
- Worldwide distribution with a high prevalence in unvaccinated populations
- Children younger than 1 year are at greatest risk for infection and mortality
- In vaccinated populations, disease is observed in older children and young adults
- Unvaccinated individuals are at greatest risk for disease
- Disease spread person to person by infectious aerosols

Diseases

- Pertussis characterized by three stages: catarrhal, paroxysmal, and convalescent
- Most severe disease is in unvaccinated individuals, particularly children

Diagnosis

- Microscopy is insensitive and nonspecific
- Culture is specific but insensitive
- Nucleic acid amplification tests are the most sensitive and specific tests
- Detection of immunoglobulin (Ig)G or IgA can be used as a confirmatory test

Treatment, Prevention, and Control

- Treatment with macrolide (i.e., azithromycin, clarithromycin) is effective in eradicating organisms and reducing length of infectious stage
- Azithromycin is used for prophylaxis
- Vaccines containing inactivated pertussis toxin, filamentous hemagglutinin, and pertactin are effective
- Pediatric vaccine administered in five doses (at ages 2, 4, 6, and 15 to 18 months, and between ages 4 and 6 years); adult vaccine administered at ages 11 to 12 years and between 19 to 65 years

BRUCELLA

Trigger Words

Small coccobacilli, slow growing, zoonotic, undulant fever

Biology and Virulence

- Very small gram-negative coccobacilli (0.5×0.6 to $1.5\ \mu m$)
- Strict aerobe; does not ferment carbohydrates
- Requires complex media and prolonged incubation for in vitro growth
- Intracellular pathogen that is resistant to killing in serum and by phagocytes
- Smooth colonies associated with virulence

Epidemiology

- Animal reservoirs are goats and sheep *(B. melitensis);* cattle and American bison *(B. abortus);* swine, reindeer, and caribou *(B. suis);* and dogs, foxes, and coyotes *(B. canis)*
- Infects animal tissues rich in erythritol (e.g., breast, uterus, placenta, epididymis)
- Worldwide distribution, particularly in Latin America, Africa, the Mediterranean basin, the Middle East, and Western Asia
- Vaccination of herds has controlled disease in the United States
- Most disease in the United States is reported in California and Texas in travelers from Mexico
- Individuals at greatest risk for disease are people who consume unpasteurized dairy products, people in direct contact with infected animals, and laboratory workers

Diseases

- Refer to Box 29.1 for diseases

Diagnosis

- Microscopy is insensitive
- Culture (blood, bone marrow, infected tissue if localized infection) is sensitive and specific if prolonged incubation is used (minimum of 3 days to 2 weeks)
- Serology can be used to confirm the clinical diagnosis; fourfold increase in titer or single titer ≥1:160; high titers can persist for months to years

Treatment, Prevention, and Control

- Recommended treatment is doxycycline combined with rifampin for a minimum of 6 weeks for nonpregnant adults; trimethoprim-sulfamethoxazole for pregnant women and for children younger than 8 years
- Human disease is controlled by eradication of the disease in the animal reservoir through vaccination and serologic monitoring of the animals for evidence of disease, pasteurization of dairy products, and use of proper safety techniques in clinical laboratories working with this organism

FRANCISELLA TULARENSIS

Trigger Words

Small coccobacilli, slow growing, cysteine-supplemented media, zoonotic, ulceroglandular, oculoglandular, pneumonic

Continued

Summaries Clinically Significant Organisms—cont'd

Biology and Virulence

- Very small gram-negative coccobacilli (0.2 × 0.2 to 0.7 μm)
- Strict aerobe; do not ferment carbohydrates
- Antiphagocytic capsule
- Intracellular pathogen resistant to killing in serum and by phagocytes

Epidemiology

- Wild mammals, domestic animals, birds, and fish, and blood-sucking arthropods are reservoirs; rabbits, cats, hard ticks, and biting flies are most commonly associated with human disease; humans are accidental hosts
- A total of 239 cases were seen in United States in 2017, although the actual number may be much higher
- Infectious dose is small when exposure is by arthropod, through skin, or by inhalation; large numbers of organisms must be ingested for infection by this route

Diseases

- Clinical symptoms and prognosis determined by route of infection: ulceroglandular, oculoglandular, glandular, typhoidal, oropharyngeal, gastrointestinal, pneumonic (see Box 29.1)

Diagnosis

- Microscopy is insensitive
- Culture on cysteine-supplemented media (e.g., chocolate agar, buffered charcoal yeast extract agar) is sensitive if prolonged incubation is used
- Serology can be used to confirm clinical diagnosis; fourfold increase in titer or single titer ≥1:160; high titers can persist for months to years

Treatment, Prevention, and Control

- Gentamicin is the antibiotic of choice; fluoroquinolones (e.g., ciprofloxacin) and doxycycline have good activity; penicillins and some cephalosporins are ineffective
- Disease prevented by avoiding reservoirs and vectors of infection; clothing and gloves are protective
- Live attenuated vaccine available but rarely used for human disease

LEGIONELLA PNEUMOPHILA

Trigger Words

Poor-staining slender rods, legionnaires disease, Pontiac fever, contaminated water, BCYE agar

Biology and Virulence

- Slender, pleomorphic, nonfermentative, gram-negative rods
- Stains poorly with common reagents
- Nutritionally fastidious, with requirement for L-cysteine and enhanced growth with iron salts
- Capable of replication in alveolar macrophages (and in amebae in nature)
- Prevents phagolysosome fusion

Epidemiology

- Capable of sporadic, epidemic, and nosocomial infections
- Commonly found in natural bodies of water, cooling towers, condensers, and water systems (including hospital systems)
- Estimated to be as many as 18,000 cases of infection in United States annually
- Patients at high risk for symptomatic disease include patients with compromised pulmonary function and patients with decreased cellular immunity (particularly transplant patients)

Diseases

- Responsible for legionnaires disease and Pontiac fever

Diagnosis

- Microscopy is insensitive
- Antigen tests are sensitive for *L. pneumophila* serogroup 1 but have poor sensitivity for other serogroups and species
- Culture on buffered charcoal yeast extract agar is the diagnostic test of choice
- Seroconversion must be demonstrated; this can take as long as 6 months to develop; positive serology may persist for months
- Nucleic acid amplification assays are as sensitive and specific as culture

Treatment, Control, and Prevention

- Macrolides (e.g., azithromycin, clarithromycin) or fluoroquinolones (e.g., ciprofloxacin, levofloxacin) are the treatment of choice
- Decrease environmental exposure to reduce risk of disease
- For environmental sources associated with disease, treat with hyperchlorination, superheating, or copper-silver ionization

A few medically important gram-negative rods have not been discussed in the preceding chapters and are the subject of this chapter (Table 29.1).

Bartonella

As with many groups of bacteria studied in recent years, analysis of the 16S ribosomal ribonucleic acid (rRNA) gene has led to reorganization of the genus *Bartonella.* Currently, 35 species are included in the genus, with 3 species most commonly associated with human disease: ***B. bacilliformis, B. henselae,*** and ***B. quintana*** (Box 29.1). Members of the genus are short (0.2 to 0.6 × 0.5 to 1.0 μm), gram-negative, coccobacillary or bacillary rods with fastidious growth requirements, requiring prolonged incubation (2 to 6 weeks) for their initial recovery in culture.

Members of the genus *Bartonella* are found in a variety of animal reservoirs and are typically present without evidence of disease. Spread of most *Bartonella* species from colonized animals to humans is either by direct contact or **insect vectors** (e.g., *B. bacilliformis,* **sandflies;** *B. quintana,* **lice;** *B. henselae,* **fleas**). Most infections with *Bartonella* are characterized by **recurrent fevers** and/or **angioproliferative lesions** (blood-filled cysts).

B. bacilliformis, the original member of the genus, is responsible for **Carrión disease,** which is an acute hemolytic bacteremia consisting of fevers and severe anemia **(Oroya fever)** followed by the development of chronic vasoproliferative nodules (**verruga peruana,** "Peruvian wart"). The disease is restricted to the Andes mountain regions of Peru, Ecuador, and Colombia, which is the endemic area of the sandfly vector *Phlebotomus.* After the bite of an infected sandfly, the bacteria enter the blood, multiply, and penetrate into erythrocytes and endothelial cells. This process increases the fragility of the infected cells and facilitates their clearance by the reticuloendothelial system, leading to acute anemia. Myalgia, arthralgia, and headache are also common. This stage of illness ends with the development of humoral immunity. In the chronic stage of Carrión disease, 1- to 2-cm cutaneous nodules, often engorged with blood (angioproliferative), appear over the course of 1 to 2 months and may persist for months to years. The link between verruga peruana skin lesions and Oroya fever was demonstrated by a medical student named Carrión who infected himself with aspirates from the skin lesions and died of Oroya fever. This act of scientific recklessness immortalized him and illustrates the high mortality associated with this disease if untreated, so it is recommended that *B. bacilliformis* infections should be treated with chloramphenicol or ciprofloxacin.

TABLE 29.1 Important Miscellaneous Gram-Negative Rods

Organism	Historical Derivation
Bartonella	Named after Barton, who originally described *B. bacilliformis*
B. bacilliformis	*bacillus,* rod; *forma,* shape (rod shaped)
B. henselae	*hensel,* named after D.M. Hensel, who worked with this organism
B. quintana	*quintana,* fifth (refers to 5-day fever)
Bordetella	Named after Jules Bordet, who first isolated the organism responsible for pertussis
B. pertussis	*per,* very or severe; *tussis,* cough (a severe cough)
B. parapertussis	*para,* resembling (resembling pertussis)
B. bronchiseptica	*bronchus,* the trachea; *septicus,* septic (an infected bronchus)
B. holmesii	Named after the microbiologist Barry Holmes
Brucella	Named after Sir David Bruce, who first recognized the organism as a cause of "undulant fever"
B. abortus	*abortus,* abortion or miscarriage (this organism is responsible for abortion in infected animals)
B. melitensis	*melitensis,* pertaining to the Island of Malta (Melita), on which the first outbreak was recognized by Bruce
B. suis	*suis,* of the pig (a swine pathogen)
B. canis	*canis,* of the dog (a dog pathogen)
Cardiobacterium hominis	*cardia,* heart; *bakterion,* small rod; *hominis,* of man (small rod of the hearts of men; refers to the predilection of this bacterium to cause endocarditis in humans)
Francisella	Named after the American microbiologist Edward Francis, who first described tularemia
F. tularensis subsp. *tularensis* (type A)	*tularensis,* pertaining to Tulare County, California, in which the disease was first described
F. tularensis subsp. *holarctica* (type B)	*holos,* whole; *arctos,* northern regions (reference to distribution in the arctic or northern regions)
F. tularensis subsp. *mediaasiatica*	*media,* middle; *asiatica,* Asian (pertaining to middle Asia)
F. tularensis subsp. *novicida*	*novus,* new; *cida,* to cut (a "new killer")
Legionella pneumophila	*Legionella,* first recognized outbreak was at an American Legion convention; *pneumôn,* lung; *phila,* loving; *pneumophila,* lung-loving.
Streptobacillus moniliformis	*streptos,* twisted or curved; *bacillus,* rod; *monile,* necklace; *forma,* shape (twisted, necklace-shaped bacillus; refers to the pleomorphic morphology of the bacteria)

B. quintana was originally described as the causative organism of **trench fever** (also called **"5-day" fever**), which is a disease prevalent during World War I. Infection can vary from asymptomatic to a severe, debilitating illness. Typically, patients have severe headache, fever, weakness, and pain in the long bones (particularly the tibia). The fever can recur at 5-day intervals, hence the name of the disease. Although trench fever does not cause death, the illness can be very severe. No animal reservoir for this disease has been identified; rather, exposure to contaminated feces of the **human body louse** spreads disease from person to person. *B. quintana* is also associated with disease in immunocompromised patients, particularly patients infected with the human immunodeficiency virus (HIV) who have **recurrent fevers with bacteremia** (Clinical Case 29.1) and **bacillary angiomatosis.** Bacteremia is characterized by an insidious onset of malaise, body aches, fatigue, weight loss, headaches, and recurrent fevers. This can lead to endocarditis or more commonly vascular proliferative diseases of the skin (bacillary angiomatosis; Fig. 29.1), subcutaneous tissues, or bone. The vascular lesions appear as multiple blood-filled nodules (resembling verruga peruana; as described previously). As with trench fever, the vector of these diseases appears to be the human body louse, and disease is primarily restricted to the homeless population, in whom personal hygiene is substandard. Oral erythromycin, doxycycline, or azithromycin is most commonly used for treatment of *B. quintana* infections.

B. henselae is also responsible for bacillary angiomatosis; however, it primarily involves the skin, lymph nodes, liver **(peliosis hepatis),** or spleen **(splenic peliosis).** The reasons for this differential tissue affinity are not known. Also like *B. quintana, B. henselae* can cause subacute endocarditis. The reservoirs for *B. henselae* are cats and their fleas. The bacteria are carried asymptomatically in the feline oropharynx and can cause transient bacteremia, particularly in young or feral cats. *B. henselae* is responsible for another disease acquired after exposure to cats (e.g., scratches, bites, contact with the contaminated feces of cat fleas) called **cat-scratch disease.** Typically, cat-scratch disease is a benign infection in children, characterized by **chronic regional adenopathy** of the lymph nodes draining the site of contact. Although most infections are self-limited, dissemination can occur to the liver, spleen, eye, or central nervous system. Bacteria may be seen in the lymph node tissues; however, culture is virtually always negative. A definitive diagnosis is based on the characteristic presentation and serologic evidence of a recent infection. Cultures are not

BOX 29.1 Clinical Summaries

Bartonella bacilliformis

Carrión disease: febrile disease characterized by acute hemolytic bacteremia (Oroya fever) followed by the development of chronic cutaneous blood-filled nodules (verruga peruana)

Bartonella quintana

Trench fever: disease characterized by severe headache, fever, weakness, and pain in the long bones; the fever recurs at 5-day intervals
Chronic bacteremia: malaise, myalgias, fatigue, weight loss, headaches, and recurrent fevers in immunocompromised patients
Subacute endocarditis: mild but progressive infection of the endocardium
Bacillary angiomatosis: vascular proliferative disease in immunocompromised patients with blood-filled nodules involving the skin, subcutaneous tissues, and bones

Bartonella henselae

Bacillary angiomatosis: same as previously mentioned, except primarily involving the skin, lymph nodes, or liver and spleen
Subacute endocarditis: same as previously mentioned
Cat-scratch disease: chronic regional lymphadenopathy associated with cat scratch

Bordetella pertussis

Pertussis: after a 7- to 10-day incubation period, disease is characterized by the catarrhal stage (resembles the common cold), progressing to the paroxysmal stage (repetitive coughs followed by inspiratory whoops), then the convalescence stage (diminishing paroxysms and secondary complication)
Bordetella parapertussis: produces a milder form of pertussis
Bordetella bronchiseptica: primarily a respiratory disease of animals but can cause bronchopneumonia in humans
Bordetella holmesii: uncommon cause of sepsis

Brucella

Brucellosis: initial nonspecific symptoms of malaise, chills, sweats, fatigue, myalgias, weight loss, arthralgias, and fever; can be intermittent (undulant fever); can progress to systemic involvement (gastrointestinal tract, bones or joints, respiratory tract, other organs)
Brucella melitensis: severe, acute systemic disease, with complications common
Brucella abortus: mild disease with suppurative complications
Brucella suis: chronic, suppurative, destructive disease
Brucella canis: mild disease with suppurative complications

Cardiobacterium hominis

Subacute endocarditis: same as previously mentioned

Francisella tularensis

Ulceroglandular tularemia: painful papule develops at the site of inoculation that progresses to ulceration; localized lymphadenopathy
Oculoglandular tularemia: after inoculation into the eye (e.g., rubbing eye with a contaminated finger), painful conjunctivitis develops, with regional lymphadenopathy
Pneumonic tularemia: pneumonitis with signs of sepsis develops rapidly after exposure to contaminated aerosols; high mortality unless promptly diagnosed and treated

Legionella pneumophila

Pontiac fever: self-limited febrile disease with chills, myalgias, malaise, and headache but no evidence of pneumonia
Legionnaires disease: severe pneumonia with acute onset of fever, chills, nonproductive cough, and headache progressing to multilobar consolidation of the lungs and multiorgan failure

Streptobacillus moniliformis

Rat-bite fever: irregular fever, headache, chills, myalgia, and arthralgia associated with rodent bite; pharyngitis and vomiting associated with exposure to bacteria in food or water

Clinical Case 29.1 Fever and Bacteremia Caused by *Bartonella*

Slater and associates (*N Engl J Med* 3323:1587–1593, 1990) described the first *Bartonella henselae* infection in an HIV-infected patient. A 31-year-old man with advanced HIV infection presented with high fevers, chills, sweats, and weight loss. Blood cultures were negative after 2 days of incubation, and despite an initial response to oral antibiotic therapy, the fevers returned after 2 weeks. The patient was pancytopenic and had elevated liver enzyme levels. Hepatomegaly was the only abnormality detected by computed tomography. All diagnostic tests were negative until after more than 2 weeks of incubation; gram-negative rods were recovered from the blood cultures. Subsequent studies characterized this as a newly discovered organism and named it *B. henselae*. The patient was treated with parenteral erythromycin and, despite recurrent fevers, subsequently became culture negative. This patient illustrates the susceptibility of HIV patients to this organism and the insidious onset and prolonged course of the disease.

Fig. 29.1 Skin lesions of bacillary angiomatosis caused by *Bartonella henselae.* (From Cohen J., Powderly, W.G., 2004. Infectious Diseases, second ed. Mosby, St Louis, MO.)

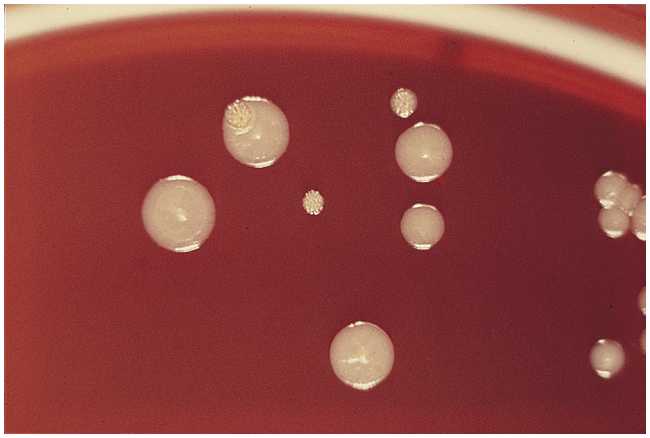

Fig. 29.2 *Bartonella henselae* growing on blood agar plates; note the two typical colonial morphologies. (From Cohen, J., Powderly, W.G., 2004. Infectious Diseases, second ed. Mosby, St Louis, MO.)

useful because relatively few organisms are present in the tissues as a result of the vigorous cellular immune reaction in immunocompetent patients. In contrast, *B. henselae* can be isolated from blood collected from immunocompromised patients with chronic bacteremia if the cultures are incubated for 4 weeks or more (Fig. 29.2).

The effectiveness of treating cat-scratch disease with antibiotics has not been demonstrated, although azithromycin is recommended if treatment is used. Oral erythromycin, doxycycline, or azithromycin is used for treatment of other *B. henselae* infections. Penicillinase-resistant penicillins, first-generation cephalosporins, and clindamycin do not appear active in vitro against *Bartonella*. The incidence of *Bartonella* infections in HIV-infected patients has declined in recent years because these patients are treated routinely with azithromycin or clarithromycin for prevention of *Mycobacterium avium* infections.

Bordetella

Bordetella is an extremely **small** (0.2 to 0.5 × 1 μm), **strictly aerobic, gram-negative coccobacillus.** Fourteen species are currently recognized, with four species responsible for human disease (see Box 29.1): ***B. pertussis,*** the agent responsible for pertussis or whooping cough; ***B. parapertussis,*** responsible for a milder form of pertussis; ***B. bronchiseptica,*** responsible for respiratory disease in dogs, swine, laboratory animals, and occasionally humans; and ***B. holmesii,*** an uncommon cause of sepsis. *Bordetella* species are differentiated on the basis of their growth characteristics, biochemical reactivity, and antigenic properties. Despite phenotypic differences, genetic studies have shown that the four species pathogenic for humans are closely related or identical species, differing only in the expression of virulence genes.

Infection with *B. pertussis* and the development of whooping cough require exposure to the organism, bacterial attachment to the ciliated epithelial cells of the respiratory tract, proliferation of the bacteria, and production of localized tissue damage and systemic toxicity. Attachment of the organisms to ciliated epithelial cells is mediated by the protein adhesins **pertactin, filamentous hemagglutinin,** and **fimbria.** Similar proteins are also found in *B. parapertussis* and *B. bronchiseptica.* Localized tissue damage is mediated by **dermonecrotic toxin** (produces localized ischemia in mouse model) and **tracheal cytotoxin** (inhibits cilia movement, disrupting normal clearance mechanisms in the respiratory tree leading to the characteristic pertussis cough). Systemic toxicity is produced primarily by **pertussis toxin.** This toxin inactivates the protein that controls adenylate cyclase activity, leading to an increase in cyclic adenosine monophosphate (cAMP) levels and a subsequent increase in respiratory secretions and mucus production, all characteristic of the paroxysmal stage of pertussis.

Pertussis is a **human disease** with no other recognized animal or environmental reservoir. Although the incidence of pertussis, with its associated morbidity and mortality, was reduced considerably after the introduction of vaccines in 1949, the disease is still endemic worldwide, with an estimated 24 million infections and 160,000 deaths in 2014 globally, primarily in unvaccinated children. The incidence of reported disease in the United States was 18,975 in 2017, representing a 42% decrease from 2014. Historically, pertussis was considered a pediatric disease, but now a significant proportion of infections are found in **adolescents and adults** (Clinical Case 29.2). The recognition of milder forms of disease in older children and adults and improved diagnostic tests have contributed to the increase in reported disease.

Infection is initiated when infectious aerosols are inhaled and the bacteria become attached to and proliferate on ciliated epithelial cells. After a 7- to 10-day incubation period, the classical presentation of pertussis proceeds through three stages (Fig. 29.3). The first stage, the **catarrhal stage,** resembles a common cold, with serous rhinorrhea, sneezing, malaise, anorexia, and low-grade fever. Because the peak number of bacteria is produced during this stage and the cause of the disease is not yet recognized, patients in the catarrhal stage pose the highest risk to their contacts. After 1 to 2 weeks, the **paroxysmal stage** begins. During this time, ciliated epithelial cells are extruded from the respiratory tract, and the clearance of mucus is impaired. This stage is characterized by the **classic whooping**

Clinical Case 29.2 **Pertussis Outbreak in Health Care Workers**

Pascual and associates (*Infect Control Hosp Epidemiol* 27:546–552, 2006) reported an outbreak of pertussis among hospital workers. The index case, a nurse anesthetist, presented acutely with coughing paroxysms followed by vomiting and apneic episodes that led to loss of consciousness. Surgical service personnel and exposed patients and family members were surveyed, with cultures, polymerase chain reaction testing, and serology obtained from patients with respiratory symptoms. Twelve (23%) health care workers and 0 of 146 patients had clinical pertussis. The lack of disease in patients was attributed to mask use, cough etiquette, and limited face-to-face contact. This outbreak emphasizes the susceptibility of adults to infection and the highly infectious nature of *Bordetella pertussis*.

cough paroxysms (i.e., a series of repetitive coughs followed by an inspiratory whoop). Mucus production in the respiratory tract is common and is partially responsible for causing airway restriction. The paroxysms are frequently terminated with vomiting and exhaustion. A marked lymphocytosis is also prominent during this stage. Affected patients may experience as many as 40 to 50 paroxysms daily during the height of the illness. After 2 to 4 weeks, the disease enters the **convalescent stage;** at this time, the paroxysms diminish in number and severity, but secondary complications can occur. It is now appreciated that this classic presentation of pertussis may not be seen in patients with partial immunity or in adults. Such patients may have a history of a chronic persistent cough without whooping or vomiting. Because this presentation is not distinctive, appropriate diagnostic tests should be performed for *Bordetella* as well as other bacterial (e.g., *Mycoplasma pneumoniae, Chlamydia pneumoniae, Legionella pneumophila*) and viral respiratory pathogens.

The laboratory diagnosis of *B. pertussis* infections has changed in recent years. The bacteria are extremely sensitive to drying and do not survive unless care is taken during collection and transport of the specimen to the laboratory. Although *Bordetella* species have simple nutritional requirements, some species are highly **susceptible to toxic substances and metabolites** present in common laboratory media. These species (particularly *B. pertussis*) require media supplemented with charcoal, starch, blood, or albumin to absorb these toxic substances. The more fastidious species also grow slowly in culture, and all require freshly prepared media. Even under ideal conditions, recovery of *B. pertussis* in culture is difficult. For these reasons, a number of nucleic acid amplification assays, either targeted for *B. pertussis* or multiplex assays for a variety of respiratory pathogens, have been developed and are the diagnostic test of choice. The performance characteristics of these assays (e.g., sensitivity, specificity) are superior to microscopy and culture. It is difficult to interpret the results of serologic tests because microscopy and culture techniques are relatively insensitive standards by which these tests have been evaluated. Enzyme-linked immunosorbent assay (ELISA) tests have been developed to detect antibodies against pertussis toxin, filamentous hemagglutinin, pertactin, and fimbriae.

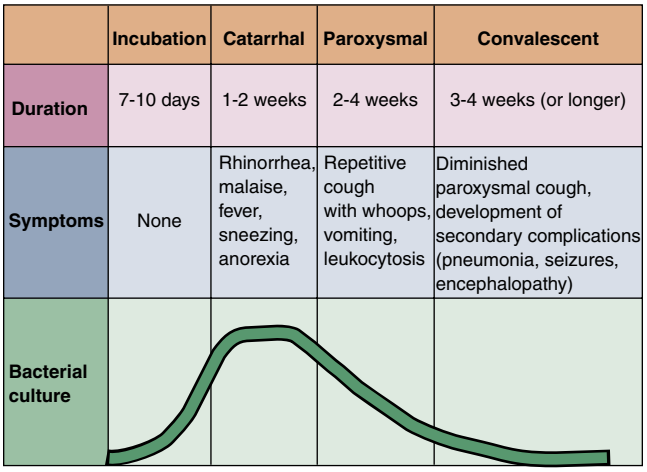

Fig. 29.3 Clinical presentation of *Bordetella pertussis* disease.

Treatment for pertussis is primarily supportive, with nursing supervision during the paroxysmal and convalescent stages of the illness. Antibiotics can ameliorate the clinical course and reduce infectivity, particularly during the early stages of disease, but convalescence depends primarily on the rapidity and degree to which the layer of ciliated epithelial cells regenerates. **Macrolides** (i.e., erythromycin, azithromycin, clarithromycin) are effective in eradicating the organisms; however, this effect has limited value because the illness is usually unrecognized during the peak of contagiousness. Azithromycin and clarithromycin are generally better tolerated and are the preferred macrolides. Trimethoprim-sulfamethoxazole or fluoroquinolones can be used in patients unable to tolerate macrolides. Postexposure antimicrobial prophylaxis with azithromycin is used for individuals at increased risk of severe disease if treatment is administered within 21 days of exposure to the symptomatic patient.

Two **acellular vaccines** (one for children, one for adults) administered in combination with vaccines for tetanus and diphtheria are currently approved in the United States. Both vaccines contain inactivated pertussis toxin, filamentous hemagglutinin, and pertactin. The pediatric vaccine is administered to children at the ages of 2, 4, 6, and 15 to 18 months, with the fifth dose between the ages of 4 and 6 years. The current recommendation for the adult vaccine is to administer it at 11 or 12 years of age, and then again between the ages of 19 and 65. Because pertussis is highly contagious in a susceptible population, and unrecognized infections in family members of a symptomatic patient can maintain disease in a community, azithromycin has been used for prophylaxis in select instances.

Other *Bordetella* Species

B. parapertussis is responsible for causing 10% to 20% of the cases of mild pertussis occurring annually in the United States. *B. bronchiseptica* causes respiratory disease primarily in animals but has been associated with human respiratory tract colonization and bronchopulmonary disease. Investigators at the Centers for Disease Control and Prevention (CDC) in Atlanta, Georgia, reported that *B. holmesii* is primarily associated with septicemia.

Brucella

Molecular studies of the genus *Brucella* demonstrate a close relationship among the strains and are consistent with a single species; however, the genus is subdivided into 12 species, with 4 species most commonly associated with human disease: ***B. abortus, B. melitensis, B. suis,*** and ***B. canis*** (see Box 29.1). The diseases caused by members of this genus are characterized by a number of names based on the original microbiologists who isolated and described the organisms (e.g., Sir David Bruce **[brucellosis],** Bernhard Bang **[Bang disease]**), their clinical presentation **(undulant fever),** and the sites of recognized outbreaks (e.g., Malta fever, Mediterranean remittent fever, rock fever of Gibraltar, county fever of Constantinople, fever of Crete). The most commonly used term is brucellosis.

Brucellae are small (0.5 × 0.6 to 1.5 μm), nonmotile, nonencapsulated, gram-negative coccobacilli. The organism grows slowly in culture (taking a week or more) and generally requires complex growth media; is strictly aerobic, with some strains requiring supplemental carbon dioxide for growth; and does not ferment carbohydrates.

Colonies can assume both smooth (translucent, homogeneous) and rough (opaque, granular, or sticky) forms, as determined by the O antigen of the cell wall lipopolysaccharide (LPS). Antisera to one form (e.g., smooth) do not cross-react with the other form (e.g., rough).

Brucella does not produce a detectable exotoxin, and the endotoxin is less toxic than that produced by other gram-negative rods. Reversion of smooth strains to the rough morphology is associated with greatly reduced virulence, so the O chain of the smooth LPS is an important marker for virulence. *Brucella* is also an **intracellular parasite** of the **reticuloendothelial system.** After the initial exposure, the organisms are phagocytosed by macrophages and monocytes, in which the bacteria survive and replicate. Phagocytosed bacteria are carried to the spleen, liver, bone marrow, lymph nodes, and kidneys. The bacteria secrete proteins that induce granuloma formation in these organs, and destructive changes in these and other tissues occur in patients with advanced disease.

Brucella infections have a **worldwide distribution,** with endemic disease most common in countries that do not have domestic animal vaccination programs, such as Latin America, Africa, the Mediterranean basin, the Middle East, and Western Asia. More than 500,000 documented cases are reported annually worldwide. In contrast, the incidence of disease in the United States is much lower (140 reported infections in 2017). The highest numbers of U.S. cases are reported in **California** and **Texas,** and most of these infections occur in residents from Mexico or visitors to that country. Laboratory personnel are also at significant risk for infection through direct contact or inhalation of the organism. Disease in cattle, swine, sheep, and goats in the United States has been eliminated effectively through the destruction of infected animals and the vaccination of disease-free animals.

Brucellosis in humans can be acquired by direct contact with the organism (e.g., a laboratory exposure), ingestion (e.g., consumption of contaminated food products), or inhalation. Of particular concern is the potential use of *Brucella* as a biological weapon, in which exposure would most likely be by inhalation.

Brucella causes mild or asymptomatic disease in the natural host: *B. abortus* infects cattle and American bison; *B. melitensis* infects goats and sheep; *B. suis* infects swine, reindeer, and caribou; and *B. canis* infects dogs, foxes, and coyotes. The organism has a predilection for infecting organs rich in **erythritol,** which is a sugar metabolized by many *Brucella* strains in preference to glucose. Animal (but not human) tissues, including breast, uterus, placenta, and epididymis, are rich in erythritol. The organisms thus localize in these tissues in nonhuman reservoirs and can cause sterility, abortions, or asymptomatic lifelong carriage. Brucellae are shed in high numbers in milk, urine, and birth products. Human disease in the United States is most commonly caused by ***B. melitensis*** and results primarily from consumption of contaminated, unpasteurized milk and other **dairy products.**

CLINICAL DISEASES

The disease spectrum of **brucellosis** (Box 29.1) depends on the infecting organism. *B. abortus* and *B. canis* tend to produce mild disease with rare suppurative complications. In contrast, *B. suis* causes the formation of destructive lesions and has a prolonged course. *B. melitensis* also causes severe disease with a high incidence of serious complications because the organisms can multiply to high concentrations in phagocytic cells.

Acute disease develops in approximately half of the patients infected with *Brucella,* with symptoms first appearing typically 1 to 3 weeks after exposure. Initial symptoms are nonspecific and consist of malaise, chills, sweats, fatigue, weakness, myalgias, weight loss, arthralgias, and nonproductive cough. Almost all patients have fever, and this can be intermittent in untreated patients, hence the name **undulant fever.** (Clinical Case 29.3) Patients with advanced disease can have gastrointestinal tract symptoms; osteolytic lesions or joint effusions; respiratory tract symptoms; and less commonly, cutaneous, neurologic, or cardiovascular manifestations. Chronic infections can also develop in inadequately treated patients, with symptoms developing within 3 to 6 months after discontinuing antibiotic therapy. Relapses are associated with a persistent focus on infections (e.g., in bone, spleen, liver) and not with the development of antibiotic resistance.

For the laboratory diagnosis of brucellosis, several blood samples should be collected for culture and serologic testing. Bone marrow cultures and cultures of infected tissues may also be useful. To ensure safe handling of the specimen, the laboratory should be notified if brucellosis is suspected. *Brucella* organisms are readily stained using conventional techniques, but their intracellular location and small size make them difficult to detect in clinical specimens. The organisms grow slowly in culture, requiring enriched blood agars and extended incubation (3 days or more). **Blood cultures should be incubated for 2 weeks** before they are considered negative. Preliminary identification of *Brucella* is based on the isolate's microscopic and colonial morphology, positive oxidase and urease reactions, and reactivity with specific antibodies. Identification at the genus level can also be accomplished by sequencing the 16S rRNA gene. Subclinical brucellosis and many cases of acute and chronic diseases are identified by a specific antibody response in the infected patient. Antibodies are detected in virtually all patients and

Clinical Case 29.3 **Brucellosis**

Lee and Fung (*Hong Kong Med J* 11:403–406, 2005) described a 34-year-old woman who developed brucellosis caused by *Brucella melitensis*. The woman presented with recurrent headaches, fever, and malaise that developed after she had handled goat placenta in China. Blood cultures were positive for *B. melitensis* after extended incubation. She was treated for 6 weeks with doxycycline and rifampicin and had a successful response. The case was a classical description of exposure to contaminated tissues high in erythritol, a presentation of recurrent fevers and headaches, and response to the combination of doxycycline and rifampicin.

can persist for many months or years; thus a significant increase in the antibody titer is required to provide definitive serologic evidence of current disease. A **presumptive diagnosis** can be made if there is a fourfold increase in the titer or a single titer is 1:160 or greater.

Tetracyclines, with **doxycycline** as the preferred agent, are generally active against most strains of *Brucella;* however, because this is a bacteriostatic drug, relapse is common after an initially successful response. The World Health Organization currently recommends the combination of **doxycycline with rifampin.** Because the tetracyclines are toxic to young children and fetuses, doxycycline should be replaced with trimethoprim-sulfamethoxazole for pregnant women and for children younger than 8 years. Treatment must be continued for 6 weeks or longer for it to be successful. Fluoroquinolones, macrolides, penicillins, and cephalosporins are either ineffective or have unpredictable activity. Relapse of disease is caused by inadequate therapy and not the development of antibiotic resistance.

Control of human brucellosis is accomplished through control of the disease in livestock, as demonstrated in the United States. This requires systematic identification (by serologic testing) and elimination of infected herds and **animal vaccination** (currently with the rough strain of *B. abortus* strain RB51). The avoidance of unpasteurized dairy products, the observance of appropriate safety procedures in the clinical laboratory, and the wearing of protective clothing by abattoir workers are further ways to prevent brucellosis. The live attenuated *B. abortus* and *B. melitensis* vaccines have been used successfully to prevent infection in animal herds. Vaccines have not been developed against *B. suis* or *B. canis,* and the existing vaccines cannot be used in humans because they produce symptomatic disease. Lack of an effective human vaccine is of concern because *Brucella* could be used as an agent of bioterrorism.

Cardiobacterium

Cardiobacterium hominis is named for the predilection of this bacterium to cause endocarditis in humans (see Box 29.1). These bacteria are nonmotile, facultatively anaerobic, and characteristically small (1 × 1 to 2 μm) pleomorphic gram-negative or gram-variable rods. The bacteria are fermentative, oxidase positive, and catalase negative. *C. hominis* is present in the upper respiratory tract of most healthy people.

Endocarditis is the primary human disease caused by *C. hominis* and the related species *C. valvarum* (Clinical Case 29.4). Many infections are likely to be unreported or undiagnosed because of the low virulence of this organism and its slow growth in vitro. Most patients with *Cardiobacterium* endocarditis have **preexisting heart disease** and either a history of oral disease or have undergone a dental procedure before the clinical symptoms developed. The organisms are able to enter the blood from the oropharynx, adhere to the damaged heart tissue, and then slowly multiply. The course of disease is insidious and subacute; patients typically have symptoms (e.g., fatigue, malaise, and low-grade fever) for months before seeking medical care. Complications are rare, and complete recovery after appropriate antibiotic therapy is common.

Clinical Case 29.4 ***Cardiobacterium*** **Endocarditis**

Hoover and associates (*Ann Intern Med* 142:229–230, 2005) described the first patient infected with *Cardiobacterium valvarum* (a newly described species in the genus *Cardiobacterium*). The patient was a 46-year-old man who, over the course of 1 month, developed anorexia and fatigue. The symptoms developed 2 weeks after a dental extraction. His physical examination was notable for fatigue, lower extremity edema, and a new heart murmur. Bilateral pleural effusions were revealed on chest radiography. All blood cultures collected over a 24-hour period were positive for a pleomorphic gram-negative rod that was subsequently identified as *C. valvarum*. Management of the patient involved replacement of the aortic valve with a prosthetic valve and 4 weeks of treatment with ceftriaxone. Follow-up visits with the patient documented complete recovery. This case illustrates the subacute presentation and generally successful outcome for patients with *Cardiobacterium* endocarditis. What is unique is that the patient did not have a history of previous heart disease, although it is likely to have been present.

The isolation of *C. hominis* from blood cultures confirms the diagnosis of endocarditis. The organism grows slowly in culture, requiring 1 week or more for growth to be detected. The organism requires enhanced carbon dioxide and humidity levels to grow on agar media, with 1-mm pinpoint colonies seen on blood or chocolate agar plates after 2 days of incubation. The organism does not grow on MacConkey agar or other selective media commonly used for gram-negative rods. *C. hominis* can be readily identified from its growth properties, microscopic morphology, and reactivity in biochemical tests.

C. hominis is susceptible to many antibiotics, and most infections are treated successfully with **penicillin or ampicillin** for 2 to 6 weeks, although penicillin-resistant strains have been reported. *C. hominis* endocarditis in people with preexisting heart disease is prevented by maintenance of good oral hygiene and use of antibiotic prophylaxis at the time of dental procedures. Long-acting penicillin is effective prophylaxis. Erythromycin should not be used because *C. hominis* is commonly resistant to it.

Francisella

Francisella is an important **zoonotic pathogen** that can cause significant human disease. The most important human pathogen in the genus *Francisella* is *F. tularensis,* which is the causative agent of **tularemia** (also called **glandular fever, rabbit fever, tick fever,** and **deerfly fever**) in animals and humans (see Box 29.1). *F. tularensis* is subdivided into three subspecies based on their biochemical properties. **Subspecies *tularensis* (type A)** and **subspecies *holarctica* (type B)** are the most important, whereas *F. tularensis* subsp. *mediaasiatica* is rarely associated with human disease. *F. novicida* and *F. philomiragia* are uncommon, opportunistic pathogens that have a predilection for patients with immunologic deficiencies

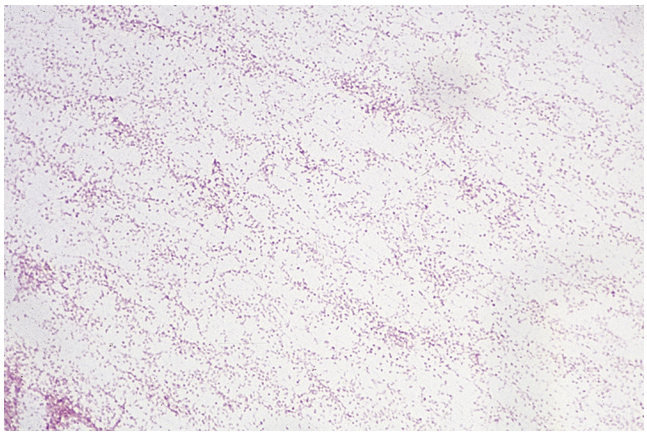

Fig. 29.4 Gram stain of *Francisella tularensis* isolated in culture; note the extremely small, dotlike coccobacilli.

(i.e., chronic granulomatous disease, myeloproliferative diseases).

F. tularensis is a **very small** (0.2 × 0.2 to 0.7 μm), faintly staining, gram-negative coccobacillus (Fig. 29.4). The organism is nonmotile, has a thin lipid capsule, and has fastidious growth requirements (i.e., most strains **require cysteine** for growth). It is **strictly aerobic** and requires 3 or more days before growth is detected in culture.

F. tularensis is an **intracellular pathogen** that can replicate in macrophages, neutrophils, epithelial cells, and endothelial cells. The organism inhibits phagosome-lysosome fusion through secretion of proteins that facilitate bacterial escape from the phagosome and subsequent replication in the cytosol. Pathogenic strains possess an antiphagocytic, **polysaccharide-rich capsule,** and loss of the capsule is associated with decreased virulence. The capsule protects the bacteria from complement-mediated killing during the bacteremia phase of disease. This organism has an endotoxin, but it is considerably less active than the endotoxin found in other gram-negative rods.

A strong, innate immune response with production of interferon (IFN)-γ and tumor necrosis factor is important for controlling bacterial replication in macrophages in the early phase of infection. Specific T-cell immunity is required for activation of macrophages for intracellular killing in the late stages of disease. B-cell–mediated immunity is less important for elimination of this facultative intracellular pathogen.

F. tularensis subsp. *tularensis* (type A) is restricted to North America, whereas subsp. *holarctica* (type B) is endemic throughout the Northern Hemisphere. Type A strains are further subdivided into **type A–west,** which predominates in the arid region from the Rocky Mountains to the Sierra Nevada Mountains, and **type A–east,** which occurs in the central southeast states of Arkansas, Missouri, and Oklahoma and along the Atlantic Coast. **Type B** strains cluster along major waterways, such as the upper Mississippi River, and in areas with high rainfall, such as the Pacific Northwest. The distribution of these strains is important because the epidemiologic features of the individual diseases are distinct and the course of clinical disease is significantly different. The geographic distribution of type A–west, type A–east, and type B strains is defined by the distribution of the natural reservoirs and vectors of *F. tularensis*. More than 200 species of mammals, as well as birds and blood-sucking arthropods, are infected naturally with *F. tularensis*. Type A infections are most commonly associated with exposure to **lagomorphs** (rabbits, hares) and **cats;** type B infections are associated with **rodents** and cats, but not lagomorphs. (Clinical Case 29.5) Infections caused by **biting arthropods** (e.g., hard ticks [*Ixodes, Dermacentor, Amblyomma* spp.], deerflies) are more common with type A than with type B strains. The spread to type A–east strains from the central southeast states to the Atlantic Coast states occurred when infected rabbits were imported from the central states to East Coast hunting clubs in the 1920s and 1930s. Type A–east infections are more commonly associated with disseminated disease and a high mortality rate when compared with disease caused by type A–west strains; the course of disease caused by type B stains is intermediate.

The reported incidence of disease is low. In 2017, 239 cases were reported in the United States; however, the actual number of infections is likely to be much higher because tularemia is frequently unsuspected and is difficult to confirm by laboratory tests. Most of the infections occur during the summer (when exposure to infected ticks is greatest). The incidence of disease increases dramatically when a relatively warm winter is followed by a wet summer, causing the tick population to proliferate. People at greatest risk for infection are hunters, laboratory personnel, and those exposed to ticks and other biting arthropods. In areas in which the organism is endemic, it is said that if a rabbit is moving so slowly that it can be shot by a hunter or caught by a pet, the rabbit could be infected (Clinical Case 29.5).

Clinical Case 29.5 **Cat-Associated Tularemia**

Capellan and Fong (*Clin Infect Dis* 16:472–475, 1993) described a 63-year-old man who developed ulceroglandular tularemia complicated by pneumonia after a cat bite. He initially presented with pain and localized swelling of his thumb 5 days after the bite. Oral penicillins were prescribed, but the patient's condition worsened, with increased local pain, swelling, and erythema at the wound site, and systemic signs (fever, malaise, vomiting). Incision of the wound was performed, but no abscess was found; culture of the wound was positive for a light growth of coagulase-negative staphylococci. Intravenous penicillins were prescribed, but the patient continued to deteriorate, with the development of tender axillary lymphadenopathy and pulmonary symptoms. A chest radiograph revealed pneumonic infiltrates in the right middle and lower lobes of the lung. The patient's therapy was changed to clindamycin and gentamicin, which was followed by defervescence and improvement of his clinical status. After 3 days of incubation, tiny colonies of faintly staining gram-negative coccobacilli were observed on the original wound culture. The organism was referred to a national reference laboratory, in which it was identified as *Francisella tularensis*. A more complete history revealed that the patient's cat lived outdoors and fed on wild rodents. This case illustrates the difficulty in making the diagnosis of tularemia and the lack of responsiveness to penicillins.

Fig. 29.5 Patient with oculoglandular tularemia (note swelling beside the ear).

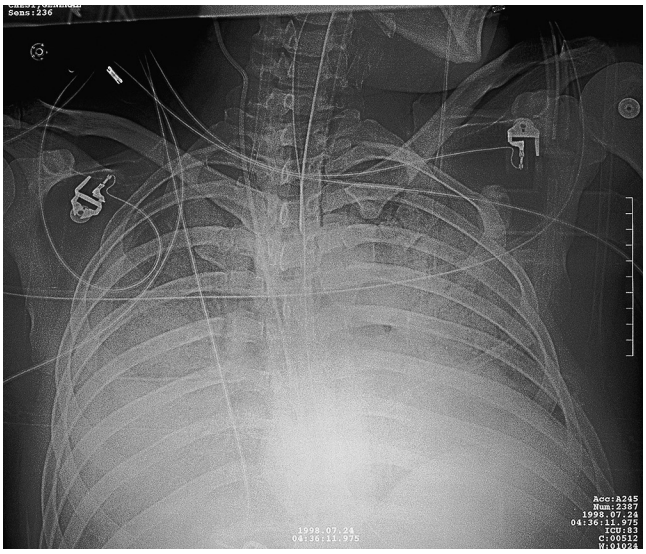

Fig. 29.6 Chest radiograph of patient with pulmonary tularemia.

Disease caused by *F. tularensis* is subdivided into several forms based on the clinical presentation: **ulceroglandular** (cutaneous ulcer and swollen lymph node), **oculoglandular** (eye involvement and swollen cervical lymph nodes), **glandular** (primarily swollen lymph nodes with no other localized symptoms), **typhoidal** (systemic signs of sepsis), **pneumonic** (pulmonary symptoms), and **oropharyngeal** and **gastrointestinal** disease after ingestion of *F. tularensis.* Variations of these presentations are also common (e.g., pneumonic tularemia typically has systemic signs of sepsis).

Ulceroglandular tularemia is the most common manifestation. The skin lesion, which starts as a painful papule, develops at the site of the tick bite or direct inoculation of the organism into the skin (e.g., a laboratory accident). The papule then ulcerates and has a necrotic center and raised border. Localized lymphadenopathy and bacteremia are also typically present (although bacteremia may be difficult to document).

Oculoglandular tularemia (Fig. 29.5) is a specialized form of the disease and results from direct contamination of the eye. The organism can be introduced into the eyes, for example, by contaminated fingers or through exposure to water or aerosols. Affected patients have a painful conjunctivitis and regional lymphadenopathy.

Pneumonic tularemia (Fig. 29.6) results from inhalation of infectious aerosols and is associated with high morbidity and mortality unless the organism is recovered rapidly in blood cultures (it is generally difficult to detect in respiratory cultures). There is also concern that *F. tularensis* could be used as a biological weapon. As such, creation of an infectious aerosol would be the most likely method of dispersal.

Collection and processing of specimens for the isolation of *F. tularensis* are hazardous for both the physician and the laboratory worker. The organism, by virtue of its small size, can penetrate through unbroken skin and the mucous membranes during collection of the sample, or it can be inhaled if aerosols are produced (a particular concern during processing of specimens in the laboratory). Although tularemia is rare, laboratory-acquired infections are disproportionately common. Gloves should be worn during collection of the specimen (e.g., aspiration of an ulcer or lymph node), and all laboratory work (both initial processing and identification tests) should be performed in a biohazard hood.

Detection of *F. tularensis* in Gram-stained aspirates from infected nodes or ulcers is almost always **unsuccessful** because the organism is extremely small and stains faintly (see Fig. 29.4). Nucleic acid amplification tests (NAATs) are primarily restricted to research labs. It has been stated that *F. tularensis* cannot be reliably recovered on common laboratory media because the organism requires sulfhydryl-containing substances (e.g., **cysteine**) for growth. However, *F. tularensis* can grow on **chocolate agar** or **buffered charcoal yeast extract (BCYE)** agar, which are media supplemented with cysteine that are used in most laboratories. If infection with *F. tularensis* is suspected, the laboratory should be notified because *F. tularensis* grows slowly and may be overlooked if the cultures are not incubated for a prolonged period. In addition, because this organism is highly infectious, special care is required for microbiological testing. Blood cultures are generally negative for the organism unless the cultures are incubated for a week or longer. Cultures of respiratory specimens will be positive if appropriate selective media are used to suppress the more rapidly growing bacteria from the upper respiratory tract. *F. tularensis* also grows on the selective media used for *Legionella* (e.g., BCYE agar). Aspirates of lymph nodes or draining sinuses are usually positive if the cultures are incubated for 3 days or longer.

Preliminary identification of *F. tularensis* is based on the slow growth of very small gram-negative coccobacilli on chocolate agar but not blood agar (blood agar is not supplemented with cysteine). The identification is confirmed by demonstrating the reactivity of the bacteria with specific antiserum (i.e., agglutination of the organism with antibodies against *Francisella*).

Tularemia is diagnosed in most patients by the finding of a fourfold or greater increase in the titer of antibodies during the illness or a single titer of 1:160 or greater. However, antibodies (including immunoglobulin [Ig]G, IgM, and IgA) can persist for many years, making it difficult to differentiate between past and current disease.

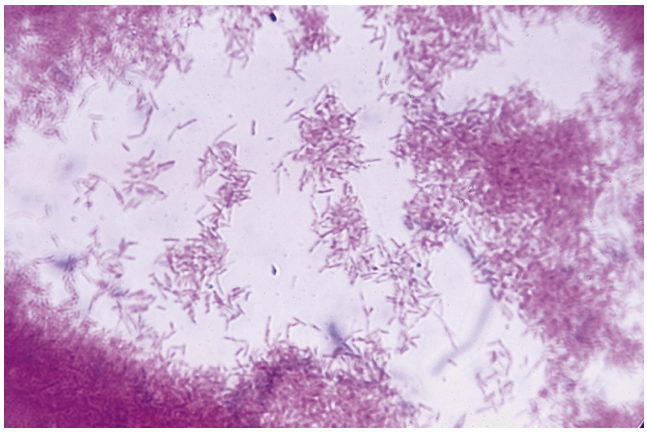

Fig. 29.7 Gram stain of *Legionella pneumophila* grown on buffered charcoal yeast extract agar. Note the pleomorphic forms characteristic of *Legionella*. (Courtesy Dr. Janet Stout, Pittsburgh, Pennsylvania.)

Gentamicin is considered the antibiotic of choice. Doxycycline and ciprofloxacin can be used to treat mild infections. *F. tularensis* strains produce β-lactamase, which renders penicillins and cephalosporins ineffective. The mortality rate is less than 1% if patients are treated promptly but is much higher in untreated patients, particularly those infected with type A–east strains.

To prevent infection, people should avoid the reservoirs and vectors of infection (e.g., rabbits, ticks, biting insects), but this is often difficult. At a minimum, people should not handle ill-appearing rabbits and should wear gloves when skinning and eviscerating animals. Because the organism is present in the arthropod's feces and not saliva, the tick must feed for a prolonged time before the infection is transmitted. Prompt removal of the tick can therefore prevent infection. Wearing protective clothing and using insect repellents reduce the risk of exposure. Persons who have a high-risk exposure (e.g., exposure to an infectious aerosol) should be treated with prophylactic antibiotics. Interest in developing a live attenuated vaccine is motivated by fear of exposure to the bacteria as a bioterrorism agent; however, an effective vaccine is not currently available. Inactivated vaccines do not elicit protective cellular immunity.

Legionella

In the summer of 1976, public attention was focused on an outbreak of severe pneumonia that caused many deaths among American Legion members attending a convention in Philadelphia. After months of intensive investigations, a previously unknown gram-negative rod was isolated. Subsequent studies found an organism, named ***Legionella pneumophila,*** to be the cause of multiple epidemics and sporadic infections. The organism was not previously recognized because it stains poorly with conventional dyes and does not grow on common laboratory media. Despite initial problems with the isolation of *Legionella* organisms, it is now known to be a ubiquitous aquatic saprophyte.

The most important member of the family Legionellaceae is *Legionella* with 61 species and 3 subspecies. Approximately half of these species have been implicated in human disease, with the others found in environmental sources. *L. pneumophila* is the cause of 90% of all infections; serotypes 1 and 6 are most commonly isolated.

Members of the genus *Legionella* are **slender, pleomorphic, gram-negative rods** measuring 0.3 to 0.9 × 2 μm in size. The organisms characteristically appear as short coccobacilli when observed in tissue but are very pleomorphic (up to 20 μm long) on artificial media (Fig. 29.7). Legionellae in clinical specimens do not stain with common reagents but can be seen in tissues stained with Dieterle silver stain.

Legionellae are obligatively aerobic and nutritionally fastidious. They require media supplemented with L-cysteine, and growth is enhanced by iron. Growth of these bacteria on supplemented media but not on conventional blood agar media has been used as the basis for the preliminary identification of clinical isolates. The bacteria have developed multiple methods to acquire iron from their host cells or in vitro media, and loss of this ability is associated with loss of virulence. The organisms derive energy from the metabolism of amino acids but not carbohydrates.

Respiratory tract disease caused by *Legionella* species develops in susceptible people who inhale infectious aerosols. Legionellae are facultative **intracellular bacteria** that multiply in free-living amebae in nature, and in alveolar macrophages, monocytes, and alveolar epithelial cells in infected hosts. This ability to infect and replicate in macrophages is mediated by first binding complement component C3b to an outer membrane porin protein on the bacterial surface and then binding to the CR3 complement receptor on the mononuclear phagocyte surface. The organisms then penetrate the cell through endocytosis and initiate replication. The bacteria are not killed in the cells by exposure to toxic superoxide, hydrogen peroxide, and hydroxyl radicals because phagolysosome fusion is inhibited. Chemokines and cytokines released by the infected macrophages stimulate a robust inflammatory response that is characteristic of infections with *Legionella*. The organisms proliferate in their intracellular vacuole and produce proteolytic enzymes (phosphatase, lipase, and nuclease) that eventually kill the host cell when the vacuole is lysed. Immunity to disease is primarily cell mediated, with humoral immunity playing a minor role. The bacteria are not killed until sensitized helper T cells (TH1 cells) activate the parasitized macrophages. Production of IFN-γ is critical for elimination of *Legionella* organisms.

Legionellae have a **worldwide distribution**, and are commonly present in natural bodies of water such as lakes and streams, as well as in air conditioning cooling towers and condensers, and in water systems (e.g., showers, hot tubs). Human infections are most commonly associated with **exposure to contaminated aerosols** (e.g., air conditioning cooling towers, whirlpool spas, showerheads, water misters). (Clinical Case 29.6) The organisms can survive in moist environments for a long time, at relatively high temperatures, and in the presence of disinfectants such as chlorine. One reason for their survival is that the bacteria parasitize amebae in the water and replicate in this protected environment (similar to their replication in human macrophages). The bacteria also survive in biofilms that develop in the pipes of water systems.

The incidence of infections caused by *Legionella* species is unknown because disease is difficult to document. The

Clinical Case 29.6 **Outbreak of Legionnaires Disease**

Kirrage and associates (*Respir Med* 101:1639–1644, 2007) described an outbreak of legionnaires disease (LD) that occurred in Hereford, England. On October 24, 2003, the public health agency was notified that an elderly man had died of LD. Three days later, the agency was notified that an elderly woman had also died of LD. As part of an active surveillance investigation, two additional patients with positive *Legionella* urine antigen tests were identified in a local hospital. Further investigations revealed 28 epidemiologically linked patients with the onset of disease from October 8 to November 20. All patients had positive urine antigen tests, four had high antibody titers, and two were culture positive. The implicated source of the outbreak was a cooling tower that had recently been restarted after a period of inactivity. After the tower was closed and recleaned, the epidemic was terminated. This outbreak illustrates the difficulty of recognizing the problem when the individuals infected may present to different hospitals. This is particularly a problem when the source is located in a hotel or vacation place.

number of reported cases has steadily risen since 2000, with almost 7500 cases reported in 2016. However, the CDC estimates that up to 18,000 cases of legionnaires disease occur each year in the United States. Serologic studies have also shown that a significant proportion of the population has acquired immunity to these organisms. It is reasonable to conclude that contact with the organism and acquisition of immunity after an asymptomatic infection are common.

Although sporadic outbreaks of the disease occur throughout the year, most epidemics of the infection occur in late summer and autumn because the organism proliferates in water reservoirs during the warm months. More than 90% of the documented infections in the United States are in persons aged 40 years or older, presumably because they are more likely to have decreased cellular immunity and compromised pulmonary function. A significant proportion of reported cases are acquired in hospitals because of the predominance of high-risk patients. Person-to-person spread or an animal reservoir has not been demonstrated.

Asymptomatic *Legionella* infections are believed to be relatively common. Symptomatic infections primarily affect the lungs and present in one of two forms (see Box 29.1): (1) an influenza-like illness (referred to as **Pontiac fever**) and (2) a severe form of pneumonia (i.e., **legionnaires disease**).

L. pneumophila was responsible for causing a self-limited, febrile illness in people working at the Pontiac, Michigan, Public Health Department in 1968. Fever, chills, myalgia, malaise, and headache, but no clinical evidence of pneumonia, are characteristic of the disease. The symptoms developed over 12 hours, persisted for 2 to 5 days, and then resolved spontaneously without antibiotic treatment and with minimal morbidity and no deaths. Other outbreaks of Pontiac fever, with and without *Legionella* pneumonia, have been reported. The precise pathogenesis of this syndrome is unknown, although it is believed that this disease is caused by a hypersensitivity reaction to bacterial toxin (e.g., endotoxin).

Legionnaires disease (legionellosis) is characteristically more severe and, if untreated, promptly causes considerable morbidity, often leading to death in 15% of previously healthy individuals and up to 75% of immunocompromised patients. After an incubation period of 2 to 10 days, systemic signs of an acute illness appear abruptly (e.g., fever and chills, a dry, nonproductive cough, headache). Multiorgan disease involving the gastrointestinal tract, central nervous system, liver, and kidneys is common. The primary manifestation is pneumonia, with multilobar consolidation and inflammation and microabscesses in lung tissue observed on histopathologic studies. Pulmonary function steadily deteriorates in susceptible patients with untreated disease. The clinical presentation of pneumonia caused by *Legionella* is not unique, so laboratory tests are required to confirm the diagnosis.

Since *Legionella* was first isolated, the laboratory diagnosis of infections caused by this organism has undergone a significant transition. Initial testing depended on microscopy, culture, and serology. Although culture remains the gold standard for diagnosis, microscopy and serology have been replaced by immunoassays for the detection of *Legionella*-specific antigens in urine, and nucleic acid amplification assays have replaced microscopy and serology for diagnosis with respiratory secretions. The bacteria stain poorly with Gram stain and are rarely observed in clinical specimens; serology is insensitive and nonspecific.

Immunoassays are used to detect soluble ***Legionella* serogroup 1–specific LPS antigens** excreted in the urine of infected patients. The sensitivity of these assays for *L. pneumophila* serogroup 1 is relatively high (up to 90%), particularly with concentrated urines, but the assays do not reliably detect other serogroups or *Legionella* species. This is an important distinction because *L. pneumophila* serogroup 1 is responsible for 80% to 90% of community-acquired infections but is responsible for less than 50% of hospital-acquired infections. Antigens persist in the urine of treated patients, with almost 50% of patients remaining positive at 1 month and 25% at 2 months. Persistence is particularly common with immunosuppressed patients, in which antigens can persist for up to 1 year.

Nucleic acid amplification assays are highly specific and have a sensitivity equivalent to culture for detection of *Legionella* species in respiratory secretions (i.e., bronchial alveolar lavage fluid). The presence of inhibitors in respiratory secretions may cause false-negative reactions, so all specimens should still be cultured.

Although legionellae were difficult to grow initially, commercially available media now make culture easy (test sensitivity, 80% to >90%). As previously mentioned, legionellae require L-cysteine, and recovery is enhanced in the presence of iron salts (supplied in hemoglobin or ferric pyrophosphate). The medium most commonly used for the isolation of legionellae is **BCYE agar,** although other supplemented media have been used. Antibiotics can be added to suppress the growth of rapidly growing, contaminating bacteria. Legionellae grow in air or 3% to 5% carbon dioxide at 35° C after 3 to 5 days. The small (1- to 3-mm) colonies have a characteristic ground-glass appearance.

It is easy to identify an isolate as *Legionella* from the findings of typical morphology and specific growth requirements. Legionellae appear as weakly staining, pleomorphic, thin,

gram-negative rods. Their growth on BCYE agar, but not on media without L-cysteine, is presumptive evidence that the organism is *Legionella.* In contrast to identification of the genus, species classification is problematic and generally relegated to reference laboratories. Although biochemical tests are useful for differentiating species, the species can be identified definitively only through sequencing species-specific gene targets or assessment of protein profiles using mass spectrometry.

In vitro susceptibility tests are not performed with legionellae because the organisms grow poorly on the media commonly used for these tests. In addition, some antibiotics that appear active in vitro are ineffective in treating infections. One explanation is that these antibiotics cannot penetrate the macrophages in which the legionellae survive and multiply. Accumulated clinical experience indicates that **macrolides** (e.g., azithromycin, clarithromycin) or **fluoroquinolones** (e.g., ciprofloxacin, levofloxacin) should be used to treat *Legionella* infections. β-Lactam antibiotics are ineffective because most isolates produce β-lactamases, and these antibiotics do not penetrate macrophages. Specific therapy for Pontiac fever is generally unnecessary because it is a self-limited hypersensitivity disease.

Prevention of legionellosis requires identification of the environmental source of the organism and reduction of the microbial burden. Hyperchlorination of the water supply and maintenance of elevated water temperatures have proved moderately successful. However, elimination of *Legionella* organisms from a water supply is often difficult or impossible to achieve. Because the organism has a low potential for causing disease, reducing the number of organisms in the water supply is often an adequate control measure. Hospitals with patients at high risk for disease should monitor their water supply on a regular basis for the presence of *Legionella* and their hospital population for disease. If hyperchlorination or superheating of the water does not eliminate disease (complete elimination of the organisms in the water supply is probably not possible), continuous copper-silver ionization of the water supply may be necessary.

Streptobacillus

Streptobacillus moniliformis, the causative agent of **rat-bite fever,** is a long, thin (0.1 to 0.5 × 1 to 5 μm), gram-negative rod that tends to stain poorly and to be more pleomorphic in older cultures. Granules, bulbous swellings resembling a string of beads, and extremely long filaments may be seen (Fig. 29.8).

Streptobacillus is found in the nasopharynx of rats and other small rodents, as well as transiently in animals that feed on rodents (e.g., dogs, cats). Human infections result from rodent bites (**rat-bite fever;** Clinical Case 29.7) or much less commonly from consumption of contaminated food or water **(Haverhill fever)** (see Box 29.1). Most cases of rat-bite fever in the United States are in children with pet rats, laboratory workers, and pet shop employees. After a 2- to 10-day incubation period, the onset of rat-bite fever is abrupt, characterized by irregular fever, headache, chills, muscle pain, and migratory pain in multiple joints (polyarthralgias). A maculopapular or petechial rash develops a few days later, with involvement extending to the hands and feet. This hemorrhagic rash in a patient with a recent history of a rat bite and migratory polyarthralgias is diagnostic. In the absence of effective antibiotics, rat-bite fever is associated with a 10% mortality rate. Despite effective treatment, some patients have persistent polyarthralgias, fatigue, and a slowly resolving rash.

Laboratory confirmation of *Streptobacillus* infections is difficult. Blood and joint fluid should be collected, and the laboratory should be notified that *S. moniliformis* is suspected because growth of the organism requires use of enriched media supplemented with 15% blood, 20% horse or calf serum, or 5% ascitic fluid. *S. moniliformis* grows slowly, taking at least 3 days to be isolated. When grown in broth, it has the appearance of "puffballs." Small, round colonies are seen when grown on agar, and the colonies of cell wall–defective variants resemble fried eggs (heaped center with spreading edges) on agar media. It is difficult to identify the organisms by biochemical tests because they are

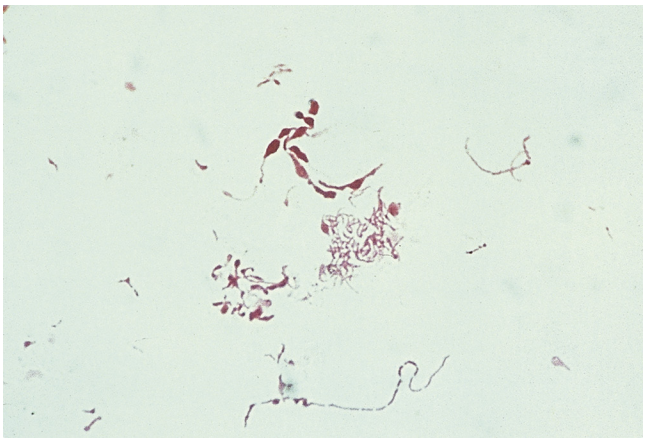

Fig. 29.8 Gram stain of *Streptobacillus moniliformis;* note the pleomorphic forms and bulbous swellings.

Clinical Case 29.7 **Rat-Bite Fever**

Irvine (*Clin Microbiol Newslett* 28:15–17, 2006) described a 60-year-old man who developed rat-bite fever. The patient was admitted to the hospital complaining of fever, confusion, headaches, and pustular lesions on both hands. The diagnosis of sepsis was made, and blood cultures, cerebrospinal fluid (CSF), and the purulent material from the lesions were collected. Lymphocytes were the predominant cells in the CSF, and no bacteria were seen on Gram stain, consistent with aseptic meningitis. A Gram stain of purulent material revealed pleomorphic gram-negative rods. After 3 days of incubation, the bacteria grew from both the blood and wound cultures. Growth in the blood culture broths appeared as clumps of organisms resembling "bread crumbs." The organism was subsequently identified as *Streptobacillus moniliformis*. The patient was treated with penicillin, and within 24 hours his fever resolved and sensorium cleared. A more complete social history revealed that the patient had a pet snake and maintained mice to feed the snake. Although he did not remember recent bites from the mice, exposure of open cuts on his hands to the rodents would have been sufficient for an infection to develop.

relatively inactive metabolically. The most reliable method for identifying isolates is to sequence the 16S rRNA gene. *S. moniliformis* is susceptible to many antibiotics, including **penicillin** (not active against cell wall–defective variants) and **tetracycline.**

Because this chapter examines a group of unrelated gram-negative bacteria, a series of case studies are presented to help the student review the chapter content.

Case Study 1 and Questions

A previously healthy 12-year-old girl developed a slowly enlarging, swollen axillary lymph node. One week before the onset of disease, she had suffered a scratch while playing with a kitten. Her physician suspected the diagnosis of cat-scratch disease.

1. What is the most sensitive diagnostic test for confirming this diagnosis?

2. What infections are caused by *B. quintana* and *B. henselae*? How does the epidemiology of these infections differ?

Case Study 2 and Questions

A 5-year-old girl was brought to the local public health clinic because of a severe, intractable cough. During the previous 10 days, she had a persistent cold that had worsened. The cough developed the previous day and was so severe that vomiting frequently followed it. The child appeared exhausted from the coughing episodes. A blood cell count showed a marked leukocytosis with a predominance of lymphocytes. The examining physician suspected that the child had pertussis.

3. What laboratory tests can be performed to confirm the physician's clinical diagnosis? What specimens should be collected, and how should they be submitted to the laboratory?

4. What is the natural progression and prognosis for this disease? How can it be prevented?

Case Study 3 and Questions

A 27-year-old man was mowing his field when he ran over two young rabbits. When he stopped his mower, he realized that two other rabbits were dead in the unmowed part of the lawn. He removed all the rabbits and buried them. Three days later he developed a fever, muscle aches, and a dry, nonproductive cough. Over the next 12 hours he became progressively sicker and was transported by his wife to the area hospital. Results of a chest radiograph showed infiltrates in both lung fields. Blood cultures and respiratory secretions were collected, and antibiotics were initiated. Blood cultures became positive, with small gram-negative rods after 3 days of incubation, and the same organism grew from the respiratory specimen that was inoculated onto BCYE agar.

5. What test should be performed to confirm the tentative diagnosis of *F. tularensis*?

6. This infection was presumably acquired by inhalation of aerosolized contaminated blood. What are the most common sources of *F. tularensis* infections and the most common routes of exposure?

Case Study 4 and Questions

A 73-year-old man was admitted to the hospital because of breathing difficulties, chest pain, chills, and fever of several days' duration. He had been well until 1 week before admission, when he noted the onset of a persistent headache and a productive cough. The patient smoked two packs of cigarettes a day for more than 50 years and drank a six-pack of beer daily; he also had a history of bronchitis. Physical examination results revealed an elderly man in severe respiratory distress with a temperature of 39° C, pulse of 120 beats/min, respiratory rate of 36 breaths/min, and blood pressure of 145/95 mm Hg. A chest radiograph revealed an infiltrate in the middle and lower lobes of the right lung. The white blood cell count was 14,000 cells/mm^3 (80% polymorphonuclear neutrophils). Gram stain of the sputum showed neutrophils but no bacteria, and routine bacterial cultures of sputum and blood were negative for organisms. Infection with *L. pneumophila* was suspected.

7. What laboratory tests can be used to confirm this diagnosis? Why were the routine culture and Gram-stained specimen negative for *Legionella* organisms?

30 Clostridium

The genus *Clostridium* consists of a large heterogeneous collection of spore-forming anaerobic rods. Pathogens such as *C. tetani* and *C. botulinum*, the agents responsible for tetanus and botulism, respectively, are well recognized and have historical significance. Disease caused by *C. difficile* has evolved in recent years as an infectious complication of antibiotic usage, in both the hospital and the community. Other species of clostridia are also well-recognized pathogens.

1. *C. perfringens* is an important cause of myonecrosis. What virulence factors are responsible for this disease?
2. Food poisoning caused by *C. perfringens* and *C. botulinum* is caused by ingestion of toxins (intoxication). Compare the clinical manifestations of these two diseases.
3. What disease is caused by *C. septicum*, and what patient population is most susceptible?

Answers to these questions are available on Student Consult.com.

Summaries Clinically Significant Organisms

CLOSTRIDIUM DIFFICILE

Trigger Words

Spore former, fecal carriage, toxins A and B, antibiotic-associated diarrhea, pseudomembranous colitis

Biology and Virulence

- Large anaerobic rod characterized by abundant spore formation, rapid growth, and production of volatile fatty acids
- Most strains produce two toxins: an enterotoxin that attracts neutrophils and stimulates their release of cytokines, and a cytotoxin that increases permeability of the intestinal wall and subsequent diarrhea
- Spore formation allows the organism to persist in the hospital environment and resist decontamination efforts
- Resistance to antibiotics such as clindamycin, cephalosporins, and fluoroquinolones allows *C. difficile* to overgrow the normal intestinal bacteria in patients exposed to these antibiotics and produce disease

Epidemiology

- Colonizes the intestines of a small proportion of healthy individuals (<5%)
- Exposure to antibiotics is associated with overgrowth of *C. difficile* and subsequent disease (endogenous infection)

Diseases

- Antibiotic-associated diarrhea: acute diarrhea generally developing 5 to 10 days after initiation of antibiotic treatment; may be brief and self-limited or more protracted with recurrent bouts of diarrhea
- Pseudomembranous colitis: most severe form of *C. difficile* disease, with profuse diarrhea, abdominal cramping, and fever; whitish plaques (pseudomembranes) form over intact colonic tissue; can progress to death

Diagnosis

- *C. difficile* disease is confirmed by detecting cytotoxin or enterotoxin or the toxin genes in the patient's feces

Treatment, Prevention, and Control

- The implicated antibiotic should be discontinued
- Treatment with metronidazole or vancomycin should be used in severe disease; fecal transplants of colonic bacteria from healthy individuals can be used to treat recurrent disease
- Relapse is common because antibiotics do not kill spores; a second course of therapy with the same antibiotic is usually successful, although multiple courses may be necessary
- The hospital room should be carefully cleaned after the infected patient is discharged

CLOSTRIDIUM PERFRINGENS

Trigger Words

Spore former, myonecrosis, sepsis, food poisoning

Biology and Virulence

- Large gram-positive rods with spores rarely observed
- Distinct colony morphology and rapid growth
- Produces many toxins and enzymes that lyse blood cells and destroy tissues, leading to diseases such as overwhelming sepsis, massive hemolysis, and myonecrosis
- Produces a heat-sensitive enterotoxin that binds to receptors on the epithelium of the small intestine leading to loss of fluids and ions (watery diarrhea)

Epidemiology

- Ubiquitous; present in soil, water, and intestinal tract of humans and animals
- Type A strains are responsible for most human infections

Diseases

- Food poisoning associated with contaminated meat products (beef, poultry, gravy) held at temperatures between 5° C and 60° C, which allows the organisms to grow to large numbers
- Soft-tissue infections typically associated with bacterial contamination of wounds or localized trauma

Diagnosis

- Reliably recognized in Gram-stained tissue specimens (large, rectangular, gram-positive rods)
- Grows rapidly in culture with characteristic colony morphology and hemolytic pattern

Treatment, Prevention, and Control

- Rapid treatment is essential for serious infections
- Severe infections require surgical debridement and high-dose penicillin therapy
- Symptomatic treatment for food poisoning
- Proper wound care and judicious use of prophylactic antibiotics will prevent most infections

CLOSTRIDIUM TETANI

Trigger Words

Spore former, environmental, neurotoxin, contaminated wounds, tetanus, vaccine

Biology and Virulence

- Organism extremely oxygen sensitive, which makes detection by culture difficult
- The primary virulence factor is tetanospasmin, which is a heat-labile neurotoxin that blocks release of neurotransmitters for inhibitory synapses (i.e., gamma-aminobutyric acid, glycine)

Continued

Summaries Clinically Significant Organisms—cont'd

Epidemiology

- Ubiquitous; spores are found in most soils and can colonize the gastrointestinal tract of humans and animals
- Exposure to spores is common, but disease is uncommon, except in developing countries in which there is poor access to vaccine and medical care
- Risk is greatest for people with inadequate vaccine-induced immunity
- Disease does not induce immunity

Diseases

- Disease is characterized by unrelenting muscle spasms and involvement of the autonomic nervous system

Diagnosis

- Diagnosis is based on clinical presentation and not laboratory tests
- Microscopy and culture are insensitive, and neither tetanus toxin nor antibodies are typically detected

Treatment, Prevention, and Control

- Treatment requires the combination of wound debridement, antibiotic therapy (penicillin, metronidazole), passive immunization with antitoxin globulin, and vaccination with tetanus toxoid
- Prevention through use of vaccination, consisting of three doses of tetanus toxoid followed by booster doses every 10 years

CLOSTRIDIUM BOTULINUM

Trigger Words

Spore former, environmental, neurotoxin, foodborne and infant botulism, no vaccine

Biology and Virulence

- Multiple distinct botulinum toxins are produced, with human disease caused most commonly by types A and B; types E and F are also associated with human disease
- Botulinum toxin prevents release of the neurotransmitter acetylcholine, blocking neurotransmission at peripheral cholinergic synapses, leading to a flaccid paralysis

Epidemiology

- *C. botulinum* spores are found in soil worldwide
- Relatively few cases of botulism in the United States but prevalent in developing countries
- Infant botulism more common than other forms in the United States; associated with ingestion of contaminated soil or contaminated foods (particularly honey)

Diseases

- Foodborne botulism is characterized by blurred vision, dry mouth, constipation, and abdominal pain, with progressive weakness of the peripheral muscles and flaccid paralysis
- Infant botulism begins with nonspecific symptoms but progresses to flaccid paralysis
- Other forms of botulism include wound botulism and inhalation botulism

Diagnosis

- Diagnosis of foodborne botulism is confirmed if toxin activity is demonstrated in the implicated food or in the patient's serum, feces, or gastric fluid
- Infant botulism is confirmed if toxin is detected in the infant's feces or serum, or the organism cultured from feces
- Wound botulism is confirmed if toxin is detected in the patient's serum or wound, or the organism cultured from the wound

Treatment, Prevention, and Control

- Treatment involves the combination of administration of metronidazole or penicillin, trivalent botulinum antitoxin, and ventilatory support
- Spore germination in foods prevented by maintaining food at an acid pH, by high sugar content (e.g., fruit preserves), or by storing the foods at 4° C or colder
- Toxin is heat labile; therefore it can be destroyed by heating of food for 10 minutes at 60° C to 100° C

Historically, the collection of all anaerobic gram-positive rods capable of forming **endospores** was in the genus *Clostridium;* however, clinically significant members of the genus can be misclassified by these criteria. Spores are only rarely demonstrated in some species *(C. perfringens, C. ramosum)*, some species are aerotolerant and can grow on agar media exposed to air (e.g., *C. tertium, C. histolyticum*), and some clostridia consistently stain gram-negative (e.g., *C. ramosum, C. clostridioforme*). It should not be surprising that the use of gene-sequencing techniques has led to reorganization of this heterogeneous collection of organisms into many new genera; however, most clinically significant species cluster in homology group I and remain in the genus *Clostridium.* These bacteria are the focus of this chapter (Table 30.1).

The clostridia are **ubiquitous** in soil, water, and sewage and are part of the normal microbial population in the gastrointestinal (GI) tracts of animals and humans. Most clostridia are harmless saprophytes, but some are well-recognized human pathogens with a clearly documented history of causing diseases such as **diarrhea** and **colitis** *(C. difficile)*, **food poisoning** *(C. perfringens)*, **tetanus** *(C. tetani)*, **botulism** *(C. botulinum)*, and **myonecrosis** (**gas gangrene)** *(C. perfringens, C. septicum, C. sordellii)* (Table 30.2; Box 30.1). The remarkable ability of clostridia to cause diseases is attributed to their (1) ability to survive adverse environmental conditions through spore formation; (2) rapid growth in a nutritionally enriched, oxygen-deprived environment; and (3) production of numerous histolytic toxins, enterotoxins, and neurotoxins.

Clostridium difficile

PHYSIOLOGY AND STRUCTURE

C. difficile is a large (0.5 to 1.9 × 3.0 to 17 μm) anaerobic rod that freely forms spores *in vivo* and in culture. The organism grows rapidly in culture, although the vegetative cells (i.e., cells without a spore) die rapidly when exposed to oxygen. *C. difficile* produces a variety of volatile fatty acids that produce a characteristic "barnyard" smell in culture.

PATHOGENESIS AND IMMUNITY

C. difficile produces two toxins: an **enterotoxin (toxin A)** and a **cytotoxin (toxin B).** The enterotoxin is chemotactic for neutrophils, stimulating the infiltration of polymorphonuclear neutrophils into the ileum with release of cytokines. Toxin A also produces a cytopathic effect, resulting in disruption of the tight cell-to-cell junction, increased permeability of the intestinal wall, and subsequent diarrhea. The cytotoxin causes actin to depolymerize, with resultant destruction of the cellular cytoskeleton both *in vivo* and *in vitro*. Although both toxins appear to interact synergistically in the pathogenesis of disease, enterotoxin A–negative

TABLE 30.1 Important Clostridia

Organism	Historical Derivation
Clostridium	*closter,* a spindle
C. botulinum	*botulus,* sausage (the first major outbreak was associated with insufficiently smoked sausage)
C. difficile	*difficile,* difficult (difficult to isolate and grow; refers to the extreme oxygen sensitivity of this organism)
C. perfringens	*perfringens,* breaking through (associated with highly invasive tissue necrosis)
C. septicum	*septicum,* putrefactive (associated with sepsis and a high mortality)
C. tertium	*tertium,* third (historically, the third most commonly isolated anaerobe from war wounds)
C. tetani	*tetani,* related to tension (disease caused by this organism characterized by muscle spasms)

TABLE 30.2 Pathogenic Clostridia and Their Associated Human Diseases[a]

Species	Human Disease	Frequency
C. difficile	Antibiotic-associated diarrhea, pseudomembranous colitis	Common
C. perfringens	Soft-tissue infections (e.g., cellulitis, suppurative myositis, myonecrosis, gas gangrene), food poisoning, enteritis necroticans, septicemia	Common
C. septicum	Gas gangrene, septicemia	Uncommon
C. botulinum	Botulism	Uncommon
C. tetani	Tetanus	Uncommon
C. tertium	Opportunistic infections	Uncommon
C. sordellii	Gas gangrene, septic shock syndrome	Uncommon

[a]Other clostridial species have been associated with human disease but primarily as opportunistic pathogens or rarely observed. In addition, some species (e.g., *C. clostridioforme, C. innocuum, C. ramosum*) are commonly isolated but rarely associated with disease.

isolates can still produce disease. In addition, production of one or both toxins alone does not appear to be sufficient for disease (e.g., carriage of *C. difficile* and high levels of toxins are common in young children, although disease is rare). Bacterial "surface layer proteins" are important for the binding of *C. difficile* to the intestinal epithelium, leading to localized production of toxins and subsequent tissue damage.

EPIDEMIOLOGY

C. difficile is part of the normal intestinal flora in a small number of healthy people and hospitalized patients. In contrast with the original belief that *C. difficile* disease is restricted to hospitalized patients, it is now recognized that a significant proportion of individuals with *C. difficile* disease develop symptomatic disease outside the hospital. For most of these patients, they have a recent history of exposure to a health care facility, in which they acquired *C. difficile*. The disease develops in people taking antibiotics because the drugs alter the normal enteric flora, either permitting overgrowth of these relatively resistant organisms or making the patient more susceptible to exogenous acquisition of *C. difficile*. The disease occurs if the organisms proliferate in the colon and produce their toxins.

BOX 30.1 Clostridial Diseases: Clinical Summaries

Clostridium difficile

Antibiotic-associated diarrhea: acute diarrhea generally developing 5 to 10 days after initiation of antibiotic treatment (particularly clindamycin, penicillins, cephalosporins, fluoroquinolones); may be brief and self-limited or more protracted
Pseudomembranous colitis: most severe form of *C. difficile* disease, with profuse diarrhea, abdominal cramping, and fever; whitish plaques (pseudomembranes) over intact colonic tissue seen on colonoscopy

Clostridium perfringens

Soft-Tissue Infections

Cellulitis: localized edema and erythema with gas formation in the soft tissue; generally nonpainful
Suppurative myositis: accumulation of pus (suppuration) in the muscle planes, without muscle necrosis or systemic symptoms
Myonecrosis: painful, rapid destruction of muscle tissue; systemic spread with high mortality

Gastroenteritis

Food poisoning: rapid onset of abdominal cramps and watery diarrhea with no fever, nausea, or vomiting; short duration and self-limited
Necrotizing enteritis: acute, necrotizing destruction of jejunum, with abdominal pain, vomiting, bloody diarrhea, and peritonitis

Clostridium tetani

Generalized tetanus: generalized musculature spasms and involvement of the autonomic nervous system in severe disease (e.g., cardiac arrhythmias, fluctuations in blood pressure, profound sweating, dehydration)
Localized tetanus: musculature spasms restricted to localized area of primary infection
Neonatal tetanus: neonatal infection primarily involving the umbilical stump; very high mortality

Clostridium botulinum

Foodborne botulism: initial presentation of blurred vision, dry mouth, constipation, and abdominal pain; progresses to bilateral descending weakness of the peripheral muscles, with flaccid paralysis
Infant botulism: initially nonspecific symptoms (e.g., constipation, weak cry, failure to thrive) that progress to flaccid paralysis and respiratory arrest
Wound botulism: clinical presentation same as with foodborne disease, although the incubation period is longer and fewer gastrointestinal symptoms are reported
Inhalation botulism: rapid onset of symptoms (flaccid paralysis, pulmonary failure) and high mortality from inhalation exposure to botulinum toxin

CLINICAL DISEASES

Until the mid-1970s, the clinical importance of *C. difficile* was not appreciated (see Box 30.1). This organism was infrequently isolated in fecal cultures, and its role in human disease was unknown. Systematic studies now show that

Clinical Case 30.1 *Clostridium difficile* Colitis

Limaye and colleagues (*J Clin Microbiol* 38:1696, 2000) presented a classic presentation of *C. difficile* disease in a 60-year-old man who received a transplanted liver 5 years previous to his hospital admission for evaluation of crampy abdominal pain and severe diarrhea. Three weeks before admission he received a 10-day course of oral trimethoprim-sulfamethoxazole for sinusitis. On physical examination, the patient was febrile and had moderate abdominal tenderness. Abdominal computed tomography scan revealed right colon thickening but no abscess. Colonoscopy showed numerous whitish plaques and friable erythematous mucosa consistent with pseudomembranous colitis. Empirical therapy with oral metronidazole and intravenous levofloxacin was initiated. A stool immunoassay for *C. difficile* toxin A was negative, but *C. difficile* toxin was detected by both culture and cytotoxicity assay (demonstration stool filtrate causes cytotoxicity to cell cultures that is neutralized by specific antisera against *C. difficile* toxins). Therapy was changed to oral vancomycin, and the patient responded with resolution of diarrhea and abdominal pain. This is an example of severe *C. difficile* disease after antibiotic exposure in an immunocompromised patient, with a characteristic presentation of pseudomembranous colitis. The diagnostic problems with immunoassays are well known and have now been replaced by polymerase chain reaction assays that target the toxin genes. Treatment with metronidazole is currently preferred, although vancomycin is an acceptable alternative.

toxin-producing *C. difficile* is the most common cause of antibiotic-associated GI diseases ranging from a relatively benign, self-limited diarrhea to severe, life-threatening pseudomembranous colitis (Figs. 30.1 and 30.2). (Clinical Case 30.1)

In 2003, disease caused by a highly virulent strain (referred to as O27) of *C. difficile* was reported in communities and hospitals in Canada, the United States, and Europe. This strain was responsible for more severe disease, a high mortality rate, increased risk of relapse, and more complications. It was initially thought that this increased virulence was related to increased toxin production combined with the presence of a second toxin, **binary toxin.** However, it is now appreciated that *C. difficile* virulence is more complex and cannot be attributed to specific genotypes; rather, it is attributed to multiple virulent phenotypes.

LABORATORY DIAGNOSIS

Isolation of the *C. difficile* in stool culture documents colonization but not disease, so the diagnosis of disease is confirmed by demonstration of the enterotoxin or cytotoxin in a stool specimen from a patient with compatible clinical symptoms or detection of the *C. difficile* toxin A and B genes directly in clinical specimens by nucleic acid amplification techniques. Commercial molecular assays with high sensitivity and specificity are now available that provide results within a few hours of sample collection.

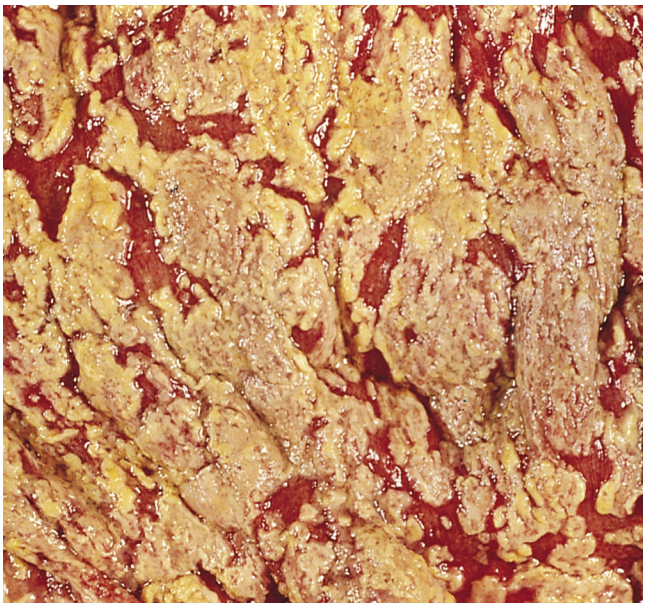

Fig. 30.1 Antibiotic-associated colitis: gross section of the lumen of the colon. Note the white plaques of fibrin, mucus, and inflammatory cells overlying the normal red intestinal mucosa.

Fig. 30.2 Antibiotic-associated colitis caused by *Clostridium difficile.* A histologic section of colon shows an intense inflammatory response, with the characteristic "plaque" *(black arrow)* overlying the intact intestinal mucosa *(white arrow)* (hematoxylin and eosin stain). (From Lambert, H.P., Farrar, W.E. (Eds.), 1982. Infectious Diseases Illustrated. Gower, London, UK.)

TREATMENT, PREVENTION, AND CONTROL

Discontinuation of the implicated antibiotic (e.g., ampicillin, clindamycin, fluoroquinolones) is generally sufficient to alleviate mild disease. However, specific therapy with **metronidazole** or **vancomycin** is necessary for the management of severe diarrhea or colitis. Relapses may occur in as many as 20% to 30% of patients after completion of therapy because only the vegetative forms of *C. difficile* are killed by the antibiotics; the spores are resistant. A second course of treatment with the same antibiotic is frequently successful, although multiple relapses are well documented in some patients. One novel approach to treat recurrent disease is to infuse fecal contents from a healthy donor ("rePOOPulate") into the intestines of the ill patient. Remarkable success

with these "fecal transplants" has been demonstrated, illustrating the fact that *C. difficile* does not become established when a healthy enteric population of bacteria is present. It is difficult to prevent the disease because the organism commonly exists in hospitals, particularly in areas adjacent to infected patients (e.g., beds, bathrooms). The spores of *C. difficile* are difficult to eliminate unless thorough housekeeping measures are used. Thus the organism can contaminate an environment for many months and can be a major source of nosocomial outbreaks of *C. difficile* disease.

Clostridium perfringens

PHYSIOLOGY AND STRUCTURE

C. perfringens is a large (0.6 to 2.4 × 1.3 to 19.0 μm), rectangular, gram-positive rod (Fig. 30.3), with **spores rarely observed** either in vivo or after in vitro cultivation, which is an important characteristic that differentiates this species from most other clostridia. Colonies of *C. perfringens* are also distinctive, with their rapid, spreading growth on laboratory media and β-hemolysis on blood-containing media (Fig. 30.4). The production of one or more "major lethal" toxins by *C. perfringens* (alpha, beta, epsilon, and iota toxins) is used to subdivide isolates into five types (A through E).

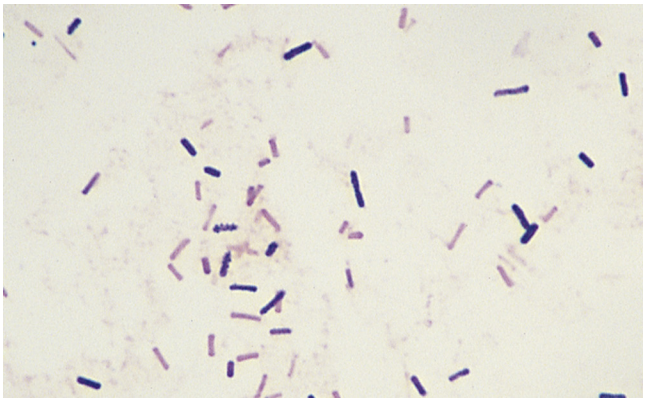

Fig. 30.3 Gram stain of *Clostridium perfringens* in a wound specimen. Note the rectangular shape of the rods, the presence of many decolorized rods appearing gram-negative, and the absence of spore and blood cells.

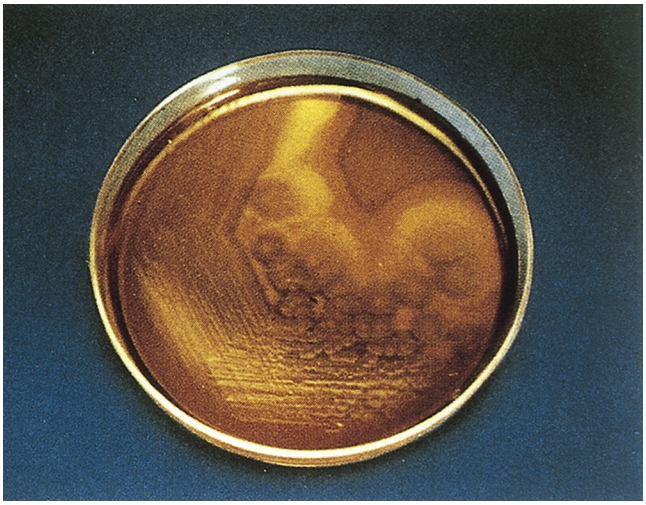

Fig. 30.4 Growth of *Clostridium perfringens* on sheep blood agar. Note the flat, spreading colonies and the hemolytic activity of the organism. A presumptive identification of *C. perfringens* can be made by detection of a zone of complete hemolysis (caused by the theta toxin) and a wider zone of partial hemolysis (caused by the alpha toxin), combined with the characteristic microscopic morphology.

PATHOGENESIS AND IMMUNITY

Alpha toxin, produced by all five types of *C. perfringens,* is a lecithinase (phospholipase C) that lyses erythrocytes, platelets, leukocytes, and endothelial cells. This toxin mediates massive hemolysis, increased vascular permeability and bleeding (augmented by destruction of platelets), tissue destruction, hepatic toxicity, and myocardial dysfunction (bradycardia, hypotension). **Beta toxin** is responsible for intestinal stasis, loss of mucosa with formation of necrotic lesions, and progression to necrotizing enteritis. **Epsilon toxin,** which is a protoxin, is activated by trypsin and increases the vascular permeability of the GI wall. **Iota toxin,** produced by type E *C. perfringens,* has necrotic activity and increases vascular permeability.

C. perfringens produces **enterotoxin,** primarily by type A strains, whose activity is enhanced by exposure to trypsin. The enterotoxin is produced during the phase transition from vegetative cells to spores and is released in the alkaline environment of the small intestine when the cells undergo the terminal stages of spore formation **(sporulation).** The released enterotoxin binds to receptors on the brush border membrane of the small intestine epithelium in the ileum (primarily) and jejunum but not the duodenum. Insertion of the toxin into the cell membrane leads to altered membrane permeability and loss of fluids and ions. The enterotoxin also acts as a superantigen, stimulating T-lymphocyte activity.

EPIDEMIOLOGY

Type A *C. perfringens* commonly inhabits the intestinal tract of humans and animals and is widely distributed in nature, particularly in soil and water contaminated with feces. Spores form under adverse environmental conditions and survive for prolonged periods. Strains of types B through E do not survive in soil but colonize the intestinal tracts of animals and occasionally humans. *C. perfringens,* particularly type A, is responsible for a variety of diseases including soft-tissue infections, food poisoning, necrotizing enteritis, and septicemia.

CLINICAL DISEASES

C. perfringens is responsible for a range of soft-tissue infections including **cellulitis** (Fig. 30.5), fasciitis or suppurative **myositis,** and **myonecrosis** with gas formation in the soft tissue (gas gangrene). Clostridial myonecrosis is most commonly caused by *C. perfringens,* although other species, particularly *C. septicum*, can also produce this disease. This is a life-threatening disease that illustrates the full virulence potential of histotoxic clostridia. The onset of disease, characterized by intense pain, generally develops within a week after clostridia are introduced into tissue by trauma or surgery. The onset is followed rapidly by extensive muscle

Fig. 30.5 Clostridial cellulitis. Clostridia can be introduced into tissue during surgery or by a traumatic injury. This patient suffered a compound fracture of the tibia. Five days after the injury, the skin became discolored, and bullae and necrosis developed. A serosanguineous exudate and subcutaneous gas were present, but there was no evidence of muscle necrosis. The patient had an uneventful recovery. (From Lambert, H., Farrar, W. (Eds.), 1982. Infectious Diseases Illustrated. Gower, London, UK.)

necrosis, shock, renal failure, and death, often within 2 days of initial onset. Macroscopic examination of muscle reveals devitalized necrotic tissue. Gas found in the tissue is caused by the metabolic activity of the rapidly dividing bacteria (hence the name **gas gangrene**). Gram stain of tissue or exudate collected from the wound of a patient with *C. perfringens* myonecrosis will reveal abundant rectangular gram-positive rods with the absence of inflammatory cells (resulting from lysis by clostridial toxins). The clostridial toxins characteristically cause extensive hemolysis and bleeding (see Box 30.1).

Clostridial food poisoning (Clinical Case 30.2), a relatively common but underappreciated intoxication, is characterized by (1) a short incubation period (8 to 12 hours); (2) a clinical presentation that includes abdominal cramps and watery diarrhea but no fever, nausea, or vomiting; and (3) a clinical course lasting less than 24 hours. Disease results from ingestion of meat products (e.g., beef, chicken, turkey, gravy) contaminated with large numbers (10^8 to 10^9 organisms) of enterotoxin-producing type A *C. perfringens*. Holding contaminated foods at temperatures less than 60° C allows spores that survived the cooking process to germinate and multiply to high numbers. Rapid refrigeration of food after preparation prevents this bacterial growth. Alternatively, reheating the food to 74° C can destroy the heat-labile enterotoxin.

Necrotizing enteritis (also called **enteritis necroticans** or **pig-bel**) is a rare necrotizing process in the jejunum characterized by acute abdominal pain, vomiting, bloody diarrhea, ulceration of the small intestine, and perforation of the intestinal wall, leading to peritonitis and shock. Mortality in patients with this infection approaches 50%. Beta toxin produced by *C. perfringens* type C is responsible for this disease. Necrotizing enteritis is most common in Papua New Guinea, with sporadic cases reported from other countries. This results from the dietary habits of the population, in which disease can follow consumption of both undercooked contaminated pork and sweet potatoes. Sweet potatoes contain a heat-resistant trypsin inhibitor that protects the beta toxin from inactivation by trypsin. Other risk factors for the disease are exposure to large numbers of organisms and malnutrition (with loss of the proteolytic activity that inactivates the toxin).

Isolation of *C. perfringens* or other clostridial species in blood cultures can be alarming; however, more than half of the isolates are clinically insignificant, representing a transient bacteremia or, more likely, contamination of the culture with clostridia colonizing the skin. Patients with clinically significant **septicemia** complicating other infections (e.g., myonecrosis, necrotizing enteritis) will typically present dramatically with massive hemolysis and overwhelming septic shock.

Clinical Case 30.2 ***Clostridium perfringens* Gastroenteritis**

The Centers for Disease Control and Prevention reported two outbreaks of *C. perfringens* gastroenteritis associated with corned beef served at St. Patrick's Day celebrations (*MMWR* 43:137, 1994). On March 18, 1993, the Cleveland City Health Department received telephone calls from 15 persons who became ill after eating corned beef purchased from one delicatessen. After publicizing the outbreak, 156 persons contacted the Health Department with a similar history. In addition to a history of diarrhea, 88% complained of abdominal cramps and 13% had vomiting, which developed an average of 12 hours after eating the implicated meat. An investigation revealed the delicatessen had purchased 1400 pounds of raw, salt-cured meat, and beginning on March 12, portions of the corned beef were boiled for 3 hours, allowed to cool at room temperature, and then refrigerated. On March 16 and 17, the meat was removed from the refrigerator, heated to 48.8° C, and served. Cultures of the meat yielded greater than 10^5 colonies of *C. perfringens* per gram. The Health Department recommended that if the meat could not be served immediately after cooking, it should be rapidly cooled in ice and refrigerated. Before it is served, it should be warmed to at least 74° C to destroy the heat-sensitive enterotoxin.

LABORATORY DIAGNOSIS

The laboratory performs a confirmatory role in the diagnosis of clostridial soft-tissue diseases because therapy must be initiated immediately. The microscopic detection of gram-positive rods in clinical specimens, usually in the absence of leukocytes, can be a very useful finding because these organisms have a characteristic morphology. It is also relatively simple to culture these anaerobes. Under appropriate conditions, *C. perfringens* divides every 8 to 10 minutes, so growth on agar media or in blood culture broths can be detected after incubation for only a few hours. The role of *C. perfringens* in food poisoning is documented by recovery of more than 10^5 organisms per gram of food or more than 10^6 bacteria per gram of feces collected within 1 day of the

onset of disease. Immunoassays have also been developed for detection of the enterotoxin in fecal specimens, However, clostridial food poisoning is primarily a clinical diagnosis and culture or immunoassays are not commonly used.

TREATMENT, PREVENTION, AND CONTROL

C. perfringens soft-tissue infections, such as suppurative myositis and myonecrosis, must be treated aggressively with **surgical debridement** and **high-dose penicillin therapy.** Hyperbaric oxygen treatment has been used to manage these infections; however, the results are inconclusive. Despite all therapeutic efforts, the prognoses in patients with these diseases is poor, with mortality reported from 40% to almost 100%. Less serious, localized soft-tissue infections can be successfully treated with debridement and penicillin.

Clostridial food poisoning is managed by oral rehydration and in severe cases intravenous fluids and electrolytes. Antibiotic therapy is not recommended because this is a self-limiting disease (i.e., the diarrhea washes the bacteria out of the intestines, and the normal intestinal flora reestablishes itself).

Exposure to *C. perfringens* is difficult to avoid because the organisms are ubiquitous. Disease requires introduction of the organism into devitalized tissues and maintenance of an anaerobic environment favorable for bacterial growth. Thus proper wound care and the judicious use of prophylactic antibiotics can do much to prevent most infections.

Clostridium tetani

PHYSIOLOGY AND STRUCTURE

C. tetani is a large (0.5 to 2 × 2 to 18 μm), motile, spore-forming rod. The organism produces round, terminal spores that give it the appearance of a drumstick. Unlike *C. perfringens, C. tetani* is difficult to grow because the organism is extremely sensitive to oxygen toxicity; when growth is detected on agar media, it typically appears as a film over the surface of the agar rather than discrete colonies. The bacteria are proteolytic but unable to ferment carbohydrates.

PATHOGENESIS AND IMMUNITY

Although the vegetative cells of *C. tetani* die rapidly when exposed to oxygen, spore formation allows the organism to survive in the most adverse conditions. Of greater significance is the fact that *C. tetani* produces two toxins, an oxygen-labile hemolysin **(tetanolysin)** and a plasmid-encoded, heat-labile neurotoxin **(tetanospasmin).** The plasmid carrying the gene for tetanospasmin is nonconjugative, so a nontoxic *C. tetani* strain cannot be converted to a toxigenic strain. Tetanolysin is serologically related to streptolysin O and the hemolysins produced by *C. perfringens* and *Listeria monocytogenes;* however, the clinical significance of tetanolysin is unknown because it is inhibited by oxygen and serum cholesterol.

Tetanospasmin is produced during the stationary phase of growth, released when the cell is lysed, and responsible for the clinical manifestations of tetanus. Tetanospasmin (an **A-B toxin**) is synthesized as a single 150,000-Da peptide that is cleaved into a light (A chain) subunit and a heavy (B chain) subunit by an endogenous protease when the cell releases the neurotoxin. A disulfide bond and noncovalent forces hold the two chains together. The carbohydrate-binding domain of the carboxyl-terminal portion of the heavy chain (100,000-Da) binds to specific sialic acid receptors (e.g., polysialogangliosides) and adjacent glycoproteins on the surface of motor neurons. The intact toxin molecules are internalized in endosomal vesicles and transported in the neuron axon to motor neuron soma located in the spinal cord. In this location, the endosome becomes acidified, resulting in a conformational change in the N-terminus domain of the heavy chain, insertion into the endosome membrane, and passage of the toxin light chain into the cytosol of the cell. The light chain is a **zinc endopeptidase** that cleaves core proteins involved in the trafficking and release of neurotransmitters. Specifically, tetanospasmin **inactivates proteins that regulate release of the inhibitory neurotransmitters** glycine and gamma-aminobutyric acid (GABA). This leads to unregulated excitatory synaptic activity in the motor neurons, resulting in **spastic paralysis.** The toxin binding is irreversible, so recovery depends on formation of new axonal terminals.

EPIDEMIOLOGY

C. tetani is **ubiquitous.** It is found in fertile soil and transiently colonizes the GI tracts of many animals, including humans. The vegetative forms of *C. tetani* are extremely susceptible to oxygen toxicity, but the organisms sporulate readily and can survive in nature for a long time. Disease is relatively rare in the United States because of the high incidence of vaccine-induced immunity. Only 33 cases were reported in 2017, and the disease occurs primarily in elderly patients with waning immunity. However, tetanus is still responsible for many deaths in developing countries in which vaccination is unavailable or medical practices are lax. It is estimated that more than 1 million cases occur worldwide, with a mortality rate ranging from 30% to 50%. At least half the deaths occur in neonates.

CLINICAL DISEASES

The incubation period for tetanus varies from a few days to weeks. The duration of the incubation period is directly related to the distance of the primary wound infection from the central nervous system (Clinical Case 30.3; see Box 30.1).

Generalized tetanus is the most common form. Involvement of the masseter muscles (trismus or lockjaw) is the presenting sign in most patients. The characteristic sardonic smile that results from the sustained contraction of the facial muscles is known as *risus sardonicus* (Fig. 30.6). Other early signs are drooling, sweating, irritability, and persistent back spasms *(opisthotonos)* (Fig. 30.7). The autonomic nervous system is involved in patients with more severe disease; the signs and symptoms include cardiac arrhythmias, fluctuations in blood pressure, profound sweating, and dehydration.

Another form of *C. tetani* disease is **localized tetanus,** in which the disease remains confined to the musculature at the site of primary infection. A variant is **cephalic tetanus,**

Clinical Case 30.3 **Tetanus**

The following is a typical history of a patient with tetanus (CDC, *MMWR* 51:613–615, 2002). An 86-year-old man saw a physician for care of a splinter wound in his right hand, acquired 3 days earlier while gardening. He was not treated with either a tetanus toxoid vaccine or tetanus immunoglobulin. Seven days later he developed pharyngitis, and after an additional 3 days, he presented to the local hospital with difficulty talking, swallowing, and breathing, and with chest pain and disorientation. He was admitted to the hospital with the diagnosis of stroke. On his fourth hospital day, he had developed neck rigidity and respiratory failure, requiring tracheostomy and mechanical ventilation. He was transferred to the medical intensive care unit, where the clinical diagnosis of tetanus was made. Despite treatment with tetanus toxoid and immunoglobulin, the patient died 1 month after admission to the hospital. This case illustrates that *Clostridium tetani* is ubiquitous in soil and can contaminate relatively minor wounds; it also illustrates the unrelenting progression of neurologic disease in untreated patients.

in which the primary site of infection is the head. In contrast to the prognosis for patients with localized tetanus, the prognosis for patients with cephalic tetanus is very poor.

Neonatal tetanus (tetanus neonatorum) is typically associated with an initial infection of the umbilical stump that progresses to become generalized. The mortality in infants exceeds 90%, and developmental defects are present in survivors. This is almost exclusively a disease in developing countries.

LABORATORY DIAGNOSIS

The diagnosis of tetanus, as with that of most other clostridial diseases, is made on the basis of the clinical presentation. The microscopic detection of *C. tetani* or recovery in culture is useful but frequently unsuccessful. Culture results are positive in only approximately 30% of patients with tetanus because disease can be caused by relatively few organisms and the slow-growing bacteria are killed rapidly when exposed to air. Neither tetanus toxin nor antibodies to the toxin are detectable in the patient because the toxin is rapidly bound to motor neurons and internalized. If the organism is recovered in culture, production of toxin by the isolate can be confirmed with the tetanus antitoxin neutralization test in mice (a procedure performed only in public health reference laboratories).

TREATMENT, PREVENTION, AND CONTROL

The mortality associated with tetanus has steadily decreased during the past century, resulting in large part from the decreased incidence of tetanus in the United States. The highest mortality is in newborns and in patients in whom the incubation period is shorter than 1 week.

Treatment of tetanus requires **debridement** of the primary wound (which may appear innocuous), use of **penicillin** or **metronidazole** to kill the bacteria and reduce toxin production, **passive immunization** with human tetanus immunoglobulin to neutralize unbound toxin, and **vaccination** with tetanus toxoid (because infection does not confer immunity). Metronidazole and penicillin have equivalent activity against *C. tetani;* however, some have recommended metronidazole treatment because penicillin, like tetanospasmin, inhibits GABA activity, which can produce central nervous system excitability. Toxin bound to nerve endings is protected from antibiotics, thus the toxic effects must be controlled symptomatically until the normal regulation of synaptic transmission is restored. Vaccination with a series of three doses of tetanus toxoid, followed by booster doses every 10 years, is highly effective in preventing tetanus.

Clostridium botulinum

PHYSIOLOGY AND STRUCTURE

The etiologic agents of botulism are a heterogeneous collection of large (0.6 to 1.4 × 3.0 to 20.2 μm), fastidious, spore-forming, anaerobic rods. These bacteria are subdivided into four groups based on phenotypic and genetic properties and

certainly represent four separate species, although they have been historically classified within a single species, *C. botulinum*. Seven antigenically distinct botulinum toxins (A to G) have been described; human disease is associated with types A, B, E, and F. Other species of clostridia produce botulinum toxins, including *C. butyricum* (type E toxin), *C. baratii* (type F toxin), and *C. argentinense* (type G toxin). Human disease has only rarely been associated with *C. butyricum* and *C. baratii* and not definitively demonstrated with *C. argentinense*.

PATHOGENESIS AND IMMUNITY

Similar to tetanus toxin, *C. botulinum* toxin is a 150,000-Da progenitor protein (A-B toxin) consisting of a small subunit (light, or A chain) with **zinc-endopeptidase** activity and a large, nontoxic subunit (B, or heavy chain). In contrast with the tetanus neurotoxin, the *C. botulinum* toxin is complexed with nontoxic proteins that protect the neurotoxin during passage through the digestive tract (this is unnecessary for tetanus neurotoxin). The carboxyl-terminal portion of the botulinum heavy chain binds specific sialic acid receptors and glycoproteins (different from those targeted by tetanospasmin) on the surface of motor neurons and stimulates endocytosis of the toxin molecule. Also, in contrast with tetanospasmin, the botulinum neurotoxin remains at the neuromuscular junction. Acidification of the endosome stimulates N-terminal, heavy-chain–mediated release of the light chain. The botulinum endopeptidase then **inactivates the proteins that regulate release of acetylcholine,** blocking neurotransmission at peripheral cholinergic synapses. Because acetylcholine is required for excitation of muscle, the resulting clinical presentation of botulism is a **flaccid paralysis.** As with tetanus, recovery of function after botulism requires regeneration of the nerve endings.

EPIDEMIOLOGY

C. botulinum is commonly isolated in soil and water samples throughout the world. In the United States, type A strains are found mainly in neutral or alkaline soil west of the Mississippi River, type B strains are found primarily in the eastern part of the country in rich organic soil, and type E strains are found only in wet soil. Although *C. botulinum* is commonly found in soil, disease is uncommon in the United States. A total of 177 cases including 137 cases of infant botulism were reported in 2017.

Four forms of botulism have been identified: (1) classic or foodborne botulism, (2) infant botulism, (3) wound botulism, and (4) inhalation botulism. In the United States, fewer than 25 cases of **foodborne botulism** are seen annually; most are associated with consumption of home-canned foods (types A and B toxins) and occasionally with consumption of preserved fish (type E toxin). The food may not appear spoiled, but even a small taste can cause full-blown clinical disease. **Infant botulism** is more common and has been associated with consumption of foods (e.g., honey, infant milk powder) contaminated with botulinum spores and ingestion of spore-contaminated soil and dust (now the most common source of infant exposure). The incidence of **wound botulism** is unknown, but the disease is very rare. **Inhalation botulism** is a major concern in this era of bioterrorism. Botulinum toxin has been concentrated for purposes of aerosolization as a biological weapon. When administered in this manner, inhalation disease has a rapid onset and potentially high mortality.

Clinical Case 30.4 **Foodborne Botulism with Commercial Carrot Juice**

The Centers for Disease Control and Prevention reported an outbreak of foodborne botulism associated with contaminated carrot juice (*MMWR* 55:1098, 2006). On September 8, 2006, three patients went to a hospital in Washington County, Georgia, with cranial nerve palsies and progressive descending flaccid paralysis resulting in respiratory failure. The patients had shared meals on the previous day. Because botulism was suspected, the patients were treated with botulinum antitoxin. The patients had no progression of their neurologic symptoms, but they remained hospitalized and on ventilators. An investigation determined that the patients had consumed contaminated carrot juice produced by a commercial vendor. Botulinum toxin type A was detected in the serum and stool of all three patients and in leftover carrot juice. An additional patient in Florida was also hospitalized with respiratory failure and descending paralysis after drinking carrot juice sold in Florida. Because carrot juice has a low acid content (pH 6.0), *Clostridium botulinum* spores can germinate and produce toxin if contaminated juice is left at room temperature.

CLINICAL DISEASES

Patients with **foodborne botulism** (Clinical Case 30.4) typically become weak and dizzy 1 to 3 days after consuming the contaminated food. Initial signs include blurred vision with fixed dilated pupils, dry mouth (indicative of the anticholinergic effects of the toxin), constipation, and abdominal pain. Fever is absent. Bilateral descending weakness of the peripheral muscles develops in patients with progressive disease (flaccid paralysis), and death is most commonly attributed to respiratory paralysis. Patients maintain a clear sensorium throughout the disease. Despite aggressive management of the patient's condition, the disease may continue to progress because the neurotoxin is irreversibly bound and inhibits the release of excitatory neurotransmitters for a prolonged period. Complete recovery in patients often requires many months to years, or until the affected nerve endings regrow. Mortality in patients with foodborne botulism, which once approached 70%, has been reduced to 5% to 10% through the use of better supportive care, particularly in the management of respiratory complications (see Box 30.1).

Infant botulism (Clinical Case 30.5) was first recognized in 1976 and is now the most common form of botulism in the United States. In contrast with foodborne botulism, this disease is caused by neurotoxin produced *in vivo* by *C. botulinum* colonizing the GI tracts of infants. Although adults are exposed to the organism in their diet, *C. botulinum* cannot survive and proliferate in their intestines. However, in the absence of competitive bowel microbes, the organism can become established in the GI tracts of infants. The disease typically affects infants younger than 1 year (most between 1 and 6 months), and the symptoms are initially nonspecific

Clinical Case 30.5 **Infant Botulism**

In January 2003, four children with infant botulism were reported by the Centers for Disease Control and Prevention (*MMWR* 52:24, 2003). The following is the description of one of the children. A 10-week-old infant with a history of constipation in the first month of life was admitted to a hospital after having difficulty in sucking and swallowing for 2 days. The infant was irritable and had loss of facial expression, generalized muscle weakness, and constipation. Mechanical ventilation was required for 10 days because of respiratory failure. A diagnosis of infant botulism was established 29 days after onset of symptoms by detection of *C. botulinum*-producing toxin type B in stool enrichment cultures. The patient was treated with Botulism Immune Globulin Intravenous (BIG-IV) and discharged fully recovered after 20 days. In contrast with foodborne botulism, diagnosis of infant botulism can be made by detecting the organism in the baby's stools.

(e.g., constipation, weak cry, or "failure to thrive"). Progressive disease with flaccid paralysis and respiratory arrest can develop; however, mortality in documented cases of infant botulism is very low (1% to 2%). Some infant deaths attributed to other conditions (e.g., sudden infant death syndrome) may actually be caused by botulism.

Wound botulism develops from toxin production by *C. botulinum* in contaminated wounds. Although the symptoms of disease are identical to those of foodborne disease, the incubation period is generally longer (4 days or more), and the GI tract symptoms are less prominent.

LABORATORY DIAGNOSIS

The clinical diagnosis of foodborne botulism is confirmed if toxin activity is demonstrated in the implicated food or in the patient's serum, feces, or gastric fluid. Infant botulism is confirmed if toxin is detected in the infant's feces or serum, or the organism cultured from feces. Wound botulism is confirmed if toxin is detected in the patient's serum or wound, or if the organism is cultured from the wound. Toxin activity is most likely to be found early in the disease. No single test for foodborne botulism has sensitivity greater than 60%; in contrast, toxin is detected in the serum of more than 90% of infants with botulism.

Isolation of *C. botulinum* from specimens contaminated with other organisms (e.g., feces, wounds) can be improved by heating the specimen for 10 minutes at 80° C to kill all non–spore-forming bacteria. Culture of the heated specimen on nutritionally enriched anaerobic media allows the heat-resistant *C. botulinum* spores to germinate. Demonstration of toxin production (typically performed at public health laboratories) must be done with a mouse bioassay. This procedure consists of the preparation of two aliquots of the isolate, mixing of one aliquot with antitoxin, and intraperitoneal inoculation of each aliquot into mice. If the antitoxin treatment protects the mice, toxin activity is confirmed. Samples of the implicated food, stool specimen, and patient's serum should also be tested for toxin activity.

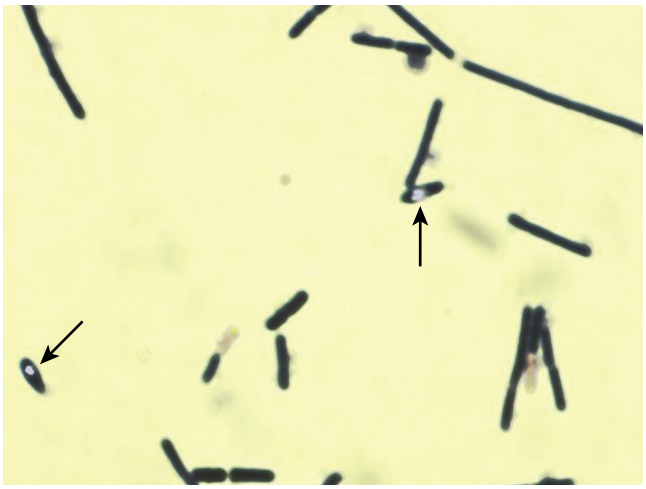

Fig. 30.8 *Clostridium septicum:* note the spores *(arrows)* within the rods.

TREATMENT, PREVENTION, AND CONTROL

Patients with botulism require the following treatment measures: (1) adequate **ventilatory support**; (2) elimination of the organism from the GI tract through the judicious use of gastric lavage and **metronidazole or penicillin** therapy; and (3) use of **trivalent botulinum antitoxin** versus toxins A, B, and E to inactivate unbound toxin circulating in the bloodstream. Ventilatory support is extremely important in reducing mortality. Protective levels of antibodies do not develop after disease, so patients remain susceptible to botulism.

Disease is prevented by destroying the spores in food (virtually impossible for practical reasons), preventing spore germination (by maintaining the food in an acid pH or storage at 4° C or colder), or destroying the preformed toxin (all botulinum toxins are inactivated by heating at 60° C to 100° C for 10 minutes). Infant botulism has been associated with consumption of honey contaminated with *C. botulinum* spores, so children younger than 1 year should not eat honey.

Other Clostridial Species

Many other clostridia have been associated with clinically significant disease. Their virulence is a result of their ability to survive exposure to oxygen by forming spores and producing many diverse toxins and enzymes. ***C. septicum*** (Figs. 30.8 and 30.9) is a particularly important pathogen because it is a cause of nontraumatic myonecrosis and often exists in patients with occult colon cancer, acute leukemia, or diabetes. If the integrity of the bowel mucosa is compromised and the patient's body is less able to mount an effective response to the organism, *C. septicum* can spread into tissue and rapidly proliferate, producing gas and tissue destruction (Fig. 30.10). Most patients have a fulminant course, dying within 1 to 2 days after initial presentation. ***C. sordellii*** is implicated in a fatal toxic shock syndrome associated with natural childbirth or medically induced abortions (Clinical Case 30.6). ***C. tertium*** is another important clostridium that is commonly isolated in soil samples. It has primarily

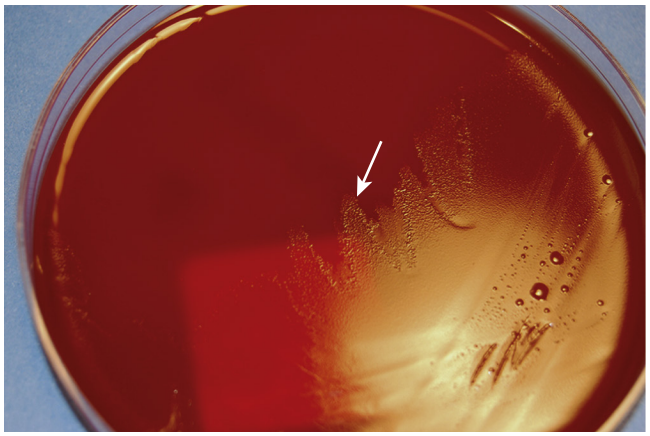

Fig. 30.9 *Clostridium septicum:* note how the growth "swarms" *(arrow)* across the surface of the blood agar plate. This rapid spreading growth is also characteristic of rapid progression of disease in an infected patient.

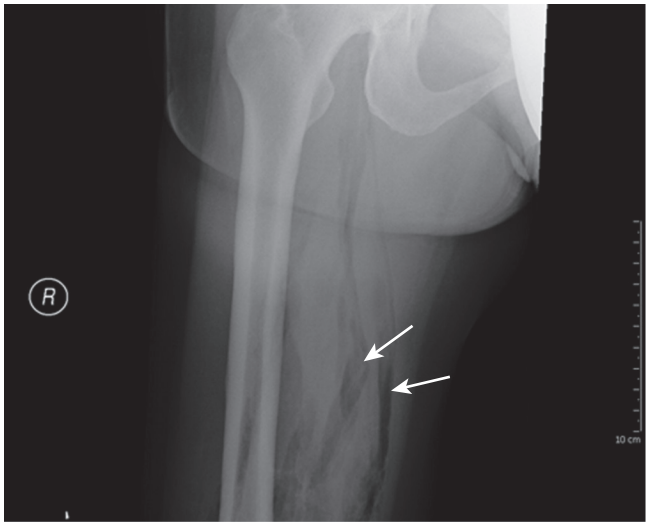

Fig. 30.10 Radiograph of the leg of a patient with myonecrosis caused by *Clostridium septicum*. Note the gas *(arrows)* in the tissue.

Clinical Case 30.6 ***Clostridium sordellii* Toxic Shock Syndrome Associated with Medical Abortions**

A fatal toxic shock syndrome caused by *C. sordellii* has been associated with medical abortions. This is a description of this disease by Fischer and associates (*N Engl J Med* 353:2352–2360, 2005). A previously healthy 22-year-old woman underwent a medically induced abortion with 200 mg of oral mifepristone followed by 800 µg of vaginal misoprostol. Five days later she presented to a local emergency department with nausea, vomiting, diarrhea, and severe abdominal pain. She was afebrile, tachycardic, and normotensive. The next day, her tachycardia (130 to 140 beats/min) remained persistent, she became hypotensive (blood pressure, 80/40 mm Hg), and her urine output decreased. Laboratory findings demonstrated hemoconcentration with elevated neutrophil count (leukemoid reaction) and severe metabolic acidosis. An emergency laparotomy was performed and revealed generalized edema of the abdominal and pelvic organs and 1 liter of serous peritoneal fluid. The patient died during the procedure, 23 hours after her initial presentation. Histopathologic examination of the uterus showed extensive inflammation, abscess formation, edema, necrosis, and hemorrhage. Numerous gram-positive rods were seen in the endometrium, and *C. sordellii* DNA was demonstrated in the uterine tissue by specific polymerase chain reaction assays. Endometritis and toxic shock syndrome caused by *C. sordellii* is an uncommon but well-described complication of natural childbirth and medically induced abortions. Characteristic of this disease are the fulminant course, afebrile presentation, and hemoconcentration.

been associated with traumatic wound infections (e.g., war wounds, a fall producing a soil-contaminated wound). This organism can pose a diagnostic challenge because it can grow on aerobically incubated agar media and appear to be gram-negative. Correct identification can be made once spores are observed and it is determined that the organism grows better anaerobically.

Case Study and Questions

A 61-year-old woman with left-sided face pain came to the emergency department of a local hospital. She was unable to open her mouth because of facial muscle spasms and had been unable to eat for 4 days because of severe pain in her jaw. Her attending physician had noted trismus and *risus sardonicus*. The patient reported that 1 week before presentation, she had incurred a puncture wound to her toe while walking in her garden. She had cleaned the wound and removed small pieces of wood from it, but she had not sought medical attention. Although she had received tetanus immunizations as a child, she had not had a booster vaccination since she was 15 years old. The presumptive diagnosis of tetanus was made.

1. How should this diagnosis be confirmed?

2. What is the recommended procedure for treating this patient? Should management wait until laboratory results are available? What is the long-term prognosis for this patient?

3. Compare the mode of action of the toxins produced by *C. tetani* and *C. botulinum.*

4. What virulence factors are produced by *C. perfringens*?

5. *C. perfringens* causes what diseases?

6. *C. difficile* causes what diseases? Why is it difficult to manage infections caused by this organism?

31 Non–Spore-Forming Anaerobic Bacteria

A 36-year-old woman with urinary retention, pelvic pain, and fever presented to the emergency department 6 days after transvaginal oocyte retrieval and embryo transfer for male infertility. The computed tomography scan revealed large multiloculated pelvic and tuboovarian abscesses. The woman improved after drainage of the abscesses and antibiotic therapy. Gram stain of the abscess material revealed a polymicrobic mixture of gram-positive and gram-negative bacteria, and both aerobic and anaerobic bacteria were recovered in culture.

1. What are the most likely anaerobic bacteria in this infection?
2. What is characteristic about most infections with *Actinomyces?*
3. What infections are typically caused by *Bacteroides fragilis?*
4. What antibiotics are usually active against *B. fragilis?*

Answers to these questions are available on Student Consult.com.

The non–spore-forming anaerobic cocci and rods are a heterogeneous group of bacteria that form the predominant bacterial population on the skin and mucosal surfaces (Table 31.1). The organisms are primarily opportunistic pathogens, typically responsible for endogenous infections, and are usually recovered in mixtures of aerobic and anaerobic bacteria. Many of these anaerobes have fastidious nutritional requirements and grow slowly on laboratory media. Fortunately, the appropriate management and treatment of most infections with these organisms can be based on the knowledge that a mixture of aerobic and anaerobic organisms is present in the clinical specimen and does not require isolation and identification of the individual organisms. An exception to these general rules is infections caused by *Bacteroides fragilis,* which is a rapidly growing gram-negative rod that can produce life-threatening disease.

Summaries Clinically Significant Organisms

BACTEROIDES FRAGILIS

Trigger Words

Pleomorphic gram-negative rod, capsule, abscess formation, drug resistance

Biology and Virulence

- Anaerobic, pleomorphic, gram-negative rod
- Surrounded by polysaccharide capsule
- Lipopolysaccharide major cell wall component but without endotoxin activity
- Polysaccharide capsule major virulence factor
- Heat-labile metalloprotease toxin responsible for diarrheal disease

Epidemiology

- Colonizes the gastrointestinal tract of animals and humans as a minor member of the microbiome; rare or absent from the oropharynx or genital tract of healthy individuals
- Endogenous infections

Diseases

- Associated with pleuropulmonary, intraabdominal, genital, and skin and soft-tissue infections characterized by abscess formation; bacteremia

Diagnosis

- Characteristic Gram stain from clinical specimens
- Grows rapidly in cultures incubated anaerobically
- Identified by biochemical tests, gene sequencing, or matrix-assisted laser desorption ionization mass spectrometry

Treatment, Prevention, and Control

- Resistant to penicillin and 25% of isolates resistant to clindamycin; uniformly susceptible to metronidazole and most strains to carbapenems and piperacillin-tazobactam

Anaerobic Gram-Positive Cocci

At one time, all clinically significant anaerobic cocci were included in the genus *Peptostreptococcus*. Unfortunately, it was recognized that these organisms were organized in a single genus based primarily on their Gram-stain morphology and inability to grow aerobically. More sophisticated methods such as gene sequencing have since been used to reclassify many of these species into new genera. Although some anaerobic cocci are more virulent than others and some are associated with specific diseases, specific identification of the different genera is generally unnecessary, and knowledge that anaerobic cocci are associated with an infection is typically sufficient.

The anaerobic gram-positive cocci normally colonize the oral cavity, gastrointestinal (GI) tract, genitourinary tract, and skin. They produce infections when they spread from these sites to normally sterile sites. For example, bacteria colonizing the upper airways can cause sinusitis and pleuropulmonary infections; bacteria in the intestines can cause intraabdominal infections; bacteria in the genitourinary tract can cause endometritis, pelvic abscesses, and salpingitis; bacteria on the skin can cause cellulitis and soft-tissue infections; and bacteria that invade the blood can spread to the bones and solid organs (Fig. 31.1).

Laboratory confirmation of infections with anaerobic bacteria is complicated by the following three factors: (1) care must be taken to prevent contamination of the clinical specimen with the anaerobes that normally colonize the skin and mucosal surfaces, (2) the collected specimen must be transported in an oxygen-free container to prevent loss of the organisms, and (3) specimens should be cultured in an anaerobic atmosphere on nutritionally enriched media for a prolonged period (i.e., 5 to 7 days). In addition, some

Answers

1. Anaerobic bacteria responsible for pelvic abscesses include anaerobic gram-positive cocci, *Actinomyces, Fusobacterium, Prevotella, Porphyromonas,* and *Bacteroides.*

2. Infections with *Actinomyces* are characteristically chronic, requiring weeks to months to develop. The organisms also grow slowly in culture and respond slowly to antibiotic treatment.

3. Infections caused by *B. fragilis* are characterized by abscess formation. Although this organism has been implicated in infections of the lungs and brain, intraabdominal and skin and soft-tissue infections are the most common.

4. Metronidazole, carbapenems, and combinations of β-lactams and β-lactamase inhibitors.

TABLE 31.1 Important Non–Spore-Forming Anaerobic Bacteria

Organism	Historical Derivation
ANAEROBIC GRAM-POSITIVE COCCI	
Anaerococcus	*an,* without; *aer,* air; *coccus,* berry or coccus (anaerobic coccus)
Atopobium	*atopos,* uncommon; *bios,* life
Finegoldia	Named after the American microbiologist Sid Finegold
Micromonas	*micro,* tiny; *monas,* cell (tiny cell)
Peptoniphilus	*peptonum,* peptone; *philus,* loving (loving peptones, major source of energy)
Peptostreptococcus	*pepto,* cook or digest (the digesting streptococcus)
Schleiferella	Named after the German microbiologist K.H. Schleifer
ANAEROBIC GRAM-POSITIVE RODS	
Actinomyces	*aktinos,* ray; *mykes,* fungus (ray fungus, referring to the radial arrangement of filaments in granules)
Bifidobacterium	*bifidus,* cleft; *bakterion,* small rod (a small clefted or bifurcated rod)
Cutibacterium	*cutis*, skin (skin bacteria)
Eubacterium	*eu,* good or beneficial (a beneficial rod, that is, a rod normally present)
Lactobacillus	*lacto,* milk (milk bacillus; organism originally recovered in milk; also, lactic acid is the primary metabolic product of fermentation)
Mobiluncus	*mobilis,* capable of movement or being active; *uncus,* hook (motile curved rod)
Propionibacterium	*propionicum,* propionic acid (propionic acid is the primary metabolic product of fermentation)
ANAEROBIC GRAM-NEGATIVE COCCI	
Veillonella	Named after A. Veillon, the French bacteriologist who isolated the type species
ANAEROBIC GRAM-NEGATIVE RODS	
Bacteroides	*bacter,* staff or rod; *idus,* shape (rod-shaped)
Fusobacterium	*fusus,* a spindle; *bakterion,* a small rod (a small, spindle-shaped rod)
Porphyromonas	*porphyreos,* purple; *monas,* unit (pigmented rods)
Prevotella	Named after the French microbiologist A.R. Prevot, a pioneer in anaerobic microbiology

species of staphylococci and streptococci initially grow only in an anaerobic atmosphere and may be mistaken for anaerobic cocci. However, these organisms eventually grow well in air supplemented with 10% carbon dioxide (CO_2), so they cannot be classified as anaerobes.

Anaerobic cocci are usually susceptible to **penicillins** and **carbapenems** (e.g., imipenem, meropenem, ertapenem); have intermediate susceptibility to broad-spectrum cephalosporins, clindamycin, erythromycin, and the tetracyclines; and are resistant to the aminoglycosides (as are all anaerobes). Specific therapy is generally indicated in monomicrobic infections; however, because most infections with these organisms are polymicrobic,

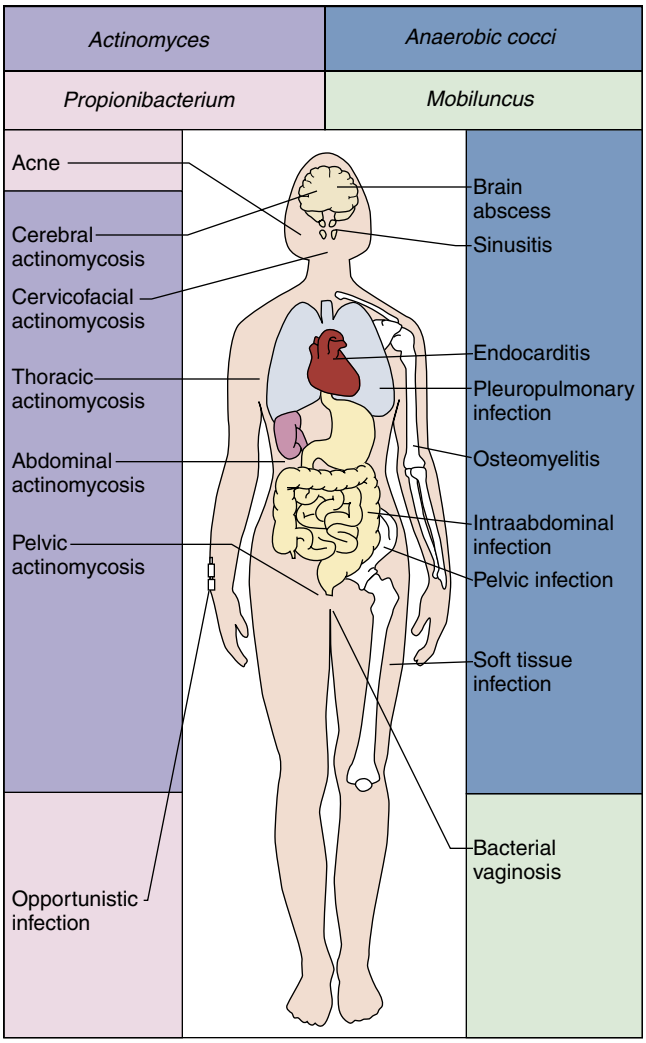

Fig. 31.1 Diseases associated with anaerobic cocci and *Actinomyces, Propionibacterium,* and *Mobiluncus;* the latter three are anaerobic, non–spore-forming, gram-positive rods.

broad-spectrum therapy against aerobic and anaerobic bacteria is usually selected.

Anaerobic Gram-Positive Rods

The non–spore-forming gram-positive rods are a diverse collection of facultatively anaerobic or strictly anaerobic bacteria that colonize the skin and mucosal surfaces (Table 31.2; also see Table 31.1). *Actinomyces, Mobiluncus, Lactobacillus,* and *Cutibacterium* (*Propionibacterium*) are well-recognized opportunistic pathogens, whereas other genera such as *Bifidobacterium* and *Eubacterium* can be isolated in clinical specimens but rarely cause human disease.

ACTINOMYCES

Actinomyces organisms are facultatively anaerobic or strictly anaerobic gram-positive rods. They are not acid-fast (in contrast to the morphologically similar *Nocardia* species), they grow slowly in culture, and they tend to produce **chronic, slowly developing infections.** They typically

TABLE 31.2 Anaerobic, Non–Spore-Forming, Gram-Positive Rods

Organism	Human Disease
Actinomyces spp.	Localized oral infections, actinomycosis (cervicofacial, thoracic, abdominal, pelvic, central nervous system)
Cutibacterium (Propionibacterium) spp.	Acne, lacrimal canaliculitis, opportunistic infections
Mobiluncus spp.	Bacterial vaginosis, opportunistic infections
Lactobacillus spp.	Endocarditis, opportunistic infections
Eubacterium spp.	Opportunistic infections
Bifidobacterium spp.	Opportunistic infections

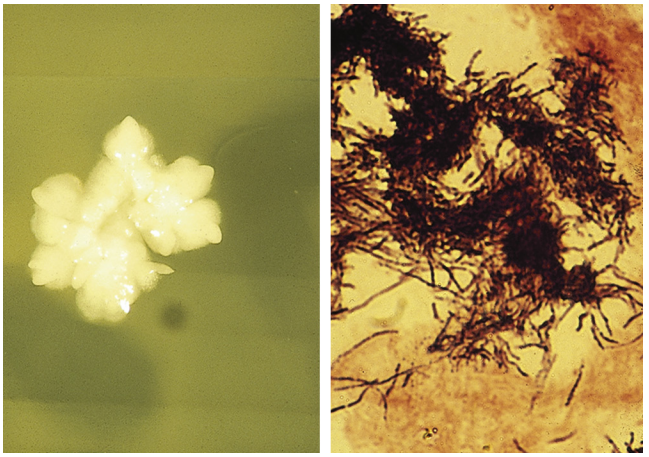

Fig. 31.2 Macroscopic colony *(left)* and Gram stain *(right)* of *Actinomyces.*

develop delicate filamentous forms or hyphae (resembling fungi) in clinical specimens or when isolated in culture (Fig. 31.2). However, these organisms are true bacteria in that they lack mitochondria and a nuclear membrane, reproduce by fission, and are inhibited by penicillin but not antifungal antibiotics. More than 50 species and subspecies have been described and many have been implicated in human disease; however, many isolates were likely misidentified before gene sequencing and mass spectrometry techniques were available. Regardless, identification at the genus level is generally sufficient.

Actinomyces organisms colonize the upper respiratory, GI, and female genital tracts but are not normally present on the skin surface. The organisms have a low virulence potential and cause disease only when the normal mucosal barriers are disrupted by trauma, surgery, or infection. Infections caused by actinomycetes are **endogenous,** with no evidence of person-to-person spread or disease originating from an exogenous source.

Classic disease caused by *Actinomyces* is termed **actinomycosis** (in keeping with the original belief that these organisms were fungi or "mycoses"). Actinomycosis is characterized by the development of chronic granulomatous lesions that become suppurative and form abscesses connected by sinus tracts. Macroscopic colonies of organisms resembling grains of sand can frequently be seen in the abscesses and sinus tracts. These colonies, called **sulfur granules** because they

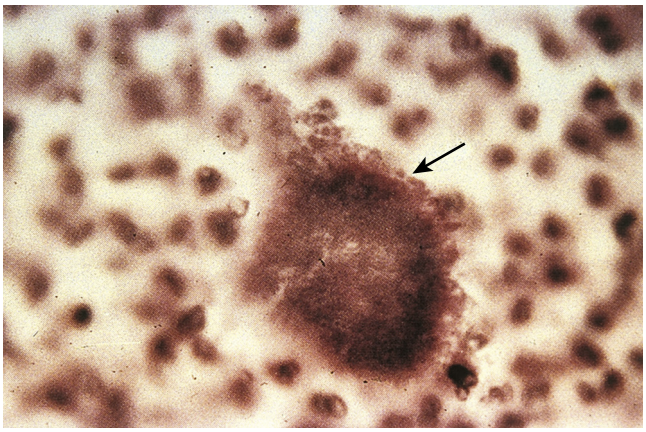

Fig. 31.3 Sulfur granule collected from the sinus tract in a patient with actinomycosis. Delicate filamentous rods *(arrow)* are seen at the periphery of the crushed granule.

Fig. 31.4 Patient suffering from cervicofacial actinomycosis. Note the draining sinus tract *(arrow).*

may appear yellow or orange, are masses of filamentous organisms bound together by calcium phosphate (Fig. 31.3). The areas of suppuration are surrounded by fibrosing granulation tissue, which gives the surface overlying the involved tissues a hard or woody consistency.

Most actinomycetes infections are **cervicofacial,** developing in patients who have poor oral hygiene or have undergone an invasive dental procedure or oral trauma (Fig. 31.4). In these patients, the *Actinomyces* present in the mouth invade into the diseased tissue and initiate the infectious process. The disease may occur as an acute pyogenic infection or as a slowly evolving, relatively painless process. The finding of tissue swelling with fibrosis and scarring, as well as draining sinus tracts along the angle of the jaw and neck, should alert the physician to the possibility of actinomycosis. Symptoms of **thoracic actinomycosis** are nonspecific. Abscesses may form in the lung tissue early in the disease and then spread into adjoining tissues as the disease progresses. **Abdominal actinomycosis** can spread throughout the abdomen, potentially involving virtually every organ system. **Pelvic actinomycosis** can occur as a relatively benign form of vaginitis or, more commonly, there can be extensive tissue destruction, including development of tuboovarian abscesses or ureteral obstruction

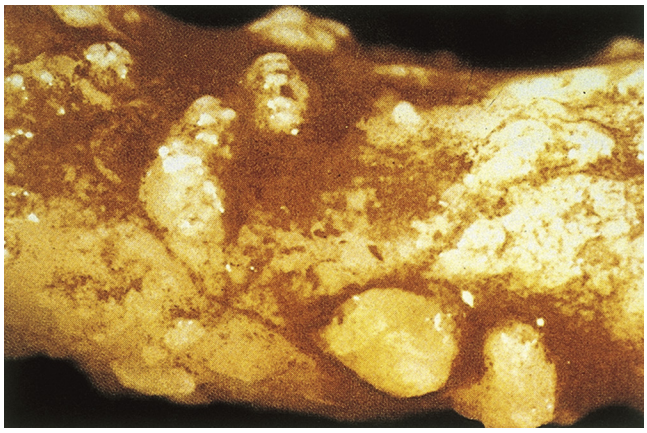

Fig. 31.5 *Actinomyces* species can colonize the surface of foreign bodies, such as this intrauterine device, leading to the development of pelvic actinomycosis. (From Smith, E., 1982. In: Lambert, H., Farrar, W. (Eds.), Infectious Diseases Illustrated. Gower, London, UK.)

Clinical Case 31.1 **Pelvic Actinomycosis**

Quercia and associates (*Med Mal Infect* 36:393–395, 2006) described a classic presentation of pelvic actinomycosis associated with an intrauterine contraceptive device (IUD). The patient was a 41-year-old woman who presented with a 5-month history of abdominal and pelvic pain, weight loss, malaise, and a yellow vaginal discharge. Since 1994 she had used an IUD, which was removed in June 2004. Her symptoms began soon after removal of the IUD. A computed tomography scan revealed a large pelvic mass involving the fallopian tubes, as well as numerous hepatic abscesses. A surgical biopsy was performed, and *Actinomyces* was recovered in culture. She underwent surgical debridement and received oral therapy with a penicillin antibiotic for 1 year. This episode illustrates the chronic nature of actinomycosis and the need for surgical drainage and long-term antibiotic therapy.

(Fig. 31.5; Clinical Case 31.1). The most common manifestation of **central nervous system actinomycosis** is a solitary brain abscess, but meningitis, subdural empyema, and epidural abscess are also seen. Actinomycosis in patients with chronic granulomatous disease, presenting as a nonspecific febrile illness, has been described.

Laboratory confirmation of actinomycosis is often difficult. Care must be used during collection of clinical specimens that they not become contaminated with *Actinomyces* that are part of the normal bacterial population on mucosal surfaces. Because the organisms are concentrated in sulfur granules and are sparse in involved tissues, a large amount of tissue or pus should be collected. If sulfur granules are detected in a sinus tract or in tissue, the granule should be crushed between two glass slides, stained, and examined microscopically. Thin, gram-positive, branching rods can be seen along the periphery of the granules (see Fig. 31.3). *Actinomyces* are fastidious and grow slowly under anaerobic conditions; it can take 2 weeks or more for the organisms to be isolated. Colonies appear white and have a domed surface that can become irregular after incubation for a week

Fig. 31.6 Molar tooth appearance of *Actinomyces israelii* after incubation for 1 week. This colonial morphology serves as a reminder that the bacteria are normally found in the mouth.

or more, resembling the top of a molar (Fig. 31.6). Recovery of *Actinomyces* in blood cultures should be evaluated carefully because most isolates represent transient, insignificant bacteremia from the oropharynx or GI tract.

Treatment for actinomycosis involves the combination of drainage of a localized abscess or **surgical debridement** of the involved tissues, and prolonged administration of antibiotics. *Actinomyces* are uniformly susceptible to **penicillin** (considered the antibiotic of choice), carbapenems, macrolides, and clindamycin. Most species are resistant to metronidazole, and the tetracyclines have variable activity. An undrained focus should be suspected in patients with infections that do not appear to respond to prolonged therapy (e.g., 4 to 12 months). The clinical response is generally good even in patients who have suffered extensive tissue destruction. Maintenance of good oral hygiene and the use of appropriate antibiotic prophylaxis when the mouth or GI tract is penetrated can lower the risk of these infections.

LACTOBACILLUS

Lactobacillus species are facultatively anaerobic or strictly anaerobic rods. They are found as part of the normal flora of the mouth, stomach, intestines, and genitourinary tract. The organisms are most commonly isolated in urine specimens and blood cultures. Because lactobacilli are the most common organism in the urethra, their recovery in urine cultures usually is a result of contamination of the specimen, even when large numbers of the organisms are present. The reason lactobacilli rarely cause infections of the urinary tract is their inability to grow in urine. Invasion into blood occurs in one of the following three settings: (1) **transient bacteremia** from a genitourinary source (e.g., after childbirth or a gynecologic procedure), (2) **endocarditis** (Clinical Case 31.2), and (3) **opportunistic septicemia** in

Clinical Case 31.2 ***Lactobacillus* Endocarditis**

The following is a classical description of endocarditis caused by *Lactobacillus* (Salvana and Frank, *J Infect* 53:5–10, 2006). A 62-year-old woman was admitted for atrial fibrillation and a 2-week history of flulike symptoms. The patient had had dental work performed 4 weeks before this admission and did not take antibiotic prophylaxis despite a history of rheumatic fever in childhood, with resultant mitral valve prolapse and regurgitation. On examination, the patient was afebrile, tachycardic, and mildly tachypneic. Cardiac examination was significant for a systolic murmur. Three blood cultures were collected, all of which yielded *Lactobacillus acidophilus* on culture. The patient was treated with the combination of penicillin and gentamicin for a total of 6 weeks, resulting in complete recovery. This case illustrates the need for antibiotic prophylaxis during dental procedures for patients with underlying damaged heart valves, and the requirement for combined antibiotic therapy for successful treatment of serious infections caused by lactobacilli.

an immunocompromised patient. Strains of lactobacilli used as probiotics have occasionally been associated with septicemia, most commonly in immunocompromised patients.

Treatment of endocarditis and opportunistic infections is difficult because lactobacilli are resistant to vancomycin (an antibiotic commonly active against gram-positive bacteria) and are inhibited but not killed by other antibiotics. A combination of **penicillin with an aminoglycoside** is required for bactericidal activity.

MOBILUNCUS

Members of the genus *Mobiluncus* are obligate anaerobic, gram-variable or gram-negative, curved rods with tapered ends. Despite their appearance in Gram-stained specimens (Fig. 31.7), they are classified as gram-positive rods because they (1) have a gram-positive cell wall; (2) lack endotoxin; and (3) are susceptible to vancomycin, clindamycin, erythromycin, and ampicillin but resistant to colistin. The organisms are fastidious, growing slowly even on enriched media supplemented with rabbit or horse serum. Of the two species of *Mobiluncus*, ***M. curtisii*** is rarely found in the vaginas of healthy women but is abundant in women with **bacterial vaginosis** (vaginitis). Their microscopic appearance is a useful marker for this disease, but the precise role of these organisms in the pathogenesis of bacterial vaginosis is unclear.

CUTIBACTERIUM (PROPIONIBACTERIUM)

In 2016 the name *Propionibacterium* was changed to *Cutibacterium*. Both names are commonly found in the literature and, because the most common species (*C. acnes*) is the bacterium responsible for acne and opportunistic infections (Clinical Case 31.3), both names are used in this edition of *Medical Microbiology*. Cutibacteria are small gram-positive rods often arranged in short chains or clumps (Fig. 31.8). They are commonly found on the skin (in contrast with the *Actinomyces*), conjunctiva, and external ear, and in the oropharynx and female genital tract. Cutibacteria are also

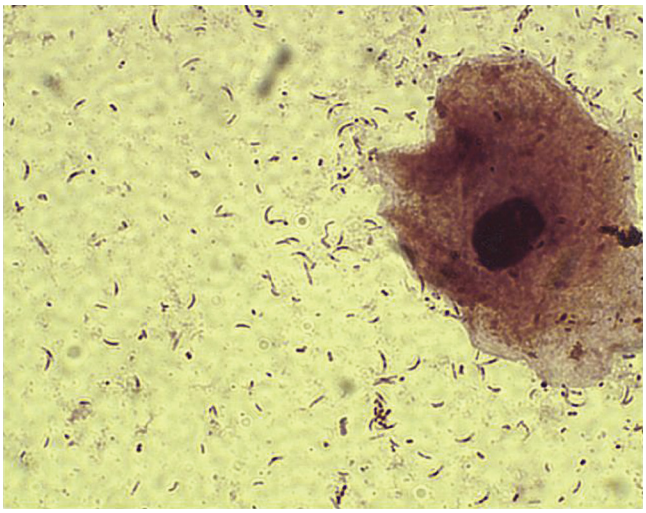

Fig. 31.7 Gram stain of *Mobiluncus*. The bacterial cells are curved and have pointed ends.

Clinical Case 31.3 ***Cutibacterium (Propionibacterium)* Shunt Infection**

Chu and associates (*Neurosurgery* 49:717–720, 2001) reported three patients with central nervous system infections with *Cutibacterium* (*Propionibacterium*) *acnes*. The following patient illustrates the problems with this organism. A 38-year-old woman with congenital hydrocephalus presented with a 1-week history of decreased level of consciousness, headaches, and emesis. She had undergone numerous ventriculoperitoneal shunt placements in the past, with the last one placed 5 years before this presentation. The patient was afebrile and had no meningeal signs, but she was somnolent and arousable only by deep stimuli. Cerebrospinal fluid (CSF) collected from the shunt contained no erythrocytes but had 55 white blood cells; protein levels were high and glucose slightly low. Pleomorphic gram-positive rods were observed on Gram stain, and *C. acnes* grew in the anaerobic culture of the CSF. After 1 week of therapy with high-dose penicillin, the CSF remained positive by Gram stain and culture. The patient was taken to surgery, during which all foreign material was removed, and she was treated with penicillin for an additional 10 weeks. This patient illustrates the chronic, relatively asymptomatic nature of this disease, the need to remove the shunt and other foreign bodies, and the need to treat for a prolonged period of time.

commonly isolated in blood cultures, but this finding usually represents contamination with bacteria on the skin at the phlebotomy site.

The central role of *C. acnes* in acne is to stimulate an inflammatory response. Production of a low-molecular-weight peptide by the bacteria residing in sebaceous follicles attracts leukocytes. The bacteria are phagocytized and, after release of bacterial hydrolytic enzymes (lipases, proteases, neuraminidase, and hyaluronidase), stimulate a localized inflammatory response.

Cutibacteria can grow on most common media, although it may take 2 to 5 days for growth to appear. Care must be taken to avoid contamination of the specimen with the

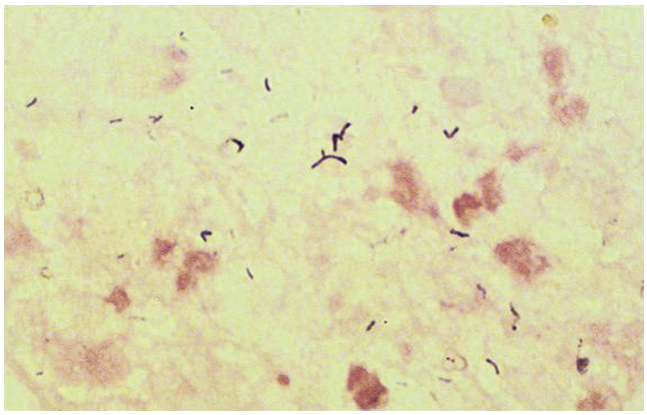

Fig. 31.8 Gram stain of *Cutibacterium (Propionibacterium)* in a blood culture.

organisms normally found on the skin. The significance of the recovery of an isolate must also be interpreted in light of the clinical presentation (e.g., a catheter or other foreign body can serve as a focus for these opportunistic pathogens).

Acne is unrelated to the effectiveness of skin cleansing because the lesion develops within the sebaceous follicles. For this reason, acne is managed primarily through topical application of benzoyl peroxide and antibiotics. Antibiotics such as erythromycin and clindamycin have proved effective for treatment.

BIFIDOBACTERIUM AND *EUBACTERIUM*

Bifidobacterium and *Eubacterium* species are commonly found in the oropharynx, large intestine, and vagina. These bacteria can be isolated in clinical specimens but have a very low virulence potential and usually represent clinically insignificant contaminants. Confirmation of their etiologic role in an infection requires their repeated isolation in large numbers from multiple specimens and the absence of other pathogenic organisms.

Anaerobic Gram-Negative Cocci

The anaerobic gram-negative cocci are rarely isolated in clinical specimens except when present as contaminants. Members of the genus *Veillonella* are the predominant anaerobes in the oropharynx, but they represent less than 1% of all anaerobes isolated in clinical specimens. The other anaerobic cocci are rarely isolated.

Anaerobic Gram-Negative Rods

The most important anaerobic gram-negative rods are in the genera *Bacteroides, Fusobacterium, Porphyromonas,* and *Prevotella* (see Table 31.1). These anaerobes are the predominant bacteria on most mucosal surfaces, outnumbering aerobic bacteria 10- to 1000-fold. Despite the abundance and diversity of these bacteria, most infections are caused by relatively few species (Table 31.3).

The genus *Bacteroides* is composed of more than 100 species and subspecies, and *B. fragilis* is the most important

TABLE 31.3 Predominant Anaerobic Gram-Negative Bacteria Responsible for Human Disease

Infection	Bacteria
Head and neck	*Bacteroides ureolyticus* *Fusobacterium nucleatum* *F. necrophorum* *Porphyromonas asaccharolytica* *P. gingivalis* *Prevotella intermedia* *P. melaninogenica*
Intraabdominal	*Bacteroides fragilis* *B. thetaiotaomicron* *P. melaninogenica*
Gynecologic	*B. fragilis* *P. bivia* *P. disiens*
Skin and soft tissue	*B. fragilis*
Bacteremia	*B. fragilis* *B. thetaiotaomicron* *Fusobacterium* spp.

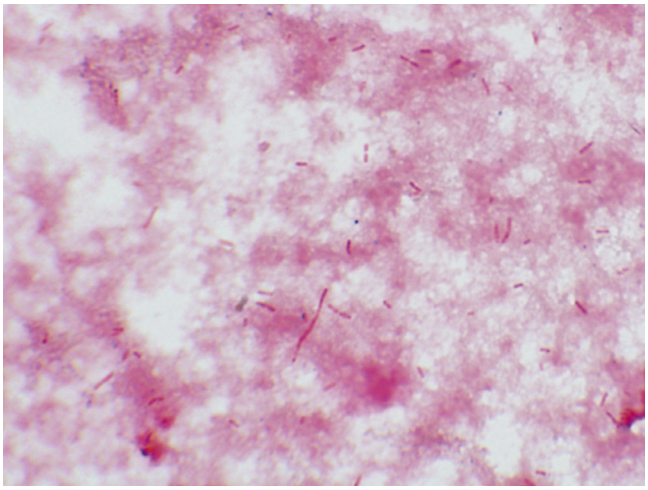

Fig. 31.9 *Bacteroides fragilis.* Organisms appear as faintly staining, pleomorphic, gram-negative rods.

member of this genus. A characteristic common to most species in the genus *Bacteroides* is that their growth is stimulated by bile. *Bacteroides* species are pleomorphic in size and shape and resemble a mixed population of organisms in a casually examined Gram stain (Fig. 31.9). Other anaerobic gram-negative rods can be very small (e.g., *Porphyromonas, Prevotella*) or elongated (e.g., *Fusobacterium;* Fig. 31.10). Most gram-negative anaerobes stain weakly with the Gram stain, so stained specimens must be carefully examined. Although *B. fragilis* grows rapidly in culture, the other anaerobic gram-negative rods are fastidious and cultures may have to be incubated for 3 days or longer before the bacteria can be detected.

PHYSIOLOGY AND STRUCTURE

Bacteroides have a typical gram-negative cell wall structure that can be surrounded by a **polysaccharide capsule.** A major component of the cell wall is a surface lipopolysaccharide (LPS). In contrast to the LPS molecules in the aerobic

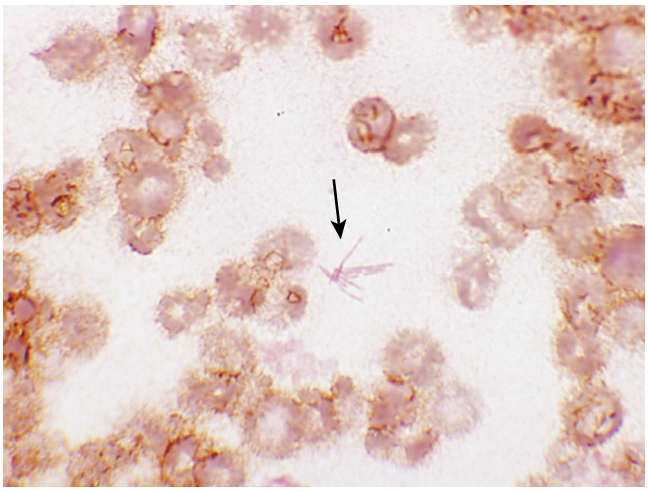

Fig. 31.10 *Fusobacterium nucleatum.* Organisms *(arrow)* are thin, faintly staining, and elongated with tapered ends (e.g., fusiform).

gram-negative rods, the *Bacteroides* LPS has little or no endotoxin activity. This is because the lipid A component of LPS lacks phosphate groups on the glucosamine residues, and the number of fatty acids linked to the amino sugars is reduced; both factors are correlated with the loss of endotoxin activity.

PATHOGENESIS AND IMMUNITY

B. fragilis, other *Bacteroides* species, and *Porphyromonas gingivalis* can adhere to epithelial cells and extracellular molecules (e.g., fibrinogen, fibronectin, lactoferrin) by means of fimbriae. The fimbriae of *P. gingivalis* are also important for inducing expression of proinflammatory cytokines such as tumor necrosis factor (TNF)-α and interleukin (IL)-1β. *B. fragilis* and *Prevotella melaninogenica* strains can also adhere to peritoneal surfaces more effectively than other anaerobes because their surface is covered with a polysaccharide capsule. This capsule is also antiphagocytic, similar to other bacterial capsules, and it is the major virulence factor in *B. fragilis*. The short-chain fatty acids (e.g., succinic acid) produced during anaerobic metabolism inhibit phagocytosis and intracellular killing. Finally, proteases are produced by some *Porphyromonas* and *Prevotella* species that degrade immunoglobulins.

In general, anaerobes capable of causing disease can tolerate exposure to oxygen. Catalase and superoxide dismutase, which inactivate hydrogen peroxide and the superoxide free radicals (O_2^-), respectively, are produced by many pathogenic strains.

Strains of enterotoxigenic *B. fragilis* that cause diarrheal disease produce a **heat-labile zinc metalloprotease toxin (*B. fragilis* toxin).** This toxin causes morphologic changes of the intestinal epithelium via F-actin rearrangement, with the resultant stimulation of chloride secretion and fluid loss. The enterotoxin also induces IL-8 secretion by intestinal epithelial cells, contributing to inflammatory damage to the epithelium.

EPIDEMIOLOGY

As previously stated, anaerobes colonize the human body in large numbers (functioning to stabilize the resident bacterial flora), prevent colonization by pathogenic organisms from exogenous sources, aid in the digestion of food, and stimulate host immunity. These normal protective organisms produce disease only when they move from their endogenous homes to normally sterile sites. Thus the organisms in the resident flora are able to spread by trauma or disease from the normally colonized mucosal surfaces to sterile tissues or fluids.

As expected, endogenous infections are characterized by the presence of a polymicrobial mixture of organisms. It is important to realize, however, that the mixture of organisms that appear on healthy mucosal surfaces differs from the mixture in diseased tissues. Studies of the microbial population, or **microbiome,** of healthy mucosal surfaces show a complex mixture of many species of bacteria. In the disease state, the mixture changes to less diversity (i.e., fewer species are represented) and predominance of the most clinically significant organisms. For example, *B. fragilis* is commonly associated with pleuropulmonary, intraabdominal, and genital infections. However, the organism constitutes less than 1% of the colonic flora and is rarely isolated from the oropharynx or genital tract of healthy people unless highly selective techniques are used.

CLINICAL DISEASES

Respiratory Tract Infections

Nearly half of the chronic infections of the sinuses and ears, and virtually all periodontal infections involve mixtures of gram-negative anaerobes, and *Prevotella, Porphyromonas, Fusobacterium,* and non-*fragilis Bacteroides* are the most commonly isolated. Anaerobes are less commonly associated with infections of the lower respiratory tract unless there is a history of aspiration of oral secretions.

Brain Abscess

Anaerobic infections of the brain are typically associated with a history of chronic sinusitis or otitis. Such history is confirmed by radiologic evidence of direct extension into the brain. A less common cause of such infections is bacteremic spread from a pulmonary source. In this case, multiple abscesses are present. The most common anaerobes in these polymicrobial infections of the brain are species of *Prevotella, Porphyromonas,* and *Fusobacterium* (as well as *Peptostreptococcus* and other anaerobic and aerobic cocci).

Intraabdominal Infections

Despite the diverse population of bacteria that colonize the GI tract, relatively few species are associated with intraabdominal infections. Anaerobes are recovered in virtually all of these infections, and *B. fragilis* is the most common organism (Fig. 31.11). Other important anaerobes are *B. thetaiotaomicron* and *P. melaninogenica,* as well as the anaerobic and aerobic gram-positive cocci.

Gynecologic Infections

Mixtures of anaerobes are often responsible for causing infections of the female genital tract (e.g., vaginitis, pelvic inflammatory disease, abscesses, endometritis, surgical wound infections). Although a variety of anaerobes can be isolated in patients with these infections, *P. bivia* and *P. disiens* are the most important; *B. fragilis* is commonly responsible for abscess formation.

Fig. 31.11 Liver abscesses caused by *Bacteroides fragilis*.

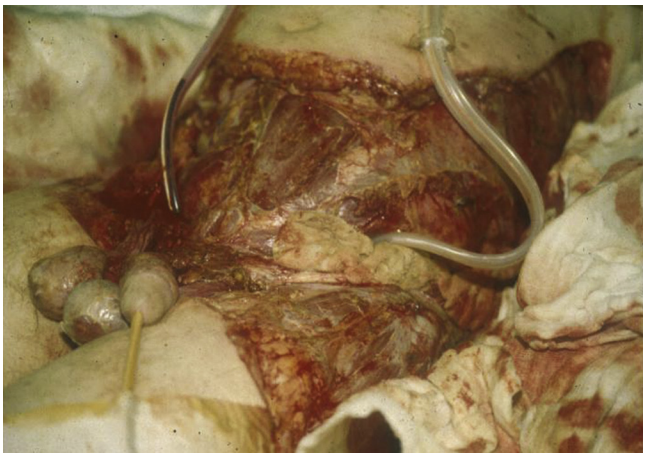

Fig. 31.12 Synergistic polymicrobial infection involving *Bacteroides fragilis* and other anaerobes. The infection started at the scrotum and rapidly spread up the trunk and down the thighs, with extensive myonecrosis.

Skin and Soft-Tissue Infections

Although anaerobic gram-negative bacteria are not part of the normal flora of the skin (in contrast to *Peptostreptococcus* and *Cutibacterium* [*Propionibacterium*] organisms), they can be introduced by a bite or through contamination of a traumatized surface. In some cases, the organisms may simply colonize a wound without producing disease; in other cases, colonization may quickly progress to life-threatening disease such as myonecrosis (Fig. 31.12). *B. fragilis* is the organism most commonly associated with significant disease (Clinical Case 31.4).

Bacteremia

Anaerobes were at one time responsible for more than 20% of all clinically significant cases of bacteremia; however, these organisms now cause less than 5% of such infections. The reduced incidence of disease is not completely understood but probably can be attributed to the widespread use of broad-spectrum antibiotics with anaerobic activity. *B. fragilis* is the anaerobe most commonly isolated in clinically significant positive blood cultures.

Gastroenteritis

Strains of enterotoxin-producing *B. fragilis* can produce a self-limited watery diarrhea. The majority of infections have been observed in children younger than 5 years, although disease has also been reported in adults.

Clinical Case 31.4 **Retroperitoneal Necrotizing Fasciitis**

Pryor and associates (*Crit Care Med* 29:1071–1073, 2001) described an unfortunate patient with a polymicrobic fasciitis. A 38-year-old man with a 10-year history of human immunodeficiency virus infection underwent an uncomplicated hemorrhoidectomy. Over the next 5 days, thigh and buttock pain developed, as well as nausea and vomiting. At the time this patient presented to the hospital, he had a heart rate of 120 beats/min, blood pressure of 120/60 mm Hg, respiratory rate of 22 respirations/min, and temperature of 38.5° C. Physical examination revealed extensive erythema around the surgical site, flank, thighs, and abdominal wall. Gas was observed in the tissues underlying the areas of erythema and extended to his upper chest. At surgery, extensive areas of tissue necrosis and foul-smelling brownish exudates were found. Multiple surgeries to aggressively debride the involved tissues were necessary. Cultures obtained at surgery grew a mixture of aerobic and anaerobic organisms, with *Escherichia coli*, β-hemolytic streptococci, and *Bacteroides fragilis* predominating. This clinical case illustrates the potential complications of rectal surgery: aggressive destruction of tissue, polymicrobic etiology with *B. fragilis* as a prominent organism, and foul-smelling necrotic tissue with gas production.

LABORATORY DIAGNOSIS

Microscopy

Microscopic examination of specimens from patients with suspected anaerobic infections can be useful. Although the bacteria may stain faintly and irregularly, the finding of pleomorphic gram-negative rods can serve as useful preliminary information.

Culture

Specimens should be collected and transported to the laboratory in an oxygen-free system, promptly inoculated onto specific media for the recovery of anaerobes, and incubated in an anaerobic environment. Because most anaerobic infections are endogenous, it is important to collect specimens so that they are not contaminated with the normal bacterial population present on the adjacent mucosal surface. Specimens should also be kept in a moist environment because drying causes significant bacterial loss.

Most *Bacteroides* grow rapidly and should be detected within 2 days; however, recovery of other gram-negative anaerobes may require longer incubation. In addition, it is sometimes difficult to recover all clinically significant bacteria because of the different organisms present in polymicrobial infections. The use of selective media, such as media supplemented with bile, has facilitated the recovery of most important anaerobes (Fig. 31.13).

Bacterial Identification

Although identification of gram-negative anaerobes has traditionally been performed by biochemical tests, the

Fig. 31.13 Growth of *Bacteroides fragilis* on *Bacteroides* bile-esculin agar. Most aerobic and anaerobic bacteria are inhibited by bile and gentamicin in this medium, whereas the *B. fragilis* group of organisms is stimulated by bile, resistant to gentamicin, and able to hydrolyze esculin, producing a black precipitate.

proliferation of newly recognized species has made this approach unreliable. Sequence analysis of species-specific genes (e.g., 16S ribosomal RNA gene) is a reliable but time-consuming and expensive approach. More recently, proteomic tools (i.e., mass spectrometry for spectral analysis of species-specific protein profiles) have been used for organism identification and is the diagnostic method of choice.

TREATMENT, PREVENTION, AND CONTROL

Antibiotic therapy combined with surgical intervention is the main approach for managing serious anaerobic infections. Virtually all members of the *B. fragilis* group, many *Prevotella* and *Porphyromonas* species, and some *Fusobacterium* isolates produce β-lactamases. This enzyme renders the bacteria resistant to penicillin and many cephalosporins. Clindamycin resistance in *Bacteroides,* which is plasmid mediated, is common. Antibiotics with the best activity against gram-negative anaerobic rods are **metronidazole**, **carbapenems** (e.g., imipenem, meropenem), and **β-lactam–β-lactamase inhibitors** (e.g., piperacillin-tazobactam).

Because *Bacteroides* species constitute an important part of the normal microbial flora, and because infections result from endogenous spread of the organisms, disease is virtually impossible to control. It is important to recognize, however, that disruption of the natural barriers around the mucosal surfaces by diagnostic or surgical procedures can introduce these organisms into normally sterile sites. If the barriers are invaded, prophylactic treatment with antibiotics is indicated.

Case Studies and Questions

A 41-year-old man entered the university hospital for treatment of a chronically draining wound in his jaw. The patient had undergone extraction of many teeth 3 months earlier and had poor oral hygiene and fetid breath at the time of admission. Multiple pustular nodules were observed overlying the carious teeth, and some nodules had ruptured. The drainage material consisted of serosanguineous fluid containing small, hard granules.

1. The diagnosis of actinomycosis is considered. How would you collect and transport specimens for confirmation of this diagnosis? What diagnostic tests can be performed?

2. Describe the epidemiology of actinomycosis. What is the risk factor for this patient?

3. What diseases does *Cutibacterium (Propionibacterium)* cause? What is the most common source of this organism?

A 65-year-old man entered the emergency department of a local hospital. He appeared to be acutely ill, with abdominal tenderness and a temperature of 40° C. He was taken to surgery because appendicitis was suspected. A ruptured appendix surrounded by approximately 20 ml of foul-smelling pus was found at laparotomy. The pus was drained and submitted for aerobic and anaerobic bacterial culture analysis. Postoperatively, the patient was started on antibiotic therapy. Gram stain of the specimen revealed a polymicrobial mixture of organisms, and the culture was positive for *B. fragilis, Escherichia coli,* and *Enterococcus faecalis.*

4. Which organism or organisms are responsible for causing the abscess formation? What virulence factors are responsible for causing abscess formation?

5. *B. fragilis* causes infections at what other body sites?

6. What antibiotics should be selected to manage this polymicrobial infection?

7. What other anaerobic gram-negative rods are important causes of human disease?

32 Treponema, Borrelia, *and* Leptospira

A 23-year-old homosexual man presented to the emergency department with a painless ulcer on the shaft of his penis. Primary syphilis was suspected and later confirmed by serologic tests. It is a very rare student who is not familiar with the diseases caused by the spirochetes discussed in this chapter: syphilis, Lyme disease, relapsing fever, and leptospirosis.

1. Why do many patients with syphilis develop chronic infections even though penicillin is uniformly active against *Treponema pallidum?*
2. What reservoir and vector are most important for the transmission of *Borrelia burgdorferi* infections in humans?
3. What diagnostic test is most useful for early localized Lyme disease and for patients who develop arthritis or neurologic complications?
4. What specimens are optimum for recovering *Leptospira* in culture?

Answers to these questions are available on Student Consult.com.

Summaries Clinically Significant Organisms

TREPONEMA PALLIDUM

Trigger Words

Thin spirochete, sexually transmitted disease, congenital infections, painless ulcer (chancre)

Biology and Virulence

- Coiled spirochete (0.1 to 0.2 × 6 to 20 μm) too thin to be seen with Gram or Giemsa stains; observed by darkfield microscopy
- Outer membrane proteins promote adherence to host cells
- Hyaluronidase facilitates perivascular infiltration
- Coating of fibronectin protects against phagocytosis
- Tissue destruction primarily results from host's immune response to infection

Epidemiology

- Humans are the only natural host
- Syphilis transmitted by sexual contact or congenitally
- Syphilis occurs worldwide, with no seasonal incidence

Diseases

- Syphilis presents as primary disease (painless ulcer [chancre] at site of infection, with regional lymphadenopathy and bacteremia), secondary syphilis (flulike syndrome with generalized mucocutaneous rash and bacteremia), and late-stage disease (diffuse chronic inflammation and destruction of any organ or tissue); congenital (latent multiorgan malformations, fetal death)

Diagnosis

- Darkfield or direct fluorescent antibody microscopy is useful if mucosal ulcers are observed in primary or secondary stages of syphilis
- Serology is very sensitive in secondary and late stages of syphilis

Treatment, Prevention, and Control

- Penicillin is the drug of choice; doxycycline is administered if patient is allergic to penicillin
- Safe sex practices should be emphasized, and sexual partners of infected patients should be treated
- No vaccine is available

BORRELIA

Trigger Words

Large spirochetes, erythema migrans, Lyme disease, relapsing fever, hard and soft ticks, body louse

Biology and Virulence

- Borreliae are large (0.2 to 0.5 × 8 to 30 μm) and can be seen when stained with aniline dyes (e.g., Giemsa, Wright stains)
- Immune reactivity against Lyme disease agents may be responsible for clinical disease

EPIDEMIOLOGY

Lyme Disease

- *B. burgdorferi* causes disease in the United States and Europe; *B. garinii* and *B. afzelii* cause disease in Europe and Asia
- Transmitted by hard ticks from mice to humans; reservoirs include mice, deer, and ticks; vectors include *Ixodes scapularis* in eastern and midwestern United States, *I. pacificus* in the western United States, *I. ricinus* in Europe, and *I. persulcatus* in Eastern Europe and Asia
- Most Lyme disease cases in the United States are from two principal foci: Northeast and Mid-Atlantic states (Maine to Virginia) and the Upper Midwest (Minnesota, Wisconsin)
- Individuals at risk for Lyme disease include people exposed to ticks in areas of high endemicity
- Worldwide distribution
- Seasonal incidence corresponds to feeding patterns of vectors; most cases of Lyme disease in the United States occur in late spring and early summer (feeding pattern of nymph stage of ticks); peak in June and July

Epidemic Relapsing Fever

- Etiologic agent is *B. recurrentis*
- Person-to-person transmission; reservoir includes humans; vector includes human body louse
- Individuals at risk are people exposed to lice (epidemic disease) in crowded or unsanitary conditions
- Occurs in Ethiopia, Eritrea, Somalia, and Sudan

Endemic Relapsing Fever

- Many *Borrelia* species are responsible
- Transmitted from rodents to humans; reservoirs include rodents, small mammals, and soft ticks; vector includes soft ticks
- Individuals at risk are people exposed to ticks (endemic disease) in rural areas
- Worldwide distribution; in the western part of the United States

Diseases

- Borreliae are responsible for two human diseases: Lyme disease and relapsing fever (epidemic and endemic)
- *Borrelia* species responsible for relapsing fever are able to undergo antigenic shift and escape immune clearance; periodic febrile and afebrile periods result from antigenic variation

Diagnosis

- Serology is test of choice for Lyme disease
- Polymerase chain reaction tests available for Lyme disease but relatively insensitive
- Microscopy is the test of choice for diagnosis of relapsing fever

Continued

Summaries Clinically Significant Organisms—cont'd

Treatment, Prevention, and Control

- For early localized or disseminated Lyme disease, treatment is with amoxicillin, tetracycline, cefuroxime; late manifestations are treated with intravenous penicillin or ceftriaxone
- For relapsing fever, treatment is with tetracycline or erythromycin
- Improved sanitary conditions to decrease risk of epidemic relapsing fever
- Reduced exposure to hard ticks (Lyme disease) and soft ticks (relapsing fever) through use of insecticides, application of insect repellents to clothing, and wearing protective clothing that reduces exposure of skin to insects

LEPTOSPIRA

Trigger Words

Thin, spirochetes, flulike disease, aseptic meningitis, Weil disease, zoonotic, contaminated water exposure

Biology and Virulence

- Thin, coiled spirochetes (0.1 × 6 to 20 μm) that grow slowly in specialized cultures
- Able to directly invade and replicate in tissues, inducing an inflammatory response
- Immune complex produces renal disease (glomerulonephritis)
- Most disease is a mild virus-like syndrome
- Systemic leptospirosis presents most commonly as aseptic meningitis
- Overwhelming disease (Weil disease) is characterized by vascular collapse, thrombocytopenia, hemorrhage, and hepatic and renal dysfunction

Epidemiology

- US reservoirs: rodents (particularly rats), dogs, farm animals, and wild animals
- Humans: accidental end-stage host
- Organism can penetrate the skin through minor breaks in the epidermis
- People are infected with leptospires through exposure to water contaminated with urine from an infected animal or handling of tissues from an infected animal
- People at risk are those exposed to urine-contaminated streams, rivers, and standing water; occupational exposure to infected animals for farmers, meat handlers, and veterinarians
- Infection is rare in the United States but has worldwide distribution
- Disease is more common during warm months (recreational exposure)

Diagnosis

- Microscopy not useful because too few organisms are generally present in fluids or tissues
- Culture blood or cerebrospinal fluid in the first 7 to 10 days of illness; urine after the first week
- Serology using the microscopic agglutination test is relatively sensitive and specific but not widely available in resource-limited countries; enzyme-linked immunosorbent assay tests are less accurate but can be used to screen patients

Treatment, Prevention, and Control

- Treatment with penicillin or doxycycline
- Doxycycline but not penicillin is used for prophylaxis
- Herds and domestic pets should be vaccinated
- Rats should be controlled

The bacteria in the order Spirochaetales have been grouped together on the basis of their common morphologic properties (Table 32.1). These spirochetes are thin, helical (0.1 to 0.5 × 5 to 20 μm), gram-negative bacteria. The order Spirochaetales is subdivided into 4 families and 14 genera, of which 3 genera (*Treponema* and *Borrelia* in the family Spirochaetaceae, and *Leptospira* in the family Leptospiraceae) are responsible for human disease (Table 32.2).

TABLE 32.1 Medically Important Genera in the Order Spirochaetales

Spirochaetales	Human Disease	Etiologic Agent
FAMILY SPIROCHAETACEAE		
Genus *Borrelia*	Epidemic relapsing fever	*B. recurrentis*
	Endemic relapsing fever	Many *Borrelia* species
	Lyme borreliosis	*B. burgdorferi, B. garinii, B. afzelii*
Genus *Treponema*	Venereal syphilis	*T. pallidum* subsp. *pallidum*
	Endemic syphilis (bejel)	*T. pallidum* subsp. *endemicum*
	Yaws	*T. pallidum* subsp. *pertenue*
FAMILY LEPTOSPIRACEAE		
Genus *Leptospira*	Leptospirosis	*Leptospira* spp.

TABLE 32.2 Important Spirochetes

Organism	Historical Derivation
Treponema	*trepo,* turn; *nema,* a thread (a turning thread; refers to the morphology of the bacteria)
T. pallidum	*pallidum,* pale (refers to the fact that these organisms are not stained with traditional dyes)
Borrelia	Named after A. Borrel
B. recurrentis	*recurrens,* recurring (reference to relapsing fever)
B. hermsii	*hermsii,* of hermsi (named after the tick vector *Ornithodoros hermsii*)
B. burgdorferi	Named after W. Burgdorfer
Leptospira	*lepto,* thin; *spira,* a coil (a thin coil; refers to the morphology of the bacteria)

Treponema

The most important treponemal species that causes human disease is *Treponema pallidum*, with three subspecies. The subspecies are distinguished by their epidemiologic characteristics, clinical presentation, and host range in experimental animals. *T. pallidum* subspecies *pallidum* (referred to as *T. pallidum* in this chapter) is the etiologic agent of the venereal disease **syphilis;** *T. pallidum* subspecies *endemicum* causes endemic syphilis **(bejel);** and *T. pallidum* subspecies *pertenue* causes **yaws.** Bejel and yaws are nonvenereal diseases.

PHYSIOLOGY AND STRUCTURE

T. pallidum and related pathogenic treponemes are thin, tightly coiled spirochetes (0.1 to 0.2 × 6 to 20 μm) with pointed, straight ends. Traditional diagnostic tests such as microscopy and culture are of little value because the spirochetes are too thin to be seen with light microscopy in specimens stained with Gram or Giemsa stains, and these spirochetes do not grow in cell-free cultures. Limited growth of the organisms has been achieved in cultured rabbit epithelial cells, but replication is slow (doubling time is 30 hours) and can be maintained for only a few generations.

The reason for this failure to grow *T. pallidum* in vitro is because the tricarboxylic acid cycle is missing in the bacteria and they are dependent on host cells for all purines, pyrimidines, and most amino acids. In addition, spirochetes are microaerophilic or anaerobic and extremely sensitive to oxygen, consistent with the discovery the bacteria have no genes for catalase or superoxide dismutase to protect them from oxygen toxicity.

PATHOGENESIS AND IMMUNITY

The inability to grow *T. pallidum* to high concentrations in vitro has limited detection of specific virulence factors in this organism. However, analysis of the entire genome sequence and the unique structural properties of this spirochete have revealed some insights. Although a number of lipoproteins are anchored in the bacterial cytoplasmic membrane, most or all are not exposed on the surface of the outer membrane. Thus the lack of species-specific antigens on the cell surface allows the spirochete to evade the immune system. Although the bacteria are able to resist phagocytosis, they can adhere to host fibronectin, allowing direct interaction with the host tissues. Analysis of the genome sequence demonstrates the presence of at least five hemolysins, but it is unclear if they mediate tissue damage. Likewise, it has been proposed that production of hyaluronidase facilitates perivascular infiltration. Most investigators believe that the tissue destruction and lesions observed in syphilis are primarily the consequence of the patient's immune response to infection.

EPIDEMIOLOGY

Syphilis is found worldwide and is the third most common sexually transmitted bacterial disease in the United States (after *Chlamydia trachomatis* and *Neisseria gonorrhoeae* infections). Overall, the incidence of disease decreased after the introduction of penicillin in the early 1940s, although periodic increases have been observed that correspond to changes in sexual practices (e.g., use of birth control pills in the 1960s, gay bath houses in the 1970s, increased prostitution related to crack cocaine use in the 1990s). A troubling trend is evolving now. Between 2000 and 2017, the incidence of newly acquired disease has increased each year. In 2017 the Centers for Disease Control and Prevention (CDC) reported that there were more than 100,000 reported new cases of syphilis, with 30,644 primary and secondary stage disease, which are the most infectious forms of syphilis. The increase in syphilis is primarily in homosexual males. This likely reflects the mistaken perception that sexually acquired diseases, including human immunodeficiency virus (HIV) infections, can be controlled effectively with antibiotics, so unprotected sex is incorrectly considered a low-risk activity. Unfortunately, patients infected with syphilis are at increased risk for transmitting and acquiring HIV when genital lesions are present. Thus despite a concerted public health effort to eliminate syphilis, this disease remains a serious problem in sexually active populations.

Natural syphilis is exclusive to humans and has no other known natural hosts (Clinical Case 32.1). *T. pallidum* is extremely labile, and is unable to survive exposure to drying or disinfectants. Thus syphilis cannot be spread through contact with inanimate objects such as toilet seats. The most common route of spread is by direct sexual contact. The disease can also be acquired congenitally or by transfusion with contaminated blood. Syphilis is not highly contagious; the risk of contracting the disease after a single sexual contact is estimated to be 30%. However, contagiousness is influenced by the stage of disease in the infectious person. *T. pallidum* is transferred primarily during the early stages of disease when many organisms are present in moist cutaneous or mucosal lesions. During the early stages of disease, the patient becomes bacteremic, and if the disease is untreated, intermittent bacteremia can persist for as long as 8 years. Congenital transmission from mother to fetus can occur at any time during this period. Even after bacteremia ceases, the disease can remain active.

Clinical Case 32.1 **History of Syphilis**

The origins of syphilis have been debated for decades. Examination of skeletal remains recovered in the Americas, Europe, Asia, and Africa may have resolved this debate. The disease we know as syphilis is likely to have evolved from yaws and, more recently, bejel. Each disease produces distinctive bone alterations. The earliest evidence of treponemal disease was in Africa and appeared to have spread to the Americas through an Asian route. At the time Columbus sailed to the Americas, syphilis was well established throughout the New World, including the Dominican Republic, where he landed. In contrast, there is no evidence of syphilis in pre-Columbian Europe, Africa, or Asia. Thus it is likely that Columbus' crew acquired this New World disease and introduced it into the Old World population on their return home.

CLINICAL DISEASES

The clinical course of syphilis evolves through three phases. The initial or **primary phase** is characterized by one or more skin lesions **(chancres)** at the site in which the spirochete penetrated (Fig. 32.1). The lesion develops 10 to 90 days after the initial infection and starts as a papule but then erodes to become a **painless ulcer** with raised borders. Histologic examination of the lesion reveals endarteritis and periarteritis (characteristic of syphilitic lesions at all stages) and infiltration of the ulcer with polymorphonuclear leukocytes and macrophages. Phagocytic cells ingest spirochetes, but the organisms often survive, with abundant organisms present in the chancre. In most patients, a painless regional lymphadenopathy develops 1 to 2 weeks after the appearance of the chancre, which represents a local focus for the proliferation of spirochetes and dissemination in the blood. The fact that this ulcer heals spontaneously within 2 months gives the patient a false sense of relief.

In the **secondary phase,** the clinical signs of disseminated disease appear, with prominent skin lesions dispersed over the entire body surface (Fig. 32.2). In this stage, patients typically experience a flulike syndrome with sore throat, headache, fever, myalgias (muscle aches), anorexia, lymphadenopathy (swollen lymph nodes), and a generalized mucocutaneous rash. The flulike syndrome and

Fig. 32.1 Primary chancre of the penile shaft. Typically the lesion is painless unless secondary bacterial infection is present. Large numbers of spirochetes are present in the lesion. (From Morse, S.A., Ballard, R.C., Holmes, K.K., et al., 2010. Atlas of Sexually Transmitted Diseases and AIDS, fourth ed. Saunders, London, UK.)

Fig. 32.2 Disseminated rash in secondary syphilis. (From Habif, T.P., 2010. Clinical Dermatology: A Color Guide to Diagnosis and Therapy, fifth ed. Mosby, London, UK.)

lymphadenopathy generally appear first and then are followed a few days later by the disseminated rash. The rash can be variable (macular, papular, or pustular) and cover the entire skin surface (including the palms and soles). Raised lesions called **condylomata lata** may occur in moist skinfolds, and erosions may develop in the mouth and on other mucosal surfaces. As with the primary chancre, these lesions are highly infectious. The rash and symptoms resolve spontaneously within a few weeks, and patients may undergo spontaneous remission, enter the latent or clinically inactive stage of disease, or progress to the **late phase** of disease.

Approximately one-third of untreated patients progress to the tertiary stage of syphilis. Clinical symptoms of the diffuse chronic inflammation characteristic of late syphilis develop after an asymptomatic period of a few years to decades and can cause devastating destruction of virtually any organ or tissue (e.g., arteritis, dementia, blindness). Granulomatous lesions **(gummas)** may be found in bone, skin, and other tissues. The nomenclature of late syphilis reflects the organs of primary involvement (e.g., neurosyphilis, cardiovascular syphilis). An increased incidence of neurosyphilis despite adequate therapy for early syphilis has been documented in patients with acquired immunodeficiency syndrome (AIDS). In addition, spirochetes are introduced into the central nervous system during the early stages of disease, and neurologic symptoms (e.g., meningitis) can develop within the first few months of disease. Thus neurosyphilis is not exclusively a late manifestation.

In utero infections (congenital syphilis) can lead to serious fetal disease, resulting in latent infections, multiorgan malformations, or death of the fetus. Most infected infants are born without clinical evidence of the disease, but rhinitis then develops and is followed by a widespread desquamating maculopapular rash. Teeth and bone malformation, blindness, deafness, and cardiovascular syphilis are common in untreated infants who survive the initial phase of disease.

LABORATORY DIAGNOSIS

Microscopy

Because *T. pallidum* is too thin to be seen by light microscopy, **darkfield microscopy** or **special fluorescent stains** must be used (Table 32.3). The diagnosis of primary, secondary, or congenital syphilis can be made rapidly by darkfield examination of the exudate from skin lesions; however, the test is reliable only when an experienced microscopist examines the clinical material immediately, when actively motile spirochetes can be observed. The spirochetes do not survive transport to the laboratory, and tissue debris can be mistaken for nonviable spirochetes. Material collected from oral and rectal lesions should not be examined because nonpathogenic spirochetes can be routinely observed in those specimens. Because of the limitations of darkfield microscopy, a more useful test for detecting *T. pallidum* is the **direct fluorescent antibody test.** Fluorescein-labeled antitreponemal antibodies are used to stain the bacteria (Fig. 32.3). A monoclonal antibody reagent is available that is specific for pathogenic treponemes, so oral and rectal specimens can be examined. In addition, nonviable spirochetes will also stain, so specimens do not need to be examined immediately after collection.

TABLE 32.3 Diagnostic Tests for Syphilis

Diagnostic Test	Method or Examination
Microscopy	Darkfield Direct fluorescent antibody staining
Culture	Not available
Serology	Nontreponemal tests: VDRL test RPR test USR test TRUST Treponemal tests: FTA-ABS TP-PA test EIA

EIA, Enzyme immunoassay; *FTA-ABS,* fluorescent treponemal antibody-absorption; *RPR,* rapid plasma reagain; *TP-PA, Treponema pallidum* particle agglutination; *TRUST,* toluidine red unheated serum test; *USR,* unheated serum reagin; *VDRL,* Veneral Disease Research Laboratory.

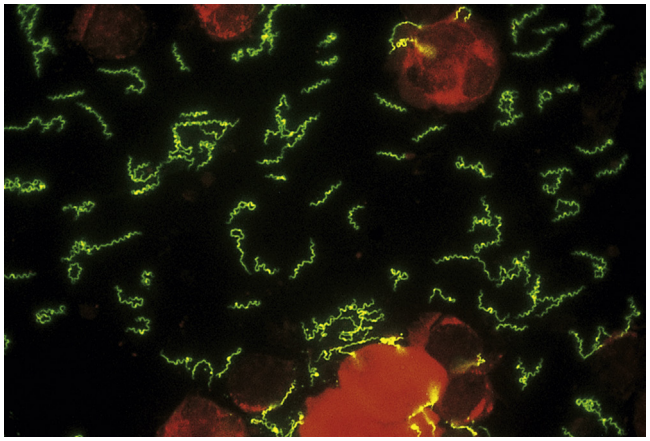

Fig. 32.3 *Treponema pallidum* in the direct fluorescent antibody test for *T. pallidum.* (From Morse, S.A., Ballard, R.C., Holmes, K.K., et al., 2010. Atlas of Sexually Transmitted Diseases and AIDS, fourth ed. Saunders, London, UK.)

Culture

Efforts to culture *T. pallidum* in vitro should not be attempted because the organism does not grow in artificial cultures.

Nucleic Acid–Based Tests

Nucleic acid amplification tests (i.e., polymerase chain reaction [PCR]) have been developed for detecting *T. pallidum* in genital lesions, infant blood, and cerebrospinal fluid (CSF) but are currently not widely available.

Antibody Detection

Syphilis is diagnosed in most patients on the basis of serologic tests. The two general types of tests used are biologically nonspecific (nontreponemal) tests and specific treponemal tests. The nontreponemal tests are used as screening tests because they are rapid to perform and inexpensive. Positive reactivity with one of these tests is confirmed with a treponemal test.

Nontreponemal tests measure immunoglobulin (Ig) G and IgM antibodies (also called **reaginic antibodies**) that developed against lipids released from damaged cells during the early stage of disease and that appear on the cell surface of treponemes. The antigen used for the nontreponemal tests is **cardiolipin,** which is derived from beef heart. The two tests used most commonly are the **Venereal Disease Research Laboratory (VDRL) test** and the **rapid plasma reagin (RPR) test.** Both tests measure the flocculation of cardiolipin antigen by the patient's serum. Only the VDRL test should be used to test CSF from patients with suspected neurosyphilis. Other nontreponemal tests in use include the unheated serum reagin (USR) test and the toluidine red unheated serum test (TRUST). All nontreponemal tests have essentially the same sensitivity (very low reactivity when the primary lesion appears but rises to 70% to 85% reactivity after 1 week; 100% reactivity for secondary disease; 70% to 75% for late syphilis) and specificity (98% to 99%).

Treponemal tests use *T. pallidum* as the antigen and detect specific anti–*T. pallidum* antibodies. The treponemal test results can be positive before the nontreponemal test results become positive in early syphilis, and they can remain positive when the nonspecific test results revert to negative in some patients who have late syphilis. Historically, the most commonly used treponemal test was the **fluorescent treponemal antibody-absorption (FTA-ABS) test**, which is an indirect fluorescent antibody test. *T. pallidum* immobilized on glass slides is used as the antigen. The slide is overlaid with the patient's serum, which has been mixed with an extract of nonpathogenic treponemes. The fluorescein-labeled antihuman antibodies are then added to detect the presence of specific antibodies in the patient's serum. Because these tests are technically difficult to interpret, most laboratories now use either the ***Treponema pallidum* particle agglutination (TP-PA) test** or one of a number of specific **enzyme immunoassays (EIAs).** The TP-PA test is a microtiter agglutination test. Gelatin particles sensitized with *T. pallidum* antigens are mixed with dilutions of the patient's serum. If antibodies are present, the particles agglutinate. A variety of specific EIAs have been developed and appear to have sensitivities (80% to 95% for primary disease, 100% for secondary and late syphilis) and specificities (96% to 99%) similar to the FTA-ABS and TP-PA tests. These immunoassays are widely used in resource-limited countries in which screening with traditional nontreponemal tests and use of more sensitive treponemal tests such as FTA-ABS is impractical.

Because positive reactions with the nontreponemal tests develop late during the first phase of disease, the serologic findings are negative in many patients who present with chancres. However, serologic results are positive within 3 months in all patients and remain positive in untreated patients with secondary syphilis. The antibody titers decrease slowly in patients with untreated syphilis, and serologic results are negative in approximately 25% to 30% of patients with late syphilis. Thus the limitation of the nontreponemal tests is reduced sensitivity in early primary disease and late syphilis. Although the results of treponemal tests generally remain positive for the life of the person who has syphilis, a negative test is unreliable in patients with AIDS.

Successful treatment of primary or secondary syphilis and, to a lesser extent, late syphilis leads to reduced titers measured in the VDRL and RPR tests. Thus these tests can be used to monitor the effectiveness of therapy, although seroreversion is slowed in patients in an advanced stage of

Acne vulgaris

disease, those with high initial titers, and those who have previously had syphilis. The treponemal tests are influenced less by therapy than are the VDRL and RPR tests, with seroreversion observed in less than 25% of patients successfully treated during the primary stage of the disease.

Transient false-positive reactions with the nontreponemal tests are seen in patients with acute febrile diseases, after immunizations, and in pregnant women. Long-term false-positive reactions occur most often in patients with chronic autoimmune diseases or infections that involve the liver or that cause extensive tissue destruction. Most false-positive reactions with the treponemal tests are observed in patients with elevated immunoglobulin levels and autoimmune diseases (Box 32.1).

Diagnosis of neurosyphilis and congenital syphilis can be problematic. The diagnosis of neurosyphilis is based on clinical symptoms and laboratory findings. A VDRL test on CSF is highly specific but not sensitive. Thus a positive VDRL confirms the diagnosis, but a negative test does not rule out neurosyphilis. In contrast, the FTA-ABS CSF test has high sensitivity but low specificity because of passive transfer of antitreponemal antibodies from blood to CSF. In this case, a positive FTA-ABS CSF test is consistent with neurosyphilis but is not diagnostic, and a negative test would essentially rule out the diagnosis. Positive serologic test results in infants of infected mothers can represent a passive transfer of antibodies or a specific immunologic response to a congenital infection. These two possibilities are distinguished by measuring the antibody titers in the sera of the infant during a 6-month period. The antibody titers in noninfected infants decrease to undetectable levels within 3 months of birth but remain elevated in infants who have congenital syphilis.

Clinical Case 32.2 Lyme Disease in Lyme, Connecticut

In 1977, Steere and associates (*Arthritis Rheum* 20:7–17, 1977) reported an epidemic of arthritis in eastern Connecticut. The authors studied a group of 39 children and 12 adults who developed an illness characterized by recurrent attacks of swelling and pain in a few large joints. Most attacks were for a week or less, but some attacks lasted for months. Twenty-five percent of the patients remembered they had an erythematous cutaneous lesion 4 weeks before the onset of their arthritis. This was the first report of Lyme disease, named after the town in Connecticut in which the disease was first recognized. We now know the erythematous lesion (erythema migrans) is the characteristic presentation of early Lyme disease. A few years after this report, the *Borrelia* responsible for Lyme disease, *B. burgdorferi,* was isolated.

TREATMENT, PREVENTION, AND CONTROL

Penicillin is the drug of choice for treating *T. pallidum* infections. A single intramuscular dose of long-acting benzathine **penicillin G** is used for the early stages of syphilis, and three doses at weekly intervals is recommended for congenital and late syphilis. **Doxycycline** or **azithromycin** can be used as alternative antibiotics for patients allergic to penicillin. Only penicillin can be used for the treatment of neurosyphilis; thus penicillin-allergic patients must undergo desensitization. This is also true for pregnant women, who should not be treated with tetracyclines. Treatment failures with macrolides have been observed, so patients treated with azithromycin should be closely monitored.

Because protective vaccines are not available, syphilis can be controlled only through the practice of safe-sex techniques and adequate contact and treatment of the sex partners of patients who have been documented with infection. The control of syphilis and other venereal diseases has been complicated by an increase in prostitution among drug abusers and high-risk sexual practices in homosexual males.

Borrelia

Members of the genus *Borrelia* cause two important human diseases: **Lyme disease** and **relapsing fever.** The recorded history of Lyme disease began in 1977 when an unusual cluster of children with arthritis was noted in Lyme, Connecticut (Clinical Case 32.2). Five years later, W. Burgdorfer discovered the spirochete responsible for this disease. Lyme disease is a tick-borne disease with protean manifestations, including dermatologic, rheumatologic, neurologic, and cardiac abnormalities. Initially it was believed that all cases of Lyme disease (or Lyme borreliosis) were caused by one organism, ***B. burgdorferi***. However, subsequent studies have determined that a complex of at least 10 *Borrelia* species are responsible for Lyme disease in animals and humans. Three species, *B. burgdorferi, B. garinii,* and *Borrelia afzelii,* cause human disease, with *B. burgdorferi* found in the United States and Europe and *B. garinii* and *B. afzelii*

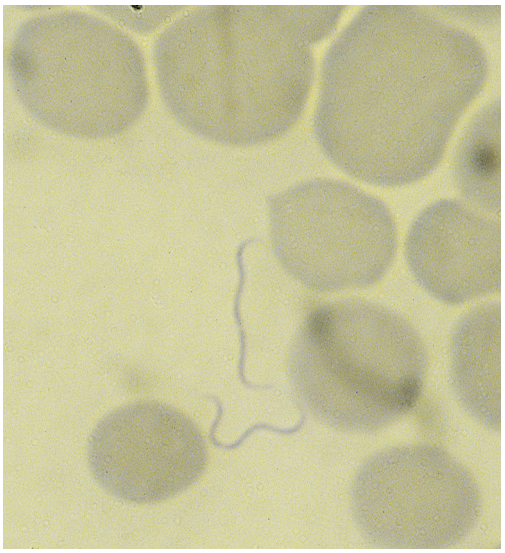

Fig. 32.4 *Borrelia* organisms are present in the blood of this patient with endemic relapsing fever (Giemsa stain).

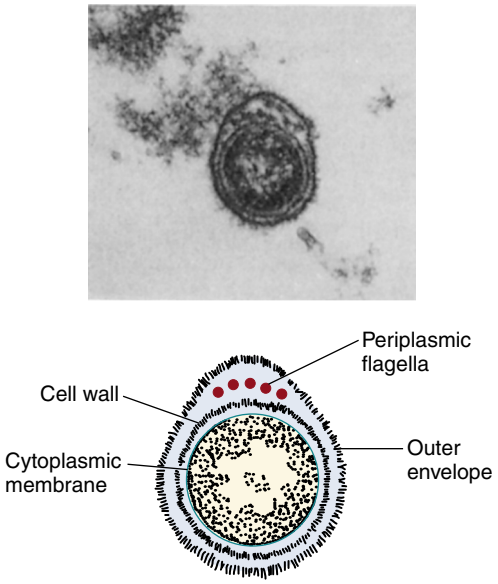

Fig. 32.5 Electron micrograph and drawing of a cross-section through *Borrelia burgdorferi,* which is the agent that causes Lyme borreliosis. The protoplasmic core of the bacterium is enclosed in a cytoplasmic membrane and conventional cell wall. This in turn is surrounded by an outer envelope, or sheath. Between the protoplasmic core and outer sheath are periplasmic flagella (also called *axial fibrils*), which are anchored at either end of the bacterium and wrap around the protoplasmic core. (From Steere, A.C., Grodzicki, R.L., Kornblatt, A.N., et al., 1983. The spirochetal etiology of Lyme disease. New Engl. J. Med. 308, 733–740.)

found in Europe and central to eastern Asia. This chapter focuses on *B. burgdorferi* infections.

Relapsing fever is a febrile illness characterized by recurrent episodes of fever and septicemia separated by afebrile periods. Two forms of the disease are recognized. *B. recurrentis* is the etiologic agent of **epidemic** or **louse-borne relapsing fever** and is spread person to person by the **human body louse** *(Pediculus humanus).* **Endemic relapsing fever** is caused by as many as 15 species of borreliae and is spread by infected **soft ticks** of the genus *Ornithodoros.*

PHYSIOLOGY AND STRUCTURE

Members of the genus *Borrelia* stain poorly with the Gram stain reagents and are considered neither gram positive nor gram negative, even though they have an outer membrane similar to gram-negative bacteria. They are larger than other spirochetes (0.2 to 0.5 × 8 to 30 μm), stain well with aniline dyes (e.g., Giemsa or Wright stain), and can be easily seen by light microscopy when present in smears of peripheral blood from patients with relapsing fever but not those with Lyme disease (too few organisms to be observed) (Figs. 32.4 and 32.5). Borreliae are microaerophilic and have complex nutritional needs (i.e., requiring *N*-acetylglucosamine, long-chain saturated and unsaturated fatty acids, glucose, amino acids), which makes them difficult to grow in the lab. The species that have been successfully cultured have generation times of 18 hours or longer. Because culture is generally unsuccessful, diagnosis of diseases caused by borreliae is by serology (Lyme disease) or microscopy (relapsing fever).

PATHOGENESIS AND IMMUNITY

The growth of borreliae in both arthropod vectors and mammalian hosts is regulated by differential gene expression with upregulation or downregulation of outer surface proteins. For example, outer surface protein A (OspA) is expressed on the surface of *B. burgdorferi* residing in the midgut of unfed ticks. This protein binds specifically to gut proteins. On feeding, expression of this protein is repressed, allowing the spirochete to migrate to the salivary glands, and outer surface protein C (OspC) expression, which appears critical for transmission from ticks to mammals, is upregulated. Unfortunately, knowledge of the complete genome sequence of *B. burgdorferi* has not led to a clear understanding of how these organisms cause disease. *B. burgdorferi* organisms are present in low numbers in the skin when erythema migrans develops. This has been shown by culture of the organism from skin lesions and detection of bacterial nucleic acids by PCR amplification; however, culture and PCR tests are relatively insensitive in the early phase of disease. In addition, spirochetes are infrequently isolated from clinical material late in the disease. It is not known whether the viable organisms cause these late manifestations of disease or whether they represent immunologic cross-reactivity to *Borrelia* antigens. Although the immune response to the organism is depressed at the time that skin lesions initially develop, antibodies develop over months to years and are responsible for producing the complement-mediated clearance of the borreliae.

Our understanding of mechanisms by which borreliae cause relapsing fever is also incomplete. Members of the genus do not produce recognized toxins and are removed rapidly when a specific antibody response is mounted. The periodic febrile and afebrile cycles of relapsing fever result from the ability of the borreliae to undergo antigenic variation. These spirochetes carry a large number of genes homologous to the OspC gene, but only one gene is expressed at a time. When specific antibodies are formed,

agglutination with complement-mediated lysis occurs, and the borreliae are cleared rapidly from the blood. However, switching of the expression of the gene family occurs at a frequency of 10^{-3} to 10^{-4} per generation. Thus a new population of spirochetes with a new lipoprotein coat will appear in the blood, heralding a new febrile episode. These antigenic shifts are the reason serology tests are not used to diagnose relapsing fever.

EPIDEMIOLOGY

Despite the relatively recent recognition of Lyme disease in the United States, retrospective studies have shown that the disease was present for many years in this and other countries. Lyme disease has been described on six continents, in many countries, and in all U.S. states. The incidence of disease has risen dramatically between 1982 (497 cases were reported) and 2017 (42,743 cases were reported). **Lyme disease is the leading vector-borne disease in the United States.** The vast majority of Lyme disease cases are reported from two U.S. foci: Northeast and Mid-Atlantic states (Maine to Virginia) and the Upper Midwest (Minnesota and Wisconsin). **Hard ticks are the major vectors** of Lyme disease: *Ixodes scapularis* in the Northeast, Mid-Atlantic, and Midwest, and *I. pacificus* on the West Coast. *I. ricinus* is the major tick vector in Europe, and *I. persulcatus* is the major tick vector in Eastern Europe and Asia. The major reservoir hosts in the United States are the white-footed mouse and the white-tailed deer. The **white-footed mouse** is the primary host of larval and nymph forms of *Ixodes* species, and the adult *Ixodes* species infest the **white-tailed deer.** Because the nymph stage causes more than 90% of the cases of documented disease, the mouse host is more relevant for human disease.

Ixodes larvae become infected when they feed on the mouse reservoir. The larva molts to a nymph in late spring and takes a second blood meal; in this case, humans can be accidental hosts. Although the borreliae are transmitted in the tick's saliva during a prolonged period of feeding (≥48 hours), most patients do not remember having had a specific tick bite because the nymph is the size of a poppy seed. The nymphs mature into adults in the late summer and take a third feeding. Although the white-tailed deer is the natural host, humans can also be infected at this stage. Most infected patients are identified in June and July, although disease can be encountered throughout the year.

As previously mentioned, the etiologic agent of louse-borne epidemic relapsing fever is *B. recurrentis,* the vector is the human body louse, and humans are the only reservoir (Fig. 32.6). Lice become infected after feeding on an infected person. The organisms are ingested, pass through the wall of the gut, and multiply in hemolymph. Disseminated disease is not believed to occur in lice; thus human infection occurs when the lice are crushed during feeding. Because infected lice do not survive for more than a few months, maintenance of the disease requires crowded, unsanitary conditions (e.g., wars, natural disasters) that permit frequent human contact with infected lice. Although epidemics of louse-borne relapsing fever swept from Eastern to Western Europe in the past century, the disease now appears to be restricted to Ethiopia, Eritrea, Somalia, and Sudan.

Infection	Reservoir	Vector
Relapsing fever epidemic (louse-borne)	Humans	Body louse 
Relapsing fever endemic (tick-borne)	Rodents, soft ticks	Soft tick 
Lyme disease	Rodents, deer, domestic pets, hard ticks	Hard tick 

Fig. 32.6 Epidemiology of *Borrelia* infections.

Several features distinguish **endemic relapsing fever** from epidemic disease. Tick-borne endemic relapsing fever is a **zoonotic disease,** with rodents, small mammals, and soft ticks (*Ornithodoros* species) as the main reservoirs and **many species of** *Borrelia* responsible for the disease. Unlike the louse-borne infections, the borreliae that cause endemic disease produce a disseminated infection in ticks. In addition, the arthropods can survive and maintain an endemic reservoir of infection by transovarian transmission. Furthermore, ticks can survive for months between feedings. A history of a tick bite may not be elicited because soft ticks are primarily nocturnal feeders and remain attached for only a few minutes. The ticks contaminate the bite wound with borreliae present in saliva or feces. Tick-borne disease is found worldwide, corresponding to the distribution of the *Ornithodoros* tick. In the United States, the disease is primarily found in the western states, with the most common occurrences in Washington and California. Worldwide, the disease is found in Mexico, Central and South America, the Mediterranean, Central Asia, and much of Africa.

CLINICAL DISEASES

Lyme Disease

Clinical diagnosis of Lyme disease is complicated by the varied manifestations of the disease caused by *B. burgdorferi* and other *Borrelia* species, as well as the lack of reliable diagnostic tests. The clinical and laboratory definitions of Lyme disease recommended by the CDC are summarized in Box 32.2. The following paragraph is a description of Lyme disease in the United States. The frequency of the skin lesions and late manifestations differ in disease observed in other countries.

Lyme disease begins as an early localized infection, progresses to an early disseminated stage, and, if untreated, can progress to a late manifestation stage. After an incubation period of 3 to 30 days, one or more skin lesions typically develop at the site of the tick bite. The lesion **(erythema migrans)** begins as a small macule or papule and then enlarges over the next few weeks, ultimately covering an area ranging from 5 cm to more than 50 cm in diameter (Fig. 32.7). The lesion typically has a flat, red border and central clearing as it develops; however, erythema, vesicle formation, and central necrosis can also be seen. The lesion

BOX 32.2 Definition of Lyme Disease

Clinical Case Definition

Either of the Following:
Erythema migrans (≈5 cm in diameter)
At least one late manifestation (i.e., musculoskeletal, nervous system, or cardiovascular involvement) and laboratory confirmation of infection

Laboratory Criteria for Diagnosis

At Least One of the Following:
Isolation of *Borrelia burgdorferi*
Demonstration of diagnostic levels of IgM or IgG antibodies to the spirochetes
Significant increase in antibody titer between acute and convalescent serum samples

Ig, Immunoglobulin.

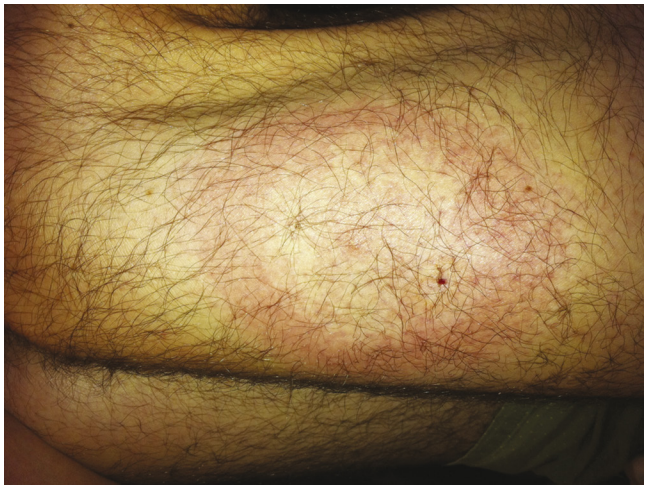

Fig. 32.7 Erythema migrans rash on the thigh of the author's (PRM) son. An engorged nymph stage of an *Ixodes* tick was found 3 days after exposure. Twelve days later, the rash appeared with accompanying localized pain and progressed to 5 cm in diameter with central clearing. The rash faded over the next week with doxycycline treatment, and the infection, confirmed by culture of the biopsy, resolved with no secondary complications.

fades and disappears within weeks, although new transient lesions may subsequently appear. Although the skin lesion is characteristic of Lyme disease, it is not pathognomonic. A similar skin lesion associated with disease of unknown etiology (*s*outhern *t*ick-*a*ssociated *r*ash *i*llness, or SARI) occurs after the bite of the *Amblyomma americanum* tick (lone star tick). These ticks, found in the southeast and south central regions of the United States, are not infected with *B. burgdorferi.* Other early signs and symptoms of Lyme disease include malaise, severe fatigue, headache, fever, chills, musculoskeletal pains, myalgias, and lymphadenopathy. These symptoms last for an average of 4 weeks.

Hematogenous dissemination will occur in untreated patients within days to weeks of the primary infection. This stage is characterized by systemic signs of disease (e.g., severe fatigue, headache, fever, malaise), arthritis and arthralgia, myalgia, erythematous skin lesions, cardiac dysfunction, and neurologic signs. Approximately 60% of patients with untreated Lyme disease will develop **arthritis,** typically involving the knee; approximately 10% to 20% will develop **neurologic manifestations** (most commonly facial nerve palsy); and 5% will have **cardiac complications** (usually varying degrees of atrioventricular block).

Fig. 32.8 Acrodermatitis chronica atrophicans. Bluish-red skin lesions characteristic of late disseminated manifestations of Lyme borreliosis. (From Cohen, J., Powderly, W.G., Opal, S.M., 2010. Infectious Diseases, third ed. Mosby, Philadelphia, PA.)

Late-stage manifestations of Lyme disease in untreated patients can develop months to years after the initial infection. Arthritis can involve one or more joints intermittently. Chronic skin involvement with discoloration and swelling (**acrodermatitis chronica atrophicans**; Fig. 32.8) is more common in Lyme disease seen in Europe. The existence of chronic, symptomatic Lyme disease in appropriately treated patients has not been demonstrated definitively.

Relapsing Fever

The clinical presentations of epidemic louse-borne and endemic tick-borne relapsing fever are essentially the same, although a small pruritic eschar may develop at the site of the tick bite. (Clinical Case 32.3) After a 1-week incubation period, the disease is heralded by the abrupt onset of shaking chills, fever, muscle aches, and headache. Splenomegaly and hepatomegaly are common. These symptoms correspond to the bacteremic phase of the disease and resolve after 3 to 7 days, when the borreliae are cleared from the blood. Bacteremia and fever return after a 1-week afebrile period. The clinical symptoms are generally milder and last a shorter time during this and subsequent **febrile episodes.** A single relapse is characteristic of epidemic louse-borne disease, and as many as 10 relapses occur in endemic tick-borne disease. The clinical course and outcome of epidemic relapsing fever tend to be more severe than they are in those with endemic disease, but this may be related to the patients' underlying poor state of health. Mortality with endemic disease is less than 5% but can be as high as 70% in louse-borne epidemic disease. Deaths are caused by cardiac failure, hepatic necrosis, or cerebral hemorrhage (Clinical Case 32.3).

LABORATORY DIAGNOSIS

Microscopy

Microscopic examination of blood or tissues from patients with Lyme disease is not recommended because *B.*

Clinical Case 32.3 **Outbreak of Tick-Borne Relapsing Fever**

In August 2002, the New Mexico Department of Health was notified of an outbreak of tick-borne relapsing fever (*MMWR* 52:809–812, 2003). Approximately 40 people attended a family gathering held in a cabin in the mountains of northern New Mexico. Half of the family members slept overnight in the cabin. Some of the family arrived 3 days before the event to clean the unoccupied cabin. Four days after the event, one of the individuals who arrived early sought care at a local hospital with a 2-day history of fever, chills, myalgia, and a raised pruritic rash on the forearms. Spirochetes were observed on a peripheral blood smear. As many as 14 individuals who attended the family gathering developed symptoms consistent with relapsing fever and had either positive serology or spirochetes observed in blood smears. The majority had a history of fever, headache, arthralgia, and myalgia. Rodent nesting material was found inside the interior walls of the cabin. This outbreak of endemic relapsing fever illustrates the risks associated with exposure to ticks that feed on infected rodents, the fact that tick bites are generally not remembered because the feeding is for a short duration at night, and the relapsing nature of this febrile illness.

burgdorferi is rarely seen in clinical specimens. Borreliae that cause relapsing fever can be observed during the febrile period on Giemsa-stained or Wright-stained preparation of blood. This is the most sensitive method for diagnosing relapsing fever, with smears positive for organisms in more than 70% of patients.

Culture

Some borreliae, including *B. recurrentis* and *Borrelia hermsii* (a common cause of endemic relapsing fever in the United States), can be cultured in vitro on specialized media. The cultures are rarely performed in most clinical laboratories because the media are not readily available and the organisms grow slowly on them. There has been limited success with the culture of *B. burgdorferi,* although isolation of the organism has been improved through the use of specialized media. However, the sensitivity of culture is low for all specimens except the initial skin lesion.

Nucleic Acid–Based Tests

Nucleic acid amplification techniques have a sensitivity of approximately 65% to 75% with skin biopsies, 50% to 85% with synovial fluid, and 25% with CSF specimens from patients with documented Lyme disease. These tests are generally restricted to research and reference laboratories, and the negative test results should be confirmed by serology.

Antibody Detection

Serologic tests are not useful in the diagnosis of relapsing fever because the borreliae that cause this condition undergo antigenic phase variation. In contrast, serologic testing is the diagnostic test of choice for patients with suspected Lyme disease. The tests most commonly used are the **immunofluorescence assay (IFA)** and **EIA.** The U.S. Food and Drug Administration has cleared more than 70 serologic assays for the diagnosis of Lyme disease. Unfortunately, all serologic tests are relatively insensitive during the early acute stage of disease. IgM antibodies appear 2 to 4 weeks after the onset of erythema migrans in untreated patients; the levels peak after 6 to 8 weeks of illness and then decline to a normal range after 4 to 6 months. The IgM level may remain elevated in some patients with a persistent infection. The IgG antibodies appear later. Their levels peak after 4 to 6 months of illness and persist during the late manifestations of the disease. Thus most patients with late complications of Lyme disease have detectable antibodies to *B. burgdorferi,* although the antibody level may be ablated in patients treated with antibiotics. Detection of antibodies in CSF is strong evidence for neuroborreliosis.

BOX 32.3 **Bacteria and Diseases Associated with Cross-Reactions in Serologic Tests for Lyme Borreliosis**

Treponema pallidum
Oral spirochetes
Other *Borrelia* species
Juvenile rheumatoid arthritis
Rheumatoid arthritis
Systemic lupus erythematosus
Infectious mononucleosis
Subacute bacterial endocarditis

Although cross-reactions are uncommon, positive serologic results must be interpreted carefully, particularly if the titers are low (Box 32.3). Most false-positive reactions occur in patients with syphilis. These false results can be excluded by performing a nontreponemal test for syphilis; the result is negative in patients with Lyme disease. Western blot analysis has been used to confirm the specificity of a positive EIA or IFA reaction. A specimen with a negative EIA or IFA reaction does not require further testing. Guidelines for interpretation of Western immunoblots are available on the CDC website (www.cdc.gov). Antigenic heterogeneity in *B. burgdorferi* and other *Borrelia* species that cause Lyme disease affects the test sensitivity. The magnitude of this problem in the United States is unknown, but it should be significant in Europe and Asia, where multiple *Borrelia* species are found to cause Lyme disease. At present, serologic tests should be considered confirmatory and should not be performed in the absence of an appropriate history and clinical symptoms of Lyme disease.

TREATMENT, PREVENTION, AND CONTROL

The early manifestations of **Lyme disease** are managed effectively with orally administered **amoxicillin, doxycycline,** or **cefuroxime.** Antibiotic treatment lessens the likelihood and severity of late complications. Despite this intervention, Lyme arthritis and acrodermatitis chronica atrophicans still occur in a small number of patients. Oral cefuroxime, doxycycline, or amoxicillin has been used for the treatment of these manifestations. Patients with recurrent arthritis or central or peripheral nervous system disease typically require parenteral treatment with intravenous ceftriaxone, cefotaxime, or penicillin G. Previously treated patients with chronic symptoms ("post–Lyme

disease syndrome") should be treated symptomatically because there is no evidence that multiple courses of oral or parenteral antibiotics relieve the symptoms.

Relapsing fever has been treated most effectively with **tetracyclines** or **penicillins.** Tetracyclines are the drugs of choice but are contraindicated for pregnant women and young children. A Jarisch-Herxheimer reaction (shock-like profile with rigors, leukopenia, an increase in temperature, and a decrease in blood pressure) can occur in patients within a few hours after therapy is started and must be carefully managed. This reaction corresponds to the rapid killing of borreliae and the possible release of toxic products.

Prevention of tick-borne *Borrelia* diseases includes avoiding ticks and their natural habitats, wearing protective clothing (e.g., long pants tucked into socks), and applying insect repellents. Rodent control is also important in the prevention of endemic relapsing fever. Epidemic louse-borne disease is controlled through the use of delousing sprays and improvements in hygienic conditions.

Vaccines are not available for relapsing fever. A recombinant vaccine directed against the OspA antigen of *B. burgdorferi* was removed from the market in 2002.

Leptospira

The taxonomy of the genus *Leptospira* is a source of great confusion. Traditionally the genus has been grouped by phenotypic properties, serologic relationships, and pathogenicity. Pathogenic strains were placed in the species *Leptospira interrogans,* and nonpathogenic strains were placed in the species *Leptospira biflexa*. Each of the two species contained many serovars (i.e., serologically distinct groups). Although this classification scheme exists in the literature, it is not consistent with nucleic acid analysis that supports subdividing the genus into three genera with 24 species in the genus *Leptospira*. To avoid confusion, leptospires will be referred to as pathogenic (for humans) or nonpathogenic without reference to either specific species or serovars.

PHYSIOLOGY AND STRUCTURE

Leptospires **are thin, coiled spirochetes** (0.1 × 6.0 to 20.0 μm) with a hook at one or both pointed ends (Fig. 32.9). Motility is by means of two periplasmic flagella extending the length of the bacteria and anchored at opposite ends. Leptospires are obligate aerobes with optimum growth at 28° C to 30° C in media supplemented with vitamins, long-chain fatty acids, and ammonium salts. The practical significance of this is that these organisms can be cultured in a highly specialized medium from clinical specimens collected from infected patients, although this is not commonly done.

PATHOGENESIS AND IMMUNITY

Pathogenic leptospires can cause subclinical infection, a mild influenza-like febrile illness, or severe systemic disease **(Weil disease)** with renal and hepatic failure, extensive vasculitis, myocarditis, and death. The number of infecting organisms, the host's immunologic defenses, and the virulence of the infecting strain influence the severity of the disease.

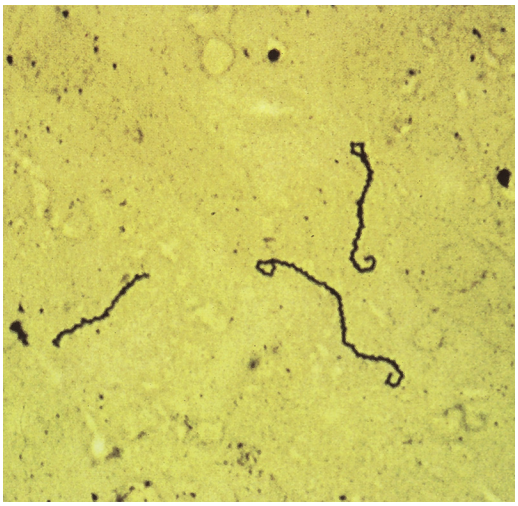

Fig. 32.9 Silver staining of leptospires grown in culture. Notice the tightly coiled body with hooked ends. (From Emond, R., Rowland, H., 1995. Color Atlas of Infectious Diseases, third ed. Wolfe, London, UK.)

Because leptospires are thin and highly motile, they can **penetrate intact mucous membranes or skin through small cuts or abrasions.** They can then spread in the blood to all tissues, including the central nervous system. Leptospires multiply rapidly and damage the endothelium of small blood vessels, resulting in the major clinical manifestations of disease (e.g., meningitis, hepatic and renal dysfunction, hemorrhage). Organisms can be **found in blood and CSF early in the disease and in urine during the later stages.** Clearance of leptospires occurs when humoral immunity develops. However, late manifestations of the disease such as vascular damage with increased vascular permeability are associated with the immune response to the organisms.

EPIDEMIOLOGY

Leptospirosis has a worldwide distribution. Approximately 100 infections occur in the United States and U.S. territories each year, with most cases reported in Puerto Rico and Hawaii. However, the incidence of disease is significantly underestimated because most infections are mild and misdiagnosed as a "viral syndrome" or aseptic viral meningitis. Because many states failed to report this disease to the public health service, mandatory reporting was discontinued in 1995; however, leptospirosis was reinstated as a nationally notifiable disease in 2013.

Leptospires infect two types of hosts: reservoir hosts and incidental hosts. Endemic, chronic infections are established in **reservoir hosts,** which serve as a permanent reservoir for maintaining the bacteria. Different species and serovars of leptospires are associated with specific reservoir hosts (important for epidemiologic investigations). The **most common reservoirs are rodents and other small mammals.** Leptospires usually cause asymptomatic infections in their reservoir host, in which the spirochetes colonize the renal tubules and are shed in urine in large numbers. Streams, rivers, standing water, and moist soil can be contaminated with urine from infected animals, with organisms surviving for as long as 6 weeks in such sites. Contaminated water or direct exposure to infected

Clinical Case 32.4 **Leptospirosis in Triathlon Participants**

There are a number of reports of leptospirosis in athletes participating in water sport events. In 1998, public health officials reported leptospirosis in triathlon participants in Illinois and Wisconsin (*MMWR* 47:673–676, 1998). A total of 866 athletes participated in the Illinois event on June 21, 1998, and 648 participated in the Wisconsin event on July 5, 1998. The case definition of leptospirosis used for this investigation was onset of fever, followed by at least two of the following symptoms or signs: chills, headache, myalgia, diarrhea, eye pain, or red eyes. Nine percent of the participants met this case definition; two-thirds sought medical care, including one-third who were hospitalized. Leptospirosis was confirmed in a portion of these patients by serologic tests. These outbreaks illustrate the potential danger of swimming in contaminated water, the presentation of leptospirosis in a previously healthy population, and the severity of disease that can be experienced.

animals can serve as a source for infection in **incidental hosts** (e.g., dogs, farm animals, rodents, humans). Most human infections result from recreational exposure to contaminated water (e.g., lakes) or occupational exposure to infected animals (farmers, slaughterhouse workers, veterinarians). Most human infections occur during the warm months, when recreational exposure is greatest. Person-to-person spread has not been documented. By definition, chronic carriage is not established in incidental hosts (Clinical Case 32.4).

CLINICAL DISEASES

Most human infections with leptospires are clinically inapparent and detected only through the demonstration of specific antibodies. Infection is introduced through skin abrasions or the conjunctiva. Symptomatic infections develop after a 1- to 2-week incubation period and in two phases. The initial phase is similar to an influenza-like illness, with fever, myalgia, chills, headache, vomiting, or diarrhea. During this phase, the patient is bacteremic with the leptospires, and the organisms can frequently be isolated in CSF even though no meningeal symptoms are present. The symptoms may remit after 1 week or the patient may progress to the second phase, which is characterized by more severe disease, with the sudden onset of headache, myalgia, chills, abdominal pain, and conjunctival suffusion (i.e., reddening of the eye). Severe disease can progress to vascular collapse, thrombocytopenia, hemorrhage, and hepatic and renal dysfunction.

Leptospirosis confined to the central nervous system can be mistaken for **aseptic viral meningitis** because the course of the disease is generally uncomplicated and has a very low mortality rate. Culture of CSF is usually negative at this stage. In contrast, the icteric form of generalized disease (≈10% of all symptomatic infections) is more severe and associated with a mortality approaching 10% to 15%. Although hepatic involvement with jaundice (icteric disease, or **Weil disease**) is striking in patients with severe leptospirosis, hepatic necrosis is not seen and surviving patients do not suffer permanent hepatic damage. Similarly, most patients recover full renal function. Congenital leptospirosis can also occur. This disease is characterized by the sudden onset of headache, fever, myalgias, and a diffuse rash.

LABORATORY DIAGNOSIS

Microscopy

Because leptospires are thin, they are at the limit of the resolving power of a light microscope and thus cannot be seen by conventional light microscopy. Neither Gram stain nor silver stain is reliable in the detection of leptospires. Darkfield microscopy is also relatively insensitive and capable of yielding nonspecific findings when cell fragments are present.

Culture

Leptospires can be cultured on specially formulated media (e.g., Fletcher, Ellinghausen-McCullough-Johnson-Harris [EMJH], Tween 80-albumin). They grow slowly (generation time, 6 to 16 hours), requiring incubation at 28° C to 30° C for as long as 4 months; however, most cultures are positive within 2 weeks. Consistent with the two phases of illness, leptospires are present in blood or CSF during the first 10 days of infection and in urine after the first week and for as long as 3 months. Because the concentration of organisms in blood, CSF, and urine may be low, several specimens should be collected if leptospirosis is suspected. In addition, inhibitors present in blood and urine may delay or prevent recovery of leptospires. Likewise, urine must be treated to neutralize the pH and concentrated by centrifugation. A few drops of the sediment are then inoculated into the culture medium. Growth of the bacteria in culture is detected by darkfield microscopy.

Nucleic Acid–Based Tests

Preliminary work with the detection of leptospires using nucleic acid probes has had limited success. Techniques using nucleic acid amplification (e.g., PCR) are more sensitive than culture. Unfortunately, this technique is not widely available at this time, particularly in resource-limited countries in which disease is common.

Antibody Detection

Because of the need for specialized media and prolonged incubation, most laboratories do not attempt to culture leptospires, relying instead on serologic techniques. The reference method for all serologic tests is the **microscopic agglutination test (MAT).** This test measures the ability of the patient's serum to agglutinate live leptospires. Because the test is directed against specific serotypes, it is necessary to use pools of leptospiral antigens. In this test, serial dilutions of the patient's serum are mixed with the test antigens and then examined microscopically for agglutination. Agglutinins appear in the blood of untreated patients after 5 to 7 days of illness, although this response may be delayed for as long as several months. Infected patients have a titer of at least 800 (i.e., agglutinins are detected in a 1:800 dilution of the patient's serum), or a fourfold increase in antibody titers. Patients treated with antibiotics may have a diminished antibody response or nondiagnostic titers. Agglutinating antibodies are detectable for many

years after the acute illness; thus the presence of low levels of antibodies may represent either a blunted antibody response in a treated patient with acute disease or residual antibodies in a person with a distant unrecognized infection with leptospires. Because the MAT uses live organisms, it is performed only in reference laboratories. Alternative tests, such as indirect hemagglutination, slide agglutination, and enzyme-linked immunosorbent assay (ELISA) are less sensitive and specific. These tests can be used to screen a patient, but positive reactions must be confirmed with the MAT or culture. Serologic cross-reactions occur with other spirochetal infections (i.e., syphilis, relapsing fever, Lyme disease) and legionellosis.

TREATMENT, PREVENTION, AND CONTROL

Leptospirosis is usually not fatal, particularly in the absence of icteric disease. Patients should be treated with either intravenously administered **penicillin** or **doxycycline.** Doxycycline, but not penicillin, can be used to prevent disease in persons exposed to infected animals or water contaminated with urine. It is difficult to eradicate leptospirosis because the disease is widespread in wild and domestic animals. However, vaccination of livestock and pets has proved successful in reducing the incidence of disease in these populations and therefore subsequent human exposure. Rodent control is also effective in eliminating leptospirosis in communities.

For a case study and questions see StudentConsult.com.

Case Study and Questions

An 18-year-old woman complained of knee pain that started 2 weeks earlier. Three months earlier, soon after vacationing in Connecticut, she noticed a circular area of redness on her lower leg; it was approximately 10 cm in diameter. During the next 2 weeks, the area enlarged and the border became more clearly demarcated; however, the rash gradually disappeared. A few days after the rash disappeared, the woman experienced the onset of headaches, an inability to concentrate, and nausea. These symptoms also gradually abated. The pain in her knee developed approximately 1 month after these symptoms disappeared. On examination of the knee, mild tenderness and pain were elicited. A small amount of serous fluid was aspirated from the joint, and it had an elevated white blood cell count. Antibodies to *B. burgdorferi* were present in the patient's serum (titers of 1:32 and 1:1024 for IgM and IgG, respectively), confirming the clinical diagnosis of Lyme arthritis.

1. What are the initial and late manifestations of Lyme disease?
2. What are the limitations of the following diagnostic tests for Lyme disease: microscopy, culture, and serology? How do these compare with the diagnostic tests for other relapsing fevers?
3. Name two examples each of nontreponemal and treponemal tests for syphilis. What reactions to those tests would you expect in patients with primary, secondary, and late syphilis?
4. What are the reservoir and vectors for syphilis, epidemic and endemic relapsing fever, Lyme disease, and leptospirosis?
5. What diagnostic tests can be used for the diagnosis of leptospirosis?

33 Mycoplasma

A 13-year-old girl was admitted to the hospital with a 5-day history of fever and a nonproductive cough. She had received 3 days of treatment with a cephalosporin as an outpatient, with no relief of symptoms. On admission, examination of the chest revealed bilateral crackling rales, dullness to percussion, and a chest radiograph that showed a right lower lobe infiltrate. Bacterial stains and cultures were negative, but a polymerase chain reaction (PCR) test for *Mycoplasma pneumoniae* was positive.

1. What is unique about the cellular structure of mycoplasmas? How does this affect their susceptibility to antibiotics?
2. What infections are attributed to *Mycoplasma pneumoniae? M. genitalium?*
3. What is the most sensitive test for the diagnosis of *M. pneumoniae* infection?

Answers to these questions are available on Student Consult.com.

Summaries Clinically Significant Organisms

MYCOPLASMA PNEUMONIAE

Trigger Words

No cell wall, person-to-person, tracheobronchitis

Biology and Virulence

- The smallest free-living bacterium; able to pass through 0.45-μm pore filters
- Absence of cell wall and a cell membrane containing sterols are unique among bacteria
- Slow rate of growth (generation time, 6 hours); strict aerobe
- P1 adhesin protein binds to base of cilia on epithelial cells, leading to eventual loss of ciliated epithelial cells
- Stimulates migration of inflammatory cells and release of cytokines

Epidemiology

- Worldwide disease with no seasonal incidence (in contrast to disease caused by most respiratory pathogens)
- Primarily infects children between ages 5 and 15 years, but all populations susceptible to disease
- Transmitted by inhalation of aerosolized droplet

Diseases

- Strict human pathogen
- Refer to Table 33.1 for disease

Diagnosis

- Refer to Table 33.2

Treatment, Prevention, and Control

- Drug of choice is erythromycin, doxycycline, or newer fluoroquinolones
- Immunity to reinfection is not lifelong, and vaccines have proved ineffective

The order Mycoplasmatales is subdivided into four genera: *Eperythrozoon, Haemobartonella, Mycoplasma,* and *Ureaplasma*. The most clinically significant genus is *Mycoplasma* (127 species) and the most important species is *M. pneumoniae* (also called **Eaton agent** after the investigator who originally isolated it). ***M. pneumoniae*** causes respiratory tract diseases such as tracheobronchitis and pneumonia. Other commonly isolated pathogens include ***M. genitalium*** and ***M. hominis*** (Table 33.1).

Physiology and Structure

Mycoplasma organisms are the **smallest free-living bacteria.** They are unique among bacteria because they **do not have a cell wall** and their cell membrane contains **sterols.** In contrast, other cell wall–deficient bacteria (called **L forms**) do not have sterols in their cell membrane and can form cell walls under the appropriate growth conditions. Absence of the cell wall renders the mycoplasmas resistant to penicillins, cephalosporins, vancomycin, and other antibiotics that interfere with synthesis of the cell wall.

The mycoplasmas form pleomorphic shapes varying from 0.2- to 0.3-μm coccoid forms to rods 0.1 to 0.2 μm in width and 1 to 2 μm long. Many can pass through the 0.45-μm filters used to remove bacteria from solutions, which was why the mycoplasmas were originally thought to be viruses. However, the organisms divide by binary fission (typical of all bacteria), grow on artificial cell-free media, and contain both ribonucleic acid (RNA) and deoxyribonucleic acid (DNA). Mycoplasmas are facultatively anaerobic (except *M. pneumoniae,* which is a **strict aerobe**), and require exogenous sterols supplied by animal serum added to the growth medium. The mycoplasmas **grow slowly,** with a generation time of 1 to 16 hours, and most form small colonies that are difficult to detect without extended incubation.

Pathogenesis and Immunity

M. pneumoniae is an extracellular pathogen that adheres to the respiratory epithelium by means of a specialized attachment structure that forms at one end of the cell. The structure consists of a complex of adhesion proteins, and the **P1 adhesin** the most important. The adhesions interact specifically with sialated glycoprotein receptors at the base of cilia on the epithelial cell surface (and on the surface of erythrocytes). Ciliostasis then

Answers

1. Mycoplasmas lack a cell wall, and their cell membrane contains sterols. The absence of a cell wall renders the bacteria resistant to antibiotics that interfere with cell wall synthesis (e.g., penicillins, cephalosporins, carbapenems, vancomycin).
2. *M. pneumoniae* causes respiratory infections (tracheobronchitis, pharyngitis, pneumonia); *M. genitalium* is implicated in urethritis, cervicitis, and pelvic inflammatory disease; *M. hominis* is implicated in infections of the respiratory tract and urinary tract, as well as in systemic infections in immunocompromised patients.
3. Laboratory diagnosis of *M. pneumoniae* infections is problematic because culture is not performed in most laboratories, microscopy has no value for diagnosis, and serology is insensitive. The best diagnostic test is PCR for species-specific targets.

Table 33.1 Important Mycoplasmataceae

Organism	Site	Human Disease
Mycoplasma pneumoniae	Respiratory tract	Tracheobronchitis, pharyngitis, pneumonia, secondary complications (neurologic, pericarditis, hemolytic anemia, arthritis, mucocutaneous lesions)
M. genitalium	Genitourinary tract	Nongonococcal urethritis, cervicitis, pelvic inflammatory disease
M. hominis	Respiratory tract, genitourinary tract	Pyelonephritis, postpartum fever, systemic infections in immunocompromised patients

occurs, after which first the cilia, then the ciliated epithelial cells, are destroyed. Loss of these cells interferes with the normal clearance of the upper airways and permits the bacteria to spread to the lower respiratory tract. This process is responsible for the persistent cough present in patients with symptomatic disease. *M. pneumoniae* functions as a superantigen, stimulating inflammatory cells to migrate to the site of infection and release cytokines, initially tumor necrosis factor (TFN)-α and interleukin (IL)-1 and later IL-6. This process contributes to both the clearance of the bacteria and the observed disease.

Some *Mycoplasma* species are able to change expression of surface lipoproteins rapidly, which is important for evading the host immune response and establishing persistent or chronic infections.

Epidemiology

M. pneumoniae is a strict human pathogen. Respiratory disease (e.g., tracheobronchitis, pneumonia) caused by *M. pneumoniae* occurs worldwide throughout the year, with no consistent increase in seasonal activity. Epidemic disease occurs every 4 to 8 years. Disease is most common in school-age children and young adults (ages 5 to 15 years), although all age groups are susceptible.

It has been estimated that 2 million cases of *M. pneumoniae* pneumonia and 100,000 pneumonia-related hospitalizations occur annually in the United States. However, *M. pneumoniae* disease is not a reportable disease, and reliable diagnostic tests are not widely available, so the true incidence is not known.

M. pneumoniae colonizes the nose, throat, trachea, and lower airways of infected individuals and is spread via large respiratory droplets during coughing episodes. Infection usually spreads among classmates, family members, or other close contacts. The attack rate is higher in children than in adults (overall average, ≈60%), presumably because most adults are partially immune from previous exposure. The incubation period and time of infectivity are prolonged, so disease can persist for months. *M. pneumoniae* is not part of the normal mucosa flora of humans; however, prolonged carriage can occur following symptomatic disease.

Genitourinary tract colonization with *M. hominis* and *M. genitalium* is common, increasing after puberty, corresponding to sexual activity. Approximately 15% of sexually active men and women are colonized with *M. hominis* and a higher proportion with *M. genitalium.* The incidence of carriage in adults who are sexually inactive is no greater than that in prepubertal children.

Clinical Case 33.1 *Mycoplasma pneumoniae* Pneumonia in a Young Adult

Caxboeck and associates (*Wien Klin Wochenschr* 119:379–384, 2007) described an unusual case of fatal *M. pneumoniae* pneumonia in a previously healthy 18-year-old woman. Before admission to the hospital, she had seen her physician with respiratory complaints and a chest radiograph consistent with pneumonia. A fluoroquinolone antibiotic was prescribed, but she failed to respond. On admission to the hospital, she had a temperature of 40° C and a productive cough. Her antibiotic was changed to a macrolide and cephalosporin; however, she continued to deteriorate, with progression of the pulmonary infiltrates, development of bilateral pleural effusions, and evidence of liver failure. Despite aggressive antibiotic therapy and respiratory support, her disease progressed to hemorrhagic pneumonia with multiorgan failure, and she died on hospital day 35. Diagnosis of *M. pneumoniae* infection was based on positive serology and the lack of other respiratory pathogens by microscopy, culture, and antigen testing. Although diagnosis by culture or polymerase chain reaction would be more convincing, the case illustrates the susceptibility of adults to mycoplasma infections and the uncommon but well-recognized occurrence of serious complications in susceptible patients. It also should be noted that this patient most likely had an undiagnosed immune defect that increased her susceptibility to this pathogen.

Clinical Diseases

Exposure to *M. pneumoniae* typically results in **asymptomatic carriage.** The most common clinical presentation of *M. pneumoniae* infection is **tracheobronchitis.** Low-grade fever; malaise; headache; and a dry, nonproductive cough develop 2 to 3 weeks after exposure. Acute **pharyngitis** may also be present. Symptoms gradually worsen over the next few days and can persist for 2 weeks or longer. The bronchial passages primarily become infiltrated with lymphocytes and plasma cells. Pneumonia (referred to as primary **atypical pneumonia** or walking pneumonia) can also develop, with a patchy bronchopneumonia seen on chest radiographs that is typically more impressive than the physical findings. Myalgias and gastrointestinal tract symptoms are uncommon. Secondary complications include neurologic abnormalities (e.g., meningoencephalitis, paralysis, myelitis), pericarditis, hemolytic anemia, arthritis, and mucocutaneous lesions (Clinical Case 33.1).

Because the genitourinary tract is colonized with other *Mycoplasma* species, it is difficult to determine the role of these organisms in disease in individual patients. However, it is accepted that *M. genitalium* can cause nongonococcal urethritis (NGU), cervicitis, and pelvic inflammatory disease; and *M. hominis* can cause pyelonephritis, postpartum fevers, and systemic infections in immunocompromised patients. The evidence implicating the organisms in these diseases is based on

Table 33.2 Diagnostic Tests for *Mycoplasma pneumoniae* Infections

Test	Assessment
Microscopy	Test is not useful because organisms do not have a cell wall and do not stain with conventional reagents
Culture	Test is slow (2 to 6 weeks before positive diagnosis) and insensitive; it is not available in most laboratories
Molecular diagnosis	Polymerase chain reaction–based amplification assays, with excellent sensitivity; specificity is not well defined
SEROLOGY	
Complement fixation	Antibody titers versus glycolipid antigens peak in 4 weeks and persist for 6 to 12 months; poor sensitivity and specificity; rarely used today
Enzyme immunoassays	Multiple assays are available, with varying sensitivity and specificity; assays directed versus P1 adhesin protein may be most specific
Cold agglutinin	Sensitivity and specificity poor, with cross-reactions with other respiratory pathogens (e.g., Epstein-Barr virus, cytomegalovirus, adenovirus); test commonly used but not recommended

detection of the bacteria in specimens from infected patients, a serologic response to the organism, clinical improvement after treatment with specific antibiotics, demonstration of disease in animal models, or a combination of these findings.

Laboratory Diagnosis

Microscopy is of no diagnostic value because mycoplasmas stain poorly with the Gram stain (Table 33.2). Likewise, antigen tests have poor sensitivity and specificity and are not recommended. The most sensitive diagnostic tests are nucleic acid amplification tests of species-specific gene targets, although the specificity for pathogenic mycoplasmas has not been established. *M. pneumoniae* can be isolated in culture from throat washings, bronchial washings, and expectorated sputum; however, the organisms grow slowly (generation time, 6 hours) and require special media supplemented with serum (provides sterols), yeast extract (for nucleic acid precursors), glucose, a pH indicator, and penicillin (to inhibit other bacteria). A positive culture result is definitive evidence of disease, but it is relatively **insensitive.** Serology tests are available for *M. pneumoniae.* A number of enzyme immunoassays for the detection of immunoglobulin (Ig)M and IgG antibodies are available. In general, the tests are more sensitive than culture. The disadvantage with these tests is that sera have to be collected early in the course of disease and then after 3 to 4 weeks to demonstrate a rise in antibody levels. Historically, it was also possible to measure nonspecific reactions to the outer membrane glycolipids of *M. pneumoniae* by the production of **cold agglutinins** (e.g., IgM antibodies that bind to antigens on the surface of human erythrocytes at 4° C). This test is insensitive and nonspecific, so it should not be performed. *M. hominis* is a facultative anaerobe that grows within 1 to 4 days. The colonies have a typical large, fried-egg appearance, and inhibition of their growth with specific antisera is used to differentiate them from other genital mycoplasmas. *M. genitalium* grows extremely slowly in culture so the diagnostic test of choice is nucleic acid amplification.

Treatment, Prevention, and Control

Macrolides (e.g., azithromycin), tetracyclines (particularly doxycycline), and fluoroquinolones are effective in treating *M. pneumoniae* infections, although the tetracyclines and fluoroquinolones are reserved for use in adults. Azithromycin is widely used for treating *M. pneumoniae* infections, although resistance has become common in some regions (e.g., greater than 90% in Asia). *M. genitalium* is commonly resistant to macrolides (e.g., azithromycin) and fluoroquinolones, so treatment of many infections is problematic. *M. hominis* is resistant to macrolides and occasionally to the tetracyclines. Clindamycin has been used to treat infections caused by these resistant strains.

The prevention of *Mycoplasma* disease is problematic. *M. pneumoniae* infections are spread by close contact; thus the isolation of infected people could theoretically reduce the risk of infection. Isolation is impractical, however, because patients are typically infectious for a prolonged period, even while receiving appropriate antibiotics. Inactivated vaccines and attenuated live vaccines have also proved disappointing. The protective immunity conferred by infection has been low. Infections with *M. hominis* and *M. genitalium* are transmitted by sexual contact; therefore these diseases can be prevented by avoidance of unprotected sexual activity.

Case Study and Questions

Increased lethargy, headache, cough, a low-grade fever, and chills and sweats at night developed in a 21-year-old university student. When she was seen at the student health center, she had a nonproductive cough and shortness of breath on exertion. Her pulse rate was 95 beats/min, and her respiratory rate was 28 breaths/min. Her pharynx was erythematous; scattered rhonchi and rales were found, but no consolidation was noted on auscultation. Results of a chest radiograph showed patchy infiltrates. A Gram stain of sputum revealed many white blood cells but no organisms. The antibody titer for a *Mycoplasma* complement fixation test performed on a specimen collected at admission was 1:8; the titer for a specimen collected a week later was 1:32. The patient was treated with erythromycin, to which her disease responded slowly during the next 2 weeks.

1. If cultures were performed, what would be the best specimen? When would the results be available? What are the sensitivity and specificity of culture in a patient infected with *M. pneumoniae*?

2. Describe the epidemiology of *M. pneumoniae* infections. What aspects of this case are characteristic of such infections?

34 Rickettsia, Ehrlichia, *and Related Bacteria*

A 24-year-old man living in North Carolina came to the local emergency department because of fever, arthralgias, myalgias, and malaise. He was well until 4 days before admission, when he developed a fever reaching 40°C, chills, severe headache, and muscle aches. Physical examination revealed a critically ill man with a temperature of 39.7°C, pulse of 110 beats/min, respiratory rate of 28 breaths/min, blood pressure of 100/60 mm Hg, and a rash over his extremities, including his palms and soles. The patient recalled having had numerous tick bites 10 days before the onset of symptoms. Rocky Mountain spotted fever was considered in the diagnosis, and serologic tests for Rickettsia species confirmed this diagnosis.

1. What antibiotics can be used to treat this infection? Which antibiotics should not be used?
2. Which rickettsiae are associated with the following vectors: ticks, lice, mites, and fleas?
3. Why is use of the Gram stain inappropriate for the diagnosis of rickettsial infections?
4. *Ehrlichia* and *Anaplasma* have been historically associated with *Rickettsia.* Compare clinical disease caused by *Ehrlichia chaffeensis* and *A. phagocytophilum.*
5. What clinical diseases are caused by *Coxiella burnetii?*

Answers to these questions are available on Student Consult.com.

Summaries Clinically Significant Organisms

RICKETTSIA RICKETTSII

Trigger Words

Intracellular bacteria, Rocky Mountain spotted fever, vasculitis, tick, microimmunofluorescence test

Biology and Virulence

- Small intracellular bacteria
- Stain poorly with Gram stain; best with Giemsa or Gimenez stains
- Replication occurs in cytoplasm and nucleus of endothelial cells, with resulting vasculitis
- Intracellular growth protects the bacteria from immune clearance

Epidemiology

- *R. rickettsii* is the most common rickettsial pathogen in the United States
- Hard ticks (e.g., dog tick, wood tick) are the primary reservoirs and vectors
- Transmission requires prolonged contact
- Distribution in Western Hemisphere; in United States, the majority of infections are reported in five states: North Carolina, Oklahoma, Arkansas, Tennessee, and Missouri
- Disease is most common from April through September

Diseases

- Rocky Mountain spotted fever characterized by high fever, severe headache, myalgias, and rash; complications common in untreated patients or where diagnosis is delayed

Diagnosis

- Serology (e.g., microimmunofluorescence test) is used most commonly for diagnosis

Treatment, Prevention, and Control

- Doxycycline is the drug of choice
- People should avoid tick-infested areas, wear protective clothing, and use effective insecticides
- People should remove attached ticks immediately
- No vaccine is currently available

RICKETTSIA PROWAZEKII

Trigger Words

Intracellular bacteria, louse-borne typhus, Brill-Zinsser disease, vasculitis, human reservoir, microimmunofluorescence test

Biology and Virulence

- Small intracellular bacteria
- Stain poorly with Gram stain; best with Giemsa or Gimenez stains
- Replicate in cytoplasm of endothelial cells, with resulting vasculitis
- Intracellular growth protects the bacteria from immune clearance

Epidemiology

- Humans are the primary reservoir, with person-to-person transmission by louse vector
- It is believed that sporadic disease is spread from squirrels to humans via squirrel fleas
- Recrudescent disease can develop years after initial infection
- People at greatest risk are those living in crowded, unsanitary conditions
- Disease is worldwide, with most infections in Central and South America and Africa
- Sporadic disease is seen in the eastern United States

Diseases

- Epidemic typhus (louse-borne typhus) characterized by high fever, severe headache, and myalgias
- Recrudescent typhus (Brill-Zinsser disease) is a milder form of the disease

Diagnosis

- The microimmunofluorescence test is the test of choice

Treatment, Prevention, and Control

- Doxycycline is the drug of choice
- Controlled through improvements in living conditions and reduction of the lice population through use of insecticides
- Inactivated vaccine is available for high-risk populations

EHRLICHIA AND ANAPLASMA

Trigger Words

- Intracellular bacteria, monocytic and granulocytic disease, ticks

Biology and Virulence

- Small intracellular bacteria that stain poorly with Gram stain; best with Giemsa or Gimenez stains
- Replicates in phagosome of infected cells
- Intracellular growth protects bacteria from immune clearance
- Able to prevent fusion of phagosome with lysosome of monocytes or granulocytes
- Initiates inflammatory response that contributes to pathology

Epidemiology

- Depending on the species of *Ehrlichia,* important reservoirs are white-tailed deer, white-footed mouse, chipmunks, voles, and canines

Continued

Summaries Clinically Significant Organisms—cont'd

- Ticks are important vectors, but transovarian transmission in inefficient
- Disease in United States is most common in the southeastern, Mid-Atlantic, midwestern, and south central states
- People at greatest risk are those exposed to ticks in the endemic areas
- Disease is most common from April to October

Diseases

- Diseases are human monocytic ehrlichiosis and human anaplasmosis (formerly called *human granulocytic ehrlichiosis*)

Diagnosis

- Microscopy of limited value
- Serology and nucleic acid amplification tests are methods of choice

Treatment, Prevention, and Control

- Doxycycline is the drug of choice; rifampin is an acceptable alternative
- Prevention involves avoidance of tick-infested areas, use of protective clothing and insect repellents, and prompt removal of embedded ticks
- Vaccines are not available

COXIELLA BURNETII

Trigger Words

Intracellular bacteria, flulike illness, subacute endocarditis, inhalation exposure, phase I and II antigens

Biology and Virulence

- Small intracellular bacteria that stain poorly with Gram stain; best with Giemsa or Gimenez stains
- Replicate in phagosomes of infected cells
- Exists in two forms: small cell variant infectious, extremely stable to environmental factors; large cell variant is the metabolically active form
- Phase transition occurs during infection: phase I with intact LPS, phase II with truncated LPS (O-antigen sugars missing)
- Intracellular growth protects the bacteria from immune clearance
- Able to replicate in acidic environment of phagosomes
- Extracellular form extremely stable; can survive in nature for a prolonged period

Epidemiology

- Many reservoirs, including mammals, birds, and ticks
- Most human infections associated with contact with infected cattle, sheep, goats, dogs, and cats
- Most disease acquired through inhalation; possible disease from consumption of contaminated milk; ticks are not an important vector for human disease
- Worldwide distribution
- No seasonal incidence

Diseases

- Most infections are asymptomatic; most common acute presentation is nonspecific influenza-like syndrome; less than 5% develop significant acute disease (pneumonia, hepatitis, pericarditis, fever)
- Endocarditis most common form of chronic disease

Diagnosis

- Detection of antibody response to phase I and phase II antigens is test of choice

Treatment, Prevention, and Control

- Doxycycline is the drug of choice for acute infections; hydroxychloroquine combined with doxycycline is used to treat chronic infections
- Phase I antigen vaccines are protective and safe if administered in a single dose before the animal or human has been exposed to *Coxiella;* not available in the United States for animals or humans

LPS, Lipopolysaccharide.

All of the bacteria discussed in this chapter were at one time classified in the family Rickettsiaceae, based on the observation that they were obligate aerobic, intracellular, gram-negative rods. Analysis of their deoxyribonucleic acid (DNA) sequences revealed that this classification was invalid, so three separate families were created: Rickettsiaceae with two genera, ***Rickettsia*** and ***Orientia;*** Anaplasmataceae with two genera, ***Ehrlichia*** and ***Anaplasma;*** and Coxiellaceae with **Coxiella** (Table 34.1).

Rickettsiaceae

The family Rickettsiaceae consists of two genera, *Rickettsia* and *Orientia,* and the genus *Rickettsia* is subdivided into the **spotted fever group** and the **typhus group.** Many species of *Rickettsia* in the spotted fever group are associated with human disease; however, only ***R. rickettsii*** (Rocky Mountain spotted fever) and ***R. akari*** (rickettsialpox) are discussed in this chapter. Two species of *Rickettsia* are members of the typhus group: *R. prowazekii* and *R. typhi.* A single species is in the genus *Orientia,* ***O. tsutsugamushi,*** is the organism responsible for the disease scrub typhus.

PHYSIOLOGY AND STRUCTURE

The organisms of the family Rickettsiaceae are small (0.3 × 1 to 2 μm), structurally similar to gram-negative rods, and grow only in the cytoplasm of eukaryotic cells. The cell wall structures of *Rickettsia* are typical of gram-negative rods, with a peptidoglycan layer and lipopolysaccharide (LPS); however, the peptidoglycan layer is minimal (stains poorly with the Gram stain), and the LPS has only weak endotoxin activity. *Orientia* lacks both the peptidoglycan layer and LPS. Both groups of organisms are seen best with Giemsa or Gimenez stains (Fig. 34.1).

Rickettsia and *Orientia* are strict intracellular parasites found free in the cytoplasm of infected cells. The bacteria enter eukaryotic cells by attaching to host cell surface receptors and stimulating phagocytosis. After engulfment, *Rickettsia* and *Orientia* degrade the phagosome membrane by producing a phospholipase and must be released into the cytoplasm or they will not survive. Multiplication in the host cell by binary fission is slow (generation time, 9 to 12 hours). The spotted fever group of *Rickettsia* and *Orientia* grow in the cytoplasm and nucleus of infected cells and are continually released from cells through long cytoplasmic projections. In contrast, the typhus group accumulates in the cell cytoplasm until the cell membranes lyse, signaling cell death and bacterial release. It is believed that the fundamental difference is caused by intracellular motility; the spotted fever group is able to polymerize host cell actin, whereas the typhus group lacks the required gene. Once these bacteria are released from the host cell, they are unstable and die quickly.

The genome of *R. prowazekii* has been sequenced, providing insight about the parasitic nature of these bacteria.

TABLE 34.1 *Rickettsia, Orientia, Ehrlichia, Anaplasma,* and *Coxiella*

Organism	Historical Derivation
Rickettsia rickettsii	Named after Howard Ricketts, who implicated the wood tick as the vector of Rocky Mountain spotted fever
R. akari	*akari,* mite; the vector of rickettsialpox
R. prowazekii	Named after Stanislav von Prowazek, an early investigator of typhus who was a victim of this disease
R. typhi	*typhi,* typhus or fever
Orientia tsutsugamushi	*Orientia,* Orient; *tsutsugamushi,* "mite disease," the popular name of this disease in the Orient
Ehrlichia	Named after the German microbiologist Paul Ehrlich
E. chaffeensis	First isolated in an Army reservist at Fort Chaffee, Arkansas
E. ewingii	Named after the American microbiologist William Ewing
Anaplasma	*an,* without; *plasma,* anything formed (a thing without form; referring to the intracytoplasmic inclusions)
A. phagocytophilum	*phago,* to eat; *kytos,* a vessel or enclosure; *philein,* to love (found in phagocytes)
Coxiella burnetii	Named after Herald Cox and F.M. Burnet who isolated the bacterium from ticks in Montana and patients in Australia, respectively

The bacteria depend on their host cell for many functions: carbohydrate metabolism, lipid biosynthesis, nucleotide synthesis, and amino acid synthesis. Additionally, the bacteria are able to produce adenosine triphosphate (ATP) by means of the tricarboxylic acid cycle, or they can act as energy parasites using the host cell ATP as long as it is available.

PATHOGENESIS AND IMMUNITY

A good model for rickettsial infections is *R. rickettsii,* which is the agent responsible for **Rocky Mountain spotted fever** and the most common rickettsia causing human disease in the United States. There is no evidence that *R. rickettsii* produces toxins or that the host's immune response is responsible for the pathologic manifestations of Rocky Mountain spotted fever. The **outer membrane protein A (OmpA)** expressed on the surface of *R. rickettsii* is responsible for the ability of the bacteria to adhere to endothelial cells. After the bacteria penetrate into the cell, they are released from the phagosome, freely multiply in both the cytoplasm and nucleus, and move from cell to adjacent cell. The primary clinical manifestations appear to result from the replication of bacteria in endothelial cells, with subsequent damage to the cells and leakage of the blood vessels. Hypovolemia and hypoproteinemia caused by the loss of plasma into tissues can lead to reduced perfusion of various organs and organ failure. The host immune response to infection is based on cytokine-mediated intracellular killing and clearance by cytotoxic CD8 lymphocytes. Antibody response to rickettsial outer membrane proteins may also be important.

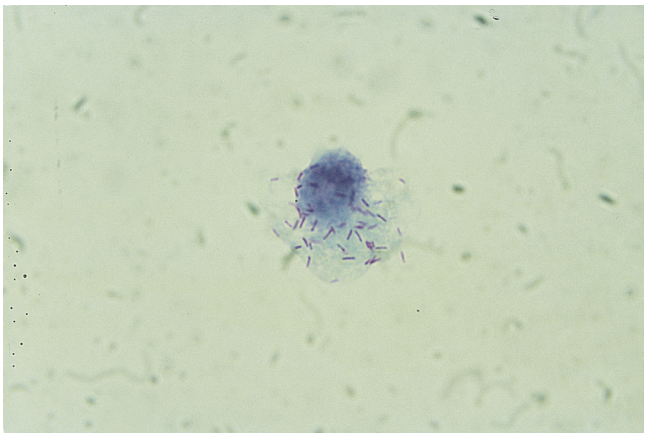

Fig. 34.1 Gimenez stain of tissue culture cells infected with spotted fever group *Rickettsia.* (From Cohen, J., Powderly, W.G., 2004. Infectious Diseases, second ed. Mosby, St Louis, MO.)

EPIDEMIOLOGY

The pathogenic species of *Rickettsia* and *Orientia* are maintained in animal and arthropod reservoirs and are transmitted by arthropod vectors (e.g., ticks, mites, lice, fleas; Table 34.2). Humans are accidental hosts. Rickettsiae are maintained in reservoir hosts (primarily rodents) and their arthropod vectors (e.g., ticks, mites, fleas). Because **transovarian transmission** occurs in arthropods, they can serve as both vector and host. The exception to this is *R. prowazekii,* for which humans are the primary host and the arthropod vector is the human body louse. The bacteria kill the louse, so transovarian transmission is not important.

The distribution of rickettsial diseases is determined by the distribution of the arthropod host/vector. Most infections with tick vectors (e.g., spotted fevers) have a restricted geographic distribution, whereas rickettsial infections with other vectors, such as lice *(R. prowazekii),* fleas *(R. typhi),* and mites *(R. akari, O. tsutsugamushi),* have worldwide distribution (see Table 34.2).

In 2017, more than 6200 cases of Rocky Mountain spotted fever were reported in the United States. More than 90% of the infections occurred from **April to September,** corresponding to the period of greatest tick activity, with the majority of infections reported in North Carolina, Oklahoma, Arkansas, Tennessee, and Missouri. The principal reservoir and vector for *R. rickettsia* are **hard ticks** in the family Ixodidae. The three hard ticks most commonly associated with disease in the United States are the **American dog tick *(Dermacentor variabilis)*** in the southeastern states and on the West Coast, the **brown dog tick (*Rhipicephalus sanguineus*)** in Arizona, and the **wood tick *(D. andersoni)*** in the Rocky Mountain States and southwestern Canada. Other tick vectors have been identified in Central and South America. A person must be exposed to the tick for a lengthy period (e.g., ≥6 hours) before transmission occurs. The dormant avirulent rickettsiae are activated by the warm blood meal and then released from the tick salivary glands into the blood of the human host.

TABLE 34.2 Epidemiology of Infections Caused by *Rickettsia* and Related Bacteria

Organism	Disease	Reservoir	Vector	Distribution
Rickettsia rickettsii	Rocky Mountain spotted fever	Ticks, wild rodents	Hard ticks (dog tick, wood tick)	Western Canada, continental United States, Mexico, Panama, Argentina, Brazil, Bolivia, Colombia, Costa Rica
R. akari	Rickettsialpox	Mites (chiggers), wild rodents	Mites	North America (particularly urban areas of northeastern United States), Mexico, Europe (e.g., Croatia, Ukraine, Turkey), Asia (e.g., Korea), Africa
R. prowazekii	Epidemic (louse-borne) typhus	Humans	Human body louse	Mountainous regions of Central and Eastern Africa (Burundi, Rwanda, Ethiopia), Central and South America, Asia
	Recrudescent typhus	Humans	Relapse disease	Worldwide
	Sporadic typhus	Flying squirrels, squirrel fleas and lice	Possibly squirrel fleas	United States
R. typhi	Endemic (murine) typhus	Cats, opossums, raccoons, skunks, wild rodents	Cat flea, rat flea	Worldwide
Orientia tsutsugamushi	Scrub typhus	Mites (chiggers), wild rodents	Mites	Japan, Eastern Asia, Northern Australia, Western and Southwestern Pacific
Ehrlichia chaffeensis	Human monocytic ehrlichiosis	Deer, dogs, foxes, coyotes, and wolves	Soft ticks (lone star tick)	North and South America, Asia
E. ewingii	Human granulocytic ehrlichiosis	Dogs, deer	Soft ticks (lone star tick	North America (uncommon, Missouri)
Anaplasma phagocytophilum	Human granulocytic anaplasmosis	Small mammals (rodents, chipmunks, voles), deer, sheep	Soft ticks (Blacklegged tick)	North America (Upper Midwest and Northeast), Europe, Asia
Coxiella burnetii	Q fever	Mammals, birds, ticks	Ticks incidental (most infections after inhalation)	Worldwide

R. akari, the agent responsible for causing **rickettsialpox,** is one of the few rickettsiae in the spotted fever group that have a **cosmopolitan** distribution and are transmitted by infected **mites.** Culture-confirmed disease has been reported from Ukraine, Croatia, Korea, and the United States, primarily in the New York City area. A cluster of cases was documented in New York City after the release of *Bacillus anthracis* in 2001, when biopsies of eschars from city residents were demonstrated to contain *R. akari* and not *B. anthracis*. Based on this experience, it is likely that rickettsialpox is underdiagnosed in endemic areas. Infections with *R. akari* are maintained in the rodent population through the bite of mouse ectoparasites (e.g., mites) and in mites by transovarian transmission. Humans become accidental hosts when bitten by infected mites.

R. prowazekii, one of two members of the typhus group of rickettsiae, is the etiologic agent of **epidemic** or **louse-borne typhus. Humans** are the principal reservoir of this disease, and the vector is the **human body louse,** *Pediculus humanus*. Epidemic typhus occurs among people living in crowded, unsanitary conditions that favor the spread of body lice; for example, conditions such as those that arise during wars, famines, and natural disasters. Lice die from their infection within 2 to 3 weeks, preventing transovarian transmission of *R. prowazekii*. The disease is present in Central and South America, Africa, and less commonly in the United States.

The incidence of the disease in the United States is unknown because it is not a disease reportable to public health departments. Sporadic disease in the United States is primarily restricted to rural areas of the eastern states. In this area, **flying squirrels** and squirrel fleas and lice are infected with *R. prowazekii.* Squirrel lice do not feed on humans, but the fleas are less discriminating and may be responsible for transmitting the *Rickettsia* from squirrels to humans. Epidemiologic and serologic evidence supports this hypothesis.

Recrudescent disease with *R. prowazekii* **(Brill-Zinsser disease)** can occur in people years after their initial infection. Such people in the United States are primarily Eastern European immigrants who were exposed to the typhus epidemic during World War II.

Endemic or murine typhus is caused by *R. typhi.* Disease is distributed worldwide primarily in warm, humid areas. In the United States, 50 to 100 cases are reported annually, with most cases in the Gulf States (especially Texas) and Southern California. Endemic disease continues to be reported in people living in the temperate and subtropical coastal areas of Africa, Asia, Australia, Europe, and South America. **Rodents** are the primary reservoir, and the **rat flea** *(Xenopsylla cheopis)* is the principal vector. However, the **cat flea** *(Ctenocephalides felis),* which infests cats, opossums, raccoons, and skunks, is considered an

important vector for disease in the United States. Most cases occur during the warm months.

O. tsutsugamushi is the etiologic agent for **scrub typhus,** which is a disease transmitted to humans by **mites** (chiggers, red mites). The reservoir is the mite population, in which the bacteria are transmitted by transovarian means. Infection is also present in the **rodent** population, which can serve as a reservoir for mite infections. Rodents are not believed to be an important reservoir for human disease because mites feed only once during their life, so they cannot transmit infection from rodents to humans. Scrub typhus is present in people living in eastern Asia, Australia, and Japan and other Western Pacific islands. It can also be imported into the United States.

Clinical Case 34.1 **Rocky Mountain Spotted Fever**

Oster and associates (*N Engl J Med* 297:859–863, 1977) described a series of patients who acquired Rocky Mountain spotted fever after working with *Rickettsia rickettsii* in the laboratory. One patient, a 21-year-old veterinary technician, presented to a clinic with complaints of myalgia and a nonproductive cough. He was treated with penicillin and discharged. Over the next few days, he developed chills and a headache. When he returned to the hospital, he had a temperature of 40.0° C and a macular rash on his extremities and trunk. Intramuscular tetracycline was started, but he remained febrile, and the rash evolved to petechiae on his truck, his extremities, and the soles of his feet. Bilateral pleural effusions developed, and intravenous tetracycline was begun. Over the next 2 weeks, the effusions resolved and the patient made a slow but uneventful recovery. Although this patient was not working directly with *R. rickettsiae,* he had visited a laboratory that was processing the bacterium. This patient illustrates the characteristic presentation of Rocky Mountain spotted fever—headache, fever, myalgias, and a macular rash—which can evolve into a petechial or spotted rash.

CLINICAL DISEASES

Symptomatic Rocky Mountain spotted fever (Clinical Case 34.1) develops 7 days (range, 2 to 14 days) after the tick bite (Table 34.3), although the patient may not recall the painless tick bite. The onset of disease is heralded by a high fever and headache that may be associated with malaise, myalgias, nausea, vomiting, abdominal pain, and diarrhea. A macular rash develops in 90% of patients after 3 days, initially on the wrists, arms, and ankles and then spreading to the trunk. The palms and soles can also be involved. The rash can evolve to the "spotted" or petechial form, which is a harbinger of more severe disease. Complications of Rocky Mountain spotted fever include neurologic manifestations, pulmonary and renal failure, and cardiac abnormalities. A delay in diagnosis, either because the clinical presentation is not characteristic or the physician does not recognize the disease, is associated with a worse prognosis. The fatality rate in untreated disease is 10% to 25%.

Clinical infection with *R. akari* (rickettsialpox) is biphasic. First a papule develops at the site in which the mite bites the host. The papule appears approximately 1 week after the bite and quickly progresses to ulceration and then **eschar formation.** During this period, the rickettsiae spread systemically. After an incubation period of 7 to 24

TABLE 34.3 Human Diseases Caused by *Rickettsia* and Related Bacteria

Disease	Average Incubation Period (Days)	Clinical Presentation	Rash	Eschar	Mortality without Treatment (%)
Rocky Mountain spotted fever	7	Abrupt onset; fever, headache, malaise, myalgias, nausea, vomiting, abdominal pain	>90%; macular; centripetal spread	No	10–25
Rickettsialpox	9–14	Abrupt onset; fever, headache, chills, myalgias, photophobia	100%; papulovesicular; generalized	Yes	Low
Epidemic typhus	8	Abrupt onset; fever, headache, chills, myalgias, arthralgia	20%–80%; macular; centrifugal spread	No	20
Endemic typhus	7–14	Gradual onset; fever, headache, myalgias, cough	50%; maculopapular rash on trunk	No	Low
Scrub typhus	10–12	Abrupt onset; fever, headache, myalgias	<50%; maculopapular rash; centrifugal	No	1–15
Human monocytic ehrlichiosis	7–14	High fever, headache malaise, myalgias; leukopenia, thrombocytopenia, elevated serum transaminases	Rash (more common in children than in adults)	No	2–3
Human granulocytic ehrlichiosis	7–14	High fever, headache malaise, myalgias	Rash	No	Insufficient data
Human granulocytic anaplasmosis	5–10	High fever, headache, malaise, myalgias, leukopenia, thrombocytopenia, elevated serum transaminases	Rash in <10% of patients	No	<1
Q fever	10–14	Abrupt onset; high fever, headache, malaise, myalgias; may progress to hepatitis, pneumonia, or subacute endocarditis (chronic Q fever)	No	No	<5

Clinical Case 34.2 **Rickettsialpox in New York City**

Koss and associates (*Arch Dermatol* 139:1545–1552, 2003) described 18 patients with rickettsialpox who were diagnosed at Columbia Presbyterian Medical Center in New York City during a 20-month period after the anthrax bioterrorism attack in the fall of 2001. The patients presented to the hospital because they had a necrotic eschar and were thought to have cutaneous anthrax. The patients also had fever, headache, and a papulovesicular rash. Many patients also complained of myalgias, sore throat, arthralgias, and gastrointestinal symptoms. Immunohistochemical staining of eschar and skin biopsies confirmed the diagnosis of rickettsialpox and not cutaneous anthrax. These patients illustrate the diagnostic difficulties of recognizing uncommon diseases even when the clinical presentation is characteristic.

days (average, 9 to 14 days), the second phase of the disease develops abruptly, with high **fever,** severe headache, chills, sweats, myalgias, and photophobia. A generalized **papulovesicular rash** forms within 2 to 3 days. A poxlike progression of the rash is then seen, in which vesicles form and then crust over. Presence of the rash distinguishes this disease from anthrax and, in a patient with a high fever and eschar, should raise suspicion of rickettsialpox. Despite the appearance of the disseminated rash, rickettsialpox is usually mild and uncomplicated, and complete healing is seen within 2 to 3 weeks without treatment (Clinical Case 34.2).

In one study of epidemic typhus in Africa, clinical disease developed an average of 8 days after exposure (range, 2 to 30 days). Most of the patients initially had nonspecific symptoms, then within 1 to 3 days, high **fever,** severe **headache,** and **myalgias.** Other symptoms can include pneumonia, arthralgia, and neurologic involvement (stupor, confusion, coma). A petechial or macular rash develops in many patients, but this may be obscured in darkly pigmented individuals. The mortality rate in the absence of treatment is 20% to 30% but may be much higher in populations with poor general health and nutrition and lacking proper supportive medical care. In patients with uncomplicated disease, the body temperature returns to normal within 2 weeks, but complete convalescence may take 3 months or longer. The rickettsiae may remain dormant for years and then reactivate to cause recrudescent epidemic typhus or Brill-Zinsser disease. At the time symptoms develop, bacteremia occurs and the patient is potentially infectious for lice. The course of this form of disease is generally milder and a rash is frequently absent, making diagnosis more difficult.

The incubation period for *R. typhi* disease (murine typhus) is 7 to 14 days. The symptoms appear abruptly, with fever, severe headache, chills, myalgias, and nausea most common. A rash develops in approximately half of infected patients, most commonly late in the illness. It is typically restricted to the chest and abdomen. The course of disease is generally uncomplicated, lasting less than 3 weeks even in untreated patients.

O. tsutsugamushi disease (scrub typhus) develops suddenly after a 6- to 18-day incubation period (average, 10 to 12 days), with severe **headache, fever,** and **myalgias.** A macular to papular rash develops on the trunk in less than half of patients and spreads centrifugally to the extremities. Generalized lymphadenopathy, splenomegaly, central nervous system complications, and heart failure can occur. Fever in untreated patients disappears after 2 to 3 weeks.

LABORATORY DIAGNOSIS

Microscopy

Although rickettsiae stain poorly with Gram stain, they can be stained with Giemsa or Gimenez stains. Specific fluorescein-labeled antibodies can also be used to stain the intracellular bacteria in biopsy tissue specimens. This direct detection of *R. rickettsiae* antigens is a rapid, specific method for confirming the clinical diagnosis of Rocky Mountain spotted fever but is primarily available only through reference laboratories.

Nucleic Acid–Based Tests

Specific nucleic acid amplification tests (NAATs) are now used in many reference laboratories for the diagnosis of rickettsial diseases. Unfortunately, these assays are relatively insensitive when blood samples are used.

Culture

Although isolation of rickettsiae in tissue culture systems or embryonated eggs is relatively easy, only reference laboratories with extensive experience with rickettsiae routinely perform these cultures. If culture is attempted, buffy coat preparations of blood or skin biopsy specimens should be processed.

Antibody Detection

Although the **Weil-Felix test** (which involves the differential agglutination of cross-reacting *Proteus* antigens) has been used historically for the diagnosis of rickettsial infections, it is no longer recommended, because it is insensitive and nonspecific. Unfortunately, this test is still used in laboratories with limited resources. The serology test that is considered the reference method is the **microimmunofluorescence (MIF)** test. This test detects antibodies directed against outer membrane proteins (species specific) and the LPS antigen. Because the LPS antigen is shared among rickettsial species, the **Western blot immunoassay** must be performed to define the individual species. The sensitivity and specificity of MIF is high, with diagnostic levels of antibodies generally detected in the second week of illness. Commercially prepared enzyme immunoassays are also available but generally have a lower sensitivity and specificity when compared with MIF.

TREATMENT, PREVENTION, AND CONTROL

The drug of choice for treating all rickettsial infections is **doxycycline.** Although tetracyclines are generally contraindicated for pregnant women and young children, this antibiotic is recommended for all patients with suspected rickettsial disease because it is the most effective antibiotic and inadequately treated disease is associated with a high morbidity and mortality. Fluoroquinolones (e.g., ciprofloxacin) have good in vitro activity, but clinical experience is inadequate to recommend this for primary therapy. Chloramphenicol also

has activity in vitro against rickettsiae, but its use for treatment of infections is associated with a higher incidence of relapse. Prompt diagnosis and institution of appropriate therapy usually result in a satisfactory prognosis; unfortunately, this scenario may not occur if key clinical signs (e.g., rash) develop late or not at all. In addition, the serologic findings often are not available until 2 or more weeks after the onset of disease, also delaying the start of treatment. Therefore it is recommended that empirical therapy with doxycycline be started as soon as the diagnosis is considered.

Vaccines are not available for rickettsial disease except for louse-borne typhus. Prevention of disease involves avoiding tick-infested areas and use of protective clothing and insect repellents, and prompt removal of attached ticks. Rodent control is important for diseases in which these represent an important reservoir. Effective louse-control measures are used to manage epidemic typhus.

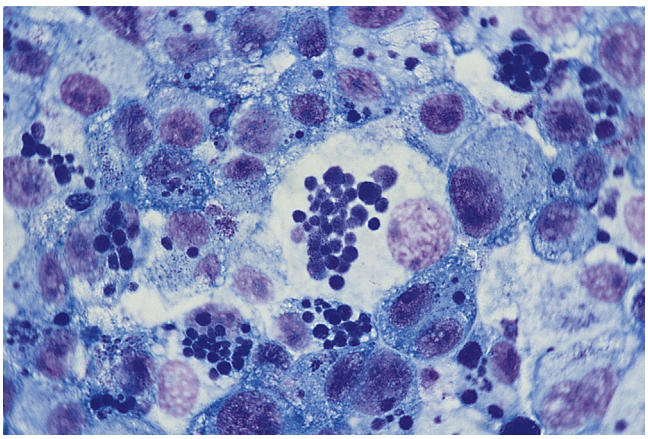

Fig. 34.2 Multiple morulae of *Ehrlichia canis (E. chaffeensis)* in DH82 tissue culture cells. (From Cohen, J., Powderly, W.G., 2004. Infectious Diseases, second ed. Mosby, St Louis, MO.)

Anaplasmataceae

The genera *Ehrlichia* and *Anaplasma* consist of intracellular bacteria that parasitize granulocytes, monocytes, erythrocytes, and platelets. Three species of these genera are important human pathogens: *E. chaffeensis,* responsible for **human monocytic ehrlichiosis;** *E. ewingii,* the etiologic agent of **human granulocytic ehrlichiosis;** and *A. phagocytophilum,* the agent for **human granulocytic anaplasmosis.**

PHYSIOLOGY AND STRUCTURE

In contrast with *Rickettsia* and *Orientia, Ehrlichia* and *Anaplasma* remain in the phagocytic vacuole after entry into the host cell. Fusion with lysosomes is prevented because expression of appropriate receptors on the phagocytic vacuole surface is interrupted. Thus the bacteria can multiply by binary fission in the phagosome without exposure to the hydrolytic lysosome enzymes. Two morphologic forms of the bacteria exist: small (0.2 to 0.4 μm) **elementary bodies** and larger (0.8 to 1.5 μm) **reticulate bodies.** A few days after the cell is infected, the replicating elementary bodies assemble into membrane-enclosed masses called **morulae** (Fig. 34.2). Progressive infection leads to lysis of the infected cell, release of bacteria, and subsequent infection of new cells. Detection of morulae when the cells are stained with **Giemsa** or **Wright stains** is a rapid, specific diagnostic test; however, relatively few infected cells may be seen, so a negative test is not helpful.

The cell wall structure of *Ehrlichia* and *Anaplasma* is similar to that of gram-negative bacteria; however, the bacteria lack genes for synthesis of peptidoglycan or LPS. In addition, many of the genes of the glycolytic pathway also are absent. A number of protein antigens are shared among species in these genera, as well as with species of other genera. For this reason, cross-reactive antibodies are commonly observed in serologic assays.

PATHOGENESIS AND IMMUNITY

The intracellular location of the organisms protects them from the host's antibody response. However, bacterial stimulation of proinflammatory cytokine production is believed to play an important role in activating macrophages that act either directly on infected cells or on antibody-opsonized bacteria during their extracellular phase.

EPIDEMIOLOGY

The first human infection in the United States with these organisms was reported in 1986. In 2017, almost 8000 cases of ehrlichiosis and anaplasmosis were reported in the United States. The prevalence of this disease is underestimated because serologic studies have shown that antibodies to *E. chaffeensis* are at least as common as antibodies to *R. rickettsii,* which has a similar geographic distribution. *E. chaffeensis* disease in the United States is found predominantly in the Midwest (Missouri, Arkansas, Oklahoma) and coastal Atlantic (Maryland, Virginia, New Jersey, New York) states. This area corresponds to the geographic distribution of *Amblyomma americanum* (lone star tick), which is the primary vector responsible for transmitting the organism, and of white-tailed deer, which are an important reservoir for *E. chaffeensis*. Other animals that can serve as hosts include domestic dogs, foxes, coyotes, and wolves. *E. ewingii* is relatively uncommon and has been primarily reported in Missouri (see Table 34.2).

Disease caused by *A. phagocytophilum* is found primarily in the upper midwestern states (Minnesota, Wisconsin) and northeast Atlantic states (Massachusetts, Connecticut, New York, New Jersey). The reservoirs are small mammals (e.g., white-footed mouse, chipmunks, voles), and the vectors are *Ixodes* ticks. More than 90% of all disease caused by *Ehrlichia* and *Anaplasma* in the United States occurs between mid-April and late October.

Transovarian transmission of *Ehrlichia* and *Anaplasma* in ticks does not occur (in contrast with *Rickettsia* and *Orientia*), so these bacteria must be maintained in reservoir vertebrate hosts. Ticks become infected when an immature stage (e.g., larva, nymph) ingests blood from a naturally infected host and then transmits the bacteria to another mammalian host (e.g., human) during the next blood meal. Humans are accidental hosts; thus transmission terminates at this stage.

CLINICAL DISEASES

Human Monocytic Ehrlichiosis

Human monocytic ehrlichiosis is caused by *E. chaffeensis* after infection of blood monocytes and mononuclear phagocytes in tissues and organs. Approximately 1 to 2 weeks after a tick bite, patients develop a flulike illness with **high fever,** headache, malaise, and myalgias. A late-onset **rash** develops in 30% to 40% of patients (more common in children than in adults). **Leukopenia, thrombocytopenia,** and **elevated serum transaminases** develop in the majority of patients and can range from mild to severe. Although mortality is low (2% to 3%), more than half the infected patients require hospitalization and experience a prolonged recovery period. A fulminant septic syndrome can develop, particularly in immunocompromised patients. The pathology of this infection is disproportionate to the number of infected cells or microbial burden present in tissue. It is believed that *E. chaffeensis* disturbs mononuclear phagocytic function and regulation of the inflammatory response. Thus the immune response both eliminates the pathogen and produces much of the tissue damage.

Human (Canine) Granulocytic Ehrlichiosis

E. ewingii primarily causes disease in canines, with humans acting as the accidental hosts. Because there is serologic cross-reactivity between *E. ewingii* and *E. chaffeensis,* the incidence of infections with this organism is likely to be underestimated. The clinical presentation is similar to that of *E. chaffeensis,* with fever, headaches, and myalgias. Leukopenia, thrombocytopenia, and elevated serum transaminases also are seen.

Human Anaplasmosis

Human granulocytic anaplasmosis is caused by *A. phagocytophilum*. (Clinical Case 34.3) Granulocytes (i.e., neutrophils, eosinophils, basophils) are primarily infected. The disease presents 5 to 10 days after exposure as a flulike illness with a high fever, headache, malaise, and myalgias; a rash is observed in less than 10% of patients. As with human monocytic ehrlichiosis, leukopenia, thrombocytopenia, and serum transaminase elevation are observed in most patients. More than half the infected patients require hospitalization, and severe complications, particularly peripheral neuropathies (e.g., demyelinating polyneuropathy, facial palsy) can occur. Despite the potential severity of this disease, mortality is less than 1%. As with *E. chaffeensis* infections, the pathology of this disease appears related to macrophage activation.

LABORATORY DIAGNOSIS

The clinical presentation of *Ehrlichia* and *Anaplasma* infections is not distinctive, and although the geographic distribution of disease has limited overlap, laboratory testing is required for a definitive diagnosis. Microscopy has limited value because the bacteria stain poorly with the Gram stain, and detection of intracytoplasmic inclusions (clumps or organisms, morulae) in Giemsa-stained preparations of peripheral blood is only useful during the first week of illness. Morulae are detected in less than 10% of patients with monocytic ehrlichiosis and in 25% to 75% of patients with granulocytic anaplasmosis. Likewise, although *Ehrlichia* organisms have been cultured in vitro in established cell lines, this procedure is not performed in most clinical laboratories. The most common methods for laboratory diagnosis of ehrlichiosis are NAATs and serology. Species-specific DNA amplification tests are available in some reference laboratories and can provide a sensitive, specific diagnostic test for acute disease. An increase in the antibody titer is typically observed 3 to 6 weeks after the initial presentation, so these serologic tests are primarily confirmatory. Sensitivity of the NAATs and serology is reduced in patients receiving effective therapy. *E. chaffeensis* and *E. ewingii* are closely related and cannot be differentiated by serology. The specificity of the serology tests is compromised by cross-reactions with organisms responsible for Rocky Mountain spotted fever, Q fever, Lyme disease, brucellosis, and Epstein-Barr virus infections.

Clinical Case 34.3 **Human Anaplasmosis**

Heller and associates (*N Engl J Med* 352:1358–1364, 2005) described a 73-year-old man who presented to their hospital with fever, weakness, and leg myalgias. Six days before his admission, he had traveled to South Carolina, and 3 days later, he developed intense leg pains, a high fever, and generalized weakness. On admission, he was febrile, tachycardic, and hypertensive; the liver and spleen could not be palpated, and no cutaneous rash was noted. Cultures for bacteria, fungi, and viruses were negative. A peripheral blood smear showed rare intracytoplasmic inclusions in the granulocytes, suggestive of morulae. Polymerase chain reaction analysis of blood samples collected on the second and third hospital days were positive for *Anaplasma phagocytophilum* DNA, confirming the diagnosis of anaplasmosis. The patient was treated successfully with a 14-day course of doxycycline, although residual muscle weakness and pain persisted. Serum collected during the convalescent period was positive for *Anaplasma.* It is noteworthy that the patient did not remember a tick bite during his South Carolina trip, consistent with the observation that the early tick stages, larva and nymphs, are most commonly associated with human disease.

TREATMENT, PREVENTION, AND CONTROL

Patients with suspected ehrlichiosis and anaplasmosis should be treated with **doxycycline.** Therapy should not be delayed to wait for laboratory confirmation of the disease. Rifampin has been used to treat patients who are unable to tolerate doxycycline. Fluoroquinolones, penicillins, cephalosporins, chloramphenicol, aminoglycosides, and macrolides are ineffective. Infection is prevented by avoidance of tick-infested areas, wearing protective clothing, and use of insect repellents. Embedded ticks should be removed promptly. Vaccines are not available.

Coxiellaceae

COXIELLA BURNETII

C. burnetii are gram-negative bacteria that stain weakly with the Gram stain, grow intracellularly in eukaryotic

cells, and are associated with arthropods (e.g., **ticks**). The disease caused by *C. burnetii* is **Q (query) fever,** so named because the initial investigation of an outbreak in Australian abattoir workers did not identify the causal organism.

Physiology and Structure

Two structural forms of *C. burnetii* are recognized: **small cell variants** that are resistant to environmental stress (e.g., heat, desiccation, chemical agents) and **large cell variants** that are the metabolically active form. Additionally, *C. burnetii* undergoes a phase transition similar to what is observed in some other gram-negative bacteria. In the phase observed in nature **(phase I),** *C. burnetii* has an intact LPS; however, mutations can occur in the LPS genes, resulting in a molecule with lipid A and core sugars but missing the outermost O-antigen sugars **(phase II).** This phase variation is important for understanding the progression of disease and for diagnostic purposes.

Small cell variants attach to macrophages and monocytes and are internalized in a phagocytic vacuole. The normal progression after phagocytosis of most organisms is fusion of the phagosome with a series of endosomes (intracellular vesicles), resulting in a drop in intracellular pH, followed by fusion with lysosomes containing hydrolytic enzymes and resultant bacterial death. This occurs with *C. burnetii* if phase II organisms are ingested; however, phase I *Coxiella* is able to arrest this process before lysosomal fusion. In addition, the organisms require acid pH for their metabolic activities, which in turn protects them from the killing activities of most antibiotics.

Pathogenesis and Immunity

Slowly replicating intracellular pathogens must avoid programmed cell death (apoptosis), which is an important component of intrinsic immunity. *Coxiella* is able to regulate the cell signaling pathways in its phagocytic home so that cell death is delayed. The ability of *C. burnetii* to cause either acute or chronic disease is determined in part by the organism's ability to survive intracellularly. In the presence of interferon-γ, phagosome-lysosome fusion occurs, leading to bacterial death; however, in chronic infections, interleukin (IL)-10 is overproduced by the host cell, which interferes with fusion and allows intracellular survival of *C. burnetii*.

Epidemiology

C. burnetii is extremely stable in harsh environmental conditions and **can survive in soil and milk for months to years** (see Table 34.2). The range of hosts for *C. burnetii* is wide, with infections being found in mammals, birds, and numerous species of ticks. Farm animals, such as sheep, cattle, and goats, and recently infected cats, dogs, and rabbits, are the **primary reservoirs** for human disease. The bacteria can reach high concentrations in the placenta of infected livestock. Dried placentas left on the ground after parturition and feces, urine, and tick feces can contaminate soil, which in turn can serve as a focus for infection if these bacteria become airborne and are inhaled. Human infections occur after the **inhalation of airborne particles** from a contaminated environmental source or, less commonly, after ingestion of contaminated **unpasteurized milk** or other dairy products. Ticks do not transmit disease to humans.

Q fever has a worldwide distribution. Although fewer than 200 infections are reported annually in the United States, this figure is certainly an underestimation of the actual prevalence of the disease. Infection is common in livestock in the United States, but symptomatic disease in livestock is rare. Human exposure—particularly for ranchers, veterinarians, and food handlers—is frequent, and experimental studies have shown that the infectious dose of *C. burnetii* is small (≤10 bacteria). Thus most human infections are asymptomatic or mild, a finding confirmed by serologic studies that have shown that most persons with detectable antibodies do not have a history of disease. Infections also go undetected because diagnostic tests for *C. burnetii* are often not considered.

Clinical Diseases

The majority of individuals exposed to *C. burnetii* have an **asymptomatic infection,** and most symptomatic infections are mild, presenting with nonspecific **flulike symptoms** with an abrupt onset, high-grade fever, fatigue, headache, and myalgias. Less than 5% of infected persons develop symptoms severe enough to require hospitalization, with the most common presentations being **hepatitis, pneumonia,** or isolated **fevers.** Hepatitis is usually asymptomatic or presents with fever and increase in serum transaminases. Most cases of pneumonia are mild with a nonproductive cough, fever, and nonspecific findings on chest radiograph. Histologically, diffuse granulomas are typically seen in the involved organs. Chronic Q fever (symptoms lasting >6 months) can develop months to years after the initial exposure and occurs almost exclusively in patients with predisposing conditions such as underlying valvular heart disease or immunosuppression. **Subacute endocarditis** is the most common presentation and can be difficult to diagnose because of the lack of specific signs and symptoms. (Clinical Case 34.4) However, chronic Q fever is a serious illness with significant mortality and morbidity, even in patients with rapid diagnosis and appropriate treatment.

Laboratory Diagnosis

Q fever can be diagnosed by culture (not commonly performed), serology, or the polymerase chain reaction (PCR). Culture can be performed in tissue culture cells and, recently, in a cell-free medium; however, culture is rarely performed except in research laboratories licensed to work with these highly contagious organisms. **Serology** is the most commonly used diagnostic test. As previously mentioned, *C. burnetii* undergoes phase variation characterized by the development of phase I and II antigens. The phase I antigens are only weakly antigenic. A variety of methods are used to measure antibody production: the microagglutination tests, indirect immunofluorescence antibody (IFA) test, and enzyme-linked immunosorbent assay (ELISA). IFA is the test of choice, although ELISA is used in many laboratories and appears to be as sensitive. Cross-reactions occur with *Bartonella,* which can cause a similar disease, so all serologic tests should include an assay for both organisms. In acute Q fever, immunoglobulin (Ig)M and IgG antibodies are developed primarily against **phase II antigens.** A diagnosis of chronic Q fever is confirmed by the demonstration of antibodies against both **phase I and II antigens,** with

Clinical Case 34.4 *Coxiella burnetii* Endocarditis

Karakousis and associates (*J Clin Microbiol* 44:2283–2287, 2006) described a 31-year-old man from West Virginia who developed chronic endocarditis caused by *C. burnetii*. At the time the patient was admitted to the hospital, he described an 11-month history of fevers, night sweats, paroxysmal coughing, fatigue, and weight loss. He had received various antibiotic treatments for bronchitis, with no relief. His past medical history was significant for congenital heart disease, with placement of a shunt as an infant. He lived on a farm and participated in birthing his calves. His cardiac examination on admission revealed a murmur; no hepatosplenomegaly or peripheral stigmata of endocarditis were noted, and his liver enzymes were elevated. All bacterial and fungal blood cultures were negative; however, serology for *Coxiella* phase I and phase II antibodies were markedly elevated. Treatment with doxycycline and rifampin was initiated, and the patient rapidly defervesced. Although prolonged treatment was recommended, the patient was unreliable, and he rapidly became symptomatic every time he discontinued one or both antibiotics. He also refused to take hydroxychloroquine because of his concerns about retinal toxicity. This patient typifies the risk for patients with underlying heart disease and the difficulties in treating this infection.

the titers to the phase I antigen typically higher. NAA techniques such as PCR have been developed in reference laboratories but are generally not available for routine diagnosis. In addition, although the tests are sensitive when tissue samples are examined, the sensitivity is poor with serum. PCR-based tests are not required for the diagnosis of chronic *C. burnetii* infections because these patients characteristically have high levels of antibodies present.

Treatment, Prevention, and Control

Treatment of acute and chronic *C. burnetii* infections is guided by clinical experience, not by in vitro susceptibility tests. Currently, it is recommended that acute infections be treated for 14 days with **doxycycline.** Chronic disease should be treated for a prolonged period with a bactericidal combination of drugs, such as **doxycycline and the alkalinizing agent hydroxychloroquine.** Fluoroquinolones (e.g., ofloxacin, pefloxacin) have been used as an alternative to doxycycline but are contraindicated in children and pregnant women.

Inactivated whole-cell vaccines and partially purified antigen vaccines for Q fever have been developed, and the vaccines prepared from phase I organisms have been shown to provide the best protection. Vaccination of animal herds appears efficacious unless the animals have been previously infected naturally. Vaccination does not eradicate *Coxiella* in infected animals or decrease asymptomatic shedding. Likewise, vaccination of humans with phase I vaccines is protective if the those vaccinated are uninfected. Vaccination of previously infected individuals is contraindicated because immune stimulation can lead to an increase in adverse reactions. For this reason, a single-dose vaccine with no booster immunizations is recommended.

Case Study and Questions

A 46-year-old man went to his physician with a 2-month history of weight loss (15 lb), night sweats, and a low-grade fever. Results of a chest examination revealed a new heart murmur. The physician suspected his patient had subacute endocarditis, and three sets of blood cultures were collected. After 1 week of incubation, the cultures remained negative.

1. What diagnostic test(s) should be performed to determine whether this patient has endocarditis caused by *C. burnetii*?

2. If this diagnosis is confirmed, how did the patient most likely acquire his infection?

3. How should this infection be treated?

35 Chlamydia

A 14-day-old girl was readmitted to the pediatric intensive care unit with respiratory distress, dyspnea, fever, and a dry, unproductive, staccato cough. Chest radiographs demonstrated right bronchopneumonia. The preliminary diagnosis of chlamydial infant pneumonia was made and confirmed by nucleic acid amplification tests (NAATs). Although Chlamydia trachomatis is the best known member of the family Chlamydiaceae, C. psittaci and C. pneumoniae also cause significant human disease.

1. Which members of the Chlamydiaceae family cause respiratory disease? Ocular disease? Genital disease?
2. Why is it significant that *C. trachomatis* serotype A does not induce immunity?
3. What laboratory tests are useful for confirming the diagnosis of infections with *Chlamydia?*

Answers to these questions are available on Student Consult.com.

Summaries Clinically Significant Organisms

CHLAMYDIA TRACHOMATIS

Trigger Words
Intracellular bacteria, elementary and reticulate bodies, trachoma, infant pneumonia, urethritis, LGV, person to person

Biology and Virulence
- Small gram-negative rods
- Strict intracellular parasite of humans
- Two distinct forms: infectious elementary bodies and noninfectious reticulate bodies
- Lipopolysaccharide antigen shared by *Chlamydia* and *Chlamydophila* species
- Major outer membrane proteins are species specific
- Two biovars associated with human disease: trachoma and LGV
- Infects nonciliated columnar, cuboidal, and transitional epithelial cells
- Prevents fusion of phagosome with cellular lysosomes

Epidemiology
- Most common sexually transmitted bacteria in United States
- Ocular trachoma primarily in North and sub-Saharan Africa, the Middle East, South Asia, South America
- LGV highly prevalent in Africa, Asia, and South America

Diseases
- Pathologic effects of trachoma caused by repeated infections
- Diseases, refer to Box 35.1

Diagnosis
- Culture is highly specific but relatively insensitive
- Antigen tests (direct fluorescent antibody, enzyme-linked immunosorbent assay) are relatively insensitive
- Molecular amplification tests are the most sensitive and specific tests currently available

Treatment, Prevention, and Control
- Treat LGV with doxycycline or erythromycin
- Treat ocular or genital infections with azithromycin or doxycycline
- Treat newborn conjunctivitis or pneumonia with erythromycin
- Safe sex practices and prompt treatment of patient and sexual partners help control infections

LGV, Lymphogranuloma venereum.

The taxonomy of the family Chlamydiaceae has been controversial since 1999 when it was proposed to divide the family into two genera: *Chlamydia* and *Chlamydophila*. Although this division was accepted officially, experts in the field point to mounting evidence that this subdivision is not justified based on deoxyribonucleic acid (DNA) sequencing data. This is mentioned in this chapter because (1) we recognized in previous editions of this textbook the recommendation for using the two genus names, and (2) we believe the evidence is compelling to revert back to the use of *Chlamydia* for all species. Maybe the only relevance for the students is they will likely see both names used in the scientific literature. Thus there are three species responsible for human disease that the student should know: ***Chlamydia trachomatis, C. (Chlamydophila) psittaci,*** and ***C. (Chlamydophila) pneumoniae*** (Table 35.1).

The Chlamydiaceae are **obligate intracellular parasites** that were once considered viruses because they are small enough to pass through 0.45-μm filters; however, the organisms have the following properties of bacteria: (1) possess inner and outer membranes similar to those of gram-negative bacteria; (2) contain both DNA and ribonucleic acid (RNA); (3) possess prokaryotic ribosomes; (4) synthesize their own proteins, nucleic acids, and lipids; and (5) are susceptible to numerous antibacterial antibiotics.

Unlike other bacteria, the Chlamydiaceae have a unique developmental cycle, forming metabolically inactive infectious forms **(elementary bodies [EBs])** and metabolically active noninfectious forms **(reticulate bodies [RBs]).** Properties that differentiate the three important human pathogens in this family are summarized in Table 35.2.

Physiology and Structure

Much like a spore, EBs are resistant to many harsh environmental factors. Although recent evidence has demonstrated a peptidoglycan layer in the cell wall of replicating RBs, this has not been demonstrated in EBs. Even though the peptidoglycan layer may be absent in EBs, they possess a central dense core surrounded by a cytoplasmic membrane and a double-layer outer membrane. The cell wall contains a **lipopolysaccharide (LPS),** which is common to all members of the family. The LPS has only **weak endotoxin activity.** The **major outer membrane protein (MOMP)** in the cell wall is an important structural component of the outer membrane and is unique for each species. Variable regions in the gene encoding this protein are found in *C. trachomatis* and are responsible for 18 serologic

variants (called **serovars**). Similar variable regions are found in *C. psittaci* MOMP; in contrast, the *C. pneumoniae* MOMP is homogenous, and only a single serovar has been described. A second highly conserved outer membrane protein, **OMP 2,** is shared by all *Chlamydia*. This cysteine-rich protein is responsible for the extensive disulfide cross-links that provide the stability in the EBs.

The EBs cannot replicate but are infectious; that is, they can bind to receptors on host cells and stimulate uptake by the infected cell. In this intracellular location, the EBs convert into RBs, the metabolically active replicating chlamydial form. Because the extensive cross-linked proteins are absent in RBs, this form is osmotically fragile; however, they are protected by their intracellular location.

Chlamydiae replicate by means of a unique growth cycle that occurs within susceptible host cells (Fig. 35.1). The cycle is initiated when the small (300- to 400-nm), infectious EBs become attached to the microvilli of susceptible cells, followed by active penetration into the host cell. After they are internalized, the bacteria remain within cytoplasmic phagosomes, in which the replicative cycle proceeds. If the outer membrane of the EB is intact, fusion of cellular lysosomes with the EB-containing phagosome is inhibited, preventing intracellular killing. If the outer membrane is damaged or the bacteria are inactivated by heat or coated with antibodies, phagolysosomal fusion occurs, with subsequent bacterial killing. Within 6 to 8 hours after entering the cell, the EBs reorganize into the larger (800- to 1000-nm), metabolically active RBs. Chlamydiae are **energy parasites** because they use host cell adenosine triphosphate for their energy requirements. Some strains may also depend on the host to provide specific amino acids. The RBs replicate by binary fission, similar to other bacteria, and histologic stains can readily detect the phagosome with accumulated RBs, which is called an **inclusion.** Approximately 18 to 24 hours after infection, the RBs begin reorganizing into the smaller EBs, and between 48 and 72 hours, the cell ruptures and then releases the infectious bacteria.

TABLE 35.1 Important Chlamydiaceae

Organism	Historical Derivation
Chlamydia	*chlamydis,* a cloak
C. trachomatis	*trachomatis,* of trachoma or rough (the disease trachoma is characterized by rough granulations on the conjunctival surfaces that lead to chronic inflammation and blindness)
C. pneumoniae	*pneumoniae,* pneumonia
C. psittaci	*psittacus,* a parrot (disease associated with birds)

CHLAMYDIA TRACHOMATIS

C. trachomatis has a limited host range, with infections restricted to humans (Box 35.1). The species responsible for human disease are subdivided into two **biovars: trachoma** and **lymphogranuloma venereum (LGV).** The biovars have been further divided into **serovars** based on antigenic differences in the MOMP. Specific serovars are associated with specific diseases (Table 35.3).

Pathogenesis and Immunity

The range of cells that *C. trachomatis* can infect is limited. Receptors for EBs are primarily restricted to nonciliated columnar, cuboidal, and transitional epithelial cells, which are found on the mucous membranes of the urethra, endocervix, endometrium, fallopian tubes, anorectum, respiratory tract, and conjunctivae. The LGV serovars are more invasive than the other serovars because they replicate in mononuclear phagocytes. The clinical manifestations of chlamydial infections are caused by (1) the direct destruction of cells during replication, and (2) the proinflammatory cytokine response they stimulate.

Chlamydiae gain access through minute abrasions or lacerations. In LGV, the lesions form in the lymph nodes draining the site of primary infection (Fig. 35.2). Granuloma formation is characteristic. The lesions may become necrotic, attract polymorphonuclear leukocytes, and cause the inflammatory process to spread to surrounding tissues. Subsequent rupture of the lymph node leads to formation of abscesses or sinus tracts. Infection with non-LGV serovars of *C. trachomatis* stimulates a severe inflammatory response consisting of neutrophils, lymphocytes, and plasma cells.

Infection does not confer long-lasting immunity; rather, reinfection characteristically induces a vigorous

TABLE 35.2 Differentiation of *Chlamydia* That Cause Human Disease

Property	*C. trachomatis*	*C. pneumoniae*	*C. psittaci*
Host range	Primarily human pathogen	Primarily human pathogen	Primarily animal pathogen; occasionally infects humans
Biovars	LGV and trachoma	TWAR	Many
Diseases	LGV; ocular trachoma, oculogenital disease, infant pneumonia	Bronchitis, pneumonia, sinusitis, pharyngitis, coronary artery disease (?)	Pneumonia (psittacosis)
Elementary body morphology	Round, narrow periplasmic space	Pear-shaped, large periplasmic space	Round, narrow periplasmic space
Inclusion body morphology	Single round inclusion per cell	Multiple uniform inclusions per cell	Multiple variably sized inclusions per cell
Plasmid DNA	Yes	No	Yes
Iodine-staining glycogen in inclusions	Yes	No	No
Susceptibility to sulfonamides	Yes	No	No

LGV, Lymphogranuloma venereum.

BOX 35.1 Chlamydiaceae: Clinical Summaries

Chlamydia trachomatis

Trachoma: chronic inflammatory granulomatous process of eye surface, leading to corneal ulceration, scarring, pannus formation, and blindness

Adult inclusion conjunctivitis: acute process with mucopurulent discharge, dermatitis, corneal infiltrates, and corneal vascularization in chronic disease

Neonatal conjunctivitis: acute process characterized by a mucopurulent discharge

Infant pneumonia: after a 2- to 3-week incubation period, the infant develops rhinitis, followed by bronchitis with a characteristic dry cough

Urogenital infections: acute process involving the genitourinary tract with characteristic mucopurulent discharge; asymptomatic infections common in women

Lymphogranuloma venereum: a painless ulcer develops at the site of infection that spontaneously heals, followed by inflammation and swelling of lymph nodes draining the area, then progression to systemic symptoms

BOX 35.1 Chlamydiaceae: Clinical Summaries—cont'd

Chlamydia pneumoniae

Respiratory infections: can range from asymptomatic or mild disease to severe atypical pneumonia requiring hospitalization

Atherosclerosis: *C. pneumoniae* has been associated with inflammatory plaques in blood vessels; the etiologic role in this disease is controversial

Chlamydia psittaci

Respiratory infections: can range from asymptomatic colonization to severe bronchopneumonia with localized infiltration of inflammatory cells, necrosis, and hemorrhage

TABLE 35.3 Clinical Spectrum of *Chlamydia trachomatis* Infections

Serovars	Disease
A, B, Ba, C	Trachoma
D–K	Urogenital tract disease
L1, L2, L2a, L2b, L3	Lymphogranuloma venereum

Fig. 35.2 Patient with lymphogranuloma venereum causing unilateral vulvar lymphedema and inguinal buboes. (From Cohen, J., Powderly, W.G., Opal, S.M., 2010. Infectious Diseases, third ed. Mosby, Philadelphia, PA.)

inflammatory response with subsequent tissue damage. This response produces the vision loss in patients with chronic ocular infections, and scarring with sterility and sexual dysfunction in patients with genital infections.

EPIDEMIOLOGY

C. trachomatis is found worldwide and causes trachoma (chronic keratoconjunctivitis), oculogenital disease, pneumonia, and LGV. Trachoma is endemic in North and sub-Saharan Africa, the Middle East, South Asia, and South America. The World Health Organization estimates 6 million people are blind because of trachoma, and more than 150 million people are in need of treatment. Trachoma is the **leading cause of preventable blindness.** Infections occur predominantly in children, who are the chief reservoir of *C.*

trachomatis in endemic areas. The incidence of infection is lower in older children and adolescents; however, the incidence of blindness continues to rise through adulthood as the disease progresses. Eye-to-eye transmission of trachoma is by droplet, hands, contaminated clothing, and flies that transmit ocular discharges from the eyes of infected children to the eyes of uninfected children. Because a high percentage of children in endemic areas harbor *C. trachomatis* in their respiratory and gastrointestinal tracts, the pathogen may also be transmitted by respiratory droplet or through fecal contamination. Trachoma generally is endemic in communities in which the living conditions are crowded, sanitation is poor, and the personal hygiene of the people is poor; they are all risk factors that promote the transmission of infections.

Most cases of *C. trachomatis* **adult inclusion conjunctivitis** occur in people who are 18 to 30 years of age, and genital infection probably precedes eye involvement. Autoinoculation and oral-genital contact are believed to be the routes of transmission. A third form of *C. trachomatis* eye infection is **newborn inclusion conjunctivitis,** which is an infection acquired during passage of the infant through an infected birth canal. *C. trachomatis* conjunctivitis develops in approximately 25% of infants whose mothers have active genital infections.

Pulmonary infection with *C. trachomatis* also occurs in newborns. A diffuse **interstitial pneumonia** develops in 10% to 20% of infants exposed to the pathogen at birth.

C. trachomatis is thought to be the most common **sexually transmitted bacterial disease** in the United States. More than 1.7 million infections were reported in the United States in 2017; however, this figure is believed to be an underestimate because most infected patients either do not seek medical treatment or are treated without a specific diagnosis. It is estimated that almost 3 million Americans are infected each year, and as many as 50 million new infections occur annually worldwide. Most genital tract infections are caused by serotypes D to K.

LGV is a chronic sexually transmitted disease caused by *C. trachomatis* serotypes L1, L2, L2a, L2b, and L3. It occurs sporadically in the United States and other industrialized countries but is highly prevalent in Africa, Asia, and South America. Acute LGV is seen more frequently in men, primarily because symptomatic infection is less common in women.

Clinical Diseases

Trachoma

Trachoma is a **chronic disease** caused by serovars A, B, Ba, and C. Initially, patients have a **follicular conjunctivitis** with diffuse inflammation that involves the entire conjunctiva. The conjunctivae become scarred as the disease progresses, causing the patient's eyelids to turn inward. The turned-in eyelashes abrade the cornea, eventually resulting in corneal ulceration, scarring, pannus formation (invasion of vessels into the cornea), and loss of vision. It is common for trachoma to recur after apparent healing, which is most likely a result of subclinical infections that have been documented in children in endemic areas and in immigrants to the United States who acquired trachoma during childhood in their native countries.

Adult Inclusion Conjunctivitis

An acute follicular conjunctivitis caused by the *C. trachomatis* strains associated with genital infections (serovars A, B, Ba, and D to K) has been documented in sexually active adults. The infection is characterized by mucopurulent discharge, keratitis, corneal infiltrates, and occasionally some corneal vascularization. Corneal scarring has been observed in patients with chronic infection.

Clinical Case 35.1 *Chlamydia trachomatis* Pneumonia in Newborn Infants

Niida and associates (*Eur J Pediatr* 157:950–951, 1998) described two infant girls with *C. trachomatis* pneumonia. The first infant was born by vaginal delivery after 39 weeks' gestation and the second by caesarean section (because of fetal distress) at 40 weeks' gestation. The infants were in good condition until fever and tachypnea developed at 3 and 13 days, respectively. Chest radiographs showed infiltrates over the entire lungs. Cultures of blood, urine, throat, feces, and cerebrospinal fluid were negative, but antigen tests for *C. trachomatis* were positive from conjunctival and nasopharyngeal swabs. These cases illustrate the presentation of pneumonia in infants infected with *C. trachomatis* at or near birth, although the characteristic staccato cough was not described.

Neonatal Conjunctivitis

Eye infections can also develop in **infants exposed to *C. trachomatis* at birth.** After an incubation of 5 to 12 days, the infant's eyelids swell, hyperemia occurs, and copious purulent discharge appears. Untreated infections may run a course as long as 12 months, during which time conjunctival scarring and corneal vascularization occur. Infants who are untreated or are treated with topical therapy only are at risk for *C. trachomatis* pneumonia.

Infant Pneumonia

The incubation period for infant pneumonia is variable, but the onset generally occurs 2 to 3 weeks after birth. Rhinitis is initially observed in such infants, after which a **distinctive staccato cough** develops. The child remains afebrile throughout the clinical illness, which can last for several weeks. Radiographic signs of infection can persist for months (Clinical Case 35.1).

Ocular Lymphogranuloma Venereum

The LGV serotypes of *C. trachomatis* have been implicated in Parinaud oculoglandular conjunctivitis, which is a conjunctival inflammation associated with preauricular, submandibular, and cervical lymphadenopathy.

Urogenital Infections

Most genital tract infections in women are asymptomatic (as many as 80%) but can nevertheless become symptomatic. The clinical manifestations include bartholinitis, cervicitis, endometritis, perihepatitis, salpingitis, and urethritis. Asymptomatic patients with chlamydial infection are an important reservoir for the spread of *C. trachomatis*. A mucopurulent discharge (Fig. 35.3) is seen in patients with symptomatic infection, whose specimens generally yield more organisms on cultures than specimens from patients with asymptomatic infections. Urethritis caused by *C. trachomatis* may occur with or without a concurrent cervical infection (Clinical Case 25.2).

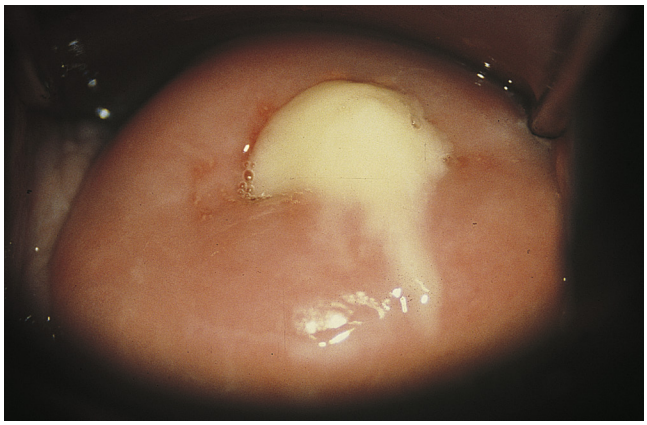

Fig. 35.3 Mucopurulent cervicitis caused by *Chlamydia trachomatis.* (From Cohen, J., Powderly, W. 2004. Infectious Diseases, second ed. Mosby, St Louis, MO; photo courtesy J. Paavonen.)

Although most *C. trachomatis* genital infections in men are symptomatic, and as many as 25% of the infections will be inapparent. Approximately 35% to 50% of cases of nongonococcal urethritis are caused by *C. trachomatis;* dual infections with both *C. trachomatis* and *Neisseria gonorrhoeae* are common. Symptoms of the chlamydial infection develop after successful treatment of the gonorrhea because the incubation period is longer and the use of β-lactam antibiotics to treat gonorrhea would be ineffective against *C. trachomatis*. Although there is less purulent exudate in patients with chlamydial urethral infections, such infections cannot be differentiated reliably from gonorrhea, so specific diagnostic tests for both organisms should be performed.

It is believed that **Reiter syndrome** (urethritis, conjunctivitis, polyarthritis, and mucocutaneous lesions) is initiated by genital infection with *C. trachomatis*. Although chlamydiae have not been isolated from the synovial fluid of such patients, chlamydial EBs have been observed in synovial fluid or tissue specimens from men with sexually acquired reactive arthritis. The disease usually occurs in young white men. Approximately 50% to 65% of patients with Reiter syndrome have a chlamydial genital infection at the onset of arthritis, and serologic studies indicate that more than 80% of men with Reiter syndrome have evidence of a preceding or concurrent infection with *C. trachomatis*.

Lymphogranuloma Venereum

After an incubation of 1 to 4 weeks, a primary lesion appears at the site of infection (e.g., penis, urethra, glans, scrotum, vaginal wall, cervix, vulva) in patients with LGV. The lesion (either a papule or an ulcer) is often overlooked because it is small, painless, and heals rapidly. The absence of pain differentiates these ulcers from those observed in herpes simplex virus infections. The patient may experience fever, headache, and myalgia when the lesion is present.

The second stage of infection is marked by inflammation and swelling of the lymph nodes draining the site of initial infection. The inguinal nodes are most commonly involved, becoming painful, fluctuant **buboes** that gradually enlarge and can rupture, forming draining fistulas. Systemic manifestations include fever, chills, anorexia, headache, meningismus, myalgias, and arthralgia.

Proctitis is common in women with LGV, resulting from lymphatic spread from the cervix or the vagina. Proctitis develops in men after anal intercourse or as the result of lymphatic spread from the urethra. Untreated LGV may resolve at this stage or may progress to a chronic ulcerative phase in which genital ulcers, fistulas, strictures, or genital elephantiasis develop.

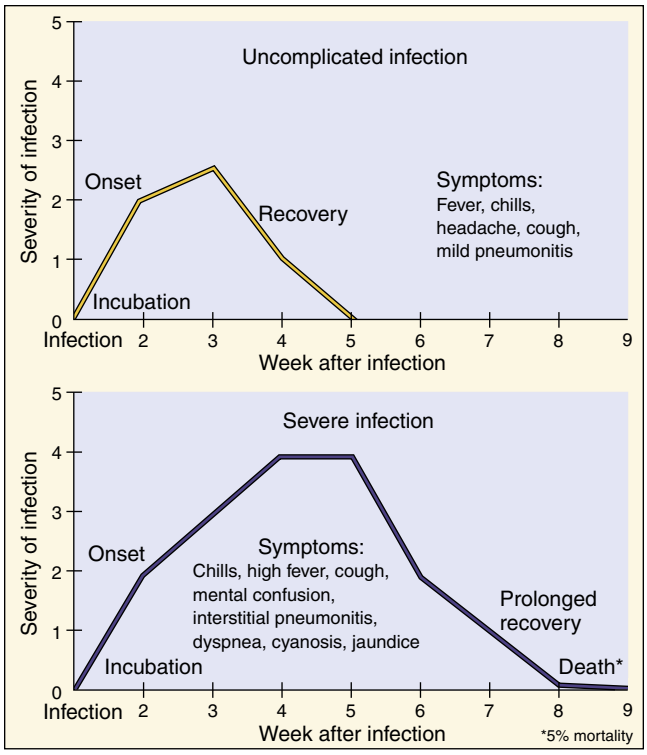

Fig. 35.4 Time course of *Chlamydia psittaci* infection.

Laboratory Diagnosis

C. trachomatis infection can be diagnosed (1) on the basis of cytologic, serologic, or culture findings; (2) through the direct detection of antigen in clinical specimens; and (3) through the use of nucleic acid–based tests. The sensitivity of each method depends on the patient population examined, the site in which the specimen is obtained, and the nature of the disease. For example, symptomatic infections are generally easier to diagnose than asymptomatic infections because more chlamydiae are present in the specimen. The quality of the specimen is also important. Although it may seem obvious, specimens must be obtained from the involved site (e.g., urethra, cervix, rectum, oropharynx, conjunctiva) and not from pus or a vaginal exudate, where relatively few organisms may be present. Chlamydiae infect columnar or squamocolumnar cells; therefore endocervical and not vaginal specimens should be collected. It has been estimated that one-third of the specimens submitted for study in patients with suspected *Chlamydia* infection are inappropriate.

Antigen Detection

Two general approaches have been used to detect chlamydial antigens in clinical specimens: **direct immunofluorescence staining** with fluorescein-conjugated monoclonal antibodies (Fig. 35.4) and **enzyme-linked immunosorbent assays.** In both assays, antibodies are used that have been prepared against either the chlamydial MOMP or the cell wall LPS. Because antigenic determinants on LPS may

Clinical Case 35.2 **Reiter Syndrome and Pelvic Inflammatory Disease**

Serwin and associates (*J Eur Acad Derm Vener* 20:735–736, 2006) described a 30-year-old man who presented to a university hospital with complaints of dysuria for a 3-year duration, penile inflammation, joint swelling, and fever. Skin lesions and nail changes were also noted. High levels of *Chlamydia* antibodies were present, but antigen tests and nucleic acid amplification tests of the urethral exudates and conjunctiva were negative for *Chlamydia trachomatis*. A diagnosis of Reiter syndrome was made, and treatment with ofloxacin was initiated. Complete remission of the skin lesions and urethral symptoms was achieved. The patient's wife was also admitted to the hospital with a history of 2 years of lower abdominal pain and vaginal bleeding and discharge. The diagnosis of pelvic inflammatory disease (PID) was made, and *C. trachomatis* infection was confirmed by positive cervical and urethral antigen tests (direct fluorescent antibody). The vaginal smear was also positive for *Trichomonas vaginalis*. These patients illustrate two complications of *C. trachomatis* urogenital infections: Reiter syndrome and PID.

be shared with other bacteria, particularly those in fecal specimens, tests that target the LPS antigen are less specific. The sensitivity of each assay method has been reported to vary enormously, but neither method is considered as sensitive as culture or nucleic acid–based tests, particularly if male urethral specimens or specimens from asymptomatic patients are used. The latter pose a problem because they may contain relatively few chlamydiae.

Nucleic Acid–Based Tests

NAATs are the test of choice for the diagnosis of chlamydia infections (generally reported to be 90% to 98% sensitive and very specific). First-voided urine from a patient with urethritis and urethral discharge can be used. Care must be used to monitor for the presence of inhibitors (e.g., urine) to the amplification reaction and to prevent cross-contamination of specimens.

Culture

The isolation of *C. trachomatis* in cell culture remains the most **specific** method of diagnosing *C. trachomatis* infections but is **relatively insensitive** compared with NAATs. The bacteria infect a restricted range of cell lines in vitro, which is similar to the narrow range of cells they infect in vivo. The sensitivity of culture is compromised if inadequate specimens are used and if chlamydial viability has been lost during transport of the specimen. It has been estimated that the sensitivity of the findings yielded by a single endocervical specimen may be only 70% to 85%.

Antibody Detection

Serologic testing is of limited value in the diagnosis of *C. trachomatis* urogenital infections in adults because the test cannot differentiate between current and past infections. Demonstration of a significant increase in antibody levels can be useful; however, this increase may not be demonstrated for a month or longer, particularly in patients who receive antibiotic treatment. Testing for immunoglobulin (Ig)M antibodies also is not usually helpful because these antibodies may not be detected in adolescents and adults. An exception is the detection of IgM antibodies in infants with chlamydial pneumonitis.

Antibody tests for the diagnosis of LGV can be helpful. Infected patients produce a vigorous antibody response that can be detected by complement fixation (CF), microimmunofluorescence (MIF), or enzyme immunoassay (EIA). The CF test is directed against the genus-specific LPS antigen. Thus a positive result (i.e., fourfold increase in titer or a single titer ≥1:256) is highly suggestive of LGV. Confirmation is determined by the MIF test, which is directed against species- and serovar-specific antigens (the chlamydial MOMPs). Similar to the CF test, EIAs are genus specific. The advantage of these tests is that they are less technically cumbersome; however, the results must be confirmed by MIF.

Treatment, Prevention, and Control

It is recommended that patients with LGV be treated with doxycycline for 21 days. Treatment with erythromycin is recommended for children younger than 9 years, pregnant women, and patients unable to tolerate doxycycline. Ocular and genital infections in adults should be treated with one dose of azithromycin or doxycycline for 7 days. Newborn conjunctivitis and pneumonia should be treated with erythromycin for 10 to 14 days.

It is difficult to prevent trachoma because the population with endemic disease commonly has limited access to medical care. The blindness associated with advanced stages of trachoma can be prevented only by prompt treatment of early disease and prevention of reexposure. Although treatment can be successful in individuals living in areas in which the disease is endemic, it is difficult to eradicate the disease within a population and to prevent reinfections unless sanitary conditions are improved. *Chlamydia* conjunctivitis and genital infections are prevented through the use of safe sex practices and the prompt treatment of symptomatic patients and their sexual partners.

CHLAMYDIA PNEUMONIAE

C. pneumoniae was first isolated from the conjunctiva of a child in Taiwan. It was initially considered a psittacosis strain because the morphology of the inclusions produced in cell culture was similar. However, it was subsequently shown that the Taiwan isolate (TW-183) was related serologically to a pharyngeal isolate designated AR-39 and was unrelated to psittacosis strains. This new organism was initially called TWAR (from the two original isolates), then classified as *Chlamydia pneumoniae.* Only a single serotype (TWAR) has been identified. Respiratory secretions transmit infection; no animal reservoir has been identified.

C. pneumoniae is a **human pathogen** that causes sinusitis, pharyngitis, bronchitis, and pneumonia. Infections are believed to be transmitted person to person by respiratory secretions. The prevalence of infections is very controversial, with wide variations reported in the literature, in large part because of significant variation in diagnostic test methods. It is believed that most *C. pneumoniae* infections are asymptomatic or mild, causing a persistent cough and malaise; most patients do not require hospitalization. More

severe respiratory tract infections typically involve a single lobe of the lungs. These infections cannot be differentiated from other atypical pneumonias such as those caused by *Mycoplasma pneumoniae, Legionella pneumophila,* and respiratory viruses.

The role of *C. pneumoniae* in the pathogenesis of atherosclerosis remains to be defined. It is known that *C. pneumoniae* can infect and grow in smooth muscle cells, endothelial cells of the coronary artery, and macrophages. The organism has also been demonstrated in biopsy specimens of atherosclerotic lesions by means of culture, polymerase chain reaction amplification, immunohistologic staining, electron microscopy, and in situ hybridization. Thus the association of *C. pneumoniae* with atherosclerotic lesions is clear. What is not clear is the role of the organism in the development of atherosclerosis. It has been proposed that the disease results from an inflammatory response to chronic infection; however, this remains to be proven.

Diagnosis of *C. pneumoniae* infections is difficult. The organisms do not grow in the cell lines used for the isolation of *C. trachomatis,* and although *C. pneumoniae* will grow in the HEp-2 cell line, this cell line is not used in most clinical laboratories. Detection of *C. pneumoniae* by NAATs has been successful; however, significant interlaboratory variation has been reported among laboratories with experience in the use of these assays. The MIF test is the only acceptable test for serodiagnosis. The criteria for the diagnosis of acute *C. pneumoniae* infection is a single IgM titer of greater than 16 or a fourfold increase in IgG titer. A single elevated IgG titer cannot be used. Because IgG antibodies do not appear for 6 to 8 weeks after infection, serologic testing has limited value for the diagnosis of an acute infection.

Macrolides (erythromycin, azithromycin, clarithromycin), doxycycline, or levofloxacin is recommended for treatment of *C. pneumoniae* infections, although evidence supporting their use is limited. Control of exposure to *C. pneumoniae* is likely to be difficult because the bacterium is ubiquitous.

CHLAMYDIA PSITTACI

C. psittaci is the cause of psittacosis (parrot fever), which can be transmitted to humans. The disease was first observed in parrots, thus the name **psittacosis** (*psittakos* is the Greek word for parrot). In reality, however, the natural reservoir of *C. psittaci* is virtually any species of bird, and the disease has been referred to more appropriately as **ornithosis** (derived from the Greek word *ornithos,* for bird). Other animals, such as sheep, cows, and goats, as well as humans, can become infected. The organism is present in the blood, tissues, feces, and feathers of infected birds that may appear either ill or healthy (Clinical Case 35.3).

Infection occurs by means of the respiratory tract, after which the bacteria spread to the reticuloendothelial cells of the liver and spleen. The organisms multiply in these sites, producing focal necrosis. The lung and other organs are then seeded as the result of hematogenous spread, which causes a predominantly lymphocytic inflammatory response in the alveolar and interstitial spaces. Edema, thickening of the alveolar wall, infiltration of macrophages, necrosis, and occasionally hemorrhage occur at these sites. Mucous plugs develop in the bronchioles, causing cyanosis and anoxia.

Clinical Case 35.3 **Psittacosis in a Previously Healthy Man**

Scully and associates (*N Engl J Med* 338:1527–1535, 1998) described a 24-year-old man who was admitted into a local hospital in acute respiratory distress. Several days before his hospitalization, he developed nasal congestion, myalgia, dry cough, mild dyspnea, and a headache. Immediately before admission, the cough became productive and he developed pleuritic pain, fever, chills, and diarrhea. Radiographs demonstrated consolidation of the right upper lobe of the lungs and patchy infiltrates in the left lower lobe. Despite the fact that his antibiotic treatment included erythromycin, doxycycline, ceftriaxone, and vancomycin, his pulmonary status did not begin to improve for 7 days, and he was not discharged from the hospital until a month after his admission. A careful history revealed the man had been exposed to parrots in a hotel lobby while vacationing. The diagnosis of *Chlamydia psittaci* pneumonia was made by growing the organism in cell culture and serologic tests.

Fewer than 25 cases of the disease are reported annually in the United States, with most infections in adults. This number certainly is an underestimation of the true prevalence of disease, however, because (1) human infections may be asymptomatic or mild, (2) exposure to an infected bird may not be suspected, (3) convalescent serum may not be collected to confirm the clinical diagnosis, and (4) antibiotic therapy may blunt the antibody response. Furthermore, because of the serologic cross-reactions with *C. pneumoniae,* specific estimates of the prevalence of disease will remain unreliable until a definitive diagnostic test is developed.

The bacterium is usually transmitted to humans through the inhalation of dried excrement, urine, or respiratory secretions from psittacine birds (e.g., parrots, parakeets, macaws, cockatiels). Person-to-person transmission is rare. Veterinarians, zookeepers, pet shop workers, and employees of poultry-processing plants are at increased risk for this infection.

The illness develops after an incubation of 5 to 14 days and usually manifests as headache, high fever, chills, malaise, and myalgias (see Fig. 35.4). Pulmonary signs include a nonproductive cough, rales, and consolidation. Central nervous system involvement is common, usually consisting of headache, but encephalitis, convulsions, coma, and death may occur in severe untreated cases. Patients may suffer gastrointestinal tract symptoms such as nausea, vomiting, and diarrhea. Other systemic symptoms include carditis, hepatomegaly, splenomegaly, and follicular keratoconjunctivitis.

Psittacosis is usually diagnosed on the basis of serologic findings. A fourfold increase in titer, shown by the CF testing of paired acute and convalescent phase sera, is suggestive of *C. psittaci* infection, but the species-specific MIF test must be performed to confirm the diagnosis. *C. psittaci* can be isolated in cell culture (e.g., with L cells) after 5 to 10 days of incubation, although this procedure is rarely performed in clinical laboratories.

Infections can be treated successfully with doxycycline or macrolides. Person-to-person transmission rarely occurs, so isolation of the patient and prophylactic treatment of contacts are not necessary. Psittacosis can be prevented only through the control of infections in domestic and imported

pet birds. Such control can be achieved by treating birds with chlortetracycline hydrochloride for 45 days. No vaccine currently exists for this disease.

Case Study and Questions

A 22-year-old man came to the emergency department with a history of urethral pain and purulent discharge that developed after he had sexual contact with a prostitute. Gram stain of the discharge revealed abundant gram-negative diplococci resembling *Neisseria gonorrhoeae*. The patient was treated with penicillin and sent home. Two days later, the patient returned to the emergency room with a complaint of persistent watery urethral discharge. Abundant white blood cells but no organisms were observed on Gram stain of the discharge. Culture of the discharge was negative for *N. gonorrhoeae* but positive for *Chlamydia trachomatis*.

1. Why is penicillin ineffective against *Chlamydia*? What antibiotic can be used to treat this patient?

2. Describe the growth cycle of *Chlamydia.* What structural features make the EBs and RBs well suited for their environment?

3. Describe the differences among the three *Chlamydia* species that cause human disease.

4. *C. trachomatis, C. pneumoniae,* and *C. psittaci* each cause respiratory tract infections. Describe the patient population most commonly infected and the epidemiology of these infections.

SECTION 5

Virology

SECTION OUTLINE

36 Viral Classification, Structure, and Replication

Viruses were first described as "filterable agents." Their small size allows them to pass through filters designed to retain bacteria. Unlike most bacteria, fungi, and parasites, **viruses are obligate intracellular parasites** that depend on the biochemical machinery of the host cell for replication. In addition, *reproduction of viruses occurs by assembly of the individual components rather than by binary fission* (Boxes 36.1 and 36.2).

The simplest viruses consist of a genome of deoxyribonucleic acid (DNA) or ribonucleic acid (RNA) packaged in a protective shell of protein and, for some viruses, a membrane (Fig. 36.1). Viruses lack the capacity to make energy or substrates, cannot make their own proteins, and cannot replicate their genome independently of the host cell. To use the cell's biosynthetic machinery, the virus must be adapted to the biochemical rules of the cell.

The physical structure and genetics of viruses have been optimized by mutation and selection to infect humans or other hosts. To do this, the virus must be capable of transmission between hosts, must traverse the skin or other protective barriers of the host, must be adapted to the biochemical machinery of the host cell for replication, and must escape elimination by the host immune response.

Knowledge of the structural **(size and morphology)** and genetic **(type and structure of nucleic acid)** features of a virus provides insight into how the virus replicates, spreads, and causes disease. The concepts presented in this chapter are repeated in greater detail in the discussions of specific viruses in later chapters.

Classification

Viruses range from the structurally simple and small parvoviruses and picornaviruses to the large and complex poxviruses and herpesviruses. Their names may describe viral characteristics, the diseases they are associated with, or even the tissue or geographic locale in which they were first identified. Names such as **picornavirus** (*pico*, "small"; *rna*, "ribonucleic acid") or **togavirus** (*toga*, Greek for "mantle," referring to a membrane envelope surrounding the virus) describe the structure of the virus. The name **retrovirus** (*retro*, "reverse") refers to the virus-directed synthesis of DNA from an RNA template, whereas the *poxviruses* are named for the disease smallpox, caused by one of its members. The **adenoviruses** (*adeno*ids) and the **reoviruses** (*r*espiratory, *e*nteric, *o*rphan) are named for the body site from which they were first isolated. Reovirus was discovered before it was associated with a specific disease; thus it was designated an "orphan" virus. Norwalk virus is named for Norwalk, Ohio; coxsackievirus is named for Coxsackie, New York; and many of the togaviruses, arenaviruses, and bunyaviruses are named after African places in which they were first isolated.

Viruses can be grouped by characteristics such as disease (e.g., hepatitis), target tissue, means of transmission (e.g., enteric, respiratory), or vector (e.g., arboviruses; arthropod-borne virus) (Box 36.3). *The most consistent and current means of classification is by physical and biochemical characteristics, such as size, morphology (e.g., presence or absence of a membrane envelope), type of genome, and means of replication* (Figs. 36.2 and 36.3). DNA viruses associated with human disease are divided into seven families (Tables 36.1 and 36.2). The RNA viruses may be divided into at least 13 families (Tables 36.3 and 36.4).

Virion Structure

The units for measurement of virion size are nanometers (nm). The clinically important viruses range from 18 nm (parvoviruses) to 300 nm (poxviruses). The latter are almost visible with a light microscope and are approximately one-fourth the size of staphylococcal bacteria. *Larger virions can hold a larger genome that can encode more proteins, and they are generally more complex.*

The **virion** (the virus particle) consists of a nucleic acid **genome** packaged into a protein coat **(capsid)** or a membrane **(envelope)** (Fig. 36.4). The virion may also contain certain essential or accessory enzymes or other proteins to facilitate initial replication in the cell. Capsid or nucleic acid–binding proteins may associate with the genome to form a **nucleocapsid,** which may be the same as the virion or surrounded by an envelope.

The genome of the virus consists either of DNA or RNA. The DNA can be single stranded or double stranded or linear or circular. The RNA can be either positive sense (+) (like messenger RNA [mRNA]) or negative sense (−) (analogous to a photographic negative), double stranded (+/−), or ambisense (containing + and − regions of RNA attached end to end). The RNA genome may also be segmented into pieces, with each piece encoding one or more genes. Just as there are many different types of computer memory devices, all of these forms of nucleic acid can maintain and transmit the genetic information of the virus. Similarly, the larger the genome, the more information (genes) it can carry and the larger the capsid or envelope structure required to contain the genome.

The outer layer of the virion is the **capsid** or **envelope.** These structures are the package, protection, and delivery vehicle during transmission of the virus from one host to another and for spread within the host to the target cell. The surface structures of the capsid and envelope mediate the interaction of the virus with the target cell through a **viral attachment protein (VAP)** or structure. *Removal or disruption of the outer package inactivates the virus. Antibodies generated against the VAP prevent virus infection.*

BOX 36.1 Definition and Properties of a Virus

Viruses are filterable agents.
Viruses are obligate intracellular parasites.
Viruses cannot make energy or proteins independently of a host cell.
Viral genomes may be RNA or DNA but not both.
Viruses have a naked capsid or an envelope morphology.
Viral components are assembled and do not replicate by "division."

BOX 36.2 Consequences of Viral Properties

Viruses are not living.
Viruses must be infectious to endure in nature.
Viruses must be able to use host cell processes to produce their components (viral messenger RNA, protein, and identical copies of the genome).
Viruses must encode any required processes not provided by the cell.
Viral components must self-assemble.

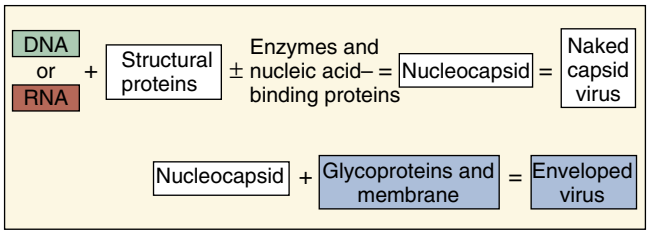

Fig. 36.1 Components of the basic virion.

BOX 36.3 Means of Classification and Naming of Viruses

Structure: size, morphology, and nucleic acid (e.g., picornavirus [small RNA], togavirus)
Biochemical characteristics: structure and mode of replication[a]
Disease: encephalitis and hepatitis viruses, for example
Means of transmission: arbovirus spread by insects, for example
Host cell (host range): animal (human, mouse, bird), plant, bacteria
Tissue or organ (tropism): adenovirus and enterovirus, for example

[a]This is the current means of taxonomic classification of viruses.

Family[a]	Members[b]
POXVIRIDAE	*Smallpox virus,* vaccinia virus, monkeypox, canarypox, molluscum contagiosum
Herpesviridae	*Herpes simplex virus types 1 and 2,* varicella-zoster virus, Epstein-Barr virus, cytomegalovirus, human herpesviruses 6, 7, and 8
Adenoviridae	*Adenovirus*
Papillomaviridae	*Papillomavirus*
Polyomaviridae	*JC virus,* BK virus, SV40
Parvoviridae	*Parvovirus B19,* adeno-associated virus
Hepadnaviridae	*Hepatitis B virus*

[a]The size of type is indicative of the relative size of the virus.
[b]The italicized virus is the prototype virus for the family.

The influence of virion structure on viral properties is summarized in Boxes 36.4 and 36.5.

The **capsid** is a rigid structure able to withstand harsh environmental conditions. Like a soccer ball, naked capsid viruses also have a tough exterior and are generally resistant to drying, acid, and detergents, including the acid and bile of the enteric tract. Many of these viruses are transmitted by the fecal-oral route and can endure transmission even in sewage.

The **envelope** is a membrane composed of lipids, proteins, and glycoproteins. The membranous structure of the envelope can be maintained only in aqueous solutions. It is readily disrupted by drying, acidic conditions, detergents, and solvents such as ether, which results in inactivation of the virus. *As a result, enveloped viruses must remain wet and are generally transmitted in fluids, respiratory droplets, blood, and tissue.* Most cannot survive the harsh conditions of the gastrointestinal tract.

CAPSID VIRUSES

The viral capsid is assembled from individual proteins associated into progressively larger units. All of the components of the capsid have chemical features that allow them to fit together and to assemble into a larger unit. Individual

structural proteins associate into **subunits,** which associate into **protomers, capsomeres** (distinguishable in electron micrographs), and finally, a recognizable **procapsid** or **capsid** (Fig. 36.5). A procapsid requires further processing to the final, transmissible capsid. For some viruses, the capsid forms around the genome; for others the capsid forms as an empty shell (procapsid) to be filled by the genome.

The simplest viral structures that can be built stepwise are symmetric and include **helical** and **icosahedral** structures. Helical structures appear as rods, whereas the icosahedron is an approximation of a sphere assembled from symmetric subunits (Fig. 36.6). Nonsymmetric capsids are complex forms and are associated with certain bacterial viruses (phages).

Helical nucleocapsids are observed within the envelope of most negative-strand RNA viruses (see Fig. 48.1). The nucleocapsid proteins bound to the genome will be delivered into the infected cell and are the enzymes necessary for transcription and replication. Simple icosahedrons are used by small viruses such as the picornaviruses and parvoviruses. The icosahedron is made of 12 capsomeres, each with fivefold symmetry (pentamer or penton). For the picornaviruses, every pentamer is made up of five protomers, each of which is composed of three subunits of four separate proteins (see Fig. 36.5). X-ray crystallography and image analysis of cryoelectron microscopy have defined the structure of the picornavirus capsid to the molecular level. These studies have depicted a canyon-like cleft, which is a "docking site" to bind to the receptor on the surface of the target cell (see Fig. 46.2).

Larger capsid virions are constructed by inserting structurally distinct capsomeres between the pentons at the vertices. These capsomeres have six nearest neighbors **(hexons).** This extends the icosahedron and is called an **icosadeltahedron,** and its size is determined by the number of hexons inserted along the edges and within the surfaces between the pentons. *Older soccer balls were icosadeltahedrons.* For example, the herpesvirus nucleocapsid has 12 pentons and 150 hexons. The herpesvirus nucleocapsid is also surrounded by an envelope. The adenovirus capsid is composed of 252 capsomeres, with 12 pentons

TABLE 36.4 Properties of Virions of Human RNA Viruses

	GENOME		VIRION			
Family	**Molecular Mass × 10^6 Da**	**Nature**	**Shape[a]**	**Size (nm)**	**Polymerase in Virion**	**Envelope[a]**
Paramyxoviridae	5–7	ss, –	Spherical	150–300	+	+
Orthomyxoviridae	5–7	ss, –, seg	Spherical	80–120	+	+
Coronaviridae	6–7	ss, +	Spherical	80–130	–	+[b]
Arenaviridae	3–5	ss, –, seg	Spherical	50–300	+	+[b]
Rhabdoviridae	4–7	ss, –	Bullet-shaped	180 × 75	+	+
Filoviridae	4–7	ss, –	Filamentous	800 × 80	+	+
Bunyaviridae	4–7	ss, –	Spherical	90–100	+	+[b]
Retroviridae	2 × (2–3)[c]	ss, +	Spherical	80–110	+[d]	+
Reoviridae	11–15	ds, seg	Icosahedral	60–80	+	–
Picornaviridae[e]	2.5	ss, +	Icosahedral	25–30	–	–
Togaviridae	4–5	ss, +	Icosahedral	60–70	–	+
Flaviviridae	4–7	ss, +	Spherical	40–50	–	+
Caliciviridae[f]	2.6	ss, +	Icosahedral	35–40	–	–

[a]Some enveloped viruses are very pleomorphic (sometimes filamentous).
[b]No matrix protein.
[c]Genome has two identical single-stranded RNA molecules.
[d]Reverse transcriptase.
[e]Hepeviridae (hepatitis E virus) resemble picornaviruses
[f]Astroviridae resemble caliciviruses
ds, Double-stranded; *seg,* segmented; *ss,* single-stranded; + *or* –, polarity of single-stranded nucleic acid.

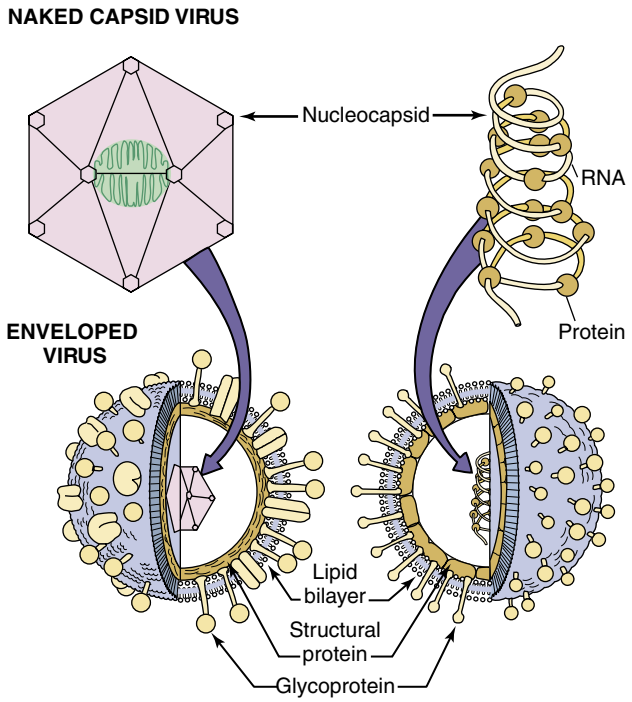

Fig. 36.4 Structures of a naked icosahedral capsid virus *(top left)* and enveloped viruses *(bottom)* with an icosahedral *(left)* nucleocapsid or a helical *(right)* ribonucleocapsid. Helical nucleocapsids are always enveloped for human viruses.

BOX 36.4 Virion Structure: Naked Capsid

Component

Protein

Properties[a]

Is environmentally stable to the following:
- Temperature
- Acid
- Proteases
- Detergents
- Drying

Is released from cell by lysis

Consequences[a]

Can be spread easily (on fomites, from hand to hand, by dust, by small droplets)
Can dry out and retain infectivity
Can survive the adverse conditions of the gut
Can be resistant to detergents and poor sewage treatment
Antibody may be sufficient for immunoprotection

[a]Exceptions exist.

and 240 hexons. A long fiber is attached to each penton of adenovirus to serve as the VAP to bind to target cells, and it also contains the type-specific antigen (see Fig. 42.1). The reoviruses have an icosahedral double capsid with fiber-like proteins partially extended from each vertex. The outer capsid protects the virus and promotes its uptake across the gastrointestinal tract and into target cells, whereas the inner capsid contains enzymes for the synthesis of RNA (see Figs. 36.6 and 51.3).

ENVELOPED VIRUSES

The virion envelope is composed of lipids, proteins, and glycoproteins (see Fig. 36.4 and Box 36.5). The envelope has a membrane structure similar to cellular membranes.

BOX 36.5 Virion Structure: Envelope

Components

Membrane
Lipids
Proteins
Glycoproteins

Properties[a]

Is environmentally labile—disrupted by the following:
- Acid
- Detergents
- Drying
- Heat

Modifies cell membrane during replication
Is released by budding and cell lysis

Consequences[a]

Must stay wet
Cannot survive the gastrointestinal tract
Spreads in large droplets, secretions, organ transplants, and blood transfusions
Does not need to kill the cell to spread
May need antibody and cell-mediated immune response for protection and control
Elicits hypersensitivity and inflammation to cause immunopathogenesis

[a]Exceptions exist.

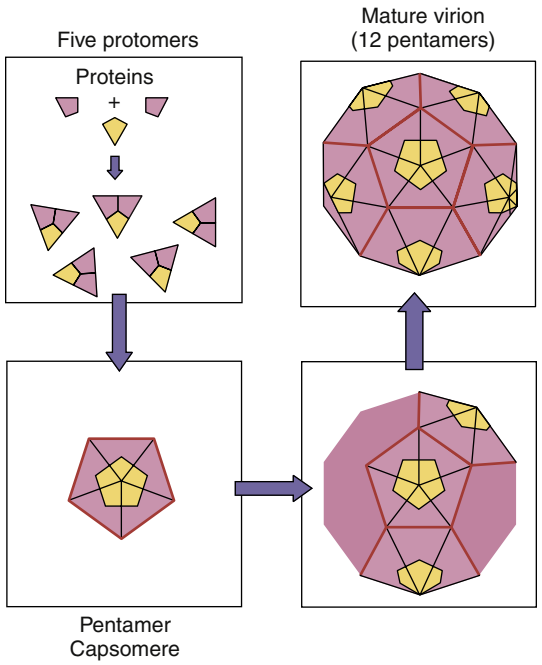

Fig. 36.5 Capsid assembly of the icosahedral capsid of a picornavirus. Individual proteins associate into subunits, which associate into protomers, capsomeres, and an empty procapsid. Inclusion of the (+) RNA genome triggers its conversion to the final capsid form.

Cellular proteins are rarely found in the viral envelope, even though the envelope is obtained from cellular membranes. Most enveloped viruses are round or pleomorphic. Two exceptions are the poxvirus, which has a complex internal and a bricklike external structure, and the rhabdovirus, which is bullet shaped.

Most viral glycoproteins have asparagine-linked (*N*-linked) carbohydrates and extend through the envelope and away from the surface of the virion. For many viruses, these can be observed as spikes (Fig. 36.7). Some glycoproteins act as **VAPs,** and are capable of binding to structures on target cells. VAPs that also bind to erythrocytes are termed **hemagglutinins (HAs).** Some glycoproteins have other functions, such as the neuraminidase (NA) of orthomyxoviruses (influenza) and the Fc receptor and the C3b receptor associated with herpes simplex virus (HSV) glycoproteins, or the fusion glycoproteins of paramyxoviruses. Glycoproteins, especially the VAPs, are also major antigens that elicit protective immunity.

The envelope of the togaviruses surrounds an icosahedral nucleocapsid containing a positive-strand RNA genome. The envelope contains spikes consisting of two or three glycoprotein subunits anchored to the virion's icosahedral capsid. This causes the envelope to adhere tightly and conform (shrink-wrap) to an icosahedral structure discernible by cryoelectron microscopy.

All of the negative-strand RNA viruses are enveloped. Components of the viral RNA-dependent RNA polymerase associate with the (−) RNA genome of the orthomyxoviruses, paramyxoviruses, and rhabdoviruses to form helical nucleocapsids. These enzymes are required to initiate virus replication, and their association with the genome ensures their delivery into the cell. **Matrix proteins** lining the inside of the envelope facilitate the assembly of the ribonucleocapsid into the virion. Influenza A (orthomyxovirus) is an example of a (−) RNA virus with a segmented genome. Its envelope is lined with matrix proteins and has two glycoproteins: the HA, which is the VAP, and an NA (see Fig. 49.1). Bunyaviruses do not have matrix proteins.

The herpesvirus envelope is a baglike structure that encloses the icosadeltahedral nucleocapsid (see Fig. 43.1). Depending on the specific herpesvirus, the envelope may contain as many as 11 glycoproteins. The interstitial space between the nucleocapsid and the envelope is called the **tegument,** and it contains enzymes, other proteins, and even RNA that facilitate the viral infection.

The poxviruses are enveloped viruses with large, complex, bricklike shapes (see Fig. 44.1). The envelope encloses a dumbbell-shaped, DNA-containing nucleoid structure; lateral bodies; fibrils; and many enzymes and proteins, including the enzymes and transcriptional factors required for mRNA synthesis.

Viral Replication

The major steps in viral replication are the same for all viruses (Fig. 36.8; Box 36.6). The cell acts as a factory, providing the substrates, energy, and machinery necessary for the synthesis of viral proteins and replication of the genome. Processes not provided by the cell must be encoded in the genome of the virus. The manner in which each virus accomplishes these steps and overcomes the cell's biochemical limitations is different for different structures of the genome and of the virion (whether it is enveloped or

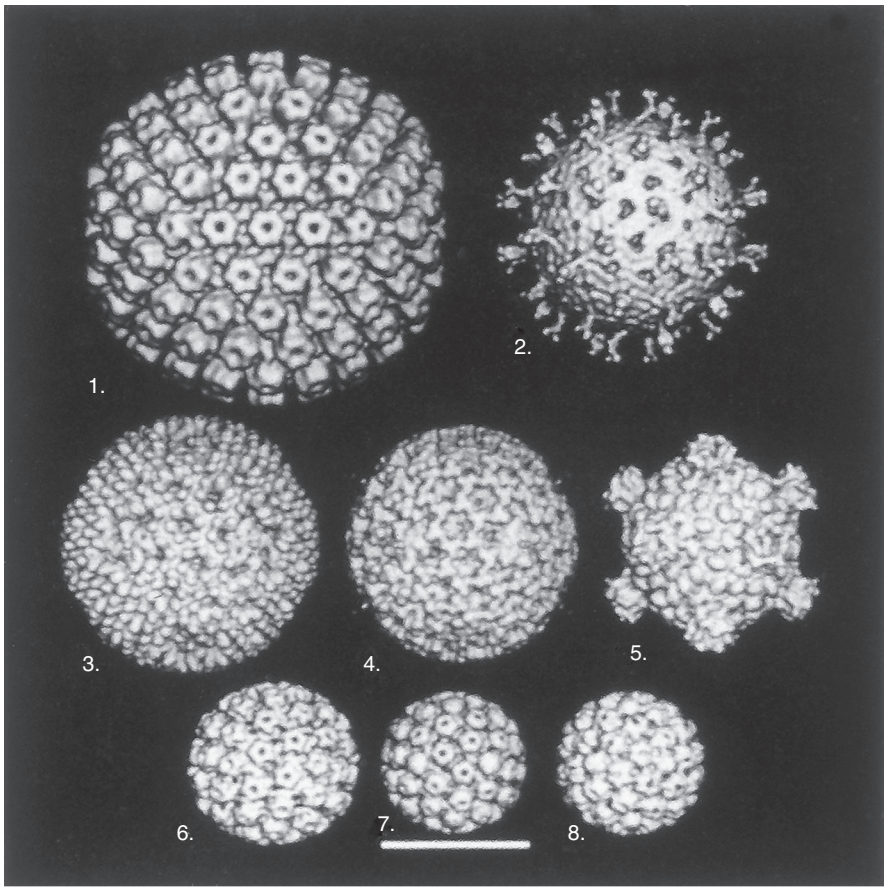

Fig. 36.6 Cryoelectron microscopy and computer-generated three-dimensional image reconstructions of several icosahedral capsids. These images show the symmetry of capsids and the individual capsomeres. has a naked capsid). This is illustrated in later figures in this chapter and in subsequent chapters (see later).

A single round of the viral replication cycle can be separated into several phases. During the **early phase** of infection, the virus must recognize an appropriate target cell; attach to the cell; penetrate the plasma membrane and be taken up by the cell; release (uncoat) its genome into the cytoplasm; and if necessary, deliver the genome to the nucleus. The **late phase** begins with the start of genome replication and viral macromolecular synthesis and proceeds through viral assembly and release. Uncoating of the genome from the capsid or envelope during the early phase abolishes its infectivity and identifiable structure, initiating the eclipse period. The **eclipse period,** like a solar eclipse, ends with the appearance of new virions after virus assembly. The **latent period** (not to be confused with latent infection), during which extracellular infectious virus is not detected, includes the eclipse period and ends with the release of new viruses (Fig. 36.9). Each infected cell may produce as many as 100,000 particles; however, only 1% to 10% of these particles may be infectious. The noninfectious particles **(defective particles)** result from mutations and errors in the manufacture and assembly of the virion. The yield of infectious virus per cell, or **burst size,** and the time required for a single cycle of virus reproduction are determined by the properties of the virus and the target cell. Although it may seem wasteful to produce so many defective particles, the virus uses this mechanism to generate mutants that may have a selective advantage, and 1% of 100,000 viruses is still a large amount of virus.

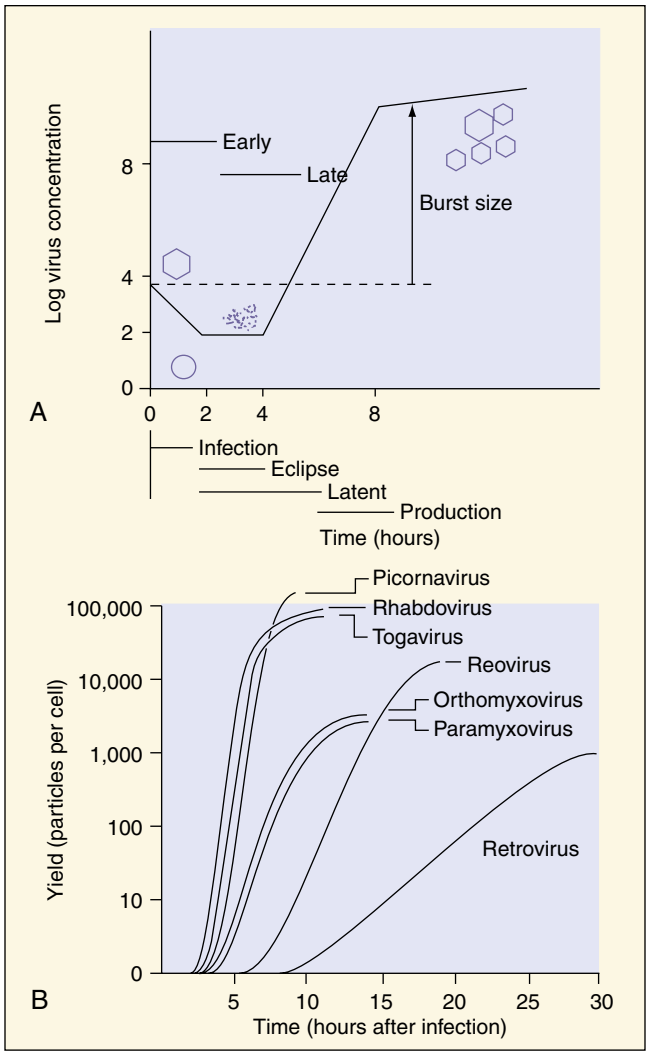

Fig. 36.9 (A) Single-cycle growth curve for a virus that is released by cell lysis. The different stages are defined by the absence of visible viral components (eclipse period) or infectious virus in the media (latent period), or the presence of macromolecular synthesis (early/late phases). (B) Growth curve and burst size (yield) of representative viruses. (A, Modified from Davis, B.D., Dulbecco, R., Eisen, H.N., et al., 1990. Microbiology, fourth ed. Lippincott, Philadelphia, PA. B, Modified from White, D.O., Fenner, F., 1986. Medical Virology, third ed. Academic, New York, NY.)

RECOGNITION OF AND ATTACHMENT TO THE TARGET CELL

The binding of the **VAPs** or structures on the surface of the virion capsid (Table 36.5) to **receptors on the cell** (Table 36.6) initially determines which cells can be infected by a virus. *The receptors for the virus on the cell may be proteins or carbohydrates on glycoproteins or glycolipids.* Viruses that bind to receptors expressed on specific cell types may be restricted to certain species **(host range)** (e.g., human, mouse) or specific cell types. The susceptible target cell defines the **tissue tropism** (e.g., neurotropic, lymphotropic). Epstein-Barr virus (EBV), a herpesvirus, has a very limited host range and tropism because it binds to the C3d receptor (CR2) expressed on human B cells. The B19 parvovirus binds to globoside (blood group P antigen) expressed on erythroid precursor cells.

The viral attachment structure for a capsid virus may be part of the capsid or a protein that extends from the capsid. A canyon on the surface of picornaviruses, such as rhinovirus 14, serves as a "keyhole" for the insertion of a portion of the intercellular adhesion molecule (ICAM-1) from the cell surface (see Fig. 46.2). The fibers of the adenoviruses and the σ-1 proteins of the reoviruses at the vertices of the capsid interact with receptors expressed on specific target cells.

Specific glycoproteins are the VAPs of enveloped viruses. The HA of influenza A virus binds to specific sialic acid carbohydrates expressed on many but not all cells of different species. Similarly, the α-togaviruses and the flaviviruses are

TABLE 36.5 Examples of Viral Attachment Proteins

Virus Family	Virus	Viral Attachment Protein
Picornaviridae	Rhinovirus	VP1-VP2-VP3 complex
Adenoviridae	Adenovirus	Fiber protein
Reoviridae	Reovirus	σ-1
	Rotavirus	VP7
Togaviridae	Semliki Forest virus	E1-E2-E3 complex gp
Rhabdoviridae	Rabies virus	G-protein gp
Orthomyxoviridae	Influenza A virus	HA gp
Paramyxoviridae	Measles virus	H gp
Herpesviridae	Epstein-Barr virus	gp350 and gp220
Retroviridae	Murine leukemia virus	gp70
	Human immunodeficiency virus	gp120

gp, Glycoprotein; *H* or *HA,* hemagglutinin.

TABLE 36.6 Examples of Viral Receptors

Virus	Target Cell	Receptor[a]
Epstein-Barr virus	B cell	C3d complement receptor (CR2, CD21)
HIV	Helper T cell	CD4 molecule and chemokine coreceptor
Rhinovirus	Epithelial cells	ICAM-1 (immunoglobulin superfamily protein)
Poliovirus	Epithelial cells	Immunoglobulin superfamily protein
Herpes simplex virus	Many cells	Herpesvirus entry mediator (HveA), nectin-1
Rabies virus	Neuron	Acetylcholine receptor, NCAM
Influenza A virus	Epithelial cells	Sialic acid
B19 parvovirus	Erythroid precursors	Erythrocyte P antigen (globoside)

[a]Other receptors for these viruses may also exist.
CD, Cluster of differentiation; *ICAM-1,* intercellular adhesion molecule; *NCAM,* neural cell adhesion molecule.

able to bind to receptors expressed on cells of many animal species, including arthropods, reptiles, amphibians, birds, and mammals. This allows them to infect animals, mosquitoes, and other insects and to be spread by them.

PENETRATION

Interactions between multiple VAPs and cellular receptors initiate the internalization of the virus into the cell. The mechanism of internalization depends on the virion structure and cell type. Most nonenveloped viruses enter the cell by receptor-mediated endocytosis or by viropexis. **Endocytosis** is a normal process used by the cell for the uptake of receptor-bound molecules such as hormones, low-density lipoproteins, and transferrin. Picornaviruses, papillomaviruses, and polyomaviruses may enter by **viropexis.** Hydrophobic structures of capsid proteins may be exposed after viral binding to the cells, and these structures help the virus or the viral genome slip through (direct penetration) the membrane.

Enveloped viruses fuse their membranes with cellular membranes to deliver the nucleocapsid or genome directly into the cytoplasm. The optimum pH for fusion determines whether penetration occurs at the cell surface at neutral pH or whether the virus must be internalized by endocytosis, and fusion occurs in an endosome at acidic pH. The fusion activity may be provided by the VAP or another protein. The HA of influenza A (see Fig. 36.7) binds to sialic acid receptors on the target cell. Under the mild acidic conditions of the endosome, the HA undergoes a dramatic conformational change to expose hydrophobic portions capable of promoting membrane fusion. Paramyxoviruses have a fusion protein that is active at neutral pH to promote virus-to-cell fusion. Paramyxoviruses can also promote cell-to-cell fusion to form multinucleated giant cells **(syncytia).** Some herpesviruses and retroviruses fuse with cells at a neutral pH and induce syncytia after replication.

UNCOATING

Once internalized, the nucleocapsid must be delivered to the site of replication within the cell and the capsid or envelope removed. The genome of DNA viruses, except for poxviruses, must be delivered to the nucleus, whereas most RNA viruses remain in the cytoplasm. The uncoating process may be initiated by attachment to the receptor or promoted by the acidic environment or proteases found in an endosome or lysosome. Picornavirus capsids are weakened by the release of the VP4 capsid protein to allow uncoating. VP4 is released by insertion of the receptor into the keyhole-like canyon attachment site of the capsid. Enveloped viruses are uncoated on fusion with cell membranes. Fusion of the herpesvirus envelope with the plasma membrane releases its nucleocapsid, which then "docks" with the nuclear membrane to deliver its DNA genome directly to the site of replication. The release of the influenza nucleocapsid from its matrix and envelope is facilitated by the passage of protons from inside the endosome through the ion pore formed by the influenza M2 membrane protein to acidify the virion.

The reovirus and poxvirus are only partially uncoated on entry. The outer capsid of reovirus is removed, but the genome remains in an inner capsid, which contains the polymerases necessary for RNA synthesis. The initial uncoating of the poxviruses exposes a subviral particle to the cytoplasm, allowing synthesis of mRNA by virion-contained enzymes. An uncoating enzyme can then be synthesized to release the DNA-containing core into the cytoplasm.

MACROMOLECULAR SYNTHESIS

Once inside the cell, the genome must direct the synthesis of viral mRNA and protein and generate identical copies of itself. The genome is useless unless it can be transcribed into functional mRNAs capable of binding to ribosomes and being translated into proteins. The means by which each virus accomplishes these steps depends on the structure of the genome (Fig. 36.10) and the site of replication.

The naked genome of DNA viruses (except poxviruses) and the positive-sense RNA viruses (except retroviruses) are

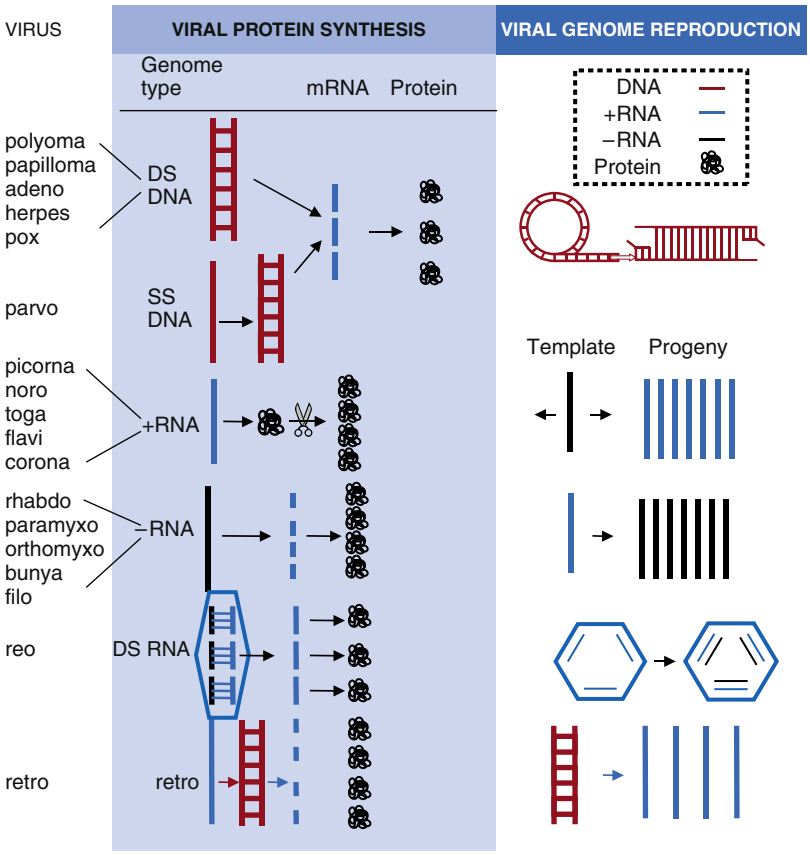

Fig. 36.10 Viral macromolecular synthesis steps: the structure of the genome determines the mechanism of viral mRNA and protein synthesis and also genome replication. (1) Double-stranded DNA *(DS DNA)* uses host machinery in the nucleus (except poxviruses) to make mRNA, which is translated by host cell ribosomes into proteins. Replication of viral DNA occurs by semiconservative means, by rolling circle, linear, and in other ways. (2) Single-stranded DNA *(SS DNA)* is converted into DS DNA and replicates like DS DNA. (3) (+) RNA resembles an mRNA that binds to ribosomes to make a polyprotein that is cleaved into individual proteins. One of the viral proteins is an RNA polymerase that makes a (–) RNA template and then more (+) RNA genome progeny and mRNAs. (4) (–) RNA is transcribed into mRNAs and a full-length (+) RNA template by the RNA polymerase carried in the virion. The (+) RNA template is used to make (–) RNA genome progeny. (5) DS RNA acts like (–) RNA. The (–) strands are transcribed into mRNAs by an RNA polymerase in the capsid. New (+) RNAs get encapsidated and (–) RNAs are made in the inner capsid. (6) Retroviruses have (+) RNA that is converted to complementary DNA (cDNA) by reverse transcriptase carried in the virion. cDNA integrates into the host chromosome, and the host makes mRNAs, proteins, and full-length RNA genome copies.

sometimes referred to as **infectious nucleic acids** because they are sufficient for initiating replication on injection into a cell. These genomes can interact directly with host machinery to promote mRNA or protein synthesis.

Most DNA viruses use the cell's machinery for transcription and mRNA processing in the nucleus, including the DNA-dependent RNA polymerase II and other enzymes to make mRNA. (*The names of the polymerases describe what they do—first the template and then the product [e.g., the polymerase that makes mRNA in the cell is a DNA-dependent RNA polymerase, and the enzyme that copies DNA is a DNA-dependent DNA polymerase]*). In addition, the viral mRNAs acquire a 3′ polyadenylated (polyA) tail and a 5′ methylated cap (for binding to the ribosome) and are processed to remove introns before being exported to the cytoplasm like the cell's mRNA. Viruses that replicate in the cytoplasm must provide these functions or an alternative. Although poxviruses are DNA viruses, they replicate in the cytoplasm; therefore they must encode enzymes for all these functions.

Most RNA viruses replicate and produce mRNA in the cytoplasm, except for orthomyxoviruses and retroviruses. RNA viruses must encode the necessary enzymes for transcription and replication because the cell has no means of replicating RNA. The mRNAs for RNA viruses may or may not acquire a 5′ cap or polyA tail.

In general, mRNA for nonstructural proteins is transcribed first. **Early gene products** (nonstructural proteins) are often DNA-binding proteins and enzymes, including virus-encoded polymerases. These proteins are catalytic, and only a few are required. Replication of the genome usually initiates the transition to transcription of late gene products. **Late viral genes** encode structural and other proteins. Many copies of these proteins are required to package the virus but are generally not required before the genome is replicated. Newly replicated genomes also provide new templates to amplify late gene mRNA synthesis. Different DNA and RNA viruses control the time and amount of viral gene and protein synthesis in different ways.

DNA VIRUSES

Transcription of the DNA virus genome (except for poxviruses) occurs in the nucleus, using host cell polymerases and other enzymes for viral mRNA synthesis (Fig. 36.11; Box 36.7).

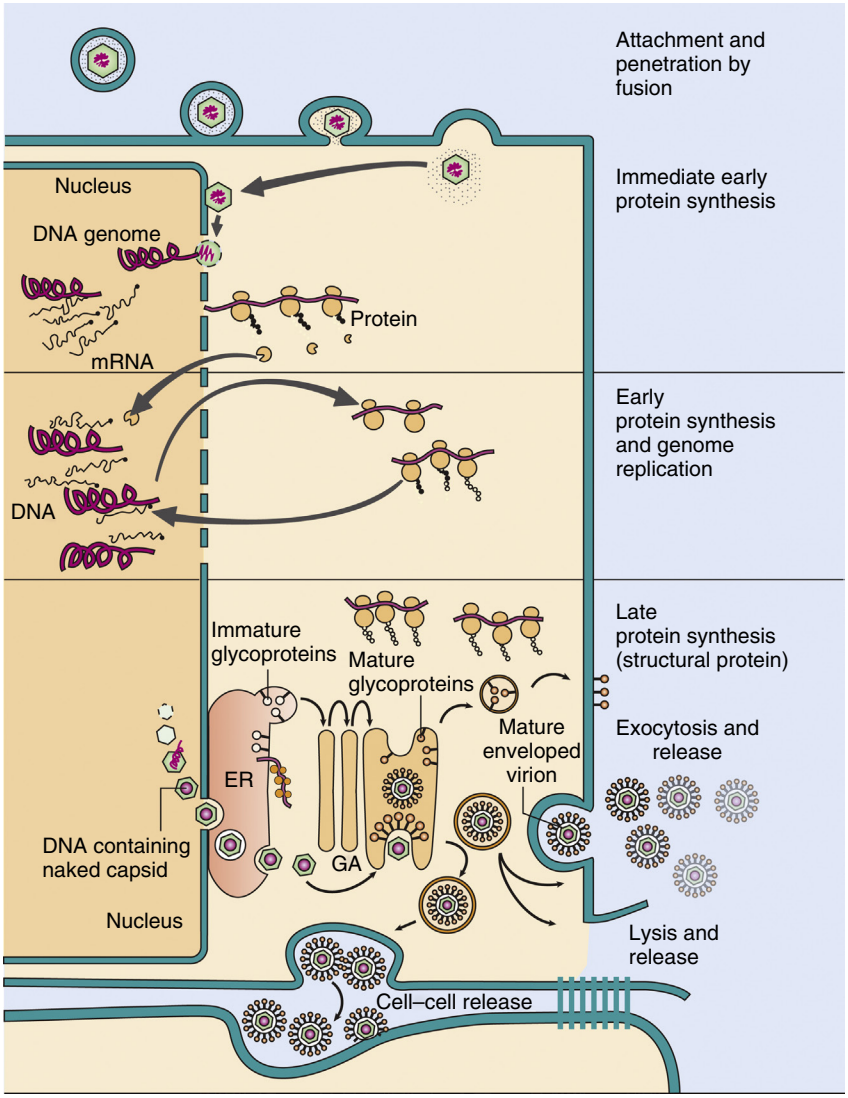

Fig. 36.11 Replication of herpes simplex virus, a complex enveloped DNA virus. The virus binds to specific receptors and fuses with the plasma membrane. The nucleocapsid then delivers the DNA genome to the nucleus. Transcription and translation occur in three phases: immediate early, early, and late. Immediate early proteins promote the takeover of the cell; early proteins consist of enzymes, including the DNA-dependent DNA polymerase; and the late proteins are structural and other proteins, including the viral capsid and glycoproteins. The genome is replicated before transcription of the late genes. Capsid proteins migrate into the nucleus, assemble into icosadeltahedral capsids, and are filled with the DNA genome. The capsids filled with genomes bud through the nuclear and endoplasmic reticulum *(ER)* membranes into the cytoplasm, acquire tegument proteins, and then acquire their envelope as they bud through the viral glycoprotein-modified membranes of the trans-Golgi network. The virus is released by exocytosis, cell lysis, or through cell-cell bridges (not shown). *GA,* Golgi apparatus.

Transcription of the viral genes is regulated by the interaction of specific DNA-binding proteins with promoter and enhancer elements in the viral genome. Cells from some tissues do not express the DNA-binding proteins necessary for activating the transcription of viral genes; thus replication of the virus in that cell is prevented or limited.

Different DNA viruses control the duration, timing, and quantity of viral gene and protein synthesis in different ways. The more complex viruses encode their own transcriptional activators, which enhance or regulate the expression of viral genes. For example, HSV encodes many proteins that regulate the kinetics of viral gene expression, including the VMW 65 (α-TIF protein, VP16). VMW 65 is carried in the virion, binds to the host cell transcription-activating complex (Oct-1), and enhances its ability to stimulate transcription of the immediate early genes of the virus.

Genes may be transcribed from either DNA strand of the genome and in opposite directions. For example, the early and late genes of the SV40 polyomavirus are on opposite, nonoverlapping DNA strands. Viral genes may have introns requiring posttranscriptional processing of the mRNA by the cell's nuclear machinery (splicing). The late genes of papillomaviruses and polyomaviruses and adenoviruses are initially transcribed as a large RNA from a single promoter and then processed to produce several different mRNAs after removal of different intervening sequences (introns).

Replication of viral DNA follows the same biochemical rules as for cellular DNA and requires a DNA-dependent

BOX 36.7 Properties of DNA Viruses

DNA is not transient or labile.
Many DNA viruses establish persistent infections (e.g., latent, immortalizing).
DNA genomes reside in the nucleus (except for poxviruses).
Viral DNA resembles host DNA for transcription and replication.
Viral genes must interact with host transcriptional machinery (except for poxviruses).
Viral gene transcription is temporally regulated.
Early genes encode DNA-binding proteins and enzymes.
Late genes encode structural and other proteins.
DNA polymerases require a primer to replicate the viral genome.
The larger DNA viruses encode means to promote efficient replication of their genome.
Parvovirus: requires cells undergoing DNA synthesis to replicate.
Papillomavirus: stimulates cell growth and DNA synthesis.
Polyomavirus: stimulates cell growth and DNA synthesis.
Hepadnavirus: stimulates cell growth, cell makes RNA intermediate, encodes a reverse transcriptase.
Adenovirus: stimulates cellular DNA synthesis and encodes its own polymerase.
Herpesvirus: stimulates cell growth, encodes its own polymerase and enzymes to provide deoxyribonucleotides for DNA synthesis, establishes latent infection in host.
Poxvirus: encodes its own polymerases and enzymes to provide deoxyribonucleotides for DNA synthesis, replication machinery, and transcription machinery in the cytoplasm.

DNA polymerase, other enzymes, and deoxyribonucleotide triphosphates, especially thymidine. Replication is initiated at a unique DNA sequence of the genome called the **origin (ori).** This is a site recognized by cellular or viral nuclear factors and the **DNA-dependent DNA polymerase.** Viral DNA synthesis is semiconservative, and viral and cellular *DNA polymerases require a primer* to initiate synthesis of the DNA chain. The parvoviruses have DNA sequences that are inverted and repeated to allow the DNA to fold back and hybridize with itself to provide a primer. Replication of the adenovirus genome is primed by deoxycytidine monophosphate attached to a terminal protein. A cellular enzyme (primase) synthesizes an RNA primer to start the replication of the papillomavirus and polyomavirus genomes, whereas the herpesviruses encode a primase.

Replication of the genome of the simple DNA viruses (e.g., parvoviruses, polyomaviruses, papillomaviruses) uses the host DNA-dependent DNA polymerases, whereas the larger, more complex viruses (e.g., adenoviruses, herpesviruses, poxviruses) encode their own polymerases *(puny parvovirus, polyomavirus, and papillomavirus all require cell polymerases)*. Viral polymerases are usually faster but less precise than host cell polymerases, causing a higher mutation rate in viruses and providing a target for nucleotide analogs as antiviral drugs.

Hepadnavirus replication is unique because a larger than genome positive-strand RNA copy is first synthesized by the cell's DNA-dependent RNA polymerase and circularizes. Viral proteins surround the RNA, which is a viral-encoded RNA-dependent DNA polymerase (reverse transcriptase) in this virion core makes a negative-strand DNA, and then the RNA is degraded. Positive-strand DNA synthesis is initiated but stops when the genome and core are enveloped, yielding a partially double-stranded, circular DNA genome.

Major limitations for replication of a DNA virus include availability of the DNA polymerase and deoxyribonucleotide substrates. Most cells in the resting phase of growth will not support DNA virus replication without help from viral encoded enzymes because they are not undergoing DNA synthesis, the necessary enzymes are not present, and deoxythymidine pools are limited. *The smaller the DNA virus, the more dependent the virus is on the host cell* to provide these functions (see Box 36.7). The parvoviruses are the smallest DNA viruses and replicate only in growing cells, such as erythroid precursor cells or fetal tissue. Speeding up the growth of the cell can enhance viral DNA and mRNA synthesis. The T antigen of SV40, the E6 and E7 of papillomavirus, and the E1a and E1b proteins of adenovirus bind to and prevent the function of growth-inhibitory proteins (p53 and the retinoblastoma gene product), resulting in cell growth, which also promotes virus replication. HSV is an example of a large DNA virus that encodes a DNA polymerase and scavenging enzymes (e.g., deoxyribonuclease, ribonucleotide reductase, thymidine kinase) to generate the necessary deoxyribonucleotide substrates for replication of its genome. Larger DNA viruses can replicate in growing and nongrowing cells.

RNA VIRUSES

Replication and transcription of RNA viruses are similar processes because the viral genomes are usually either an mRNA (positive-strand RNA) (Fig. 36.12) or a template for mRNA (negative-strand RNA) (Fig. 36.13; Box 36.8). During replication and transcription, a double-stranded RNA replicative intermediate is formed. Double-stranded RNA is not normally found in uninfected cells and is a strong inducer of innate host protections.

The RNA virus genome must code for **RNA-dependent RNA polymerases (replicases and transcriptases)** and enzymes for synthesis and processing of the viral mRNA because the cell has no means of replicating RNA. Transcription of viral mRNA may require adding a terminal protein to the RNA for the picornaviruses or, like eukaryotic mRNA, the addition of a 5′ methylguanosine cap and 3′ polyadenosine. Negative-strand and double-strand RNA viruses bring the machinery for these processes into the cell together with the genome as part of the nucleocapsid.

Because RNA is degraded relatively quickly, the RNA-dependent RNA polymerase must be provided or synthesized soon after uncoating to generate more viral RNA, or the infection will be aborted. Most viral RNA polymerases work at a fast pace but are also error prone, causing mutations. Replication of the genome provides new templates for the production of more mRNA and genomes, which amplifies and accelerates virus replication.

The **positive-strand RNA viral genomes** of the picornaviruses, **caliciviruses, coronaviruses, flaviviruses,** and togaviruses act as mRNA, bind to ribosomes, and direct protein synthesis. *The naked positive-strand RNA viral genome is sufficient to initiate infection by itself.* Viral proteins are translated from the genome as a polyprotein that is cleaved by viral and cellular proteases into active proteins. These viruses create a **replication organelle** and scaffold to contain and organize the genome and viral and cellular enzymes necessary for replication and transcription of the genome.

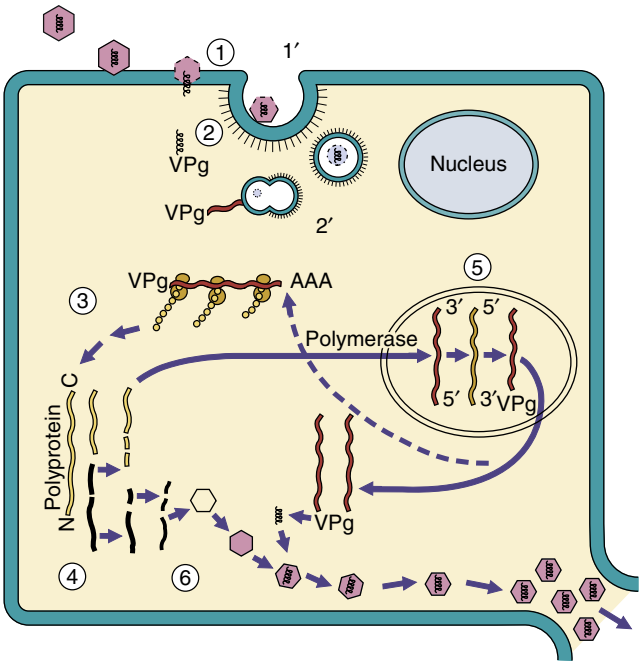

Fig. 36.12 Replication of picornaviruses: a simple (+) RNA virus. *1,* Interaction of the picornaviruses with receptors on the cell surface defines the target cell and weakens the capsid. *2,* The genome is injected through the virion and across the cell membrane. *2′,* Alternatively, the virion is endocytosed, and then the genome is released. *3,* The genome is used as mRNA for protein synthesis. One large polyprotein is translated from the virion genome. *4,* Then the polyprotein is proteolytically cleaved into individual proteins, including an RNA-dependent RNA polymerase. *5,* Macromolecular synthesis proceeds in a replication organelle created by the virus. The polymerase makes a (–) strand template from the genome and replicates the genome. A protein *(VPg)* is covalently attached to the 5′ end of the viral genome. *6,* The structural proteins associate into the capsid structure, the genome is inserted, and the virions are released on cell lysis.

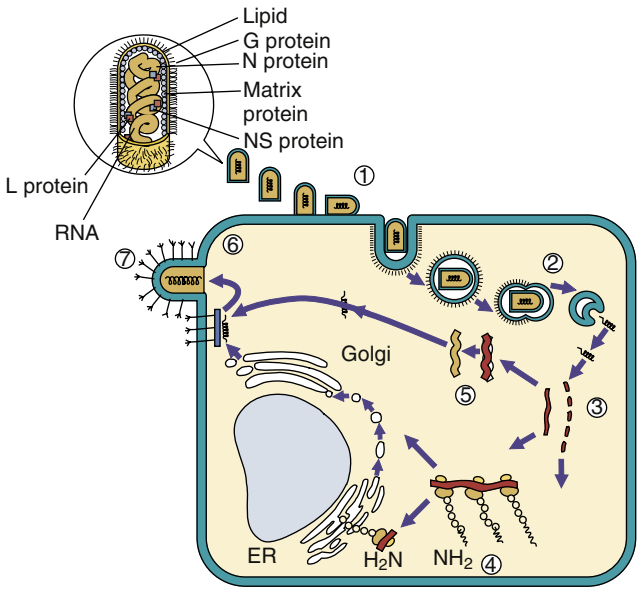

Fig. 36.13 Replication of rhabdoviruses: a simple enveloped (–) RNA virus. *1,* Rhabdoviruses bind to the cell surface and are *(2)* endocytosed. The envelope fuses with the endosome vesicle membrane to deliver the nucleocapsid to the cytoplasm. The virion must carry a polymerase, which *(3)* produces five individual messenger RNAs (mRNAs) and a full-length (+) RNA template. *4,* Proteins are translated from the mRNAs, including one glycoprotein (G), which is cotranslationally glycosylated in the endoplasmic reticulum *(ER),* processed in the Golgi apparatus, and delivered to the cell membrane. *5,* The genome is replicated from the (+) RNA template, and N, L, and NS proteins associate with the genome to form the nucleocapsid. *6,* The matrix protein associates with the G-protein–modified membrane, which is followed by assembly of the nucleocapsid. *7,* The virus buds from the cell in a bullet-shaped virion.

The virus-encoded RNA-dependent RNA polymerase produces a negative-strand RNA template (antigenome), and this template is used to generate more mRNA and to replicate the genome. For picornaviruses and flaviviruses, the genome and negative-sense template RNA and mRNA are the same size. For the togaviruses, coronaviruses, and caliciviruses, a full-length template and mRNA are initially produced, and then later, several smaller mRNAs for structural and other proteins (late genes) are generated from the template.

The **negative-strand RNA virus genomes** of the rhabdoviruses, orthomyxoviruses, paramyxoviruses, filoviruses, and bunyaviruses are the templates for production of individual mRNAs. The negative-strand RNA genome is not infectious nor can it bind to the ribosome, and a polymerase must be carried into the cell with the genome (associated with the genome as part of the nucleocapsid) to make the mRNAs for the different viral proteins. As a result, a full-length positive-strand RNA must also be produced by the viral polymerase to act as a template to generate more copies of the genome. The (–) RNA genome is like the negative from a roll of photographic film: each frame encodes a photo/mRNA, but a full-length positive is required for replicating the roll. Except for influenza viruses, transcription and replication of negative-strand RNA viruses occur in the cytoplasm. The influenza transcriptase requires a primer to produce mRNA. It uses the 5′ ends of cellular mRNA in the nucleus as primers for its polymerase and, in the process, steals the 5′ cap from the cellular mRNA. The influenza genome is also replicated in the nucleus.

The reoviruses have a **segmented, double-stranded RNA genome** and undergo a more complex means of replication and transcription. The reovirus RNA polymerase is part of the inner capsid core; individual mRNA units are transcribed from each of the 10 or more segments of the genome while they are still in the core. The negative strands of the genome segments are used as templates for mRNA production in a manner similar to that of the negative-strand RNA viruses. Reovirus-encoded enzymes contained in the inner capsid core add the 5′ cap to viral mRNA. The mRNA does not have polyA. The mRNAs are released into the cytoplasm, in which they direct protein synthesis or are sequestered into new cores. The positive-strand RNA in the new cores acts as a template for negative-strand RNA, and the core polymerase produces the progeny double-stranded RNA.

The arenaviruses have an **ambisense genome** with (–) sequences colinear to (+) sequences. The early mRNAs of the virus are transcribed from the negative-sense portion of the genome, a full-length replicative intermediate is produced to generate a new genome, and the late mRNAs of the virus are transcribed from the region of the replicative intermediate that is complementary to the (+) sequences.

Although the **retroviruses** have a positive-strand RNA genome, the virus provides no means for replication of the RNA in the cytoplasm. Instead, the retroviruses carry two

BOX 36.8 Properties of RNA Viruses

RNA is labile and transient.
Most RNA viruses replicate in the cytoplasm.
Cells cannot replicate RNA. RNA viruses must encode an RNA-dependent RNA polymerase.
The genome structure determines the mechanism of transcription and replication.
RNA viruses are prone to mutation.
The genome structure and polarity determine how viral mRNA is generated and proteins are processed.
RNA viruses, except for (+) RNA genome, must carry polymerases.
All (–) RNA viruses are enveloped.

Picornaviruses, Hepeviruses, Astroviruses, Togaviruses, Flaviviruses, Caliciviruses, and Coronaviruses

(+) RNA genome resembles mRNA and is translated into a polyprotein, which is proteolyzed. A (–) RNA template is used for replication. For togaviruses, coronaviruses, and caliciviruses, early proteins are translated from the genome and late proteins from smaller mRNAs transcribed from the template.

Orthomyxoviruses, Paramyxoviruses, Rhabdoviruses, Filoviruses, and Bunyaviruses

(–) RNA genome is a template for individual mRNAs, but the full-length (+) RNA template is required for replication. Orthomyxoviruses replicate and transcribe in the nucleus, and each segment of the genome encodes one mRNA and is a template.

Reoviruses

(+/–) Segmented RNA genome is a template for mRNA (+RNA). (+) RNA may also be encapsidated to generate the (+/–) RNA and then more mRNA.

Retroviruses

(+) Retrovirus RNA genome is converted into DNA, which is integrated into the host chromatin and transcribed as a cellular gene.

mRNA, Messenger RNA.

copies of the genome, two transfer RNA (tRNA) molecules, and an RNA-dependent DNA polymerase **(reverse transcriptase)** in the virion. The tRNA is used as a primer for synthesis of a circular complementary DNA **(cDNA)** copy of the genome. The cDNA is synthesized in the cytoplasm, travels to the nucleus, and it is then integrated into the host chromatin. The viral genome becomes a cellular gene. Promoters at the end of the integrated viral genome enhance the transcription of the viral DNA sequences by the cell. Full-length RNA transcripts are used as new genomes, and individual mRNAs are generated by differential splicing of this RNA.

The most unusual mode of replication is reserved for the **deltavirus.** The deltavirus resembles a viroid. The genome is a circular, rod-shaped, single-stranded RNA, which is extensively hybridized to itself. As the exception, the deltavirus RNA genome is replicated by the host cell DNA-dependent RNA polymerase II in the nucleus. A portion of the genome forms an RNA structure called a ribozyme, which cleaves the RNA circle to produce an mRNA.

VIRAL PROTEIN SYNTHESIS

All viruses depend on the host cell ribosomes, tRNA, and mechanisms for posttranslational modification to produce their proteins. The binding of mRNA to the ribosome is mediated by a 5′ cap structure of methylated guanosine or a special RNA loop structure (internal ribosome entry sequence [IRES]), which binds within the ribosome to initiate protein synthesis. The cap structure, if used, is acquired in different ways by different viruses. The IRES structure was discovered first in the picornavirus genome and then in selected cellular mRNAs. Most but not all viral mRNA have a polyA tail, like eukaryotic mRNAs.

Unlike bacterial ribosomes, which can bind to a polycistronic mRNA and translate several gene sequences into separate proteins, the eukaryotic ribosome binds to mRNA and can make only one continuous protein, and then it falls off the mRNA. Each virus deals with this limitation differently, depending on the structure of the genome. For example, the entire genome of a positive-strand RNA virus is read by the ribosome and translated into one giant **polyprotein.** The polyprotein is subsequently cleaved by cellular and viral proteases into functional proteins. DNA viruses, retroviruses, and most negative-strand RNA viruses transcribe separate mRNA for smaller polyproteins or individual proteins. The orthomyxovirus and reovirus genomes are segmented, and most of the segments code for single proteins for this reason.

Viruses use different tactics to promote preferential translation of their viral mRNA instead of cellular mRNA. In many cases, the concentration of viral mRNA in the cell is so large it occupies most of the ribosomes, preventing translation of cellular mRNA. Adenovirus infection blocks the egress of cellular mRNA from the nucleus. HSV and other viruses inhibit cellular macromolecular synthesis and induce degradation of the cell's DNA and mRNA. To promote selective translation of its mRNA, poliovirus uses a virus-encoded protease to inactivate the 200,000-Da cap-binding protein of the ribosome to prevent binding and translation of the cell's 5′-capped cellular mRNA. Togaviruses and many other viruses increase the permeability of the cell's membrane; thus the ribosomal affinity for most cellular mRNA is decreased. All these actions also contribute to the cytopathology of the virus infection. The pathogenic consequences of these actions are discussed further in Chapter 37.

Some viral proteins require **posttranslational modifications** such as phosphorylation, glycosylation, acylation, or sulfation. Protein phosphorylation is accomplished by cellular or viral protein kinases and is a means of modulating, activating, or inactivating proteins. Several herpesviruses and other viruses encode their own protein kinases. *Viral glycoproteins are synthesized on membrane-bound ribosomes and have the amino acid sequences to allow insertion into the rough endoplasmic reticulum and N-linked glycosylation.* The high-mannose precursor form of the glycoproteins progresses from the endoplasmic reticulum through the vesicular transport system of the cell and is processed through the Golgi apparatus. The mature, sialic acid–containing glycoprotein is expressed on the plasma membrane of the cell. Some glycoproteins express protein sequences for distribution to different sides of a polarized epithelial cell (e.g., lung) or retention in an intracellular organelle. *The membrane presence of the glycoproteins determines whether the virion will assemble on internal membranes or at the apical or basolateral surfaces.* Other modifications, such as *O*-glycosylation, acylation, and sulfation of the proteins, can also occur during progression through the Golgi apparatus.

ASSEMBLY

Virion assembly is analogous to a three-dimensional interlocking puzzle that puts itself together in the box. The virion is built from small, easily manufactured parts that enclose the genome in a functional package. Each part of the virion has recognition structures that allow the virus to form the appropriate protein–protein, protein–nucleic acid, and (for enveloped viruses) protein–membrane interactions needed to assemble into the final structure. The assembly process begins when the necessary pieces are synthesized, and the concentration of structural proteins in the cell is sufficient to drive the process thermodynamically, much like a crystallization reaction. The assembly process may be facilitated by scaffolding proteins or other proteins, some of which are activated or release energy on proteolysis. For example, cleavage of the VP0 protein of the poliovirus releases the VP4 peptide, which solidifies the capsid.

The site and mechanism of virion assembly in the cell depend on where genome replication occurs and whether the final structure is a naked capsid or an enveloped virus. Assembly of the DNA nucleocapsid for viruses other than poxviruses occurs in the nucleus and requires transport of the virion proteins into the nucleus. RNA virus and poxvirus assemblies occur in the cytoplasm.

Capsid viruses may be assembled as empty structures (procapsids) to be filled with the genome (e.g., picornaviruses), or they may be assembled around the genome. Nucleocapsids of the retroviruses, togaviruses, and the negative-strand RNA viruses assemble around the genome and are subsequently enclosed in an envelope. The helical nucleocapsid of negative-strand RNA viruses includes the RNA-dependent RNA polymerase necessary for mRNA synthesis in the target cell.

For enveloped viruses, newly synthesized and processed viral glycoproteins are delivered to cellular membranes by vesicular transport. Acquisition of an envelope occurs after association of the nucleocapsid with the viral glycoprotein-containing regions of host cell membranes in a process called **budding.** Matrix proteins for some negative-strand RNA viruses line and promote the adhesion of nucleocapsids with the glycoprotein-modified membrane. As more interactions occur, the membrane surrounds the nucleocapsid, and the virus buds from the membrane.

The type of genome and the protein sequence of the glycoproteins determine the site of budding. Most RNA viruses bud from the plasma membrane, and the virus is released from the cell at the same time without killing the cell. The flaviviruses, coronaviruses, and bunyaviruses acquire their envelope by budding into the endoplasmic reticulum and Golgi membranes and may remain cell associated in these organelles. The HSV nucleocapsid assembles in the nucleus and buds into and then out of the adjacent endoplasmic reticulum. The nucleocapsid is dumped into the cytoplasm, viral proteins associate with the capsid, and then the envelope is acquired by budding into a trans-Golgi network membrane decorated with the 10 viral glycoproteins. The virion is transported to the cell surface and released by exocytosis, on cell lysis, or transmitted through cell-to-cell bridges.

Viruses use different tricks to ensure that all the parts of the virus are assembled into complete virions. The RNA polymerase required for infection by negative-strand RNA viruses is carried on the genome as part of a helical nucleocapsid. The human immunodeficiency virus (HIV) and other retrovirus genomes are packaged in a procapsid consisting of a polyprotein containing the protease, polymerase, integrase, and structural proteins. This procapsid binds to viral glycoprotein-modified membranes, and the virion buds from the membrane. The virus-encoded protease is activated within the virion and cleaves the polyprotein to produce the final infectious nucleocapsid and the required proteins within the envelope.

Assembly of viruses with segmented genomes, such as influenza or reovirus, requires accumulation of at least one copy of each gene segment to be infectious. The segments nest within structures created by the viral proteins.

Errors are made by the viral polymerase and during viral assembly. Empty virions and virions containing defective genomes are produced. As a result, the particle–to–infectious virus ratio, also called *particle-to-plaque–forming unit ratio,* is high, usually greater than 10, and during rapid viral replication can even be 10^4. Defective viruses can occupy the machinery (e.g., bind to the receptor) required for normal virus replication to prevent (interfere with) virus production **(defective interfering particles).**

RELEASE

Viruses can be released from cells after lysis of the cell, by exocytosis, or by budding from the plasma membrane. Naked capsid viruses are generally released after lysis of the cell. Release of most enveloped viruses occurs after budding from the plasma membrane without killing the cell. Survival of the cell allows continual production and release of virus from the factory. Lysis and plasma membrane budding are efficient means of release. Viruses that assemble, bud, or acquire their membrane in the cytoplasm (e.g., flaviviruses, poxviruses) remain cell associated and are released by exocytosis or cell lysis. Viruses that bind to sialic acid receptors (e.g., orthomyxoviruses, certain paramyxoviruses) may also have an NA. The NA removes potential sialic acid receptors on the glycoproteins of the virion and host cell to prevent clumping within the cell and facilitate release.

SPREAD OF THE INFECTION

Virus can be spread to other cells on release to the extracellular medium, but alternatively the virus, nucleocapsid, or genome can be transmitted *through cell-to-cell bridges, after cell-to-cell fusion, or vertically to daughter cells.* These alternate routes allow the virus to escape antibody detection. Some herpesviruses, retroviruses, and paramyxoviruses can induce cell-to-cell fusion to merge the cells into multinucleated giant cells **(syncytia),** which become huge virus factories. The retroviruses and some DNA viruses can transmit their integrated copy of the genome vertically to daughter cells on cell division.

Viral Genetics

Mutations spontaneously and readily occur in viral genomes, creating new virus strains with properties

different from the **parental** or **wild-type, virus.** Most mutations have no effect or are detrimental to the virus, but mutations in essential genes can inactivate the virus. Mutations in other genes may produce antiviral drug resistance or alter the antigenicity or pathogenicity of the virus.

Viral polymerases are error prone and generate many mutations during replication of the genome. In addition, RNA viruses lack a genetic error-checking mechanism. As a result, the rates of mutation for RNA viruses are usually greater than for DNA viruses.

Mutations that inactivate essential genes are termed **lethal mutations.** These mutants are difficult to isolate because the virus cannot replicate. A **deletion mutant** results from loss or selective removal of a portion of the genome and the function it encodes. Other mutations may produce **plaque mutants,** which differ from the wild type in the size or appearance of the infected cells; **host range mutants,** which differ in the tissue type or species of target cell that can be infected; or **attenuated mutants,** which are variants that cause less serious disease in animals or humans. **Conditional mutants,** such as **temperature-sensitive (ts)** or **cold-sensitive mutants,** have a mutation in a gene for an essential protein that allows virus production only at certain temperatures. Whereas ts mutants generally grow well or relatively better at 30°C to 35°C, the encoded protein is inactive at elevated temperatures of 38°C to 40°C, preventing virus production. Live virus vaccines are often conditional or host range mutants and attenuated for human disease.

New virus strains can also arise by genetic interactions between viruses or between the virus and the cell (Fig. 36.14). Intramolecular genetic exchange between viruses or the virus and the host is termed **recombination.** Recombination can occur readily between two related DNA viruses. For example, coinfection of a cell with the two closely related herpesviruses (HSV types 1 and 2) yields intertypic recombinant strains. These new hybrid strains have genes from types 1 and 2. Integration of retroviruses into host cell chromatin is a form of recombination. Recombination of two related RNA viruses, Sindbis and eastern equine encephalitis virus, resulted in creation of another togavirus, western equine encephalitis (WEE) virus.

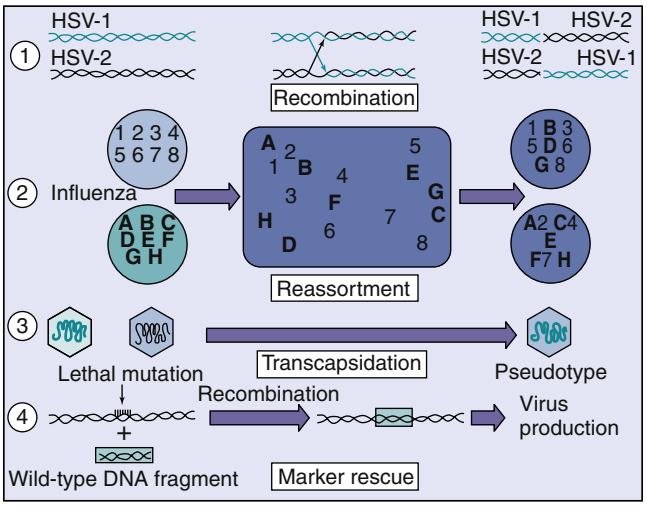

Fig. 36.14 Genetic exchange between viral particles can give rise to new viral types, as illustrated. Representative viruses include the following: *1,* intertypic recombination of herpes simplex virus type 1 *(HSV-1)* and type 2 *(HSV-2); 2,* reassortment of two strains of influenza virus; *3,* rescue of a polyomavirus defective in assembly by a complementary defective virus (transcapsidation); and *4,* marker rescue of a lethal or conditional mutation.

Viruses with segmented genomes (e.g., influenza viruses and reoviruses) form hybrid strains on infection of one cell with more than one virus strain. This process, termed **reassortment,** is analogous to picking 10 marbles out of a box containing 10 black and 10 white marbles. Very different strains of influenza A virus are created on coinfection with a virus from different species (see Fig. 49.5).

A defective virus can be rescued and replicate **(complementation)** if the missing function required by the mutant is provided by the replication of another mutant, by the wild-type virus, or by a cell line that expresses the missing function. An experimental disabled infectious single-cycle HSV (DISC-HSV) vaccine lacks an essential gene and is grown in a cell line that expresses that gene product to "complement" the virus. The vaccine virus can infect the normal cells of the individual, but the virions that are produced lack the function necessary for replication in other cells and cannot spread. Rescue of a lethal or conditional-lethal mutant with a defined genetic sequence, such as a restriction endonuclease DNA fragment, is called **marker rescue.** Marker rescue is used to map the genomes of viruses such as HSV. Virus produced from cells infected with different virus strains may be phenotypically mixed and have the proteins of one strain but the genome of the other **(transcapsidation). Pseudotypes** are generated when transcapsidation occurs between different types of viruses, but this is rare outside of the lab.

Individual virus strains or mutants are **selected** by their ability to use the host cell machinery and to withstand the conditions of the body and the environment. Cellular properties that can act as **selection pressures** include the growth rate of the cell, tissue-specific expression of certain proteins required by the virus (e.g., enzymes, glycoproteins, transcription factors) and proteins that prevent essential virus functions. The conditions of the body, its elevated temperature, innate and immune defenses, tissue structure and antiviral drug treatment are also selection pressures for viruses. The viruses that cannot endure these conditions or evade the host defenses are eliminated. A small selective advantage in a mutant virus can shortly lead to its becoming the predominant viral strain. The high mutation rate of HIV promotes a switch in target cell tropism to include different types of T cells, the development of antiviral drug-resistant strains, and the generation of antigenic variants during a patient's course of infection.

The growth of virus under benign laboratory conditions allows weaker strains to survive because of the absence of the selective pressures of the human body. This process is used to select attenuated virus strains for use in vaccines.

Viral Vectors for Therapy

Genetically manipulated viruses can be excellent delivery systems for foreign genes. Viruses can provide gene replacement therapy, can be used as vaccines to promote immunity to other agents or tumors, and can act as targeted killers of tumors. The advantages of using viruses are that they can

be readily amplified by replication in appropriate cells, and they target specific tissues and deliver the DNA or RNA into the cell. Viruses that are being developed as vectors include retroviruses, adenoviruses, HSV, an adeno-associated virus (parvovirus), poxviruses (e.g., vaccinia and canarypox) (see Fig. 44.7), and even some togaviruses. The viral vectors are usually defective or attenuated viruses in which the foreign DNA replaces a virulence or unessential gene. The foreign gene may be under the control of a viral promoter or even a tissue-specific promoter. Defective virus vectors are grown in cell lines that express the missing viral functions "complementing" the virus. The progeny can deliver their nucleic acid but not produce infectious virus. Retroviruses and adeno-associated viruses can integrate into cells and permanently deliver a gene into the cell's chromosome. Adenovirus and HSV promote targeted delivery of the foreign gene to receptor-bearing cells. Genetically attenuated HSVs (oncolytic viruses) are used to specifically kill the growing cells of glioblastomas while sparing the surrounding neurons. Adenovirus and canarypox virus are being used to carry and express HIV and other genes as vaccines. Vaccinia virus carrying a gene for the rabies glycoprotein is already being used successfully to immunize raccoons, foxes, and skunks in the wild. Someday, virus vectors may be routinely used to treat cystic fibrosis, Duchenne muscular dystrophy, lysosomal storage diseases, and immunologic disorders.

Questions

1. Describe the structural and replicative features that are similar, and those that are different, and the implications of the differences.
   a. Poliovirus and rhinovirus
   b. Poliovirus and rotavirus
   c. Poliovirus and WEE virus
   d. Yellow fever virus and dengue virus
   e. EBV and cytomegalovirus (CMV)

2. Match the characteristics from column A with ALL of the appropriate viral families in column B, based on your knowledge of their physical and genome structure and their implications.

PROPERTIES	VIRUSES
a. Are resistant to detergents	A. Picornaviruses
b. Are resistant to drying	B. Togaviruses
c. Genome replication in the nucleus	C. Orthomyxoviruses
d. Genome replication in the cytoplasm	D. Paramyxoviruses
e. Can be released from the cell without cell lysis	E. Rhabdoviruses
f. Provide targets for approved antiviral drug action	F. Reoviruses
g. Undergo reassortment on coinfection with two strains	G. Retroviruses
h. Make DNA from an RNA template	H. Herpesviruses
i. Use a (+) RNA template to replicate the genome	I. Papillomaviruses
j. Genome translated into a polyprotein	J. Adenoviruses
	K. Poxviruses
	L. Hepadnaviruses
	M. Caliciviruses

3. Based on structural considerations, which of the virus families listed in question 2 should be able to endure fecal-oral transmission?

4. Indicate the type of polymerase that is encoded by the viruses listed in question 2.

5. A mutant defective in the HSV type 1 DNA polymerase gene replicates in the presence of HSV type 2. The progeny virus has a predominantly HSV type 1 genome but infection is blocked by antibodies to HSV type 2. Which genetic mechanisms may be occurring? What type of protein was most likely encoded by the HSV type 2 gene to allow neutralization by antibody?

6. Which types of proteins are encoded by the early and late genes of the togaviruses, polyomaviruses, and herpesviruses, and how is the time of their expression regulated?

7. What are the consequences (no effect, decreased efficiency, or inhibition of replication) of a deletion mutation in the following viral enzymes?
   a. EBV polymerase
   b. HSV thymidine kinase
   c. HIV reverse transcriptase
   d. Influenza B virus NA
   e. Rabies virus (rhabdovirus) G-protein

37 Mechanisms of Viral Pathogenesis

Viruses cause disease after they break through the natural protective barriers of the body, evade immune control, and either kill cells of an important tissue (e.g., brain) or trigger a destructive immune and inflammatory response. The outcome of a viral infection is determined by the nature of the virus–host interaction and the host's response to the infection (Box 37.1). The immune response is the best treatment, but it often contributes to the pathogenesis of a viral infection. The tissue targeted by the virus defines the nature of the disease and its symptoms. Viral and host factors govern the severity of the disease; they include the strain of virus, the inoculum size, and the general health of the infected person. The ability of the infected person's immune response to control the infection determines the severity and duration of the disease. A particular disease may be caused by several viruses that have a common tissue **tropism** (preference), such as hepatitis (the liver), common cold (the upper respiratory tract), and encephalitis (the central nervous system). On the other hand, a particular virus may cause several different diseases or no observable symptoms. For example, herpes simplex virus type-1 (HSV-1) can cause gingivostomatitis, pharyngitis, herpes labialis (cold sores), genital herpes, encephalitis, or keratoconjunctivitis, depending on the affected tissue, or it can cause no apparent disease at all. Although rarely lethal in an adult, HSV infection can be life-threatening in a newborn or an immunocompromised person.

Viruses encode activities **(virulence factors)** that promote the efficiency of viral replication, viral transmission, access and binding of the virus to target tissue, or escape of the virus from host defenses and immune resolution (see Chapter 10). These activities may not be essential for viral growth in tissue culture but are necessary for the pathogenicity or survival of the virus in the host. Loss of these virulence factors results in **attenuation** of the virus. Many live-virus vaccines are attenuated virus strains.

The discussion in this chapter focuses on viral disease at the cellular level (cytopathogenesis), the host level (mechanisms of disease), and the population level (epidemiology and control). The antiviral immune response is discussed here and in Chapter 10.

Basic Steps in Viral Disease

Viral disease in the body progresses through defined steps, just like viral replication in the cell (Fig. 37.1A). These steps are noted in Box 37.2.

The incubation period may proceed without symptoms **(asymptomatic)** or may produce nonspecific, cytokine-induced early symptoms, such as fever, head or body aches, or chills, termed the **prodrome.** Often the viral infection is resolved by innate host protections, without symptoms. The symptoms of the disease are caused by tissue damage and systemic effects caused by the virus and the immune system. These symptoms may continue through **convalescence** while the body repairs the damage. The individual usually develops a memory immune response for future protection against a similar challenge with this virus.

Infection of the Target Tissue

The virus gains **entry into the body** through breaks in the skin (cuts, bites, injections) or across the mucoepithelial membranes that line the orifices of the body (eyes, respiratory tract, mouth, genitalia, and gastrointestinal tract). The skin is an excellent barrier to infection. Tears, mucus, ciliated epithelium, stomach acid, bile, and immunoglobulin (Ig)A protect the orifices. *Inhalation is probably the most common route of viral infection.*

On entry into the body, the virus replicates in cells that express viral receptors and have the appropriate biosynthetic machinery. Many viruses initiate infection in the oral mucosa or upper respiratory tract. Disease signs may accompany viral replication at the primary site. The virus may replicate and remain at the primary site, disseminate to other tissues via the bloodstream or within mononuclear phagocytes and lymphocytes, or disseminate through neurons (see Fig. 37.1B).

The bloodstream and lymphatic system are the predominant means of viral transfer in the body. The virus may gain access to them after tissue damage; on uptake by macrophages; or on transport past the mucoepithelial cells of the oropharynx, gastrointestinal tract, vagina, or anus. Several enteric viruses (picornaviruses and reoviruses) bind to receptors on M cells, which translocate the virus to the underlying Peyer patches of the lymphatic system.

The transport of virus in the blood is termed **viremia.** The virus may either be free in the plasma or be cell associated in lymphocytes or macrophages. Viruses taken up by phagocytic macrophages may be inactivated, replicate, or be delivered to other tissues. Replication of a virus in macrophages, the endothelial lining of blood vessels, the lung, or the liver can cause the infection to be amplified and initiate development of a **secondary viremia.** In many cases, a secondary viremia precedes delivery of the virus to the **target tissue** (e.g., liver, brain, skin) and the manifestation of characteristic symptoms.

Viruses can gain access to the central nervous system or brain (1) from the bloodstream (e.g., arboencephalitis viruses), (2) from infected meninges or cerebrospinal fluid, (3) by means of the migration of infected macrophages, or (4) by infection of peripheral and sensory (olfactory) neurons. The meninges are accessible to many of the viruses spread by viremia, which may also provide access

BOX 37.1 Determinants of Viral Disease

Nature of the Disease

Target tissue
Portal of entry of virus
Access of virus to target tissue
Tissue tropism of virus
Permissiveness of cells for viral replication
Pathogenic activity (strain specific)

Severity of Disease

Cytopathic ability of virus
Virus inoculum size
Immune status (naive or immunized)
Competence of the immune system
Immunopathology
Length of time before resolution of infection
General health of the person
Nutrition
Other diseases influencing immune status
Genetic makeup of the person
Age

to neurons. Herpes simplex, varicella-zoster, and rabies viruses initially infect mucoepithelium, skin, or muscle, and then the peripheral innervating neuron, which transports the virus to the central nervous system or brain.

Viral Pathogenesis

CYTOPATHOGENESIS

The five potential outcomes of a viral infection of a cell are as follows (Box 37.3; Table 37.1):

1. Failed infection (abortive infection)
2. Cell death (lytic infection)
3. Replication without cell death (**persistent infection**).
4. Replication without cell death but with immortalization of the cell
5. Presence of virus without virus production but with potential for reactivation (latent-recurrent infection)

Persistent infections may be (1) **chronic** (nonlytic, productive), (2) **latent** (limited viral macromolecular but no virus synthesis), (3) **recurrent** (periods of latency then virus production), or (4) **transforming** (immortalizing).

The nature of the infection is determined by the characteristics of the virus and the target cell. Viral mutants, which do not multiply, cause abortive infections and therefore disappear. A **nonpermissive cell** may lack a receptor, important enzyme pathway, or transcriptional activator or express an antiviral mechanism that will not allow replication of a particular type or strain of virus. For example, neurons and nongrowing cells lack the machinery and substrates for replication of some deoxyribonucleic acid (DNA) viruses. These cells can also limit viral protein synthesis by phosphorylation of the elongation initiation factor-2α (eIF-2α) to prevent the assembly of ribosomes on 5′-capped mRNA. This protection is triggered by the large amount of protein synthesis required for virus production (unfolded protein response) or its activation by the antiviral

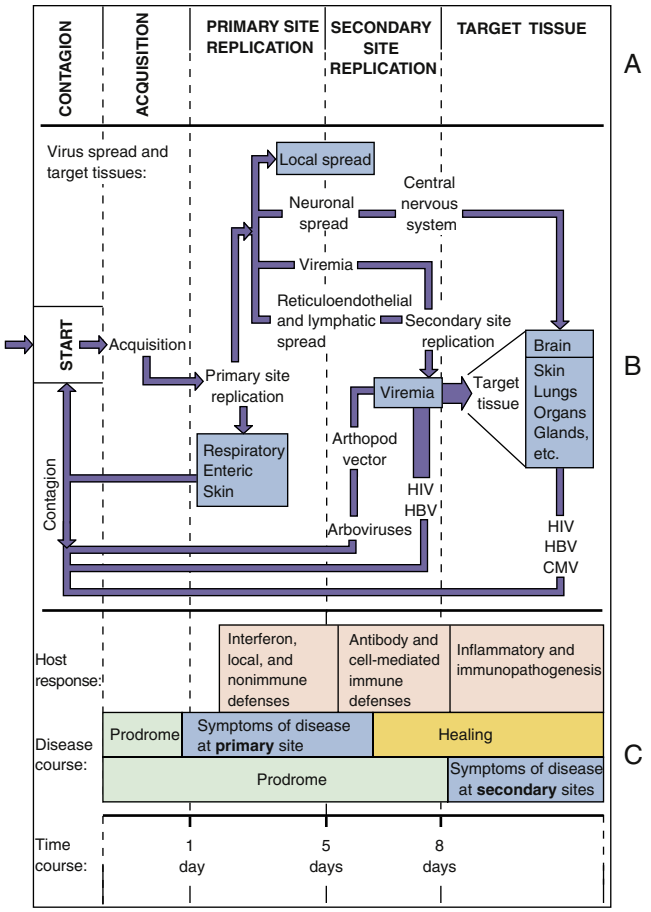

Fig. 37.1 1 (A) Stages of viral infection. The virus is released from one person, is acquired by another, replicates, and initiates a primary infection at the site of acquisition. Depending on the virus, it may then spread to other body sites and finally to a target tissue characteristic of the disease. (B) The cycle starts with acquisition, as indicated, and proceeds until the release of new virus. The thickness of the arrow denotes the degree to which the original virus inoculum is amplified on replication. The boxes indicate a site or cause of symptoms. (C) Time course of viral infection. The time course of symptoms and the immune response correlate with the stage of viral infection and depend on whether the virus causes symptoms at the primary site or only after dissemination to another (secondary) site. *CMV,* Cytomegalovirus; *HBV,* hepatitis B virus; *HIV,* human immunodeficiency virus.

BOX 37.2 Progression of Viral Disease

1. **Acquisition** (entry into the body)
2. Initiation of infection at a primary site
3. Activation of innate protections
4. An **incubation period,** when the virus is amplified and may spread to a secondary site
5. Replication in the **target tissue,** which causes the characteristic disease signs
6. **Host responses** that limit and contribute (immunopathogenesis) to the disease
7. Virus production in a tissue that releases the virus to other people for **contagion**
8. **Resolution** or **persistent infection/chronic disease**

BOX 37.3 Determinants of Viral Pathogenesis

Interaction of Virus with Target Tissue

Access of virus to target tissue
Stability of virus in the body
  Temperature
  Acid and bile of the gastrointestinal tract
Ability to cross skin or mucosal epithelial cells (e.g., cross the gastrointestinal tract into the bloodstream)
Ability to establish viremia
Ability to spread through the reticuloendothelial system
Target tissue
  Specificity of viral attachment proteins
  Tissue-specific expression of receptors

Cytopathologic Activity of the Virus

Efficiency of viral replication in the cell
  Optimum temperature for replication
  Permissiveness of cell for replication
Cytotoxic viral proteins

TABLE 37.1 Types of Viral Infections at the Cellular Level

Type	Virus Production	Fate of Cell
Abortive	–	No effect
Cytolytic	+	Death
Persistent		
Productive	+	Senescence
Latent	–	No effect
Transforming		
DNA viruses	–	Immortalization
Retroviruses	+	Immortalization

state induced by interferon (IFN)-α, IFN-β of IFN λ antiviral state. Herpesviruses and some other viruses prevent this by inhibiting the phosphorylating enzyme (protein kinase R) or by activating a cellular protein phosphatase to remove the phosphate on eIF-2α. Another example is APOBEC3, which is an enzyme that causes hypermutation inactivation of the cDNA of retroviruses. This is a mechanism for restricting the growth of the numerous endogenous retroviruses that are part of the human chromosome. The viral infectivity factor (Vif) protein of human immunodeficiency virus (HIV) overcomes this block by promoting the degradation of APOBEC3.

A **permissive cell** provides the biosynthetic machinery to support the complete replicative cycle of the virus. Replication of the virus in a **semipermissive cell** may be very inefficient, or the cell may support some but not all the steps in viral replication.

Lytic Infections

Lytic infection results when virus replication kills the target cell. Some viruses damage the cell and prevent repair by inhibiting the synthesis of cellular macromolecules or by producing degradative enzymes and toxic proteins. For example, HSV and other viruses produce proteins that inhibit the synthesis of cellular DNA and mRNA and synthesize other proteins that degrade host DNA to provide substrates for viral genome replication. Cellular protein synthesis may be actively blocked (e.g., poliovirus inhibits translation of 5′-capped cellular mRNA) or passively blocked (e.g., through production of a great deal of viral mRNA that successfully competes for ribosomes) (see Chapter 36).

Replication of the virus and accumulation of viral components and progeny within the cell can disrupt the structure and function of the cell or disrupt lysosomes, causing cell death. Expression of viral antigens on the cell surface and disruption of the cytoskeleton can change cell-to-cell interactions and the cell's appearance, making the cell a target for immune cytolysis. Viral nucleic acids in the cytoplasm can activate pathogen-associated molecular pattern receptors (PAMPRs) to activate the inflammasome, cytokine, and interferon responses that can limit virus replication.

Viral infection or cytolytic immune responses may induce **apoptosis** in the infected cell. Apoptosis is a preset cascade of events that, when triggered, leads to cellular suicide. This process may facilitate release of the virus from the cell, but it also limits the amount of virus that is produced by destroying the viral "factory." As a result, *many viruses (e.g., herpesviruses, adenoviruses, hepatitis C virus [HCV]) encode methods for inhibiting apoptosis.*

Cell-surface expression of the glycoproteins of some paramyxoviruses, herpesviruses, and retroviruses triggers the fusion of neighboring cells into **multinucleated giant cells** called **syncytia.** Syncytia formation allows the viral infection to spread from cell to cell and escape antibody detection. Syncytia may be fragile and susceptible to lysis. The syncytia that occurs in infection with HIV also causes death of the cells.

Some viral infections cause cytolysis or characteristic changes in the appearance and properties of the target cell, which is called the **cytopathologic effect (CPE)**. The effects on the cell may result from viral takeover of macromolecular synthesis, accumulation of viral proteins or particles, modification or disruption of cellular structures, or manipulation of cellular functions (Table 37.2). For example, chromosomal aberrations and degradation may occur and can be detected with histologic staining (e.g., marginated chromatin ringing the nuclear membrane in HSV-infected and adenovirus-infected cells). In addition, new stainable structures called **inclusion bodies** may

TABLE 37.2 Mechanisms of Viral Cytopathogenesis

Mechanism	Examples
Inhibition of cellular protein synthesis	Poliovirus, HSV, togaviruses, poxviruses
Inhibition and degradation of cellular DNA	Herpesviruses
Alteration of cell membrane structure	Enveloped viruses
Viral glycoprotein insertion in cell membrane	All enveloped viruses
Syncytia formation	HSV, varicella-zoster virus, paramyxoviruses, human immunodeficiency virus
Disruption of cytoskeleton	Nonenveloped viruses (accumulation), HSV
Permeability	Togaviruses, herpesviruses
Toxicity of virion components	Adenovirus fibers, reovirus NSP4 protein
Inclusion Bodies	
Negri bodies (intracytoplasmic)	Rabies
Intranuclear basophilic (owl's eye)	Cytomegalovirus (enlarged cells), adenoviruses
Cowdry type A (intranuclear)	HSV, subacute sclerosing panencephalitis (measles) virus
Intracytoplasmic acidophilic	Poxviruses
Perinuclear cytoplasmic acidophilic	Reoviruses

HSV, Herpes simplex virus.

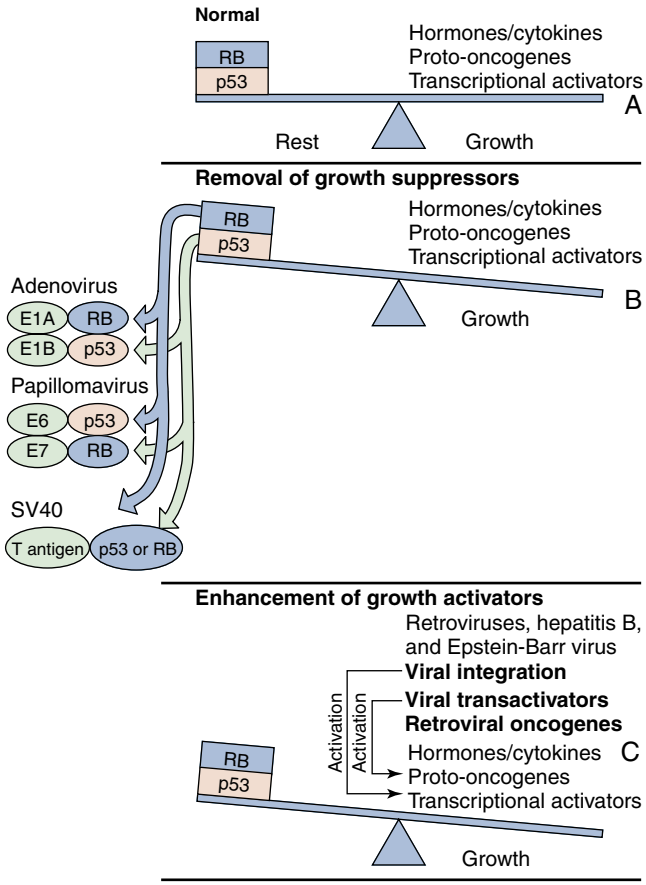

Fig. 37.2 Mechanisms of viral transformation and immortalization. Cell growth is controlled (A) by the maintenance of a balance in the external and internal growth activators (accelerators) and by growth suppressors such as p53 and the retinoblastoma *(RB)* gene product (brakes). Oncogenic viruses alter the balance by removing the brakes (B) or by enhancing the effects of the accelerators (C).

appear within the nucleus or cytoplasm. These structures may result from virus-induced changes in the membrane or chromosomal structure or may represent the sites of viral replication or accumulations of viral capsids. Because the nature and location of these inclusion bodies are characteristic of particular viral infections, their presence facilitates laboratory diagnosis (see Table 37.2). Viral infection may also cause vacuolization, rounding of the cells, and other nonspecific histologic changes that are characteristics of sick cells.

Nonlytic Infections

A **persistent infection** occurs in an infected cell that is not killed by the virus. Some viruses cause a persistent productive infection because the virus is released gently from the cell through exocytosis or through budding (many enveloped viruses) from the plasma membrane. Thinking like a parasite, the virus does not want to kill the cell because *the longer a cell is alive, the longer the virus remains in the body, and the more virus is produced to spread to other cells or individuals.*

A **latent infection** may result from DNA virus infection of a cell that restricts or lacks the machinery for transcribing all the viral genes, or the virus may encode functions that suppress virus replication (e.g., cytomegalovirus) to extend its parasitism. The specific transcription factors required by such a virus may be expressed only in specific tissues, in growing but not resting cells, or after hormone or cytokine induction. For example, HSV establishes a latent infection in neurons that do not express the nuclear factors required to transcribe the immediate early viral genes, but stress and other stimuli can activate the cells to allow viral replication.

Oncogenic Viruses

Some DNA viruses and retroviruses establish persistent infections that can also stimulate uncontrolled cell growth, causing **transformation** or **immortalization** of the cell (Fig. 37.2). *Characteristics of transformed cells include continued growth without senescence, alterations in cell morphology and metabolism, increased cell growth rate and sugar transport, loss of cell-contact inhibition of growth, and ability to grow in a suspension or pile up into foci when grown in a semisolid agar.*

Different **oncogenic** viruses have different mechanisms for immortalizing cells. Viruses immortalize cells by (1) activating or providing growth-stimulating genes, (2) removing the inherent braking mechanisms that limit DNA synthesis and cell growth, (3) preventing apoptosis, or (4) providing or inducing growth-stimulating cytokines. Immortalization by DNA viruses occurs in semipermissive cells, which express only selected viral genes but do not produce virus. Synthesis of viral DNA, late mRNA, late proteins, or virus leads to cell death, which precludes immortalization. Several oncogenic DNA viruses integrate into the host cell chromosome. Papillomavirus, SV40 virus, and adenovirus encode proteins

that bind and inactivate cell growth–regulatory proteins, such as p53 and the retinoblastoma gene product, releasing the brakes on cell growth. Loss of p53 also makes the cell more susceptible to mutation. Epstein-Barr virus immortalizes B cells by stimulating cell growth (as a B-cell mitogen) and by preventing programmed cell death (apoptosis).

Retroviruses (RNA viruses) use three approaches to oncogenesis. Some oncoviruses encode **oncogene** proteins (e.g., SIS, RAS, SRC, MOS, MYC, JUN, FOS) that are almost identical to the cellular proteins involved in cellular growth control (e.g., components of a growth-factor signal cascade [receptors, G-proteins, protein kinases], or growth-regulating transcription factors). The overproduction or altered function of these oncogene products stimulates cell growth. These oncogenic viruses *rapidly* cause tumors to form. *However, no human retrovirus of this type has been identified.*

Human T-cell lymphotropic virus 1 (HTLV-1), the only human oncogenic retrovirus identified, uses more subtle mechanisms of leukemogenesis. It encodes a protein **(TAX)** that **transactivates** gene expression, including genes for growth-stimulating cytokines (e.g., interleukin [IL]-2). This constitutes two approaches for oncogenesis. The third approach is integration of the DNA copy of HTLV-1 near a cellular growth-stimulating gene, which can also cause the gene to be activated by the strong viral enhancer and promoter sequences encoded at each end of the viral genome (long terminal repeat [LTR] sequences). *HTLV-1–associated leukemias* ***develop slowly,*** *occurring 20 to 30 years after infection.* Retroviruses continue to produce the virus in immortalized or transformed cells.

Some viruses may initiate tumor formation indirectly. Hepatitis B virus (HBV) and HCV may have mechanisms for direct oncogenesis; however, both viruses establish persistent infections that cause inflammation and require significant tissue repair. Inflammation and continuous stimulation of liver cell growth and repair may promote mutations that lead to tumor formation. Human herpesvirus-8 (HHV-8) promotes the development of Kaposi sarcoma by means of growth-promoting cytokines encoded by the virus; this disease occurs most often in immunosuppressed patients, such as those with AIDS.

Viral transformation is the first step but is generally not sufficient to cause oncogenesis and tumor formation. Instead, over time, immortalized cells are more likely than normal cells to accumulate other mutations or chromosomal rearrangements that promote development of tumor cells. Immortalized cells may also be more susceptible to cofactors and tumor promoters (e.g., phorbol esters, butyrate) that enhance tumor formation. Approximately 15% of human cancers can be related to oncogenic viruses such as HTLV-1, HBV, HCV, human high risk papillomaviruses, HHV-8, and Epstein-Barr virus.

HOST DEFENSES AGAINST VIRAL INFECTION

The ultimate goals of the host antiviral innate and immune responses are to prevent entry, prevent spread, and eliminate the virus and the cells harboring or replicating the virus **(resolution).** The immune response is the best and in most cases the only means of controlling a viral infection. Interferon and cytotoxic T-cell responses may have evolved primarily as antiviral defense mechanisms. Innate humoral and cellular immune responses are important for antiviral immunity. *The longer the virus replicates in the body, the greater the dissemination of the infection, the more rigorous the immune response necessary to control the infection, and the greater the potential for immunopathogenesis.* A detailed description of the antiviral immune response is presented in Chapter 10.

The skin is the best barrier to infection. The orifices of the body (e.g., mouth, eyes, nose, ears, and anus) are protected by mucus, ciliated epithelium, tears, the gastric acid and bile of the gastrointestinal tract, and secreted IgA. After the virus penetrates these natural barriers, it activates the **antigen-nonspecific (innate) host defenses** (e.g., fever, interferon, macrophages, dendritic cells, natural killer [NK] cells), which attempt to limit and control local viral replication and spread. Unlike for bacteria, the innate response is triggered by infected cells or against infected cells, and the initial response is more likely to be mediated by interferon and cytokines, which induce flulike symptoms rather than inflammation mediated by complement and neutrophils. Viral molecules, including double-stranded RNA (which is the replicative intermediate of RNA viruses), certain forms of DNA and single-stranded RNA, and some viral glycoproteins, activate type I and III interferon production (see Box 10.4) and innate cellular responses through interaction with cytoplasmic receptors or the Toll-like receptors (TLRs) in endosomes. *Innate responses prevent most viral infections from causing disease.*

Antigen-specific immune responses (see Box 10.3) take several days to be activated and become effective. The goal of these protective responses is to resolve the infection by eliminating all infectious virus and virus-infected cells from the body. ***Antibody*** *is effective against extracellular virus and may be sufficient to control cytolytic viruses because viral replication will eliminate the virion factory within the infected cell. Antibody is essential to control virus spread to target tissues by viremia.* ***Cell-mediated immunity*** *is required for lysis of cells infected with a* ***noncytolytic virus*** *(e.g., hepatitis A virus) and infections caused by* ***enveloped viruses.***

Prior immunity may not prevent the initial stages of infection but, in most cases, it does prevent disease progression. Cell-mediated responses are more effective at limiting the local spread of virus, and serum antibody can prevent viremic spread of the virus to the target tissue to prevent the characteristic disease presentation. Memory immune responses can be generated by prior infection or vaccination.

Many viruses, especially the larger viruses, have the means to escape one or more aspects of immune control (see Table 10.3). These mechanisms include preventing interferon action, changing viral antigens, spreading by cell-to-cell transmission to escape antibody, and suppressing antigen presentation and lymphocyte function. By preventing the consequences of the antiviral state induced by IFN-α and IFN-β, HSV protein synthesis and replication can continue. Inhibition of major histocompatibility complex (MHC) I expression by cytomegalovirus and adenoviruses prevents T-cell killing of the infected cell. Antigenic variation over the course of several years (antigenic shift and drift) by influenza or during the lifetime of the infected individual by HIV limits the antiviral efficacy of antibody.

TABLE 37.3 Viral Immunopathogenesis

Immunopathogenesis	Immune Mediators	Examples
Flulike symptoms	Interferon, cytokines	Respiratory viruses, arboviruses (viremia-inducing viruses)
Type IV hypersensitivity and inflammation	T cells, macrophages, and polymorphonuclear leukocytes	Enveloped viruses
Immune complex disease	Antibody, complement	Hepatitis B virus, rubella
Hemorrhagic disease	T cells, antibody, complement	Yellow fever, dengue, Lassa fever, Ebola viruses
Postinfection cytolysis	T cells	Enveloped viruses (e.g., postmeasles encephalitis)
Cytokine storm	Antigen-presenting cells, T cells, cytokines	Enveloped and other viruses
Immunosuppression	T cells, macrophages, dendritic cells	Human immunodeficiency virus, cytomegalovirus, measles virus, influenza virus

Failure to resolve the infection may lead to persistent infection, chronic disease, or death of the patient.

IMMUNOPATHOLOGY

The hypersensitivity and inflammatory reactions initiated by antiviral immunity can be the major cause of the pathologic manifestations and symptoms of viral disease (Table 37.3). Early responses to the virus and viral infection (e.g., interferon, cytokines) can initiate local inflammatory and systemic responses. For example, interferon and cytokines stimulate the **flulike systemic symptoms** (e.g., fever, malaise, headache) usually associated with *respiratory viral infections and viremias* (e.g., arboencephalitis viruses). These symptoms during the viremic stage often precede **(prodrome)** the characteristic symptoms of the viral infection. Some viral infections induce a large cytokine response (cytokine storm), and this can dysregulate immune responses and may trigger autoimmune diseases in genetically predisposed individuals. Later, immune complexes and complement activation (classic pathway), CD4 T-cell–induced type IV hypersensitivity, and CD8 cytolytic T-cell action may induce tissue damage. These actions often promote neutrophil infiltration and more cell damage.

The inflammatory response initiated by cell-mediated immunity is difficult to control and damages tissue. Infections by enveloped viruses, in particular, induce cell-mediated immune responses that usually produce more extensive immunopathologic conditions. For example, the classic symptoms of measles, mumps, and the hepatitis viruses result primarily from the **T-cell–induced inflammatory responses** rather than from cytopathologic effects of the virus. The presence of large amounts of antigen and antibody in blood during viremias or chronic infections (e.g., HBV infection) can initiate the **classic type III immune complex hypersensitivity reactions.** These **immune complexes** can activate the complement system, triggering inflammatory responses and tissue destruction. These immune complexes often accumulate in the kidney and cause glomerulonephritis.

In the case of dengue, partial immunity to a related, or for measles, to an inactivated virus, can result in a more severe host response and disease on subsequent challenge with a related or virulent virus. This is because antigen-specific T-cell and antibody responses are enhanced and induce significant inflammatory and hypersensitivity damage to infected endothelial cells **(dengue hemorrhagic fever)** or skin and the lung **(atypical measles).** In addition, a nonneutralizing antibody can facilitate the uptake of dengue and yellow fever viruses into macrophages through Fc receptors, in which they can replicate.

Children generally have a less active cell-mediated immune response (e.g., NK or natural killer T [NKT] cells) than adults; therefore they usually have milder symptoms during infections by some viruses (e.g., measles, mumps, Epstein-Barr, and varicella-zoster viruses). However, in the case of HBV, mild or no symptoms correlate with an inability to resolve the infection, resulting in chronic disease.

Viral Disease

The relative **susceptibility** of a person and the **severity** of the disease depend on the following factors:

1. Mechanism of exposure and site of infection
2. Immune status, age, and general health of the person
3. Viral dose
4. Genetics of the virus and the host

Once the host is infected, however, the host's immune status and competence are probably the major factors that determine whether a viral infection causes a life-threatening disease, a benign outcome, or no symptoms at all.

The stages of viral disease are shown in Fig. 37.1C. During the **incubation period,** the virus is replicating but has not reached the target tissue or induced sufficient damage to cause the disease. *The incubation period is relatively short if the primary site of infection is the target tissue and produces the characteristic symptoms of the disease. Longer incubation periods occur when the virus must spread to other sites and be amplified before reaching the target tissue, or the symptoms are caused by immunopathology.* Nonspecific or flulike symptoms may precede the characteristic symptoms during the **prodrome.** The incubation periods for many common viral infections are listed in Table 37.4. Specific viral diseases are discussed in subsequent chapters and reviewed in Chapter 38.

The nature and severity of the symptoms of a viral disease are related to the function of the infected target tissue (e.g., liver, hepatitis; brain, encephalitis) and the extent of the immunopathologic responses triggered by the infection. **Inapparent infections** result if (1) the infected tissue is

TABLE 37.4 Incubation Periods of Common Viral Infections

Disease	Incubation Period (Days)[a]
Influenza	1–2
Common cold	1–3
Herpes simplex	2–8
Bronchiolitis, croup	3–5
Acute respiratory disease (adenoviruses)	5–7
Dengue	5–8
Enteroviruses	6–12
Poliomyelitis	5–20
Measles	9–12
Smallpox	12–14
Chickenpox	13–17
Mumps	16–20
Rubella	17–20
Mononucleosis	30–50
Hepatitis A	15–40
Hepatitis B	50–150
Rabies	30–100+
Papilloma (warts)	50–150
HIV	1–15 years
AIDS	1–10 years

[a]Until first appearance of prodromal symptoms. Diagnostic signs (e.g., rash, paralysis) may not appear until 2–4 days later.
Modified from White, D.O., Fenner, F., 1986. Medical Virology, third ed. Academic, New York, NY.

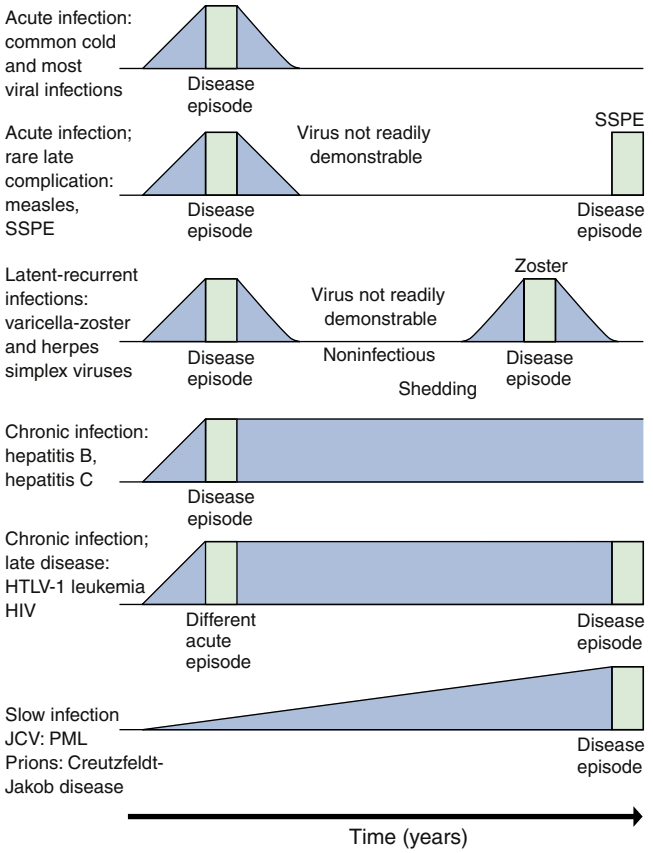

Fig. 37.3 Acute infection and various types of persistent infection, as illustrated by the diseases indicated in the column at the left. *Blue* represents presence of virus; *green* indicates episode of disease. *HIV,* Human immunodeficiency virus; *HTLV-1,* human T-cell lymphotropic virus 1; *JCV,* JC virus; *PML,* progressive multifocal leukoencephalopathy; *SSPE,* subacute sclerosing panencephalitis. (Modified from White, D.O., Fenner, F.J., 1986. Medical Virology, third ed. Academic Press, New York, NY.)

undamaged, (2) the infection is controlled before the virus reaches its target tissue, (3) the target tissue is expendable, (4) the damaged tissue is rapidly repaired, or (5) the extent of damage is below a functional threshold for that particular tissue. For example, many infections of the brain are inapparent or are below the threshold of severe loss of function, but encephalitis results if the loss of function becomes significant. Despite the lack of symptoms, virus-specific antibody will be produced. *Inapparent or asymptomatic infections are major sources of contagion.*

Viral infections may cause **acute** or **chronic disease (persistent infection).** The ability and speed with which a person's immune system controls and resolves a viral infection usually determine whether acute or chronic disease ensues, as well as the severity of the symptoms (Fig. 37.3). The acute episode of a persistent infection may be asymptomatic (JC polyomavirus) or may cause symptoms later in life similar to (varicella and zoster) or different from (HIV: acute versus AIDS) those of the acute disease. **Slow viruses and prions** have long incubation periods during which sufficient virus or tissue destruction accumulates before a rapid progression of symptoms.

Epidemiology

Epidemiology studies the spread of disease through a population. Infection of a population is similar to infection of a person in that the virus must spread through the population and is controlled by immunization of the population (Box 37.4). *To endure, viruses must continue to infect new, immunologically naive, susceptible hosts.*

EXPOSURE

People are exposed to viruses throughout their lives. However, some situations, vocations, lifestyles, and living arrangements increase the likelihood that a person will come in contact with certain viruses. In contrast, many viruses are ubiquitous. Previous exposure to HSV-1, HHV-6, varicella-zoster virus, parvovirus B19, Epstein-Barr virus, and many respiratory and enteric viruses can be detected in most young children or by early adulthood by the presence of antibodies to the virus.

Poor hygiene and crowded living, school, and job conditions promote exposure to respiratory and enteric viruses. Day-care centers are consistent sources of viral infections, especially viruses spread by the respiratory and fecal-oral routes. Travel, summer camp, and vocations that bring people in contact with a virus vector (e.g., mosquitoes) put them at particular risk for infection by arboviruses and other zoonoses. Sexual promiscuity also promotes the spread and acquisition of several viruses. Health care workers, such as

BOX 37.4 Viral Epidemiology[a]

Mechanisms of Viral Transmission[b]

Aerosols
Food, water
Fomites (e.g., tissues, clothes)
Direct contact with secretions (e.g., saliva, semen)
Sexual contact, birth
Blood transfusion or organ transplant
Zoonoses (animals, insects [arboviruses])
Genetic (vertical) (e.g., retroviruses)

Disease and Viral Factors That Promote Transmission

Stability of virion in response to environment (e.g., drying, detergents, temperature)
Replication and secretion of virus into transmissible aerosols and secretions (e.g., saliva, semen)
Asymptomatic transmission
Transience or ineffectiveness of immune response to control reinfection or recurrence

Risk Factors

Age
Health
Immune status
Occupation: contact with agent or vector
Travel history
Lifestyle
Children in day-care centers
Sexual activity

Critical Community Size

Seronegative, susceptible people

Geography and Season

Presence of cofactors or vectors in the environment
Habitat and season for arthropod vectors (mosquitoes)
School session: close proximity and crowding
Home-heating season

Modes of Control

Quarantine
Elimination of the vector
Immunization/vaccination
Treatment
Education

[a]Infection of a population instead of a person.
[b]See also Table 37.5.

TABLE 37.5 Viral Transmission

Mode	Examples
Respiratory transmission	Paramyxoviruses, influenza viruses, picornaviruses, rhinoviruses, varicella-zoster virus, B19 virus
Fecal-oral transmission	Picornaviruses, rotavirus, reovirus, noroviruses, adenovirus
Contact (lesions, fomites)	HSV, rhinoviruses, poxviruses, adenovirus
Zoonoses (animals, insects)	Togaviruses (alpha), flaviviruses, bunyaviruses, orbiviruses, arenaviruses, hantaviruses, rabies virus, influenza A virus, orf (pox)
Transmission via blood	HIV, HTLV-1, HBV, HCV, hepatitis delta virus, cytomegalovirus
Sexual contact	HSV, human papillomavirus, molluscum contagiosum, Zika, HIV, HTLV-1, HBV, HCV
Maternal-neonatal transmission	Rubella virus, cytomegalovirus, B19 virus, echovirus, HSV, varicella-zoster virus, HIV
Genetic	Prions, retroviruses

HBV, Hepatitis B virus; *HCV,* hepatitis C virus; *HSV,* herpes simplex virus; *HTLV-1,* human T-cell lymphotropic virus 1.

physicians, dentists, nurses, and technicians, are frequently exposed to respiratory and other viruses but are uniquely at risk for acquiring viruses from contaminated blood (HBV, HIV) or vesicle fluid (HSV).

TRANSMISSION OF VIRUSES

Viruses are transmitted by direct contact (including sexual contact), injection with contaminated fluids or blood, transplantation of organs, and the respiratory and fecal-oral routes (Table 37.5). *The route of transmission depends on the source of the virus (the tissue site of viral replication and secretion) and the ability of the virus to endure the hazards and barriers of the environment and the body en route to the target tissue.* For example, viruses that replicate in the respiratory tract (e.g., influenza A virus) are released in aerosol droplets, whereas enteric viruses (e.g., picornaviruses and reoviruses) are passed by the fecal-oral route. Cytomegalovirus is transmitted in most bodily secretions because it infects mucoepithelial, secretory, and other cells found in the skin, secretory glands, lungs, liver, and other organs.

The presence or absence of an envelope is the major structural determinant of the mode of viral transmission. **Nonenveloped viruses** (naked capsid viruses) can withstand drying, the effects of detergents, and extremes of pH and temperature, whereas enveloped viruses generally cannot (see Box 36.4). Specifically, most nonenveloped viruses can withstand the acidic environment of the stomach and the detergent-like bile of the intestines and mild disinfection and insufficient sewage treatment. These viruses are generally transmitted by the respiratory and fecal-oral routes and can often be acquired from contaminated objects **(fomites).** For example, hepatitis A virus, which is a picornavirus, is a nonenveloped virus that is transmitted by the fecal-oral route and acquired from contaminated water, shellfish, and food. Adenoviruses and many other nonenveloped viruses can be spread by contact with fomites such as handkerchiefs and toys.

Unlike the sturdy nonenveloped viruses, most **enveloped viruses** are comparatively fragile (see Box 36.5). They require an intact envelope for infectivity. These viruses must remain wet and are spread (1) in respiratory droplets, blood, mucus, saliva, and semen; (2) by injection; or (3) in organ transplants. Most enveloped viruses are also labile to treatment with acid and detergents, which is a feature that precludes their being transmitted by the fecal-oral route. Exceptions are HBV and coronaviruses.

Animals and insects can also act as **vectors** that spread viral disease to other animals and humans and even to other locales. They can also be **reservoirs** for the virus, maintaining and amplifying the virus in the environment.

Viral diseases that are shared by animals or insects and humans are called **zoonoses.** For example, raccoons, foxes, bats, dogs, and cats are reservoirs and vectors for the rabies virus. Arthropods (e.g., mosquitoes, ticks, sandflies) can act as vectors for togaviruses, flaviviruses, bunyaviruses, or reoviruses. These viruses are often referred to as **arboviruses** because they are *ar*thropod *bo*rne. A more detailed discussion of arboviruses is presented in Chapter 52. Most arboviruses have a very broad host range, capable of replicating in specific insects, birds, amphibians, and mammals, in addition to humans. Also, the arboviruses must establish a sufficient viremia in the animal reservoir so that the insect can acquire the virus during its blood meal.

Other factors that can promote transmission of viruses are the potential for asymptomatic infection, crowded living conditions, certain occupations, certain lifestyles, day-care centers, and travel. Viral transmission during an asymptomatic infection (e.g., HIV, varicella-zoster virus) occurs unknowingly and is difficult to restrict. This is an important characteristic of **sexually transmitted diseases.** Viruses that cause persistent productive infections (e.g., cytomegalovirus, HIV) are a particular problem because the infected person is a continual source of virus that can be spread to immunologically naive people. Viruses with many different serotypes (rhinoviruses) or viruses capable of changing their antigenicity (influenza and HIV) also readily find immunologically naive populations.

MAINTENANCE OF A VIRUS IN THE POPULATION

The persistence of a virus in a community depends on the availability of a critical number of immunologically naive (seronegative), susceptible people. The efficiency of virus transmission determines the size of the susceptible population necessary for maintenance of the virus in the population. Measles will spread if only 5% to 10% of the population are unimmunized and this includes infants. Immunization produced by natural means or by vaccination provides herd immunity and is the best way of reducing the number of such susceptible people.

AGE

A person's age is an important factor in determining his or her susceptibility to viral infections. Infants, children, adults, and elderly persons are susceptible to different viruses and have different symptomatic responses to the infection. These differences may result from variations in body size, recuperative abilities, and most important, immune status in people in these age groups. Differences in lifestyles, habits, school environments, and job settings at different ages also determine when people are exposed to viruses.

Infants and children acquire a series of respiratory and exanthematous viral diseases at first exposure because they are immunologically naive. Infants are especially prone to more serious presentations of paramyxovirus respiratory infections and viral gastroenteritis because of their small size and physiologic requirements (e.g., nutrients, water, electrolytes). However, children generally do not mount as severe an immunopathologic response as adults, and some diseases (herpesviruses) are more benign in children.

Elderly persons are especially susceptible to new viral infections and the reactivation of latent viruses. Because they are less able to initiate a new immune response, repair damaged tissue, and recover, elderly persons are therefore more susceptible to complications after infection and outbreaks of the new strains of the influenza A and B viruses. Elderly persons are also more prone to zoster (shingles), which is a recurrence of varicella-zoster virus, as a result of a decline in this specific immune response with age.

IMMUNE STATUS

The competence of a person's immune response and immune history determine how quickly and efficiently the infection is resolved and can also determine the severity of the symptoms. The rechallenge of a person with prior immunity usually results in asymptomatic or mild disease without transmission. People who are in an immunosuppressed state as a result of AIDS, cancer, or immunosuppressive therapy are at greater risk of suffering more serious disease on primary infection (measles, vaccinia) and are more prone to suffer recurrences of infections with latent viruses (e.g., herpesviruses, papovaviruses).

OTHER HOST FACTORS

General health plays an important role in determining the competence and nature of the immune response and ability to repair diseased tissue. Poor nutrition can compromise a person's immune system and decrease his or her tissue regenerative capacity. Measles becomes much more deadly for individuals deficient in vitamin A, possibly because of an antiinflammatory action of vitamin A. Immunosuppressive diseases and therapies may allow viral replication or recurrence to proceed unchecked. Genetic makeup also plays an important role in determining the response of the immune system to viral infection. Specifically, genetic differences in immune response genes, genes for viral receptors, and other genetic loci affect susceptibility to a viral infection and severity of disease.

GEOGRAPHIC AND SEASONAL CONSIDERATIONS

The geographic distribution of a virus is usually determined by whether the requisite cofactors or vectors are present or whether there is an immunologically naive, susceptible population. For example, many of the arboviruses are limited to the ecologic niche of their arthropod vectors. Extensive global transportation is reducing many of the geographically determined restrictions to virus distribution.

Seasonal differences in the occurrence of viral disease correspond with behaviors that promote spread of the virus. For example, respiratory viruses are more prevalent in the winter because crowding facilitates the spread of such viruses, and the temperature and humid conditions stabilize them. Enteric viruses, on the other hand, are more prevalent during the summer, possibly because hygiene is more lax during this season. The seasonal differences in arboviral diseases reflect the life cycle of the arthropod vector or its reservoir (e.g., birds).

OUTBREAKS, EPIDEMICS, AND PANDEMICS

Outbreaks of a viral infection often result from the introduction of a virus (e.g., hepatitis A) into a new location. The outbreak originates from a **common source** (e.g., food preparation) and often can be stopped once the source is identified. Norovirus outbreaks on cruise ships or from restaurants can often be traced to the dirty hands of an employee. **Epidemics** occur over a larger geographic area and generally result from the introduction of a new strain of virus into an immunologically naive population. **Pandemics** are worldwide epidemics, usually resulting from the introduction of a new virus (e.g., HIV). Pandemics of influenza A used to occur approximately every 10 years as the result of the introduction of new strains of the virus.

Control of Viral Spread

The spread of a virus can be controlled by quarantine, good hygiene, changes in lifestyle, elimination of the vector, or immunization of the population. **Quarantine** was once the only means of limiting epidemics of viral infections and is most effective for limiting the spread of viruses that always cause symptomatic disease (e.g., smallpox). It is now used in hospitals to limit the **nosocomial spread** of viruses, especially to high-risk patients (e.g., immunosuppressed people). Proper sanitation of contaminated items and disinfection of the water supply are means of limiting the spread of enteric viruses. Education and resultant changes in lifestyle have made a difference in the spread of sexually transmitted viruses such as HIV, HBV, and HSV. Elimination of an arthropod or its ecologic niche (e.g., drainage of the swamps it inhabits) has proved effective for controlling arboviruses.

The **best way to limit viral spread, however, is to immunize the population.** Immunization, whether produced by natural infection or by vaccination, protects individuals and reduces the size of the immunologically naive, susceptible population necessary to promote the spread and maintenance of the virus. Immunization of the population to prevent infection of the individual is called **herd immunity**.

Questions

1. What are the routes by which viruses gain entry into the body? For each route, list the barriers to infection and a virus that infects by it.

2. Describe or draw the disease path in the body of a virus that is transmitted by an aerosol and causes lesions on the skin (similar to varicella).

3. Identify the structures that elicit a protective antibody response to adenovirus, influenza A virus, poliovirus, and rabies virus.

4. Describe the major roles of each of the following in promoting resolution of a viral infection: interferon, macrophage, NK cells, CD4 T cells, CD8 T cells, and antibody.

5. Why are IFN-α and IFN-β produced before IFN-γ?

6. How does the nucleoprotein of influenza virus become an antigen for cytolytic CD8 T cells?

7. What events occur during the prodromal periods of a respiratory virus disease (e.g., parainfluenza virus) and encephalitis (e.g., St. Louis encephalitis virus)?

8. List the viral characteristics (structure, replication, target tissue) that would promote transmission by the fecal-oral route, by arthropods, by fomites, by mother's milk, and by sexual activity.

9. What are the different mechanisms by which oncogenic viruses immortalize cells? Describe them.

38 Role of Viruses in Disease

Most viral infections cause mild or no symptoms and do not require extensive treatment. When disease occurs, it often results from the spread of the virus to important tissues and the killing of their cells by either virus replication, inflammation, or other host protections. In addition, viruses are excellent inducers of interferon and cytokine production, which results in systemic symptoms, including flulike symptoms.

In general, the symptoms and severity of a viral infection are determined by (1) the patient's ability to prevent the spread or rapidly resolve the infection before the virus can reach important organs or cause significant damage, (2) the importance of the target tissue, (3) the virulence of the virus, (4) the extent of immunopathology induced in response to the infection, and (5) the ability of the body to repair the damage.

Immunization by prior infection or vaccination is the best means of protection against viral disease. Unlike bacteria, there are relatively few targets for the development of antiviral drugs, but drugs are available for certain viruses.

In this chapter, viral diseases are discussed with respect to their symptoms, the organ system they target, and the host factors that influence their presentation. Subsequent chapters will discuss the characteristics of the members of specific viral families and the diseases they cause. **A return to this chapter will provide a good review of the viruses and their diseases.**

Viral Diseases

The major sites of viral disease are the respiratory tract; the gastrointestinal tract; the epithelial, mucosal, and endothelial linings of the skin, mouth, and genitalia; the lymphoid tissue; the liver and other organs; and the central nervous system (CNS) (Fig. 38.1). The examples given in this chapter represent the more common viral causes of disease.

ORAL AND RESPIRATORY TRACT INFECTIONS

The oropharynx and respiratory tract are the **most common sites** of viral infection and disease (Table 38.1). The viruses are spread in respiratory droplets, aerosols, food, water, and saliva, as well as by close contact and on hands. Similar respiratory symptoms can be caused by several different viruses. For example, bronchiolitis may be caused by respiratory syncytial or parainfluenza virus. Alternatively, one virus may cause different symptoms in different people. Influenza virus can cause a mild upper respiratory tract infection in one person and life-threatening pneumonia in another.

Many viral infections start in the oropharynx or respiratory tract, infect the lung, and spread without causing significant respiratory symptoms. Varicella-zoster virus (VZV) and the measles virus initiate infection in the lung and can cause pneumonia but generally cause systemic infections, resulting in an exanthem (rash). Other viruses that establish primary infection of the oropharynx or respiratory tract and then progress to other sites include rubella, mumps, enteroviruses, and several human herpesviruses (HHVs).

The symptoms and severity of a respiratory viral disease depend on the nature of the virus, the site of infection (upper or lower respiratory tract), and the immune status and age of the person. Conditions such as cystic fibrosis and smoking, which compromise the ciliated and mucoepithelial barriers to infection, increase the risk of serious disease.

Pharyngitis and oral disease are common viral presentations. Most enteroviruses (picornaviruses) infect the oropharynx and then progress by way of a viremia to other target tissues. For example, symptoms such as acute-onset pharyngitis, fever, and oral vesicular lesions are characteristic of coxsackievirus A infections (herpangina, hand-foot-and-mouth disease) and some coxsackievirus B and echovirus infections. Adenovirus and the early stages of Epstein-Barr virus (EBV) disease are characterized by sore throat and tonsillitis with exudative membranes; EBV goes on to cause infectious mononucleosis. Herpes simplex virus (HSV) causes local primary infections of the oral mucosa and face (gingivostomatitis) and then establishes a latent neuronal infection that can recur in the form of herpes labialis (cold sores, fever blisters). HSV is also a common cause of pharyngitis. HSV and coxsackievirus A may also involve the tonsils, but with vesicular lesions. Vesicular lesions on the buccal mucosa (Koplik spots) are an early diagnostic feature of measles infection.

Upper respiratory tract viral infections, including the common cold and pharyngitis, account for at least 50% of absenteeism from schools and the workplace, despite being generally benign. Rhinoviruses and coronaviruses are the predominant causes of upper respiratory tract infections. A runny nose (rhinitis) followed by congestion, cough, sneezing, conjunctivitis, headache, and sore throat are typical symptoms of the common cold. Other causes of the common cold or pharyngitis are specific serotypes of echoviruses and coxsackieviruses, adenoviruses, influenza viruses, parainfluenza viruses, metapneumovirus, and respiratory syncytial virus (RSV).

Tonsillitis, laryngitis, and **croup** (laryngotracheobronchitis) may accompany certain respiratory tract viral infections. Inflammatory responses to viral infection cause the trachea to narrow below the vocal cords (subglottic area), resulting in laryngitis (adults) and croup (children). This narrowing causes loss of voice; a hoarse, barking cough; and the risk, especially in young children, for a blocked airway and choking. Children infected with parainfluenza viruses are especially at risk for croup.

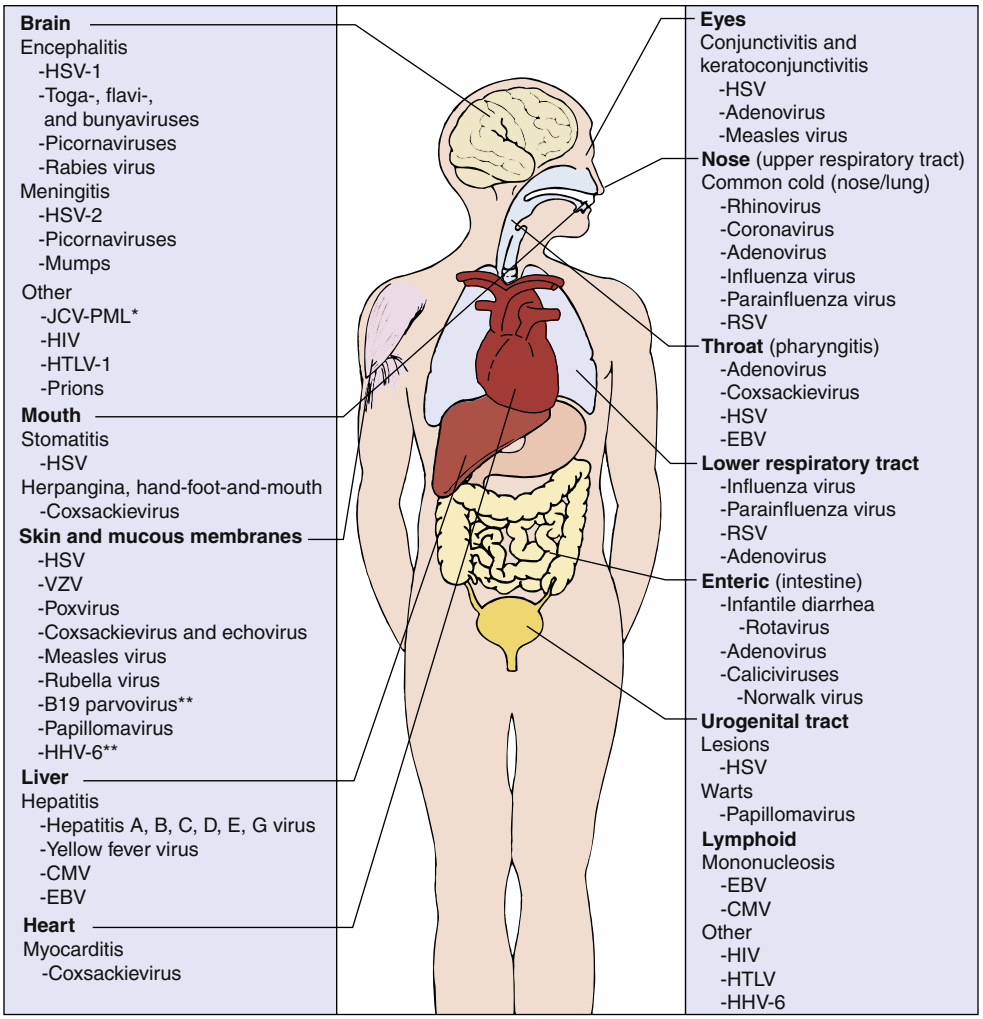

Fig. 38.1 Major target tissues of viral disease. Asterisk *(*)* indicates progressive multifocal leukoencephalopathy *(PML)*. Infection by viruses indicated by double asterisks *(**)* results in an immune-mediated rash. *CMV,* Cytomegalovirus; *EBV,* Epstein-Barr virus; *HHV-6,* human herpesvirus 6; *HIV,* human immunodeficiency virus; *HSV,* herpes simplex virus; *HTLV,* human T-cell lymphotropic virus; *JCV,* JC virus; *RSV,* respiratory syncytial virus; *VZV,* varicella-zoster virus.

Lower respiratory tract viral infections can result in more serious disease. Symptoms of such infections include bronchiolitis (inflammation of the bronchioles), pneumonia, pneumonitis, and related diseases. Parainfluenza virus, metapneumovirus, and RSVs are major problems for infants and children but usually cause asymptomatic infections or common cold symptoms in adults. Parainfluenza 3 virus, and especially RSV infections, are major causes of life-threatening pneumonia or bronchiolitis in infants younger than 6 months. Infection with these viruses does not provide lifelong immunity.

Influenza virus is probably the best known and most feared of the common respiratory viruses, with the annual introduction of new strains of virus ensuring the presence of immunologically naive victims. Children are universally susceptible to new strains of virus, whereas older people may have been immunized during a prior outbreak of the annual strain. Despite such immunization, elderly people are especially susceptible to pneumonia caused by new strains of virus because they may not be able to mount a sufficient primary immune response to the new strain of influenza virus or to repair the tissue damage caused by the disease. Influenza infection also increases risk for life-threatening pneumonia by *Staphylococcus aureus* or streptococcal coinfections. Other possible viral agents of pneumonia are adenovirus, paramyxoviruses, and primary VZV infections of adults.

FLULIKE AND SYSTEMIC SYMPTOMS

Many viral infections cause classic **flulike symptoms** (e.g., fever, malaise, anorexia, headache, body aches). During the viremic phase, many viruses induce the release of interferon and cytokines, which cause these symptoms. In addition to the respiratory viruses, flulike symptoms may accompany infections by arboencephalitis viruses, HSV type 2 (HSV-2), and other viruses.

Arthritis, arthralgia, and other inflammatory diseases may result from the cytokine storm and immune hypersensitivity responses induced by the infection or

RSV, Respiratory syncytial virus.

immune complexes containing viral antigen that accompany viremia. For example, parvovirus B19 infection (of adults); rubella; the hepatitis A, B, and C viruses; and infection with some arboviruses elicit arthritis and arthralgia. The arthralgia and myalgia of dengue earned the title "break-bone fever." Immune complex disease that is associated with chronic hepatitis B virus (HBV) can result in various presentations, including arthritis and nephritis.

GASTROINTESTINAL TRACT INFECTIONS

Infections of the gastrointestinal tract can result in gastroenteritis, vomiting, diarrhea, or no symptoms (Box 38.1). These viruses are naked capsid viruses with a physical structure that can withstand the harsh conditions of the gastrointestinal tract. Norwalk virus, caliciviruses, astroviruses, adenoviruses, reoviruses, and rotaviruses infect the small intestine but not the colon, altering the function or damaging the epithelial lining and the absorptive villi. This leads to malabsorption of water and an electrolyte imbalance. The resultant diarrhea in older children and adults is generally self-limited and can be treated with rehydration and restoration of the electrolyte balance. These viruses, especially rotavirus, are major problems for adults and children in regions in which there is drought and starvation.

Astrovirus
Rotavirus A and B (outbreaks in China)
Reovirus

[a]Most common causal agents.

Viral gastroenteritis has a more significant effect on infants and may necessitate hospitalization. The extent of tissue damage and consequent loss of fluids and electrolytes may be life-threatening. Rotavirus and adenovirus serotypes 40 and 41 are the major causes of infantile gastroenteritis.

Fecal-oral spread of the enteric viruses is promoted by poor hygiene and is especially prevalent in day-care centers. Norwalk virus and calicivirus outbreaks affecting older children and adults are generally linked to a common contaminated food or water source. Vomiting usually accompanies diarrhea in patients infected with the Norwalk virus and rotavirus. Although enteroviruses (picornaviruses) are spread by the fecal-oral route, they usually cause only mild or no gastrointestinal symptoms. Instead, these viruses establish a viremia, spread to other target organs, and then cause clinical disease.

EXANTHEMS, HEMORRHAGIC FEVERS, AND ARTHRITIDES

Virus-induced skin disease (Table 38.2) can result from infection through the mucosa or small cuts or abrasions in the skin (HSV), as a secondary infection after establishment of a viremia (VZV and smallpox), or as a result of the inflammatory response mounted against viral antigens (parvovirus B19). The major classifications of viral rashes are maculopapular, vesicular, nodular, and hemorrhagic. **Macules** are flat, colored spots. **Papules** are slightly raised areas of the skin that may result from immune or inflammatory responses rather than the direct effects of the virus. **Nodules** are larger raised areas of the skin. **Vesicular lesions** are blisters and are likely to contain virus. Human papillomaviruses (HPVs) cause warts, and molluscum contagiosum causes wartlike growths (nodules) by stimulating the growth of skin cells.

The classic childhood exanthems are roseola infantum (exanthem subitum [HHV-6]); fifth disease (erythema infectiosum [parvovirus B19]); and (in unvaccinated children) varicella, measles, and rubella. The rash follows a viremia and is accompanied by fever. Rashes are also caused by enterovirus, alpha togaviruses, and dengue and other flavivirus infections. They also are occasionally seen in patients with infectious mononucleosis.

The yellow fever virus, dengue virus, Ebola virus, Lassa fever, Sin Nombre virus, Zika, and other hemorrhagic

fever viruses establish a viremia and infect the endothelial cell lining of the vasculature, possibly compromising the structure of the blood vessel (Box 38.2). Viral or immune cytolysis can then lead to greater permeability or rupture of the vessel, producing a hemorrhagic rash with petechiae (pinpoint hemorrhages under the skin) and ecchymoses (massive bruises) and hence internal bleeding, loss of electrolytes, and shock.

Arthritis can be a consequence of direct infection of the joint or immune responses to viruses such as the togaviruses (e.g., Chikungunya, rubella), parvovirus B19, flaviviruses (e.g., dengue and hepatitis C virus [HCV]), HBV, human immunodeficiency virus (HIV), and human T-cell lymphotropic virus 1 (HTLV-1). Immune complexes containing viral antigen may trigger inflammatory responses, or the virus infection may trigger autoimmune responses, but most viral arthritis is temporary.

INFECTIONS OF THE EYE

Infections of the eye result from direct contact with a virus or from viremic spread (Box 38.3). Conjunctivitis (pinkeye) is a normal feature of many childhood infections and is a characteristic of infections caused by specific adenovirus serotypes (3, 4a, and 7), measles virus, and rubella virus. Keratoconjunctivitis, caused by adenovirus (8, 19a, and 37), HSV, or VZV, involves the cornea and can cause severe damage. HSV disease can recur, causing scarring and blindness. Enterovirus 70 and coxsackievirus A24 can cause an acute hemorrhagic conjunctivitis. Cataracts are classic features of babies born with congenital rubella syndrome. Chorioretinitis is associated with cytomegalovirus (CMV) infection in newborns (congenital) and in immunosuppressed people (e.g., those with acquired immunodeficiency syndrome [AIDS]).

INFECTIONS OF THE ORGANS AND TISSUES

Infection of the major organs may cause significant disease or result in further spread or secretion of the virus (see Box 38.3). The symptoms may arise from tissue damage or inflammatory responses.

The liver is a prominent target for many viruses that reach the liver by means of a viremia or the mononuclear phagocyte (reticuloendothelial) system. The liver acts as a source for a secondary viremia but can also be damaged by the infection. Infections with hepatitis A, B, C, G, D, and E viruses and yellow fever virus cause classic symptoms of hepatitis. Immunopathology is a major cause of the signs and symptoms of hepatitis. Hepatosplenomegaly (enlarged liver and spleen) is often associated with EBV infectious mononucleosis and CMV infections. The liver is also a

major target in disseminated HSV infection of neonates and infants.

The heart and other muscles are also susceptible to viral infection and damage. Coxsackievirus can cause myocarditis or pericarditis in newborns, children, and adults. Coxsackievirus B can infect muscle and cause pleurodynia (Bornholm disease). Other viruses (e.g., influenza virus, CMV) can also infect the heart.

Infection of the secretory glands, accessory sexual organs, and mammary glands results in contagious spread of CMV. An inflammatory response to the infection, as occurs in **mumps** (parotitis, orchitis), may be the cause of the symptoms. Coxsackievirus B infection of islet cells can initiate autoimmune responses that cause type 1 diabetes. CMV infection of the kidney and reactivation are problems for immunosuppressed people and a predominant reason for kidney transplant failure.

INFECTIONS OF THE CENTRAL NERVOUS SYSTEM

Viral infections of the brain and CNS may cause the most serious viral diseases because of the importance of the CNS and its very limited capacity to repair damage (Box 38.4). Tissue damage is usually caused by a combination of viral pathogenesis and immunopathogenesis. Most potentially neurotropic viral infections are asymptomatic, however, because the virus does not reach the brain from its peripheral infection site or does not cause sufficient tissue damage to produce symptoms.

Virus may spread to the CNS in blood (arboviruses) or in macrophages (HIV); it may spread from a peripheral infection of the neurons (olfactory), or it may first infect skin (HSV) or muscle (polio, rabies) and then progress to the innervating neurons. The virus may have a predilection for certain sites in the brain. For example, the temporal lobe is targeted in HSV encephalitis, the Ammon horn in rabies, and the anterior horn of the spinal cord and motor neurons in polio.

Viral infections of the CNS are usually distinguished from bacterial infections by the finding of mononuclear cells, low numbers of polymorphonuclear leukocytes, and normal or slightly reduced levels of glucose in the cerebrospinal fluid. Immunoassay detection of specific antigen, polymerase chain reaction (PCR) or reverse transcriptase (RT)-PCR detection of viral genomes or mRNA, or isolation of the virus from a cerebrospinal fluid or biopsy specimen confirms the diagnosis and identifies the viral agent. The season of the year also facilitates the diagnosis, in that enteroviral and arboviral diseases generally occur during the summer, whereas HSV encephalitis and other viral syndromes may be observed year-round.

Aseptic meningitis is caused by an inflammation and swelling of the meninges that envelopes the brain and spinal cord in response to infection with enteroviruses (especially echoviruses and coxsackieviruses), HSV-2, the mumps virus, or the lymphocytic choriomeningitis virus. The disease is usually self-limited and, unlike bacterial meningitis, resolves without sequelae unless the virus gains access to and infects neurons or the brain **(meningoencephalitis).** The viruses gain access to the meninges by means of a viremia.

Human immunodeficiency virus (AIDS dementia)
Human T-cell lymphotropic virus 1 (tropical spastic paraparesis)

[a]Most common causal agents.
AIDS, Acquired immunodeficiency syndrome.

Encephalitis and **myelitis** result from a combination of viral pathogenesis and immunopathogenesis in brain tissue and neurons and are either fatal or cause significant damage and permanent neurologic sequelae. HSV, VZV, rabies virus, California encephalitis viruses, West Nile and St. Louis encephalitis viruses, mumps, and measles virus are potential causes of encephalitis. Poliovirus and several other enteroviruses cause paralytic disease (myelitis).

HSV and VZV are ubiquitous and usually cause asymptomatic latent infections of the CNS but can also cause encephalitis. Most arboencephalitis virus infections result in flulike symptoms rather than encephalitis. Postmeasles encephalitis and subacute sclerosing panencephalitis were rare sequelae of measles in the prevaccine era.

Other virus-induced neurologic syndromes are HIV dementia, HTLV-1 tropical spastic paraparesis, JC papovavirus–induced progressive multifocal leukoencephalopathy (PML) in immunodeficient people, and the prion-associated spongiform encephalopathies (kuru, Creutzfeldt-Jakob

disease, Gerstmann-Sträussler-Scheinker disease). PML and the spongiform encephalopathies have long incubation periods.

HEMATOLOGIC DISEASES

Lymphocytes and macrophages are not very permissive for viral replication but are targets for several viruses that establish persistent infections. These cells are also antigen-presenting cells, and during the acute phase of infection, viral replication of EBV, HIV, or CMV elicits a large T-cell response, resulting in **mononucleosis-like syndromes.** In addition, CMV, measles virus, and HIV infections of T cells are immunosuppressive. HIV reduces the numbers of CD4 helper T cells, further compromising the immune system. HTLV-1 infection causes little disease on infection but may lead to **adult T-cell leukemia** or tropical spastic paraparesis much later in life (Box 38.5).

Macrophages and cells of the macrophage lineage can be infected by many viruses. Macrophages act as vehicles for spreading the virus throughout the body because viruses replicate inefficiently in them, and the cells are generally not lysed by the infection. This process promotes persistent and chronic infections. The macrophage is the primary target cell for the dengue virus. Nonneutralizing antibody can promote uptake of dengue virus and HIV into the cell through Fc receptors. Macrophages and cells of the myeloid lineage are the initial cells infected with HIV and provide a reservoir for the virus and access to the brain. AIDS dementia is thought to result from the actions of HIV-infected macrophages and microglial cells in the brain.

SEXUALLY TRANSMITTED VIRAL DISEASES

Sexual transmission is a major route for the spread of papillomavirus, HSV, CMV, HIV, HTLV-1, HBV, HCV, and hepatitis D virus (HDV) (Box 38.6). Such viruses establish chronic and latent recurrent infections, with asymptomatic shedding into semen and vaginal secretions. These viral properties foster dissemination via a route of transmission that is used relatively infrequently and might be avoided during symptomatic disease. The viruses can also be transmitted neonatally or perinatally to infants. Papillomaviruses and HSV establish local primary infections, with recurrent disease at the initial site. Lesions and asymptomatic shedding are sources for sexual transmission and for perinatal transmission to the newborn. CMV and HIV infect myeloid and lymphoid cells under the mucosal lining, whereas the hepatitis viruses are delivered to the liver. CMV, HIV, and the hepatitis viruses are present in blood, semen, and vaginal secretions, which can transmit the virus to sexual partners and neonates. Zika virus can also be spread by sexual transmission.

Zika virus

VIRUSES SPREAD BY TRANSFUSION AND TRANSPLANTATION

HBV, HCV, HDV, HIV, HTLV-1, and CMV are transmitted by blood and organ transplants. These viruses are also present in semen and therefore are sexually transmitted. The chronic nature of the infection, the persistent asymptomatic release of the virus, or the infection of macrophages and lymphocytes promotes transmission by these routes. West Nile encephalitis virus establishes a sufficient viremia for a long enough period that transmission by transfusion has occurred. Screening of the blood supply for HBV, HCV, HIV, and HTLV has controlled transmission of these viruses in blood transfusions (Box 38.7). Blood for babies and organ recipients are screened for CMV.

VIRUSES SPREAD BY ARTHROPODS AND ANIMALS

Arthropod-borne viruses **(arboviruses)** include many of the togaviruses, flaviviruses, and bunyaviruses and the Colorado tick fever reovirus. These viruses establish sufficient viremia in birds or animals (host) to allow their acquisition by mosquitos or ticks (vector) and subsequent transmission to humans when humans enter the habitat of the vector and host. If a virus can establish a sufficient viremia in humans, then the virus, such as yellow fever virus, West Nile, or St. Louis encephalitis virus, will be spread from people in an urban setting. Arenavirus, hantavirus, and rhabdovirus are transmitted to humans in saliva, urine, or feces or through the bite of an infected animal (Table 38.3). Rabies vaccines are available for individuals whose jobs put them at risk or who are suspected to have been infected with rabies.

SYNDROMES OF POSSIBLE VIRAL ETIOLOGY

Several diseases either produce symptoms or have epidemiologic or other characteristics that resemble those of viral infections or may be the sequelae of viral infections (e.g., inflammatory responses to a persistent viral infection). They include **multiple sclerosis, Kawasaki disease, systemic lupus erythematosus, arthritis, diabetes,** and **chronic fatigue syndrome.** Also, the strong cytokine response to many virus infections and the resemblance of viral proteins to host proteins (molecular mimicry) may trigger a loss of tolerance to self-antigens to initiate autoimmune diseases.

Chronic and Potentially Oncogenic Infections

Chronic infections occur when the immune system has difficulty resolving the infection. The DNA viruses (except parvovirus and poxvirus) and the retroviruses cause latent infections with the potential for recurrence. CMV and other herpesviruses; hepatitis viruses B, C, G, and D; and retroviruses cause chronic productive infections. These "passengers" may influence the health of the individual in subtle ways.

HBV, HCV, EBV, HHV-8, HPV, and HTLV-1 are associated with **human cancers.** EBV, HPV, and HTLV-1 can immortalize cells; after immortalization, cofactors, chromosomal aberrations, or both enable a clone of virus-containing cells to grow into a cancer. EBV normally causes infectious mononucleosis but is also associated with African Burkitt lymphoma, Hodgkin lymphoma, lymphomas in immunosuppressed individuals, and nasopharyngeal carcinoma; HTLV-1 is associated with human adult T-cell leukemia. Many papillomaviruses induce a simple hyperplasia characterized by the development of a wart; however, several other strains of HPV have been associated with human cancers (e.g., types 16, 18, 33, 35, 58, and 68 are associated with cervical, anal, penile and oropharyngeal cancers.). Direct viral action or the inflammation and chronic cell damage and repair in livers infected by HBV or HCV can result in a tumorigenic event leading to hepatocellular carcinoma. Immunosuppression in patients who have AIDS, patients undergoing cancer chemotherapy, or transplant recipients also allows the production of lymphoma by EBV. HHV-8 infection produces many cytokines to stimulate cell growth, and this growth can progress to Kaposi sarcoma, especially in persons with AIDS.

Vaccines are now available for HBV and high-risk HPV strains. Vaccination has reduced the spread of viral hepatitis, which will reduce the occurrence of primary hepatocellular carcinoma. Similarly, the HPV vaccines should also reduce the incidence of cervical and other HPV associated cancers.

TABLE 38.3 Arboviruses and Zoonoses

Virus	Family	Reservoir/Vector
Eastern equine encephalitis	Togaviridae	Birds/*Aedes* mosquito
Western equine encephalitis	Togaviridae	Birds/*Culex* mosquito
West Nile encephalitis	Flaviviridae	Birds/*Culex* mosquito
St. Louis encephalitis	Flaviviridae	Birds/*Culex* mosquito
Chikungunya	Togaviridae	Birds, mammals/*Aedes* mosquito
California encephalitis	Bunyaviridae	Small mammals/*Aedes* mosquito
La Crosse encephalitis	Bunyaviridae	Small mammals/*Aedes* mosquito
Yellow fever	Flaviviridae	Birds/*Aedes* mosquito
Dengue	Flaviviridae	Monkeys/*Aedes* mosquito
Zika	Flaviviridae	*Aedes* mosquito
Colorado tick fever	Reoviridae	Tick
Lymphocytic choriomeningitis	Arenaviridae	Rodents
Lassa fever	Arenaviridae	Rodents
Sin Nombre hantavirus	Bunyaviridae	Deer mice
Ebola	Filoviridae	Bats and other
Rabies	Rhabdoviridae	Bats, foxes, raccoons, etc.
Influenza A	Orthomyxoviridae	Birds, swine, etc.

Infections in Immunocompromised Patients

Patients with **deficient cell-mediated immunity** are generally more susceptible to serious disease from enveloped viruses (especially the herpesviruses, measles virus, and even the vaccinia virus used for smallpox vaccinations) and to recurrences of infections with latent viruses (herpesviruses and papovaviruses). Severe T-cell deficiencies also affect the antiviral antibody response. Cell-mediated immunodeficiencies can be congenital or acquired. They may result from genetic defects (e.g., Duncan disease, DiGeorge syndrome, Wiskott-Aldrich syndrome), leukemia or lymphoma, infections (e.g., AIDS), or immunosuppressive therapy.

Viruses cause atypical and more severe presentations in immunosuppressed people. For example, infections with herpesviruses (e.g., HSV, CMV, VZV) or the vaccinia smallpox vaccine, which are normally benign and localized, can progress locally or may disseminate and cause visceral and neurologic infections that can be life-threatening. A measles infection might cause a giant cell (syncytial) pneumonia rather than the characteristic rash.

People with immunoglobulin A deficiency or hypogammaglobulinemia (antibody deficiency) have more problems with respiratory and gastrointestinal viruses. Hypogammaglobulinemic people are more likely to suffer significant disease after infection by viruses that progress by viremia, which also include the live polio vaccine, echovirus, and VZV.

Congenital, Neonatal, and Perinatal Infections

The development and growth of the fetus are so ordered and rapid that a viral infection can damage or prevent appropriate formation of important tissues, leading to miscarriage or congenital abnormalities. Infection can occur in utero (prenatal, e.g., rubella, parvovirus B19, CMV, HIV), during transit through the birth canal by contact with lesions or blood (neonatal, e.g., HSV, HBV, CMV, HPV), or soon after birth (postnatal, e.g., HIV, CMV, HBV, HSV, coxsackievirus B, echovirus).

Neonates depend on the mother's immunity to protect them from viral infections. They receive maternal antibodies through the placenta and then in the mother's milk. This type of passive immunity can remain effective for 6 months to 1 year after birth. Maternal antibodies can (1) protect against spread of virus to the fetus during a viremia (e.g., rubella, B19), (2) protect against many enteric and respiratory tract viral infections, and (3) reduce the severity of other viral diseases after birth. Nevertheless, because the cell-mediated immune system is not mature at birth, newborns are susceptible to viruses that spread by cell-to-cell contact (e.g., RSV, HSV, VZV, CMV, HIV).

Rubella virus and CMV are examples of **teratogenic viruses** that can cause congenital infection and severe congenital abnormalities. HIV infection acquired in utero or from mother's milk initiates a chronic infection, leading to lymphadenopathy, failure to thrive, or encephalopathy within 2 years of birth. HSV can be acquired during passage through an infected birth canal and can result in life-threatening disseminated disease. Nosocomial infection of newborns can result in a similar outcome. If parvovirus B19 is acquired in utero, it can cause spontaneous abortion.

39 Laboratory Diagnosis of Viral Diseases

Viral laboratory studies are primarily performed to confirm the diagnosis by identifying the viral agent of infection; however, to guide the choice of appropriate antimicrobial therapy, check on the compliance of the patient taking antiviral drugs, define the course of the disease, monitor the disease epidemiologically, and educate physicians and patients (Box 39.1). The molecular and immunologic techniques used for many of these procedures are described in Chapters 5 and 6.

There have been many new developments that have changed laboratory viral diagnosis of clinical samples. Methods are more rapid and sensitive, less expensive, technically easier, and commercially available. These include genome amplification techniques and genomic sequencing for direct identification of the virus, better antibody reagents and more sensitive assays for antigen and serology, and assays that can identify multiple viruses (multiplex) and be automated. Often, isolation of the organism is unnecessary and avoided to minimize the risk to laboratory and other personnel. The quicker turnaround allows a more rapid choice of the appropriate therapy, whether antiviral, antibacterial, or other.

Specimen Collection

Selection of the appropriate specimen is dependent on the differential diagnosis for the patient and the tests to be performed (Table 39.1). The selection is often complicated because several viruses may cause the same clinical disease. For example, the development of meningitis symptoms during the summer suggests an arbovirus, in which case cerebrospinal fluid (CSF) and blood should be collected, or an enterovirus, in which case CSF, a throat swab, and stool specimens should be collected for genome analysis and possible virus isolation. A focal encephalitis with a temporal lobe localization preceded by headaches and disorientation suggests herpes simplex virus (HSV) infection, for which CSF can be relatively quickly analyzed for viral deoxyribonucleic acid (DNA) sequences by polymerase chain reaction (PCR) amplification.

Specimens should be collected early in the acute phase of infection, before the virus ceases to be shed. For example, respiratory viruses may be shed for only 3 to 7 days, and shedding may lapse before the symptoms cease. HSV and varicella-zoster virus (VZV) or viral DNA may not be recoverable from lesions more than 5 days after the onset of symptoms. It may be possible to isolate an enterovirus from the CSF for only 2 to 3 days after the onset of the central nervous system manifestations. In addition, antibody produced in response to the infection may block the detection of virus.

The shorter the interval between the collection of a specimen and its delivery to the laboratory, the greater is the potential for isolating a virus. This is because many viruses are labile, and the samples are susceptible to bacterial and fungal overgrowth. Viruses are best transported and stored on ice and in special media that contain antibiotics and proteins, such as serum albumin or gelatin. Significant losses in infectious titers occur when enveloped viruses (e.g., HSV, VZV, influenza virus) are kept at room temperature or frozen at −20° C. This is less of a risk for nonenveloped viruses (e.g., adenoviruses, enteroviruses).

Cytology

Many viruses produce a characteristic cytopathologic effect (CPE). Characteristic CPEs in the tissue sample or in cell culture include changes in cell morphology, cell lysis, vacuolation, syncytia, and inclusion bodies. **Syncytia** are multinucleated giant cells formed by viral fusion of individual cells (Fig. 39.1). *Paramyxoviruses, HSV, VZV, and human immunodeficiency virus (HIV) promote syncytia formation.* **Inclusion bodies** are either histologic changes in the cells caused by viral components or virus-induced changes in cell structures. For example, intranuclear basophilic (owl's-eye) inclusion bodies found in large cells of tissues with cytomegalovirus (CMV) (see Chapter 43, Fig. 43.17) or in the sediment of urine from patients with the infection are readily identifiable. Cowdry type A nuclear inclusions in single cells or in large syncytia (multiple cells fused together) are a characteristic finding in cells infected with HSV or VZV (Fig. 39.2). Rabies may be detected through the finding of cytoplasmic Negri bodies (rabies virus inclusions) in brain tissue (Fig. 39.3).

Often the cytologic specimens will be examined for the presence of specific viral antigens or viral genomes by in situ hybridization or processed for PCR for a rapid, definitive identification. These tests are specific for individual viruses and must be chosen based on the differential diagnosis. These methods are discussed later.

Electron Microscopy

Electron microscopy is not a standard clinical laboratory technique, but it can be used to detect and identify some viruses if sufficient viral particles are present. The addition of virus-specific antibody to a sample can cause viral particles to clump, facilitating the detection and simultaneous identification of the virus (immunoelectron microscopy). Enteric viruses (e.g., rotavirus) that are produced in abundance and have a characteristic morphology can be detected in stool by these methods. Appropriately processed tissue from a biopsy or clinical specimen can also be examined for the presence of viral structures.

Viral Isolation and Growth

Isolation of the virus allows subsequent analysis and archiving of samples but may put personnel at risk for infection. A virus can be grown in tissue culture, embryonated eggs, and experimental animals (Box 39.2). Although embryonated eggs are still used for the growth of virus for some vaccines (e.g., influenza), they have been replaced by cell cultures for routine virus isolation in clinical laboratories. Experimental animals are rarely used in clinical laboratories for isolating viruses.

CELL CULTURE

Specific types of tissue culture cells are used to grow viruses. **Primary cell cultures** are obtained by dissociating specific animal organs with trypsin or collagenase. The cells obtained by this method are then grown as monolayers (fibroblast or epithelial), as organoids (mini-organs) or in suspension (lymphocyte) in artificial media supplemented with bovine serum or another source of growth factors. Primary cells can be dissociated and allowed to grow into new monolayers to become secondary cell cultures. **Diploid cell lines** are cultures of a single cell type that are capable of being passed a large but finite number of times before they senesce or undergo a significant change in their characteristics. **Tumor cell lines** and **immortalized cell lines,** usually initiated from human or animal tumors or by treatment of primary cells with oncogenic viruses or chemicals, consist of single cell types that can be passed continuously without senescing.

Primary monkey kidney cells are excellent for the recovery of influenza viruses, paramyxoviruses, many enteroviruses, and some adenoviruses. Human fetal diploid cells, which are generally fibroblastic cells, support the growth of a broad spectrum of viruses (e.g., HSV, VZV, CMV, adenoviruses, picornaviruses). HeLa cells, a continuous line of epithelial cells derived from a human cervical cancer, are also appropriate for the recovery of many different viruses including respiratory syncytial virus, adenoviruses, and HSV. Many clinically significant viruses can be recovered in at least one of these cell cultures.

BOX 39.1 Laboratory Procedures for Diagnosing Viral Infections

Cytologic examination
Electron microscopy
Virus isolation and growth
Detection of viral proteins (antigens and enzymes)
Detection of viral genomes
Serology

VIRAL DETECTION

A virus can be detected and initially identified through observation of the virus-induced CPE in the cell monolayer (Fig. 39.4; Box 39.3), by immunofluorescence, or by

TABLE 39.1 Specimens for Viral Diagnosis

Common Pathogenic Viruses	Specimens for Culture	Procedures and Comments
RESPIRATORY TRACT		
Influenza virus, paramyxoviruses, coronavirus, rhinovirus, enterovirus (picornavirus)	Nasal washing, throat swab, nasal swab, sputum	RT-PCR, ELISA, multiplex assays detect several agents; cell culture
GASTROINTESTINAL TRACT		
Reovirus, rotavirus, adenovirus, Norwalk virus, other calicivirus	Stool, rectal swab	PCR, RT-PCR, ELISA; viruses are not cultured
MACULOPAPULAR RASH		
Adenovirus, enterovirus (picornavirus)	Throat swab, rectal swab	PCR, RT-PCR
Rubella virus, measles virus	Urine	RT-PCR, ELISA
VESICULAR RASH		
Coxsackievirus, echovirus, HSV, VZV	Vesicle fluid, scraping, or swab, enterovirus in stool	HSV and VZV: vesicle scraping (Tzanck smear), cell culture, PCR, IF; enterovirus: RT-PCR
CENTRAL NERVOUS SYSTEM (ASEPTIC MENINGITIS, ENCEPHALITIS)		
Enterovirus (picornavirus)	Stool, CSF	RT-PCR
Arboviruses (e.g., togaviruses, bunyavirus)	Blood, CSF; rarely cultured	RT-PCR, serology; multiplex assays detect several agents
Rabies virus	Tissue, saliva, brain biopsy, CSF	IF of biopsy, RT-PCR
HSV, CMV, mumps virus, measles virus	CSF	PCR or RT-PCR, virus isolation, and antigen are assayed
URINARY TRACT		
Adenovirus, CMV	Urine	PCR; CMV may be shed without apparent disease
BLOOD		
HIV, human T-cell leukemia virus, hepatitis B, C, and D viruses, EBV, CMV, HHV-6	Blood	ELISA for antigen or antibody, PCR, RT-PCR, multiplex assays

CMV, Cytomegalovirus; *CSF,* cerebrospinal fluid; *EBV,* Epstein-Barr virus; *ELISA,* enzyme-linked immunosorbent assay; *HHV-6,* human herpes virus 6; *HIV,* human immunodeficiency virus; *HSV,* herpes simplex virus; *IF,* immunofluorescence; *PCR,* polymerase chain reaction; *RT-PCR,* reverse transcriptase polymerase chain reaction; *VZV,* varicella-zoster virus.

genome analysis of the infected cell culture. A **plaque** is formed when a single virus infects, spreads, and kills surrounding cells. The type of cell culture, characteristics of the CPE, and rapidity of viral growth can be used to initially identify many clinically important viruses. This approach to identifying viruses is similar to that used in the identification of bacteria, which is based on the growth and morphology of colonies on selective differential media.

Some viruses grow slowly or not at all or do not readily cause a CPE in cell lines typically used in clinical virology laboratories. Some viruses cause diseases that are hazardous to personnel. These viruses are not cultured but diagnosed on the basis of serologic findings or through detection of viral genomes or proteins.

Characteristic viral properties can also be used to identify viruses. For example, the rubella virus may not cause a CPE, but it does prevent (interfere with) the replication of picornaviruses in a process known as **heterologous interference,** which can be used to detect the rubella virus. Cells infected with the influenza virus, parainfluenza virus, mumps virus, and togavirus express a viral glycoprotein (hemagglutinin) that binds erythrocytes of defined animal species to the infected cell surface **(hemadsorption)** (Fig. 39.5). When released into the cell culture medium, such viruses can be detected by the agglutination of erythrocytes, which is a process termed **hemagglutination.** The virus can then be identified from the specific antibody that blocks

BOX 39.3 Viral Cytopathologic Effects[a]

Cell death
- Cell rounding
- Degeneration
- Aggregation
- Loss of attachments to culture dish

Characteristic histologic changes: inclusion bodies in the nucleus or cytoplasm, margination of chromatin

Syncytia: multinucleated giant cells caused by virus-induced cell-to-cell fusion

Cell surface changes
- Viral antigen expression
- Hemadsorption (hemagglutinin expression)

[a]The effects may be characteristics of specific viruses.

the hemagglutination, which is a process called **hemagglutination inhibition (HI).** An innovative approach to detection of HSV infection uses genetically modified tissue culture cells that express the β-galactosidase gene and can be stained blue when infected with HSV (enzyme-linked virus-inducible system [ELVIS]).

One can quantitate a virus by determining the greatest dilution that retains the following properties **(titer):**

1. **Tissue culture dose (TCD_{50}):** titer of virus that causes cytopathologic effects in half the tissue culture cells

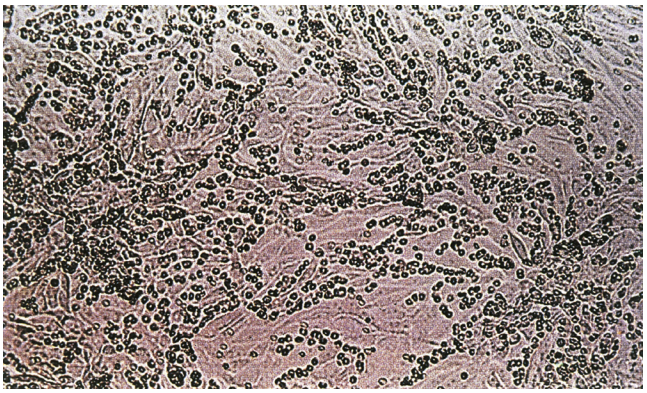

Fig. 39.5 Hemadsorption of erythrocytes to cells infected with influenza viruses, mumps virus, parainfluenza viruses, or togaviruses. These viruses express a hemagglutinin on their surfaces, which binds to erythrocytes of selected animal species.

2. **Lethal dose (LD_{50}):** titer of virus that kills 50% of a set of test animals
3. **Infectious dose (ID_{50}):** titer of virus that initiates a detectable symptom, antibody, or other response in 50% of a set of test animals

The number of infectious viruses can also be evaluated with a count of the plaques produced by 10-fold dilutions of sample **(plaque-forming units).** The ratio of viral particles (from electron microscopy) to plaque-forming units (**particle to plaque-forming unit ratio**) is always much greater than 1 because numerous defective viral particles are produced during viral replication.

Detection of Viral Genetic Material

The genetic sequence of a virus is a major distinguishing characteristic of the family, type, and strain of virus (see Chapter 5 and Box 39.4). Sequence-specific genetic probes, genome amplification techniques, and next generation sequencing techniques allow rapid detection, identification, and quantitation with a minimum of risk from infectious virus.

GENOME AMPLIFICATION

For many laboratories, the method of choice for detection, quantification, and identification of viruses uses genome amplification techniques, including **PCR** for DNA genomes, **reverse transcriptase (RT)-PCR** for ribonucleic acid (RNA) genomes, and **real-time PCR** for identification and quantification of RNA or DNA. Use of the appropriate primers for PCR can promote a millionfold amplification of a target sequence in a few hours. This technique is especially useful for detecting latent and integrated sequences of viruses, such as retroviruses, herpesviruses, papillomaviruses, and other papovaviruses, as well as evidence of viruses present in low concentrations and viruses that are difficult or too dangerous to isolate in cell culture. RT-PCR uses the retroviral reverse transcriptase to convert viral RNA to DNA and allow PCR amplification of the viral nucleic acid sequences.

BOX 39.4 Assays for Viral Proteins and Nucleic Acids

Proteins

Antigen detection (e.g., direct and indirect immunofluorescence, enzyme-linked immunosorbent assay, Western blot)
Protein patterns (electrophoresis)
Enzyme activities (e.g., reverse transcriptase)
Hemagglutination and hemadsorption

Nucleic Acids

PCR (DNA)
Reverse transcriptase PCR (RNA)
Real-time quantitative PCR
Branched-chain DNA and related tests (DNA, RNA)
Genome sequencing
Restriction endonuclease cleavage patterns
Size of RNA for segmented RNA viruses (electrophoresis)
DNA genome hybridization in situ (cytochemistry)
Southern, Northern, and dot blots

DNA, Deoxyribonucleic acid; *PCR,* polymerase chain reaction; *RNA,* ribonucleic acid.

Automated commercial systems are available to analyze a panel of microbes from multiple samples. These systems process the sample, concentrate the genomic sequences, simultaneously amplify the genomes for the different microbes (multiplex), and then utilize rapid techniques for detection of the amplified DNA to indicate the presence of the viral genome. For example, a commercially available respiratory panel detects 17 viruses and 3 bacteria.

Real-time PCR is a rapid means of identifying and quantifying the number of genomes that can be extrapolated to patient levels (**virus load**). The concentration of the viral genome (RNA genomes would first be converted to DNA) is proportional to the initial rate of the PCR amplification of the genomic DNA. This test is readily automated and has become important for identification of many viruses and for quantifying blood levels of HIV and other viral genomes.

PCR is the prototype for several other genome amplification techniques. **Transcription-based amplification** uses reverse transcriptase and viral sequence–specific primers to make a complementary DNA (cDNA) and also attaches a sequence recognized by the DNA-dependent RNA polymerase from the T7 bacteriophage to the sample DNA. The DNA is transcribed to RNA by the T7 RNA polymerase, and the new RNA sequences are then cycled back into the reaction to amplify the relevant sequence. The amplified genome is detected by hybridization of a luminescent DNA probe. Unlike PCR, these reactions do not require special equipment.

Some other genome amplification and detection approaches are similar in concept to enzyme-linked immunosorbent assay (ELISA). These approaches use immobilized DNA sequences complementary to the relevant viral genomic sequence to capture the viral genome. This is followed by the binding of another complementary sequence that contains a marker that can be detected by an antibody or other detection system. ELISA methods can then be used to detect the presence of the genome. Like ELISA, these methods can be automated and set up to analyze a panel of viruses.

Viral genomes can also be analyzed after genome amplification. Methods for sequencing DNA **(next generation sequencing)** have become sufficiently rapid and inexpensive to be routine procedures. Once the sequence of a fragment or the entire genome has been obtained, its identity can be determined by computer comparison to established databases.

IN SITU ANALYSIS

Virus-specific **DNA probes** can be used like antibodies as sensitive and specific tools for detecting a virus. These probes can detect the virus even in the absence of viral replication. Specific viral genetic sequences in fixed, permeabilized tissue biopsy specimens can be detected by **in situ hybridization** (e.g., **fluorescence in situ hybridization [FISH]**). DNA probe analysis is especially useful for detecting slowly replicating or nonproductive viruses, such as CMV and human papillomavirus, or when the viral antigen cannot be detected using immunologic tests (see Fig. 5.1).

Detection of Viral Proteins

Viral enzymes and other proteins are produced during viral replication and can be detected by biochemical, immunologic, and molecular biological means (see Box 39.4). The viral proteins can be separated by electrophoresis and their patterns used to identify and distinguish different viruses. For example, the electrophoretically separated HSV-infected cell proteins and virion proteins exhibit different patterns for different types and strains of HSV-1 and HSV-2.

The detection and assay of characteristic enzymes or activities can identify and quantitate specific viruses. For example, the presence of reverse transcriptase in serum or cell culture indicates the presence of a retrovirus or hepadnavirus. Antibodies can be used as sensitive and specific tools to detect, identify, and quantitate the virus and viral antigen in clinical specimens or cell cultures (immunohistochemistry). Specifically, monoclonal or monospecific antibodies are useful for distinguishing viruses. Viral antigens on the cell surface or within the cell can be detected by **immunofluorescence** and **enzyme immunoassay (EIA)** (see Figs. 6.2 and 6.3). Virus or antigen released from infected cells can be detected and quantitated by **ELISA, latex agglutination (LA)** (see Chapter 6 for definitions), and variations on these assays. Test kits to detect single and multiple (multiplex) viral agents are commercially available. Rapid ELISA-like detection kits, similar to pregnancy tests, are available for influenza and HIV.

SIGNIFICANCE OF VIRUS DETECTION

In general, the detection of any virus in host tissues, CSF, blood, or vesicular fluid can be considered a highly significant finding. However, viral shedding may occur and be unrelated to the disease symptoms. Certain viruses can be intermittently shed without causing symptoms in the affected person for periods ranging from weeks (enteroviruses in feces) to many months or years (HSV or CMV in the oropharynx and vagina; adenoviruses in the oropharynx

and intestinal tract). Similarly, a negative result cannot be conclusive because the sample may have been improperly handled, contain neutralizing antibody, or be acquired before or after viral shedding.

Viral Serology

The humoral immune response provides a history of a patient's infections. Serologic studies are used for the identification of viruses that are difficult to isolate and grow in cell culture, as well as viruses that cause diseases of long duration (e.g., EBV, HBV, HIV) (see Box 6.2). Serology can be used to identify the virus and its strain or serotype, whether it is an acute or chronic disease, and determine whether it is a primary infection or a reinfection. The detection of **virus-specific immunoglobulin (Ig)M antibody,** which is present during the first 2 or 3 weeks of a primary infection, generally indicates a recent primary infection. **Seroconversion** is indicated by at least **a fourfold increase in the antibody titer** between the serum obtained during the acute phase of disease and that obtained at least 2 to 3 weeks later during the convalescent phase. Reinfection or recurrence later in life causes an anamnestic (secondary or booster) response. Antibody titers may remain high in patients who suffer frequent recurrence of a disease (e.g., herpesviruses).

Because of the inherent imprecision of serologic assays based on twofold serial dilutions, a fourfold increase in the antibody titer between acute and convalescent sera is required to indicate seroconversion. For example, samples with 512 and 1023 units of antibody would both give a signal on a 512-fold dilution but not on a 1024-fold dilution, and the titers of both would be reported as 512. On the other hand, samples with 1020 and 1030 units are not significantly different but would be reported as titers of 512 and 1024, respectively.

The presence of antibodies to several key viral antigens and their titers can be used to identify the stage of disease caused by certain viruses. This approach is especially useful for the diagnosis of viral diseases with slow courses (e.g., infectious mononucleosis caused by Epstein-Barr virus [EBV], hepatitis B) (see Chapters 43 and 55). In general, the first antibodies to be detected are directed against the antigens most available to the immune system (e.g., expressed on the virion or infected-cell surfaces). Later in the infection, when the infecting virus or the cellular immune response has lysed the cells, antibodies directed against the intracellular viral proteins and enzymes are detected. For example, antibodies to the envelope and capsid antigens of EBV are detected first. Then during convalescence, antibodies to nuclear antigens, such as the EBV nuclear antigen (EBNA), are detected.

A **serologic battery or panel** consisting of assays for several viruses may be used for the diagnosis of certain diseases. For example, HSV and the viruses of mumps, western and eastern equine encephalitides, and St. Louis, West Nile, and California encephalitides might be included in a panel of tests for central nervous system diseases. An ELISA test that detects antibodies to HIV-1 and HIV-2 and the HIV p24 protein has obviated the need for the Western blot confirmative test for HIV infection.

SEROLOGIC TEST METHODS

The serologic tests that can be used in virology are listed in Box 6.1. **Neutralization** and **HI tests** assay antibody on the basis of its recognition of and binding to virus. The antibody coating of the virus blocks its binding to indicator cells and subsequent infection (Fig. 39.6). For HI, antibody in patient serum prevents a standardized amount of virus from binding to and agglutinating erythrocytes.

The indirect fluorescent antibody test and solid-phase immunoassays, such as LA and **ELISA,** are commonly used to detect and quantitate viral antigen and antiviral antibody. The ELISA test is used to screen the blood supply to exclude individuals who are seropositive for hepatitis B and C viruses and HIV. **Western blot** analysis can be used to determine the specific proteins recognized by patient serum and was used to confirm seroconversion and hence infection with HIV (Fig. 39.7).

LIMITATIONS OF SEROLOGIC METHODS

The presence of an antiviral antibody indicates previous infection but is not sufficient to indicate when the infection occurred. False-positive or false-negative test results may confuse the diagnosis. In addition, patient antibody may be bound with viral antigen (as occurs in patients with hepatitis B) in immune complexes, preventing antibody detection.

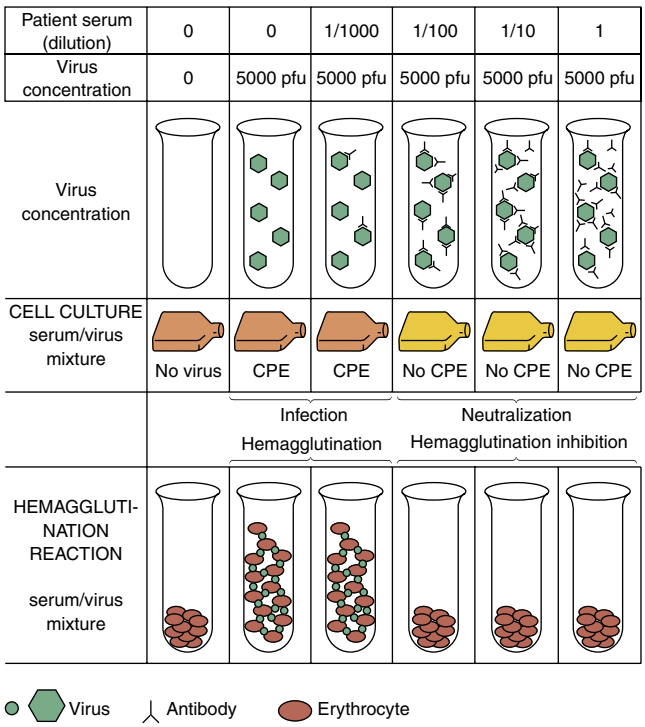

Fig. 39.6 Neutralization, hemagglutination, and hemagglutination inhibition assays. In the assay shown, 10-fold dilutions of serum were incubated with virus. Aliquots of the mixture were then added to cell cultures or erythrocytes. In the absence of the antibody, the virus infected the monolayer (indicated by cytopathologic effect *[CPE]*) or caused hemagglutination (i.e., formed a gel-like suspension of erythrocytes). In the presence of the antibody, infection was blocked, preventing CPE (neutralization), or hemagglutination was inhibited, allowing the erythrocytes to pellet. The titer of antibody of this serum would be 100. *pfu,* Plaque-forming units.

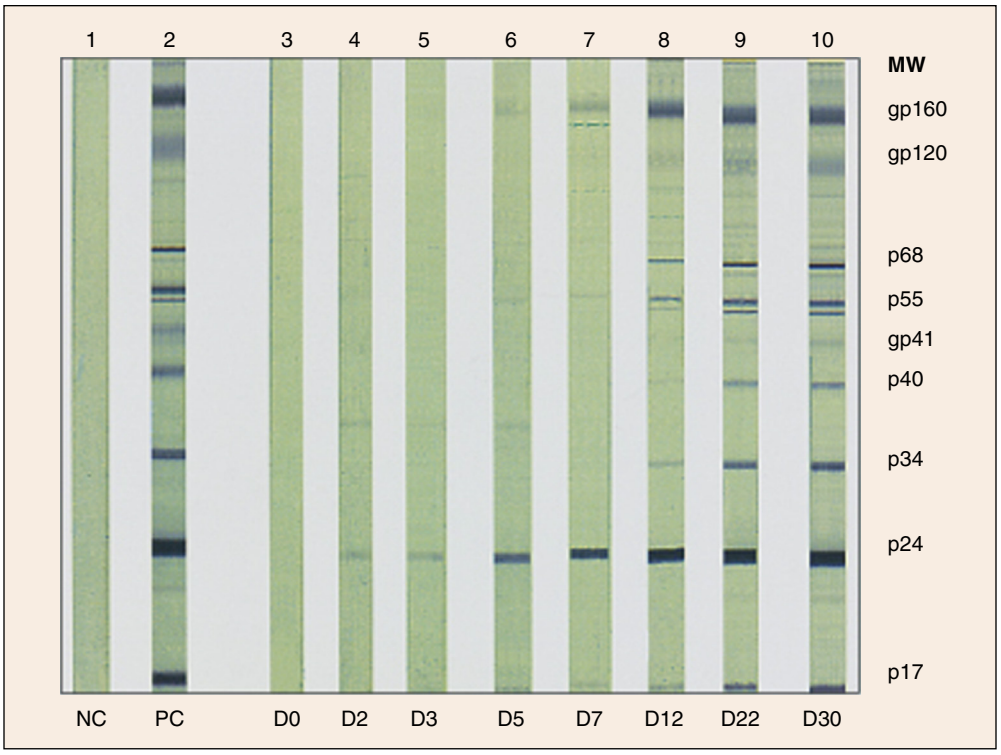

Fig. 39.7 Western blot analysis of human immunodeficiency virus (HIV) antigens and antibody. HIV protein antigens are separated by electrophoresis and blotted onto nitrocellulose paper strips. Each strip is incubated with patient antibody, washed to remove the unbound antibody, and then reacted with enzyme-conjugated antihuman antibody and chromophoric substrate. Serum from an HIV-infected person binds and identifies the major antigenic proteins of HIV. These data demonstrate the seroconversion of one HIV-infected individual with sera collected on day 0 *(D0)* to day 30 *(D30)* compared with a known positive control *(PC)* and negative control *(NC)*. *MW,* molecular weight. (From Kuritzkes, D.R., 2004. Diagnostic tests for HIV infection and resistance assays. In: Cohen, J., Powderly, W.G. (Eds.), Infectious Diseases, second ed. Mosby, St Louis, MO.)

Serologic cross-reactions between different viruses may also confuse the identity of the infecting agent (e.g., parainfluenza and mumps express related antigens). Conversely, the antibody used in the assay may be too specific (many monoclonal antibodies) and may not recognize strains of virus from the same family, giving a false-negative result (e.g., rhinovirus). A good understanding of the clinical symptoms and knowledge of the limitations and potential problems with serologic assays aid the diagnosis.

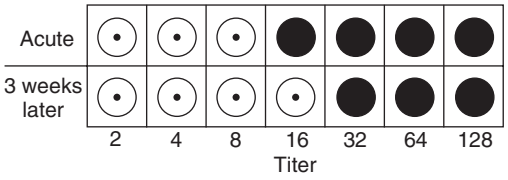
Questions

1. Brain tissue is obtained at autopsy from a person who died of rabies. What procedures could be used to confirm the presence of rabies virus–infected cells in the brain tissue?

2. A cervical Papanicolaou smear is taken from a woman with a vaginal papilloma (wart). Certain types of papillomas have been associated with cervical carcinoma. What method or methods would be used to detect and identify the type of papilloma in the cervical smear?

3. A legal case would be settled by identification of the source of an HSV infection. Serum and viral isolates are obtained from the infected person and two contacts. What methods could be used to determine whether the person is infected with HSV-1 or HSV-2? What methods could be used to compare the type and strain of HSV obtained from each of the three people?

4. A 50-year-old man experiences flulike symptoms. The following figure shows results of HI tests on serum specimens collected when the disease manifested (acute) and 3 weeks later. The HI data for the current strain of influenza A (H3N2) are presented. Filled circles indicate hemagglutination. Is the patient infected with the current strain of influenza A?



5. A policeman accidentally sticks his finger with a drug addict's syringe needle. He is concerned that he may be infected with HIV. Samples are taken from the policeman a month later for analysis. What assays would be appropriate to determine whether the man is infected with the virus? In this case, it may be too early to detect an antibody response to the virus.

40 Antiviral Agents and Infection Control

Unlike bacteria, viruses are obligate intracellular parasites that use the host cell's biosynthetic machinery and enzymes for replication (see Chapter 36). Hence it is more difficult to inhibit viral replication without also being toxic to the host. Most antiviral drugs are targeted toward viral-encoded enzymes or structures of the virus that are important for replication. Most of these compounds are classic biochemical inhibitors of viral-encoded enzymes. Some antiviral drugs are actually stimulators of host innate immune protective responses.

Antiviral drugs are available for viruses that cause significant morbidity and mortality and provide reasonable targets for drug action (Box 40.1), but unlike antibacterial drugs, the activity of most antiviral drugs is limited to a specific virus. Antiviral drugs may be used for prophylaxis or treatment. Many antiviral drugs cause serious side effects because of their toxicity. As has occurred with antibacterial drugs, resistance to antiviral drugs is becoming more of a problem because of the high rate of mutation for viruses, especially RNA viruses, and the long-term treatment of some patients with chronic infections, especially those who are immunocompromised (e.g., patients with acquired immunodeficiency syndrome [AIDS]).

Targets for Antiviral Drugs

The different targets for antiviral drugs (e.g., structures, enzymes, or processes important or essential for virus production) are discussed with respect to the steps of the viral replication cycle they inhibit. These targets and their respective antiviral agents are listed in Table 40.1 (see also Fig. 36.8).

VIRION DISRUPTION

Enveloped viruses are susceptible to certain lipid and detergent-like molecules that disperse or disrupt the envelope membrane, preventing acquisition of the virus. Rhinoviruses are susceptible to acid, and citric acid can be incorporated into facial tissues as a means of blocking viral transmission.

ATTACHMENT

The first step in viral replication is mediated by the interaction of a viral attachment protein with its cell-surface receptor. This interaction can be blocked by **neutralizing antibodies,** which bind to the viral attachment protein, or by **receptor antagonists.** The administration of specific antibodies **(passive immunization)** is the oldest form of antiviral therapy. Receptor antagonists include peptide or sugar analogs of the cell receptor or the viral attachment protein that competitively blocks interaction of the virus with the cell. Compounds that bind to the C-C chemokine receptor 5 (CCR5) molecule block binding of human immunodeficiency virus (HIV) to macrophages and some CD4 T cells to prevent the initial infection. Acidic polysaccharides (e.g., heparan, dextran sulfate) interfere with viral binding and have been suggested for the treatment of infection with HIV, herpes simplex virus (HSV), and other viruses.
